Introduction to Biophotonics

Marion Jürgens, Thomas Mayerhöfer, and Jürgen Popp

1.1
Definition of and General Introduction to Biophotonics

1.1.1
Definition

Biophotonics is an emerging multidisciplinary research area, embracing all light-based technologies applied to the life sciences and medicine. The expression itself is the combination of the Greek syllables "*bios*" standing for life and "*phos*" standing for light. Photonics is the technical term for all methodologies and technologies utilizing light over the whole spectrum from ultraviolet through the visible and the infrared to the terahertz region, and its interaction with any matter (Figure 1.1).

Beyond this definition, biophotonics is a scientific discipline of remarkable societal importance. For hundreds of years, researchers have utilized light-based systems to explore the biological basics of life. After the invention of the light microscope dating back to the seventeenth century and the systematic improvements introduced by Carl Zeiss, Ernst Abbé and Otto Schott in Jena in the nineteenth century, it became an essential tool in the life sciences and medicine and had a crucial influence on the work of biologists of this time, such as Ernst Haeckel. Since then, its importance has grown even stronger. Today, ultrahigh resolving microscopes enable us to observe cellular structures smaller than 20 nm across and their functions, and thus to study diseases right at their origin. We also benefit greatly from photonic technologies in medical practice – in fact both in diagnosis and in therapy of diseases. For example, laser scalpels have become routine tools which reduce the expense of many surgeries, sometimes even down to an ambulant intervention ("keyhole surgery"). Due to novel photonic technologies such as fluorescence endoscopy and photodynamic therapy (PDT), some types of cancer can be recognized much earlier and treated more gently than several years before. In ophthalmology, optical coherence tomography (OCT) has become the gold standard for detecting morphological changes in the eye by adding the third dimension, helping to obtain high-resolution 3D images of the retina and diagnose prevalent diseases such as glaucoma and macular degeneration.

Handbook of Biophotonics. Vol.1: Basics and Techniques, First Edition.
Edited by Jürgen Popp, Valery V. Tuchin, Arthur Chiou, and Stefan H. Heinemann.

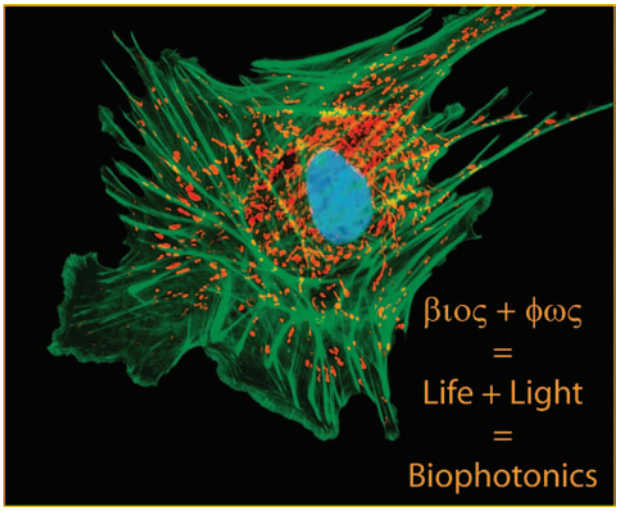

Figure 1.1 Shedding light on life: biophotonics utilizes light-based technologies for applications in medicine and the life sciences (fluorescence image: PCO AG).

The widespread use of biophotonic systems and methods is also reflected in economic terms. Regarding market shares as well as growth rates, biophotonics belongs to the most important sectors of the global photonics market [1, 2].

1.1.2 Visions Connected with Biophotonics Research

The controlled use of light has already revolutionized life in many respects (Figure 1.2). There is high hope that light as a tool will provide further breakthroughs in the life sciences and medicine, and also in closely related topics and subjects such as nutrition, the environment and well-being in general. A current example from the field of medicine is a novel approach for the early recognition of Alzheimer's disease, which so far is considered incurable. In the next few years, fluorescence imaging could provide reliable early recognition and help to verify novel therapeutic approaches which aim at an early intervention in the future [3]. Basically, light allows us to explore cellular structures and functions rapidly and with utmost sensitivity and precision. At the same time, light allows us to manipulate tissues and cellular structures without damaging them. These features make light a unique tool for the whole range of modern medicine:

1) **Understanding diseases on a molecular level:** Light helps to explore fundamental life processes on a cellular and molecular level, and thus to develop novel, targeted therapies.
2) **Early recognition of diseases:** Light allows us to recognize changes on the cellular scale as early signs of diseases, even long before manifest symptoms occur. The earlier is the diagnosis, the better are the chances of healing.
3) **Targeted treatment of diseases:** Light measures and cures in a careful manner, paving the way towards minimally invasive medicine.

Figure 1.2 Visions connected with biophotonics (photographs: LMU Munich/BIZ, World of Medicine AG, Fraunhofer IZM).

4) **Preventing diseases:** Light can measure a multitude of health-relevant parameters, including endogenous parameters such as genetic dispositions and physiological conditions, and also exogenous parameters such as pathogens in air, water, and food. This helps to monitor the health state of individuals and possible harmful influences, which is an important prerequisite to prevent diseases.

Thus the term "biophotonics" covers a wide spectrum of biomedical questions from understanding life processes to prevention, early recognition, and therapy of diseases. Attention should be paid to an alternative use of the term as a complement to the term "biomedical optics." In that context, the field of biophotonics only covers applications of photonics in the life sciences and fundamental biomedical research such as the investigation of cellular processes, whereas the field of biomedical optics covers the clinical applications of light in diagnostics and therapy. This distinction seems to have evolved historically, as the term "photonics" was only coined about 50 years ago, when light-based technologies were already well established in medicine. In this book, the term "biophotonics" is used for both mentioned areas. Furthermore, it reaches into the fields of environmental, food and pharmaceutical analysis and thus even applies to the fields of process control and security applications. The authors consider this definition more conclusive, more purposeful and more forward-looking, as it provides a holistic perspective. This approach advances a likewise holistic, modern health care, and particularly the groundbreaking paradigm change from the treatment of diseases towards health maintenance. Moreover, the close linking of diagnosis, therapy, preventive and follow-up care paves the way towards

personalized medicine. This promises major benefits not only for individual patients, but also for society as a whole: Personalized, targeted therapies can help significantly in limiting health-care costs, and thus in facing the challenges associated with population aging and the consequent increase in age-related diseases.

1.1.3 Why Photons?

What makes light an ideal tool in medicine and the life sciences? A multitude of favorable properties of light and light-related technologies:

1) **Spatial scale: six orders of magnitude:** Light as a tool helps to observe and manipulate objects on a scale from several nanometers to centimeters (Figure 1.3). This opens up a whole range of biomedical applications, reaching from the detection and manipulation of macromolecules to subcellular manipulation and macroscopic diagnosis and surgery of tissue. This is a huge advantage, as novel diagnostic options that work in single cells can be directly adapted to the inspection of cellular networks and tissues. In clinical diagnostics, values can be integrated optically using arbitrary volumes.
2) **Time scale: from 10^{-15} to 10^{6} s:** Using the ultrashort light pulses of femtosecond lasers, extremely fast processes can be analyzed or manipulated with the required high precision in time. On the other hand, light sources are stable enough for long-term monitoring of structures and processes, even covering several days. The repeated application of short light pulses also allows the monitoring of changes in fast processes over long time periods. Photonics is the only available technology to cover this immense time scale.
3) **Multiple functionality:** Optical technologies allow the determination of very different features of molecules, cells, and tissue:
   a) Morphological features [e.g., by measuring reflection, transmission (absorption), and scattering]
   b) Chemical features and their changes (using spectroscopy, e.g., Raman and fluorescence)
   c) Mechanical features (using optical trapping and holography)
   d) Movement (using, e.g., Doppler spectroscopy and dynamic light scattering measurements).
4) **Compatibility:** Optical methods can be combined smoothly with one another. This applies to different diagnostic methods, and also to combinations of diagnostic and therapeutic methods. Moreover, measurements can similarly

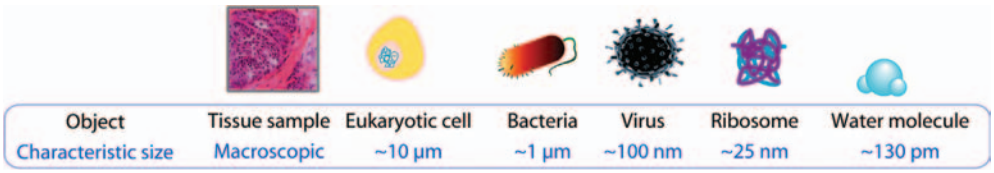

Figure 1.3 Characteristic size of selected objects of biomedical interest.

be performed in the spatial and temporal domain. This wide compatibility facilitates a multitude of feedback-controlled therapies on the microscopic and macroscopic scales. Optical methods can also be combined with non-optical methods and with other advanced technologies such as nanotechnology (e.g., nanoparticles, optically activatable nanocapsules, optical nanostructures) and microsystem technology (e.g., integrated microoptics, microfluidics).

5) **Practicability:** Apart from their fundamental properties, optical technologies also offer important practical advantages. Among them are contactless application, even in therapy, and the easy transmission of energy and signals using light conductors. The application of light has no or only minor side effects and thus enjoys wide acceptance among patients. Moreover, optoelectronic compounds have become increasingly compact and inexpensive to produce (e.g., laser diodes), which allows the development of reasonably priced systems. The mentioned properties and advantages are unequaled by any other biomedical tools, be they ultrasound, X-ray, or magnetic and nuclear medical technologies. Like no other technology, photonics is suited as cross-sectional technology to master a broad variety of biomedical challenges.

1.1.4 Fields of Application and Technology

The scientific discipline covers a broad range of applications and technologies (Figure 1.4). The following overview cannot provide a complete list of them, but

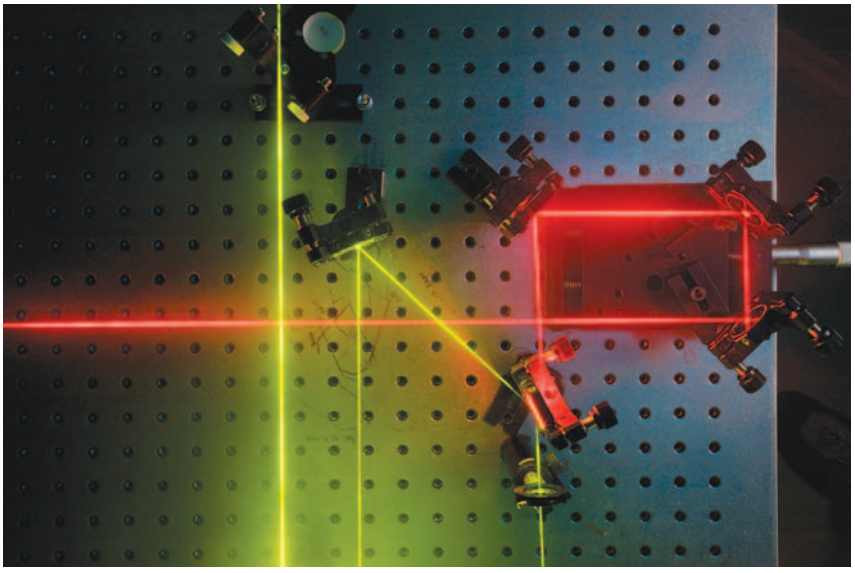

Figure 1.4 Light measures fast, gently, and with high precision, and thus holds unique potential for medical applications. This includes both medical practice and fundamental research in the life sciences (photograph: IPHT Jena).

is rather intended as a first map for readers who are new to this field. The emerging discipline covers a growing multitude of technologies and applications; moreover, many applications in medicine and the life sciences require the combined use of different technologies.

Important Fields of Application

Fundamental biomedical research: Cell biology, molecular biology: understanding of life processes, and also the origin and genesis of diseases, on a cellular and molecular level.
Pharmacological research: Drug development, for example, target evaluation, high-throughput screening (HTS) and/or high-content screening (HCS) of drug candidates, drug delivery.
Laboratory tests, point of care (POC) diagnostics: Analysis of body liquids, for example, in allergology, immunology, hematology, cardiology, epidemiology, endocrinology, medical microbiology; Optical sensing, for example, optical oximetry.
Clinical diagnostics, therapy control, and therapy: (Methods in clinical routine or testing): see Table 1.1.
Regenerative medicine: Stem cell research, tissue engineering, transfection of genetic material.
Environmental monitoring, food safety: On-site testing and monitoring of harmful compounds in air, water, and food, for example, pathogens, fine dust, pollen, chemicals.
Process control: Controlling composition and quality of pharmaceuticals, nutrition and cosmetics.
Security applications: Detection of harmful biological and chemical substances and weapons.

Important Methods and Technologies

Spectroscopy

- Absorption (THz, microwaves, IR, UV–Vis).
- Emission (all fluorescence methods: one-photon/multi-photon fluorescence, FRET, FRAP, FLIM, FLIP).
- Elastic and inelastic light scattering (e.g., Rayleigh, Raman, CARS, SRS, SERS, TERS, Mie, LIDAR).

Light Microscopy

- Fluorescence microscopy (observing autofluorescence or using fluorescence labels, e.g., proteins), including sub-diffraction techniques (optical nano-

scopy, e.g., STED, NSOM, PALM/STORM, structured illumination) and 3D imaging techniques (e.g., confocal and multi-photon excitation microscopy).
- Raman Microscopy (CARS, SRS, TERS).
- Other contrast methods, for example, phase contrast microscopy, digital holographic microscopy (DHM).

Multimodal Approaches, Molecular Imaging

- Combinations of molecular techniques, for example, spectroscopy, and imaging techniques, for example, microscopy. Spectroscopy can provide molecular information for each spot of a microscopic image to deliver multidimensional images of the examined cells or tissues. This allows visualization of cellular functions and following of molecular process in living organisms without perturbing them.
- Other multimodal approaches also include combinations with nonphotonic technologies, for example, PET imaging and PCR assays.

Chip-Based Analysis

- Biochips for POC diagnostics ("lab-on-a-chip").

Therapeutic Methods

- PDT, controlled release of bioactive agents, Laser-in-situ Keratomileusis (LASIK), low-level laser therapy (LLLT), laser-induced thermotherapy (LITT).

Optical Micromanipulation

- Optical tweezers, optical stretcher, laser catapulting, cell sorting and cell positioning.

Optical Components

- Innovative light sources and detectors, optics and optical devices for biophotonics, e.g., ultrafast lasers, adaptive optics, fiber endoscopes.

Enabling Technologies (Not Photonics Based, Yet Preliminary)

- For example, micro- and nanofluidics, nanoparticles, biochemistry (evaluation of targets, development of markers), data modeling (image analysis, chemometrics), data management (user-oriented GUI, handling massive amounts of data, integrating information from multiple channels), system integration.

Table 1.1 Important fields of application in clinical diagnostics, therapy control, and therapy.

Medical discipline	Field of application	Examples
Cardiology, angiology	Intracoronary diagnostics Microcirculation Imaging laser surgery of atrial fibrillation Varicose vein treatment	Imaging of atherosclerotic plaques
Dentistry	Dental diagnosis	Caries, stress/cracks, pulp vitality, periodontal disease
	Dental laser surgery (restoration, prosthetics)	Endodontic therapy, ablation of soft and hard tissue and of restorative materials
Dermatology	Skin diagnosis (structural and functional imaging)	Melanoma and nonmelanoma skin cancers, actinic keratosis, skin injuries, tissue vasculature, atopic dermatitis, acne, psoriasis. Age-related skin conditions, evaluation of transdermal processes (e.g., drug and agent delivery)
	Skin therapy	Photonic therapy, photodynamic therapy, and surgery of above-mentioned diseases
Gastroenterology	Endoscopy and optical imaging PDT of Barrett's esophagus	Laryngoscopy
Laboratory medicine	Pathogen detection	Detecting and identifying pathogens and host response in case of sepsis
Oncology	Tissue-based cancer diagnostics	Tumor detection, staging and grading based on visual inspection and molecular analysis of biopsies
	In vivo cancer diagnostics	Endoscopic detection of tumors
	Intraoperative cancer diagnostics	Tumor border delineation
	PDT	
Ophthalmology	Structural and functional ocular imaging	Retinal angiography and structural imaging, corneal surface
	Eye as diagnostic window to the body	Early recognition of Alzheimer's disease
	Ocular laser therapy	Corneal (refractive eye) surgery, retinal surgery, for example, treatment of glaucoma, AMD, and cataract
Urology	Endoscopic diagnosis	Ureteroscopy, prostatectomy
	Minimally invasive surgery	Removal of benign hyperplasia, strictures, and renal calculi

1.1.5 Societal Relevance of Biophotonics

1.1.5.1 Fighting Prevalent and Severe Diseases

The motivation of biophotonics research is most often the battle against the most prevalent and severe diseases of mankind. As an example, many research studies in Germany are currently focusing on diseases such as cancer, cardiovascular diseases, eye disorders and infections [4]. For comparison purposes, Figure 1.5 lists the leading causes of death as published by the World Health Organization (WHO) [5].

In order to ensure a sustainable and capable health care, the role of biophotonics will probably grow even more in the next decades. The reason is the ongoing demographic change in industrialized countries, which is about to confront their health care systems with their greatest challenges. The case numbers of age-related diseases such as dementia, cardiovascular diseases, and loss of sight are expected to rise sharply in the coming decades. At the same time, the financial resources of public health care systems will probably stagnate and thus not keep pace with the expected increase in costs for treatment and nursing care. Here, biophotonics can meet urgent needs: Early, targeted, and gentle interventions could attenuate or even avoid diseases and thus improve the quality of people's lives, especially for the elderly. This would also help savings of therapeutic costs and economic follow-up costs. The dimensions of the above-mentioned effects are estimated by a number of forecasts and studies:

1) **Demographic change in industrialized countries:** All developed countries are facing rapid demographic changes towards an aging society. A key figure for health care systems is the "elderly dependent ratio" (EDR), indicating the number of people aged 65 years or above, expressed as a percentage of people of working age (Figure 1.6). According to a forecast by the United Nations [6], the EDR is expected to increase from currently about 23% to 45% by 2050 in developed regions. Here, the group of working age is defined as those aged from 15 to 64 years. Although even in the Western world the pace and extent of this aging process differ significantly, the trend itself holds true worldwide. As a consequence, considerably fewer people of working age will be available to fulfill the intergenerational contract and help bear health expenses in a solidarity-based system. Extreme pressure on the public health care system is expected, for example, in Germany. Here, the number of people aged 80 years or above will probably more than double from 2007 to 2050. At the same time, the group of people of working age (here 20–64 years) will probably decrease by nearly one-third. Whereas today about three people of working age correspond to one elderly person, this ratio will shrink to 1.6 : 1 by 2050 [7].
2) **Growing case numbers of age-related diseases:** As the described demographic change stems not only from an improved health care but also from other effects (e.g., decreasing birth rates), one cannot conclude that people will age healthier

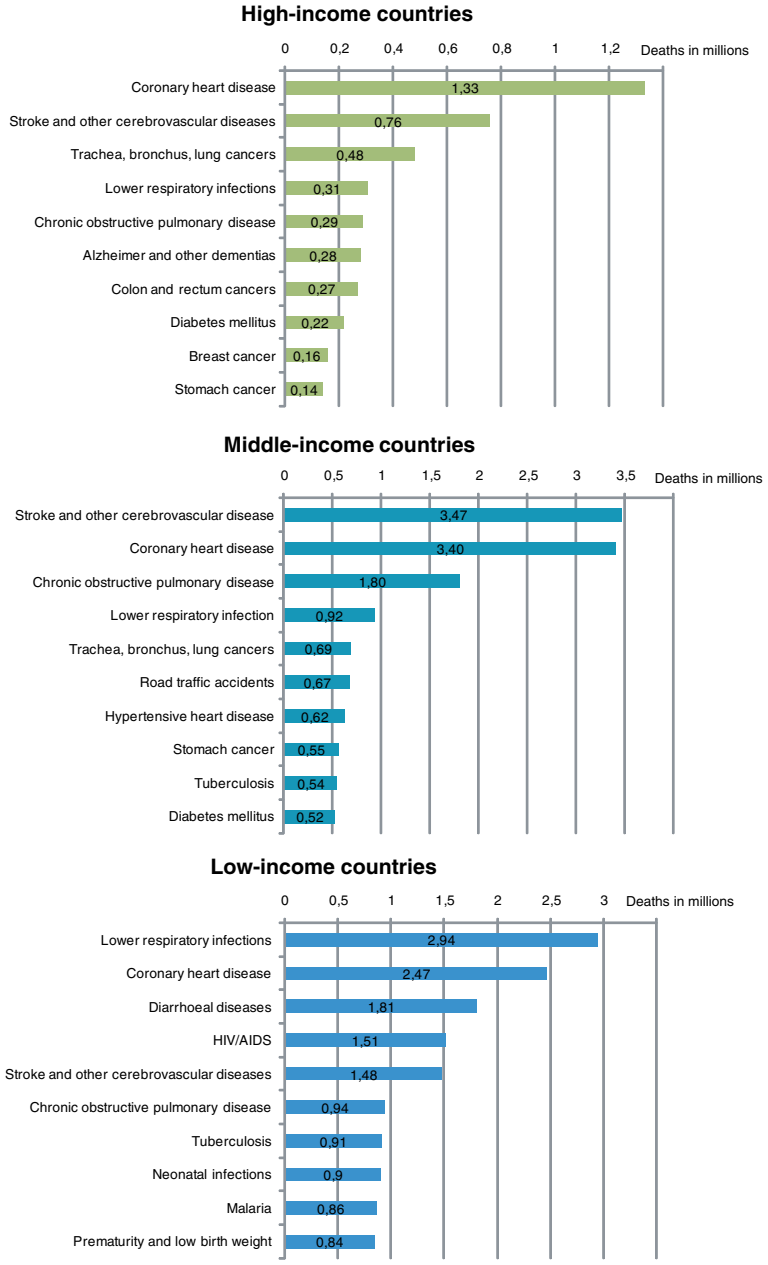

Figure 1.5 The 10 leading causes of death by broad income group (2004). Low-, middle- and high-income categories as defined by the World Bank; countries grouped based on their 2004 gross national income [5].

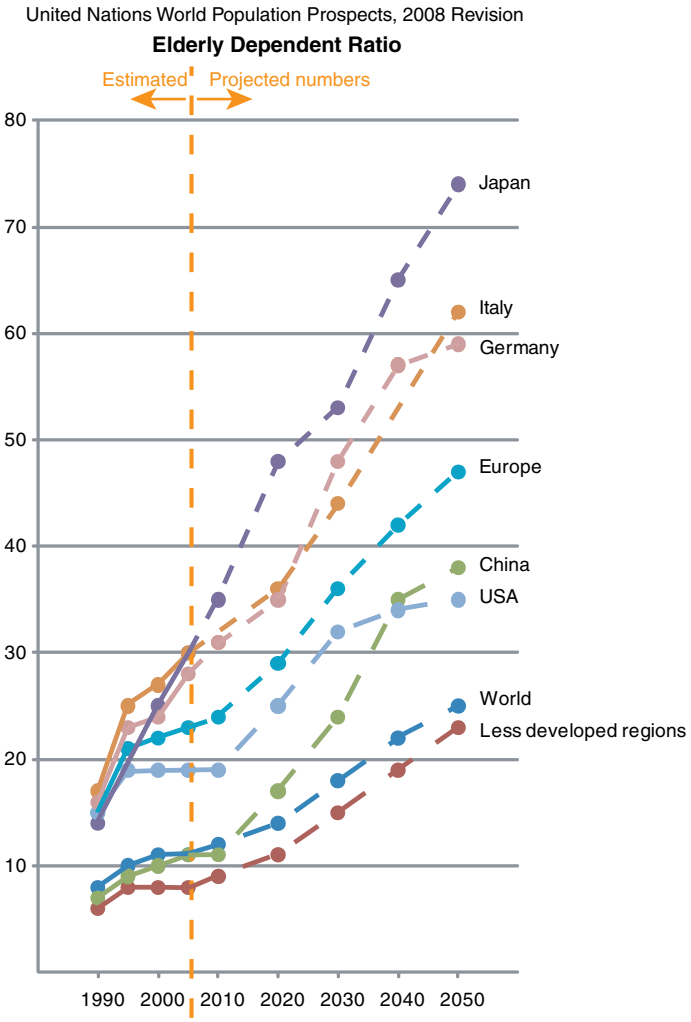

Figure 1.6 Elderly dependent ratio of selected countries and regions: estimated values 1995–2005 and values for a medium projection scenario 2010–2050 [6].

than today. In fact, age-related diseases, and also chronic and lifestyle-related diseases, are expected to become more prevalent in industrial countries. A recent study predicted the expected case numbers of selected widespread diseases in Germany for the years 2030 and 2050, based on current case numbers and the expected demographic development [7] (Figure 1.7). According to this study, the number of patients suffering from dementia as related to the total population will more than double by 2050. The same holds true for the number of patients suffering from age-related macular degeneration (AMD), which is the most prevalent cause of sight of loss in elderly people. Likewise,

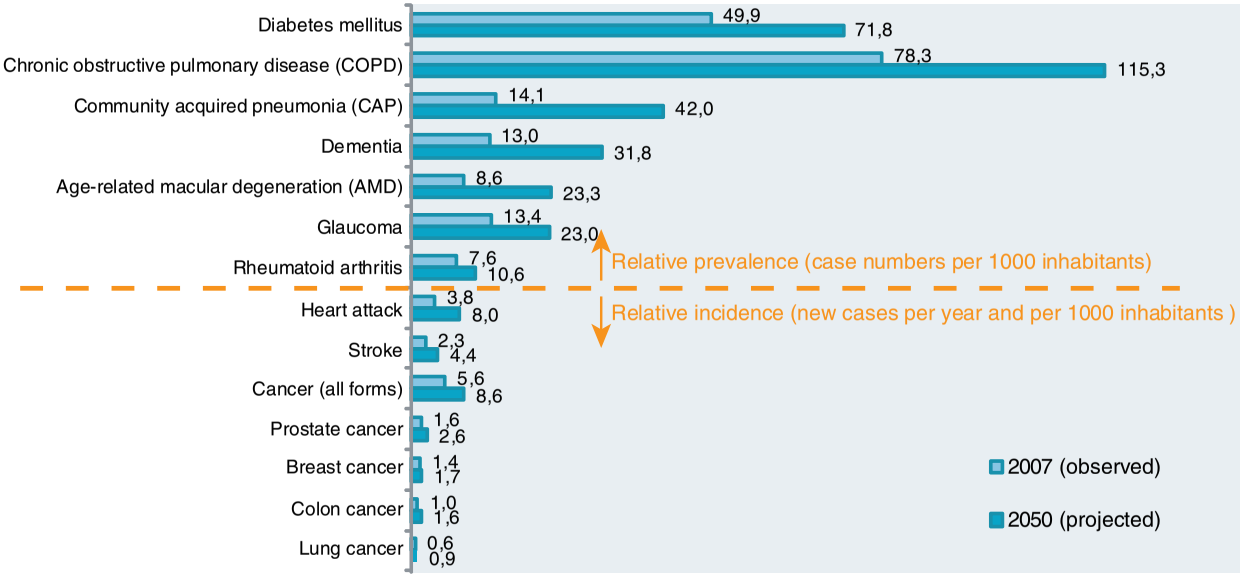

Figure 1.7 Case numbers of selected, widespread and/or severe diseases in Germany, expressed as a percentage of the total population, current as of 2007 and prognosis for 2050 [7].

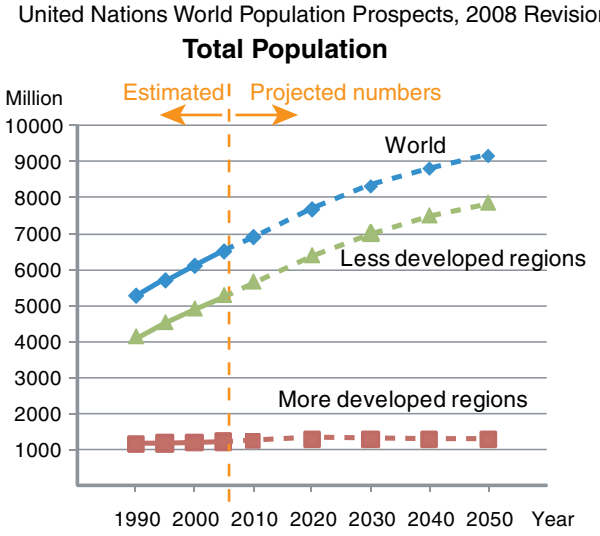

Figure 1.8 Development of world population: estimated values 1995–2005 and medium projection value 2010–2050 [6].

the relative incidence of heart attacks and stroke cases will about double, and the relative incidence of community-acquired pneumonia (CAP) will even be threefold higher than today.

3) **Increasing spendings on health care:** Health care spendings represent a substantial portion of the gross domestic product (GDP) in developed countries. In many European countries, total expenditure amounts to about 10% of the GDP [8]. In the US, the total expenditure on healthcare reached 16% in 2007 [8] and is expected to rise to 20% by 2020 [9]. The study cited above expects that the expenditure on benefits in German health care will more than triple per inhabitant of working age, from €320 in 2000 to €1078 by 2050 [7].

1.1.5.2 Unmet Medical Needs in Third World Countries

The demographic development is also expected to impose major burdens on medical care in Third World countries, as the population will probably continue to grow rapidly in the foreseeable future. The United Nations expects the world population to exceed 7 billion in 2012 and to reach 9.2 billion by 2050 in a medium projection case [6] (Figure 1.8). If this development is not accompanied by a corresponding economic growth, the quality of life will decrease further for many individuals. In the health care sector, this development can only be stopped or even reversed by major breakthroughs towards cost-effective medical procedures that possibly could be applied even in the absence of a physician. Particular attention must be paid to the fast and reliable identification of life-threatening infections in order to prevent their unimpeded propagation. Here, optical technologies might contribute greatly to sustainable health care.

Theses on Future Trends in Health Care, Especially in Developed Countries

- The aging societies will generally experience growing case numbers of diseases, even in the case of a shrinking population. This particularly affects age-related diseases such as neurodegenerative, cardiovascular and eye diseases, and also cancer.
- People's expectations for their own health state will grow, especially in the elderly. Healthy aging is desired; the tolerance towards age-related handicaps will decrease.
- A paradigm change will occur from disease treatment towards health maintenance. Systems and methods for preventive monitoring of the health state, and here especially self-monitoring solutions, will be strongly demanded.
- Due to increasing worldwide traveling activities and urbanization in Third World countries, the risk of pandemics is growing. Fast and easy-to-use screening methods for infectious diseases will be required to counter this.
- Antibiotic-resistant germs ("hospital germs") will occur to a greater extent, including multi-resistant germs.
- The requirements on medical treatments will grow. Patients will expect them to be less invasive, highly efficient and precise.
- Medical treatments will become more personalized. This includes gene and stem cell therapies, and also individual medications (active ingredients, dosage).
- Financial resources in public health care will not grow proportionally to the expected performance and benefit.

1.1.6 Economic Impact of Biophotonics

Market analyses have identified biophotonics among the most important growth segments of the worldwide photonics market [1, 2, 9, 10]. However, quantification of the market situation suffers from several peculiarities. First, the existing studies start from different definitions of the term "biophotonics," which entails different considerations of products and product classes. Growth prognoses are especially complicated as the biophotonics market is fairly young and features many technologies in an early stage of commercialization. Effects such as the development of new markets and the replacement of existing technologies can hardly be estimated.

A market study published by the German Federal Ministry of Education and Research [1] estimated the world market for biophotonics products to be worth about €19 billion in 2005; at about 10%, a significant growth rate was expected for the following years. When excluding the area of ophthalmic optics (spectacle and contact lenses, which are not biophotonic products according to the definition used in this book), the biophotonics market is worth about €10 billion. This includes medical therapeutic systems, "systems for *in vivo* and *in vitro* diagnostics, and

optical systems for the life sciences and for drug discovery. Lee *et al.* estimated the biophotonics market to be worth $53–63 billion in 2004 [10]. However, this study included not only photonic technologies but also technologies such as X-ray, PET and ultrasound.

As typical of the photonics sector, small and medium-sized enterprises (SMEs) are driving the market to a significant extent. Only a few major enterprises appear alongside hundreds of SMEs [2]. Typically, biophotonics is only one of several areas of business in these companies.

1.2
Worldwide Research Activities in Biophotonics

1.2.1
Biophotonics – a Cross-Disciplinary Science

Biophotonics is a highly cross-disciplinary science and bundles knowledge from a wide range of scientific disciplines (Figure 1.9), including, but not restricted to:

- optics and photonics (e.g., optical components and systems)
- cell biology and molecular biology (e.g., handling and examination of cells and tissues)
- physics and physical chemistry (e.g., molecular spectroscopy)
- biochemistry (e.g., development/verification of markers and labels)

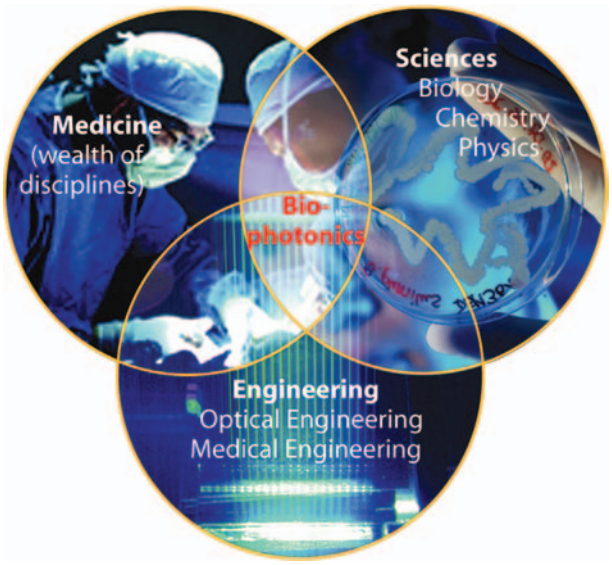

Figure 1.9 Biophotonics bundles knowledge from a wide range of scientific disciplines.

- bioinformatics (e.g., data handling and presentation)
- a wealth of medical disciplines.

Biophotonics research is driven by numerous research groups at university hospitals, universities, and other research institutions, and also through corporate R&D. However, optical solutions for medicine and the life sciences rarely develop from the isolated work of a single research group or company. Many tasks require intense communication, networking and collaboration of experts from the mentioned areas, for example, in the course of collaborative research projects. As many governments have recognized biophotonics as a scientific discipline of high economic and societal importance, they have established national funding programs which have driven such collaborations significantly. At the same time, the number of research groups working in the field has grown remarkably throughout the world. The number of institutes which have established a main area of their research in the field has increased strongly in recent years and is still growing. With extensive funding, the US has even set up a National Research Center on Biophotonics.

However, many indicators show that the interdisciplinary dialog and cooperation still need further improvement. Experts believe that especially the communication between developers and users of biophotonic solutions must be considerably intensified [9, 11, 12]. According to a survey among German biophotonics companies, this communication gap between developers and users is the most important bottleneck to further advances in the field (Figure 1.10).

From our observations, one consequence of this communication gap is that biophotonics research generally remains too much technology driven. To overcome this, technologists should become more aware of important, yet unmet medical needs: Which important diseases cannot be diagnosed or treated adequately yet? On the other hand, more medical doctors and life scientists should become acquainted with the latest optical technologies in order to recognize their value and potential use

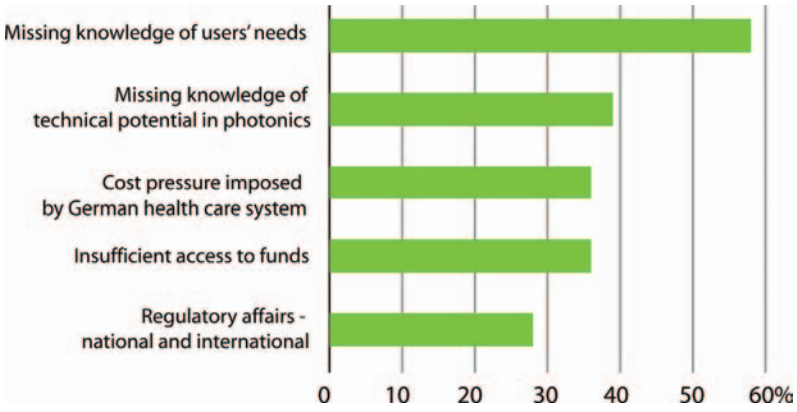

Figure 1.10 Barriers to innovation in biophotonics, as mentioned in a survey among German companies involved in the field [11].

for their specific application. Ideally, users and developers of biophotonic solutions should jointly evaluate which technologies promise the greatest benefit in selected applications, and collaborate on rapid implementations. This would ensure that applications drive the development of technologies and devices (technology "pull") rather than "pushing" technologies into applications. Although of course this interdisciplinary dialog already takes place in many collaborations and informal networks, it can also be amplified further by cross-disciplinary conferences and workshops, such as the International Congress on Biophotonics (ICOB). Furthermore, interdisciplinary efforts should also include suitable education. In academia, foresighted planning would include special lectures in master studies, or even completely new courses of study that cover both photonics and medical topics in such a way that students learn both languages right from the start. Fortunately, several dedicated summer schools for graduates have already been established, including the International Graduate Summer School on Biophotonics (Ven, Denmark), the Nano-Biophotonics Summer School (US) and the Biophotonics and Imaging Graduate Summer School (BIGSS (Ireland)).

1.2.2 Scientific Landscape

1.2.2.1 International Conferences

A number of recurring conferences are dedicated to the field of biophotonics or biomedical optics. Some of the most important among them are organized by the optical societies SPIE and OSA. Moreover, biophotonic methods and applications are showcased at numerous other meetings with related or overlapping topics, some of them focusing on specialist topics such as spectroscopy, microscopy, or therapeutic laser applications. Selected, important conferences include the following:

- SPIE conferences, particularly Photonics West (US; subconference BIOS – Biomedical Optics), Photonics Europe (Brussels, Belgium; subconference Biophotonics)
- OSA conferences, particularly BIOMED, Biomedical Optics (US)
- EOS conferences (EOSAM, Paris, France; subconference Biophotonics – Advanced Trapping and Optofluidics in Life Science)
- ECBO (European Conferences on Biomedical Optics) (Munich, Germany; joint SPIE–OSA conference)
- APS (American Physical Society) annual meeting
- CLEO/QELS – Conference on Lasers and Electro Optics
- Biophotonics and Imaging Conference (BioPIC) (Meath, Ireland)
- IEEE (Institute of Electrical and Electronics Engineers) conferences
- BMES (Biomedical Engineering Society) annual meeting
- ICOB (International Congress on Biophotonics)
- Frontiers in Neurophotonics
- OWLS (Optics Within the Life Sciences)
- APBP (Asian and Pacific Rim Symposium on Biophotonics)

- International Symposium on Topical Problems of Biophotonics
- International Conference on Laser Applications in Life Sciences (LALS)
- International Conference on Photonics and Imaging in Biology and Medicine
- Medical Laser Applications
- International Photodynamic Association meeting
- European Society for Photobiology meeting
- European Platform for Photodynamic Medicine.

1.2.2.2 **Scientific and Trade Journals**

To date, there are two peer-reviewed scientific journals that are fully dedicated to the field of biophotonics: the *Journal of Biophotonics* published by Wiley-Blackwell and the *Journal of Biomedical Optics* published by SPIE. Moreover, biophotonic methods and applications are published in numerous journals with related or overlapping topics. Some of the peer-reviewed journals attracting the most readership among biophotonics researchers are listed below. The data were collected by polling approximately 120 scientists, students, industry researchers, and other participants at the first International Congress on Biophotonics in 2008.

- *Journal of Biophotonics*
- *Journal of Biomedical Optics*
- *Applied Optics*
- *Biophysical Journal*
- *Nature Photonics*
- *Nature*
- *Optics Express*
- *Optics Letters*
- *Physical Review Letters*
- *Proceedings of the National Academy of Sciences of the Unites States of America*
- *Science*
- *Journal of Innovative Optical Health Sciences*.

There are also a number of trade journals that publish news in the field, upcoming events, interviews with scientists, information about new instruments, and other materials related to biophotonics. Specialized titles on biophotonics include *BioOptics World*, *Biophotonics International* (both US) and *BioPhotonik* (Germany).

1.2.2.3 **Networks and Funding Programs**

All over the world, many governments have recognized the economic, scientific, and social importance of biophotonics. Their funding programs (Table 1.2) are stimulating further advances in the field, but also strengthen the pressure of competition between research institutions, regions, and countries. The vast majority of funds are provided for infrastructure (e.g., research centers; see table entries for the US and Singapore), and for research projects to ensure the fast transfer of scientific findings into products and services (see the entry for Germany). Additionally, networking and knowledge management activities are also supported, as in the case of the European

Table 1.2 Worldwide initiatives and funding programs on biophotonics, data retrieved in 2008 (without claiming to be complete) [9].

Country	Project name	Main focus	Budget
The Netherlands	IOP Photonic Devices for Health and Medicine	Imaging techniques, cancer diagnosis, molecular imaging, Raman spectroscopy, optical coherence technology, breath analysis, fluorescence microscopy, SPECT	€25 million
Germany	BMBF Forschungsschwerpunkt Biophotonik	• Optical imaging for medical research and diagnostics, optical POC testing and on-site monitoring • Improved understanding, detection, and treatment of widespread diseases such as cancer, neurodegenerative, dermal, and cardiovascular diseases • Rapid detection of environmental quality, for example, germs in air and water; fine dust in air • Technology focus: microscopy (live cell, 3D, high-resolution), spectroscopy, fluorescence, molecular imaging	~€100 million (2002–2010)
Scotland	SUPA	• Spectral imaging • Optical manipulation of molecules and cells • *In vivo* sensing and imaging • Multi-planar imaging microscope • Micron-sized sources and nanooptics with single-photon (quantum dot) sources and detectors	~£14 million (first 5 years)
Ireland	NBIPI	• Molecular imaging • Live cell and histology imaging • 3D reconstruction and stereology • Small animal *in vivo* imaging • Human diagnostic imaging • Numerical and computational image analysis	€30 million for 2007–2010

(*Continued*)

Table 1.2 (*Continued*)

Country	Project name	Main focus	Budget
USA	NSF Center for Biophotonics	• Bioimaging • Cellular and molecular biophotonics • Medical biophotonics • Education and human resource development • Knowledge transfer	$52 million for the first 10 years (2002–2012)
USA	Biophotonics for Life	• Create and foster a global consortium • Develop a worldwide network • Develop a strategic roadmap	Initially $1.5 million
Japan	Large-scale R&D projects initiated by the Ministry of Economy, Trade and Industry (METI), the Ministry of Education, Culture, Sports, Science, and Technology (MEXT), and the Ministry of Health, Labor, and Welfare (MHLW)	Molecular imaging research program: • Imaging equipment for early detection of lifestyle-related diseases • Molecule imaging equipment for malignant tumor therapy support Knowledge cluster initiative (e.g., Hamamatsu Optronics Cluster): • Next-generation imaging devices, which feature a dynamic range of previously unattainable width and smart imaging, permitting efficient acquisition of only the necessary image information • Highly functional microscope systems, endoscope systems, and surgery support systems • Camera device for high-energy rays used in nondestructive inspection and X-ray CT	~€20.5 million for 5 years (start: 2005)

Canada	Biophotonics Initiative in the framework of the Network of Excellence, Canadian Institute for Photonic Innovations (CIPI)	Biophotonics as one of three main focal areas: • CellLab: the living cell as a laboratory • Advanced photonic technologies on a chip for single-cell analysis • Two-photon excitation photodynamic therapy • Integration of digital micro-mirror devices with confocal macroscopy for improved genetic microarray reading and tissue imaging • Biophotonic systems using high-resolution and diversity imaging • Improved femtosecond laser-based approaches for cellular imaging in live tissue	Can$4.2 million for fiscal year 2006–2007
Australia	Research Network for Fluorescence Applications	• Development of time-resolved fluorescence instrumentation for ultrasensitive microbial screening • Laser-based biochemical assays to instantly recognize heart attack • Extraction of commercially significant fluorescent proteins native to Australian reef corals • Specific microorganisms in complex environments such as industrial waste using high-level multiplex fluorescent probes	A$2 million (2004–2009)
Australia	Center for Biophotonics and Laser Science (at the University of Queensland)	• Fundamentals of light–matter interactions • Biological imaging and sensing • Biological spectroscopy and devices • Laser manipulation • Biomedical and clinical applications	?
Taiwan	Institute of Biophotonics, National Yang Ming University	?	?

(*Continued*)

Table 1.2 (*Continued*)

Country	Project name	Main focus	Budget
Singapore	Biomedical Sciences (BMS), Biopolis Initiative	Institute of Bioengineering and Nanotechnology: • Nanobiotechnology • Delivery of drugs • Proteins and genes • Tissue engineering • Artificial organs and implants • Medical devices • Biological and biomedical imaging Bioimaging Consortium (SBIC) • Coordinated national program of imaging research • Identification and consolidation of the various bioimaging capabilities across research institutes, universities and hospitals • Fostering closer collaboration in bioimaging among researchers and medical practitioners. Technology platforms (used to support research in areas such as cancer, metabolic medicine, and regenerative medicine): • Optical imaging • Image processing and management • Small animal imaging with magnetic resonance • Development of chemical/biological probes	Biopolis 2003–2006: ~$570 million (infrastructure only), ~$600 million venture capital (via Agency for Science, Technology and Research – A*STAR) $4 million
China	Laser manipulation	Optical brain imaging and neuroinformatics • Optical molecular imaging and systems biology • Digital life and biomedical informatics • Optical probes and nanobiophotonics • Multimodal biomedical imaging and tissue optics	?

Network of Excellence (NoE) Photonics4Life and the worldwide network Biophotonics4Life (see also Section 1.3 below).

1.2.3 Current Research Trends and Future Goals

Here we want to emphasize a selection of important areas where biophotonics promises major progress in the near future. Many of the current research activities in biophotonics can be summarized with the following global trends:

Current Global Trends in Biophotonics

- From microscopy of fixed (dead) cells towards video-rate nanoscopy of processes in and between living cells in 3D
- From structural imaging (morphology) towards molecular and functional imaging
- From two-dimensional towards multidimensional imaging
- Seamless imaging from the level of the entire body down to the subcellular and molecular level
- From biopsy and *ex vivo* examination towards minimally-invasive or non-invasive *in vivo* diagnostics
- From laboratory analysis towards rapid testing (POC tests or even home self-tests)
- Closer alliance of diagnosis and therapy (e.g., intraoperative diagnosis, feedback-controlled therapies, combined diagnostic–therapeutic laser systems).

1.2.3.1 Photonic Methods for Biomedical Research

Today, a wide range of microscopic and spectroscopic methods allow the detailed examination of physiological processes in cells and cellular networks and thus have paved the way for molecular cell research (Table 1.3). The investigation of cellular communication, or in more general the investigation of life processes on a cellular or even subcellular level, is a prerequisite for a fundamental understanding of the origin and progression of diseases. This understanding could open up new avenues of curing diseases right at their point of origin. For these scientific questions, fluorescence methods have become indispensable tools. Especially fluorescence microscopy has provided us with novel, manifold insights into the building blocks of the human body. However, until recently such studies were restricted to the examination of fixed, that is, dead cells and thus could only deliver snapshots. Moreover, with lateral resolutions of above 200 nm, many important cellular components were not resolved sufficiently (see Figure 1.3). In contrast, a true understanding of signaling processes, cellular communication or transport processes requires the observation of living cells and cell aggregates, namely three-dimensional, real-time imaging with improved penetration depth and at resolutions down to a few nanometers in all spatial directions. A major breakthrough was the introduction of stimulated emission depletion (STED) microscopy, a few years ago. This technology allows the mapping

Table 1.3 Photonic methods for health research and cellular and molecular biology: important fields of current research.

Application	Optical technology
Investigation of biomolecular interactions (e.g., receptor–ligand, receptor–drug), elucidation of biomolecular modes of action, analysis of signal cascades, identification of specific cellular states	Fluorescence spectroscopy: • Spectrally resolved, temporally resolved (FLIM) • FRET • Ultrahigh resolving in space (STED, structured illumination, dSTORM; two-photon) • Fluorescence correlation spectroscopy (FCS) Raman spectroscopy: • Linear, spectrally resolved • Coherent anti-Stokes Raman scattering (CARS) • Stimulated Stokes–Raman scattering (SRS) • Tip-enhanced Raman scattering (TERS)
Identification of specific receptors and antigens and their mapping on cell surfaces	TIRFS, surface enhanced Raman spectroscopy (SERS)
Cell mapping, distribution of metabolic products in cells	Raman spectroscopy, CARS, fluorescence
Characterization of extracellular matrix	Second harmonic generation (SHG), third harmonic generation (THG)
Analysis of mechanic properties of cells	(Multifocal) optical tweezers, holography
"Cell surgery," membrane perforation, "optical knockout"	Pico- and femtosecond lasers ("two-photon or multi-photon surgery")
Separation of defined histological areas	Laser microdissection

of cellular structures with a lateral resolution of a few nanometers. The technique uses the nonlinear de-excitation of fluorescent dyes to narrow the size of the excitation spot. Unfortunately, this requires high laser intensities and thus might induce photobleaching and damage living cells. Resolution on the nanoscale is also provided by single-molecule microscopic techniques such as PALM (photoactivated localization microscopy) and STORM (stochastic optical reconstruction microscopy). Here, special fluorescence dyes are used that can be switched on and off optically and reversibly, which allows their localization as single molecules. Nevertheless, improvements in order to leverage nanoscopy for widespread use in biochemical laboratories, or even in clinical environments, are still necessary. This includes the development of novel fluorescent labels. Here, novel fluorescent proteins will probably play a major role, as they allow photostable and highly specific labeling. Further innovations are also required on the hardware side for the examination of living cells, including concepts for their handling [13], novel short-pulse lasers for non-damaging excitation,

fast detection methods and innovative software and data management in order to handle the enormous amount of data associated with 3D and video-rate imaging.

Dynamic processes in and within cells can particularly be observed using special fluorescence methods such as FLIM (fluorescence lifetime imaging) and FRET (Förster resonance energy transfer). Both methods can also be carried out in a spatially resolved mode and thus can be used for imaging. Even more detailed insights down to the molecular level are provided by the Raman-based CARS (coherent anti-Stokes Raman scattering) microscopy, SRS (Stimulated Raman Scattering), and fluorescence correlation spectrometry (FCS). All these methods are fairly demanding in technical respects and therefore are not yet used extensively, but are in the process of being commercialized. In contrast, two-photon microscopy is already widespread. With gentle illumination of the sample and comparably high penetration depth, this technology is ideally suited for the spatial imaging of living cellular structures and is already being used in clinical *in vivo* diagnostics (Figure 1.11). As an alternative to fluorescence microscopy, marker-free technologies such as DHM and phase contrast microscopy are being developed further.

Optical methods allow not only the observation but also the active micromanipulation of cellular processes. An important example is the breeding of cell lines for biotechnical production of pharmaceutically active substances [13]. Today, many drugs are based on biomolecules such as hormones, enzymes, growth and coagulation factors, antibodies, and vaccines. To an increasing extent, these substances are produced using microorganisms and cell lines that have to be optimized beforehand through genetic modification to suit the target substance. In practice, the selection and subsequent sorting of living cells from cultures can be performed using so-called optical tweezers that hold or move microparticles with the help of a laser beam that is coupled into the microscope and focused onto the object. Another application is the exact dissection of selected cell areas from tissues using ultrashort laser pulses (laser dissection, laser catapulting, "cell surgery"). This technology is

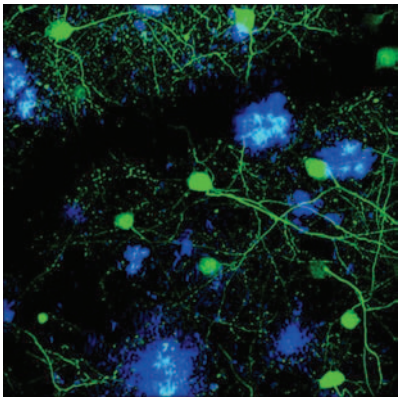

Figure 1.11 Two-photon microscopy reveals cellular and molecular structures *in vivo*: amyloid plaques (blue) between the neurons of transgene Alzheimer's mice (image: Zentrum für Neuropathologie, LMU München).

already used in clinical tissue pathology, for example, for a precise diagnosis and prognosis of cancer. For this purpose, selected areas are cut out from the tumorous tissue and submitted to molecular diagnosis using microarrays or polymerase chain reaction (PCR). In addition, optical micromanipulation is also employed as a tool in regenerative medical applications, including cartilage growth and transplantation, new methods of wound treatment, and the transfection of genetic material into single cells. In order to integrate the described micromanipulation technologies smoothly into laboratory and clinical routines, system manufacturers are currently working on integrated platforms for microscopic imaging and cellular, or even subcellular, manipulation.

Fluorescence methods are also of great importance in pharmaceutical drug discovery. Today, the drug libraries of large pharmaceutical companies contain millions of substances. Their number is growing further, due to genomic analyses which deliver more and more drug targets for novel therapies. During the drug discovery process, the potential effectiveness of drug candidates has to be tested in the laboratory. Here, fluorescence methods are used for HTS of thousands of candidates per day, and also for HCS [13]. This helps to reduce costs and analysis times drastically compared with other methods.

1.2.3.2 **Photonic Methods for Point-of-Care Diagnostics**

For an improved early recognition or even prevention of diseases or for therapy monitoring, the further spread of low-cost, easy-to-handle test systems for the fast examination of readily obtainable samples such as body fluids would be highly beneficial. Such POC devices could facilitate routine examinations of patients and risk groups directly at the doctor's practice (Table 1.4). Technically, this application is covered by chip-based systems that work on a molecular level: Selected proteins, DNA, or small biomolecules are detected as biomarkers, that is, as a precursor or an early sign of a possible disease, or quantified to monitor the progress of a therapy. Crucial success factors for novel POC devices are the sensitivity, selectivity, and robustness of detection, but also the cost per information, the time elapsed from sample collection to result, and the possibility of acquiring several parameters in parallel. Here optical technologies offer a unique potential, as described previously in Section 1.1.3. This is also reflected by their widespread use in comparable diagnostic

Table 1.4 Photonic methods for POC diagnostics: important fields of current research.

Application	Optical technology
Detection and identification of pathogens (bacteria, viruses)	Fluorescence measurements, in combination with antigens
Identification of metabolic products and biomarkers, analysis of the composition of cells, tissues, and body fluids	Fluorescence measurements (spectral and temporal domain), Raman spectroscopy
Analysis of morphological abnormalities (with sub-microscopic resolution)	Light-scattering microscopy

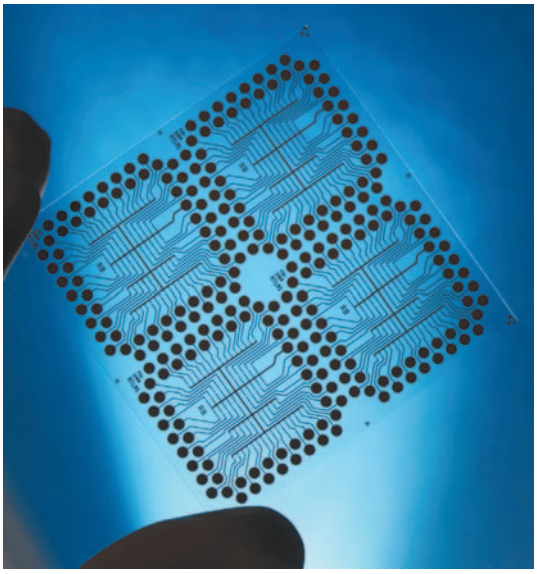

Figure 1.12 This electro-photonic biochip for POC can simultaneously screen for up to 40 different biomolecules such as DNA or proteins (photograph: IPHT Jena).

applications performed in the laboratory. However, existing systems that work on a macroscopic scale cannot be miniaturized arbitrarily as, for example, many optical detection paradigms such as absorbance and fluorescence suffer at smaller geometries. In many cases, new principles that are only effective on the microscale must be implemented. A current approach is also the combination of electrochemical and photonic detection (electro-photonic biochip, Figure 1.12). Microfluidics also plays an important role, as it permits the handling of liquids (e.g., dosage, mixture, separation) in extremely small amounts. Especially sample preparation and manipulation can be automated and miniaturized in this way. This is one of the key factors for a device that can be handled easily and possibly even by untrained persons, for example, in patient self-testing. Most often, sample preparation is the most critical and difficult analysis step, especially with complex samples or samples with complex optical behavior such as blood. The combination of microfluidic and optical technologies results in a so-called optofluidic system.

An important area of application of molecular-based POC devices is the detection of risk factors for cardiovascular diseases. Medical research has revealed a number of relevant biomarkers, including certain protein fragments, proteins and enzymes [14]. For the analysis of single biomarkers, for example, C-reactive protein (CRP), compact, fast immunoassays have already been introduced on the market. However, a fast test that detects several biomarkers in parallel would deliver more significant results (see, e.g., www.labonfoil.eu). The implementation of such multiplex assays ranks among the most important research topics in the field of optical POC testing. For this purpose, multichannel readers for fluorescence lifetime measurements and spectroscopic methods such as SERS (surface-enhanced Raman

spectroscopy) are currently being investigated, among other methods. For fluorescence methods, stable fluorescence labels must be developed that bind to the desired biomarkers with high selectivity. Here, so-called quantum dots hold great promise [14]. In addition to POC solutions, systems for patient self-testing have considerable market potential. Generally, they must meet even higher requirements concerning cost and reliability and therefore will need more time to succeed in the market compared with systems for the doctor's practice. Here, remarkable potential lies also in the field of wellness and health maintenance. Portable systems might help to adjust physical training by monitoring physiological parameters during sports activities, and to control nutrition by monitoring selected blood parameters such as triglycerides, cholesterol and γ-glutamyl transpeptidase (γ-GT) values.

An urgent, yet largely unmet, medical need is the fast identification of pathogens in the case of sepsis. Despite all hygiene efforts, about 150 people per day die from sepsis in German hospitals alone [15]. In order to avoid mortal cases, the time for pathogen identification must be reduced from currently about 36 h to about 30 min after onset of sepsis. Here, optical cell-based diagnostics (readout of spectral signatures) promises a considerable gain of time compared with conventional culture-based methods. Not only must the pathogen be reliably identified but also resistances and host responses must be determined.

1.2.3.3 **Photonic Methods for Clinical Imaging**

Clinical imaging delivers images of the human body (or parts and function thereof) for clinical purposes, especially for the diagnosis of diseases, but also for prognosis, follow-up, and therapy control. In addition to widespread methods such as positron emission tomography (PET) and magnetic resonance tomography (MRT), optical methods have become increasingly important (Table 1.5). Technically, this includes a broad range of methods that deliver two- or multi-dimensional images of tissue

Table 1.5 Photonic methods for clinical imaging: important fields of current research.

Application	Optical technology
Early detection of tumors	One- and two-photon fluorescence spectroscopy, possibly together with endoscopy
Intraoperative recognition of tumor borders	Fluorescence and Raman spectroscopy, with surgical microscopes/endoscopes
Detection and quantification of (hidden) caries	(Red excitation) fluorescence, terahertz spectroscopy, CARS, OCT
Structural examination of the ocular fundus	OCT
Determination of plaques in blood vessels	Endoluminal OCT
Microscopic characterization of dermal changes	OCT, two-photon microscopy, confocal reflection spectroscopy
Monitoring of biomarkers, metabolic products, pharmaceutical agents, and so on for control of therapy and progression	Fluorescence and Raman spectroscopy

surfaces or from within the body. Preferably, the optical window in biological tissue is used, which lies in the near-infrared (NIR) region (700–900 nm). The most important optical technologies for clinical imaging are endoscopy, OCT, microscopy and spectroscopy, and also combinations of them (so-called multimodal approaches). In the sense of patient-friendly diagnostics, especially noninvasive and minimally invasive technologies are advanced. As biopsies cannot be avoided in all cases, the imaging of tissue samples remains an important field of research, however.

In addition to the well-established structural (or morphological) imaging, current research also tends towards functional and molecular imaging. While functional imaging seeks to explore, for example, changes in metabolism, blood flow, and regional chemical composition, molecular imaging aims at the visualization of biological processes in living organisms on a cellular and molecular level. Especially molecular imaging is expected to revolutionize clinical diagnostics, as this method can trace pathological changes in the body already on a molecular scale – and thus possibly long before the first perceptible symptoms occur. It is known that some types of cancer can lead to the production of modified proteins as soon as 10 years before they develop into a solid, palpable tumor. This offers the opportunity to detect and influence abnormally changed cells before they turn into malignant tumor cells. Similar latency is presumed for neurodegenerative diseases such as Alzheimer's disease, which currently can only be diagnosed safely at an advanced stage when the brain is already severely damaged. Furthermore, the understanding and targeted treatment of widespread skin diseases such as neurodermatitis and actinic keratosis might be improved due to molecular imaging. For these purposes, multi-photon imaging is already deployed in clinical environments. Endoscopic molecular imaging also allows a sensitive and gentle intraoperative diagnosis. Further improvements in diagnostic imaging are needed, especially with respect to selectivity. Possible approaches are the development of new fluorescent labels, but also the further development of label-free methods. Although optical imaging methods are already well established in oncology and ophthalmology, great demand exists also in cardiology and in the area of neurodegenerative diseases.

In the field of cancer diagnostics, current biophotonics research seeks to expand the existing methods in three directions:

1) **Early recognition:** The recognition of cancer at the earliest possible stage remains one of the most important aims in modern health care. As an example, cancer organizations estimate that the number of mortal cases due to colon cancer (the most prevalent form of cancer, e.g., in Germany) might be reduced by about half if screening was performed consistently. Today, tumors can only be visualized by radiography at a size of about 100 million cells or more. Here, the method of fluorescence endoscopy holds great promise: Current research gives rise to the hope that soon small tumors of about 1 mm diameter (1 million cells) or even smaller might be differentiated safely from healthy tissue. Fluorescence endoscopy is already used to detect tumors of the bladder and brain, and is currently being extended to permit highly specific detection of tumors in other organs (e.g., colon, lung) [16]. Typically 5-aminolevulinic acid (5-ALA) is administered to

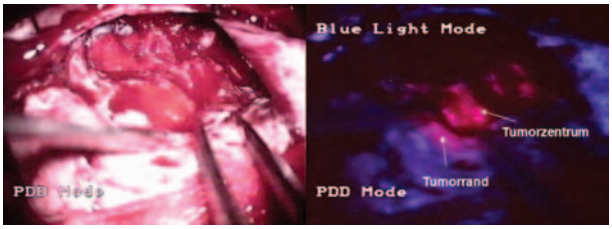

Figure 1.13 Fluorescence endoscopy using 5-ALA provides a much clearer picture of this malignant brain tumor than classical whitelight endoscopy. Especially the infiltrating borders (purple) can be better distinguished from healthy tissue. *Tumorzentrum*, center of tumor; *Tumorrand*, tumor border (source: LMU Munich, LIFE Center, Laser-Forschungslabor).

the patient ahead of the examination, which induces increased generation and accumulation of a fluorescent dye in possibly existing tumor cells (Figure 1.13). The future perspective is to intervene at a much earlier stage of tumorigenesis and to recognize the very first tumor precursors. However, this requires the development of novel, highly specific fluorescent probes that bind to known tumor markers such as TKTL-1 [17]. At present, peptide and nanoparticulate probes are being investigated for this purpose. As the development of such probes is comparably extensive, marker-free technologies such as autofluorescence, Raman spectroscopy and CARS are also advanced further.

2) **Closer linkage of diagnosis and therapy:** At present, fluorescence endoscopy enables the surgeon to recognize the exact borders of tumorous lesions in internal organs and thus to perform surgery in a highly precise and gentle mode. In the future, small tumors might even be removed easily during endoscopic examination using an endoscope that is equipped for laser-induced, thermal, or photodynamic destruction of the detected tumor [16].
3) **Improved grading and individual therapy recommendations:** Today, optical technologies offer important improvements for the histological examination of tissue samples. Although pathologists can answer the question "cancer – yes or no?" safely after microscopic inspection of tissue slices, unfortunately their prognosis of the course of disease often remains vague. Many experts are convinced that multimodal tumor diagnostics can fundamentally change this. By refining classical morphological diagnostics and combining it with molecular methods, for example, optical spectroscopy and biomolecular assays, a better grading and prognosis might become possible, which would permit individual therapy recommendations.

In the field of ophthalmology, OCT has become the gold standard for detecting morphological changes in the eye over the last 20 years. In contrast to fundus imaging, OCT allows one to visualize also deeper layers below the surface, opening the third dimension and allowing, for example, macular thickness measurements. Thereby a multitude of different eye diseases can be diagnosed, such as pigment epithelial detachment (PED) and the diagnosis of glaucoma in a non-invasive and fast way [9]. On the other hand, many age-related diseases such as cardiovascular diseases, diabetes,

Figure 1.14 Laser fibers have paved the way towards minimally invasive medicine (Photograph: World of Medicine AG, Berlin).

and neurodegenerative diseases might be diagnosed at an early stage and in a gentle manner by utilizing the eye as a "diagnostic window to the body". Here, suitable techniques for the measurement of morphological and functional parameters, for example, autofluorescence and fluorescence lifetime measurements, are currently being advanced towards clinical systems. Again, multimodal approaches seem favorable – especially combinations of OCT with fluorescence methods.

1.2.3.4 **Photonic Methods for Therapeutic Applications**

At present, laser radiation is routinely used for the targeted treatment of tissues. For this purpose, the radiation can be conducted through optical fibers and adjusted for a highly precise local application (Figure 1.14). Different effects can be achieved by adjusting wavelength, intensity, and duration of radiation. The most common application (Table 1.6) lies in ophthalmology (e.g., refractive surgery), followed by applications in dermatology (e.g., PDT) and surgery. More optical procedures for clinical use are currently being developed, including the use of ultrashort laser pulses

Table 1.6 Photonic methods for therapeutic applications: important fields of current research.

Application	Optical technology
Precision surgery (e.g., cornea)	Excimer lasers, femtosecond lasers
Selective therapies, restricted to abnormal cells	PDT, (pulsed) lasers with optical feedback
Treatments on a molecular scale (gene switching, activation of molecules)	Pulsed lasers combined with optical switches, nanoparticles
Novel antimicrobial strategies	PDT and combined methods

for precision surgery of the eye, brain, and nerves, and therapeutic lasers for dentistry. Furthermore, closer diagnostic feedback will fundamentally change and enrich medical interventions, as indicated above. They will become even more precise and gentle (due to, e.g., intraoperative *in vivo* diagnostics), but also develop into personalized therapies (due to, e.g., multimodal tumor diagnostics). Moreover, novel methods such as the optical selection of living cells from tissues or cultures and their examination and manipulation will provide new perspectives for regenerative medicine (see Section 1.2.3.1).

1.2.3.5 Photonics in Pharmaceutics, Bioanalysis, and Environmental Research

As described in Section 1.2.3.2, optical POC devices can match urgent analytical needs in the fields of environmental analysis, food analysis, and drug safety. This includes agricultural applications such as prevention or stemming of animal and plant epidemics. In addition, wellness applications can be assumed to gain further importance, for example, the evaluation of blood values (lactose, antioxidant agents) to determine the level of fitness and to control the success of exercises and also the evaluation of stress levels. Another important contribution of biophotonics to this field is the development of optical systems for the continuous monitoring of the quality of air, water, soil, food, pharmaceuticals, and cosmetics with respect to quality and possible contamination. Already introduced on the market are online monitoring systems for pollen and for germs in air (Figure 1.15). Current research includes the fast detection of germs in potable water [18] and an improved detection method for fine dust in air, which might even help to trace individual sources of pollution [19]. Furthermore, security applications have become more and more important over recent years, comprising the detection of harmful biological and chemical substances (pathogens, toxins, explosives, etc.) and weapons. Last but not least, the search for new biomarkers and the screening for new pharmaceutics via optical high-throughput and content screening belong to this group of applications, which will be covered in more detail in volume III of this handbook.

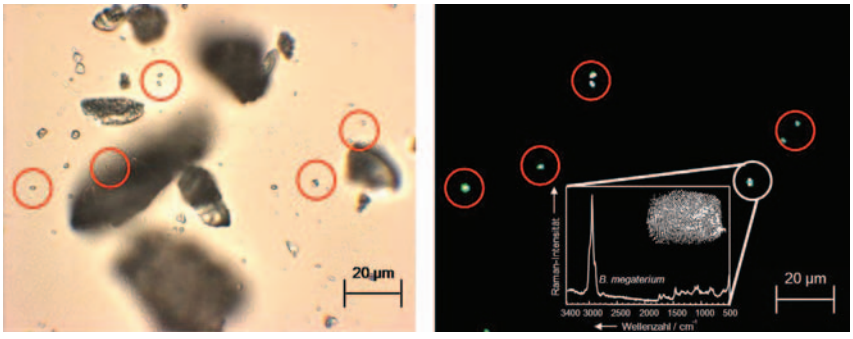

Figure 1.15 Fast on-site monitoring of bacteria: a combination of fluorescence analysis and Raman spectroscopy allows reliable identification down to the strain within a few minutes (Images: Jena Univ., Institute of Physical Chemistry).

1.3
The Biophotonics4Life Worldwide Consortium

Gabriela Lee, Dennis L. Matthews, Jürgen Popp, and Brian C. Wilson

1.3.1
Mission and Purpose of the Biophotonics4Life Worldwide Consortium

The Biophotonics4Life (BP4Life) Worldwide Consortium is a network of biophotonics researchers, educators, companies, and end-users from 20 nodes or regional "hot spots" of activity in many countries around the world. The mission of BP4Life is to spearhead activities that better harness global talent and resources in biophotonics and then focus these on fundamental discovery and innovation in order to meet major challenges in health care and other biotechnology needs. Examples of how this will work include: providing end-users with access to the very best possible technologies and expertise instead of just that available in their region; providing end-users with team-based, multi-institutional, even multi-national solutions; providing quality assessment of biophotonics techniques and educational materials – basically, letting the research community create its own standards; fostering worldwide community participation in a web-based knowledge bank known as http://www.biophotonicsworld.org (see later under BP4Life activities); having medical experts define the "grand challenges" in their specialty, followed by worldwide community brainstorming to create solutions; engaging private industry regionally and globally to create products based on innovations and needs defined by a worldwide community of researchers and end-users; providing students of all levels with access to webinars and blogs to learn from experts within the field of biophotonics; and many more ideas to come from our global social network of scientists, corporations, and end-users.

1.3.2
History and Organization of the Consortium

BP4Life was itself founded as a partnership between the UC Davis Center for Biophotonics Science and Technology (CBST), the Canadian Institute for Photonic Innovations (CIPI) and a European Network of Excellence called Photonics4Life. These are major centers or networks of researchers in North America and Europe. CBST (http://cbst.ucdavis.edu) consists of nine participating institutions, more than 10 affiliated foreign and domestic universities, and numerous industry partners all focused on developing and deploying photon-based technologies for grand challenges in the biosciences and medicine. The CIPI (www.cipi.ulaval.ca) is headquartered at the University of Laval, Quebec, but spans nearly all of Canada. Its participants focus on many different projects, from novel fiber-optic systems for biomedicine to optical biosensors to advanced light-based therapeutics. Photonics4Life (www.photonics4life.eu) is a European Network of Excellence which is funded by the European Commission (EC) and coordinated from the Institute of Photonic

Technologies (Jena, Germany). The network bundles the forces of 13 research partners from 10 EC Member States, in addition to associated partners and local cluster partners. It aims at providing a coherent framework for the strongly fragmented field of biophotonics in Europe and has the important goal of bridging the gap between different disciplines working in the field. The founding Co-Chairs of the BP4Life Consortium are the current Director of CBST, Dennis L. Matthews of UC Davis and Lawrence Livermore National Laboratory, the CIPI Biophotonics Program Leader, Brian C. Wilson of the University of Toronto, and Photonics4Life Coordinator, Jürgen Popp of the University of Jena and Institute of Photonics Technology. All three researchers have been pioneers and leaders in the field of biophotonics and are joined by many other researchers and students from their respective programs, centers, and networks. Ms. Gabriela Lee, who is also a co-author on this section and one of the knowledge transfer officers at CBST, serves as the BP4Life Coordinator, managing all of the activities of the Consortium and its Node Leaders and their assistants. The Co-Chairs and Coordinator meet virtually via monthly web conferences and in person at major biophotonics events, together with the Node Leaders from major centers of research throughout the world. These meetings discuss how to support the Consortium, define its roles, and improve the content and utility of the web portal (http://www.biophotonicsworld.org), in addition to focusing on regional and global opportunities for the application of biophotonics.

1.3.3
Node Leaders for the Consortium

The 20 current nodes (more are being developed as we write) are shown in Table 1.7. The rationale for the choice of nodes is largely geographic, so as to ensure that every region globally has good representation. The primary purpose of the nodes is to assemble information about "who is doing what and where" within their region, basically to function like a local chapter of special interest in the field of biophotonics and its applications. Table 1.7 also names the current Node Leaders or co-leaders if the responsibilities are shared. These individuals were chosen because of their expertise in the field of biophotonics and also their ability to access and assemble resources and lead programs. Currently their roles and responsibilities are to:

- represent BP4Life at a local/country/node level
- participate in monthly teleconferences among node leaders and Chairs
- discuss upcoming activities such as webinars and conferences
- make suggestions for continuously improving the www.biophotonicsworld.org website
- pass along opportunities for collaboration and funding
- communicate any other biophotonics-related items of interest
- identify other biophotonics researchers and companies in their region
- present webinars on their fields of research
- promote the field of biophotonics and communicate the potential that photonics technologies have in health care, research, agriculture, biometrics, and so on.

Table 1.7 BP4Life Nodes and Node Leaders.

Node no.	Node	Node Leaders
1	US West	Bruce Tromberg Steven Jacques
2	US Central	Lihong Wang Stephen Boppart
3	US East	Gary Tearney
4	Canada	Brian Wilson Yves de Koninck
5	Mexico/Argentina/Chile	Oscar Martinez
6	Brazil	Vanderlei Bagnato
7	North-West Europe	Tia Keyes Kishan Dholakia
8	Europe/Photonics4Life	Jürgen Popp
9	Southern Europe	Francesco Pavone Turgut Durduran
10	Benelux	H.J.C.M. Sterenborg
11	Scandinavia	Peter E. Andersen Stefan Andersson-Engels
12	Central/Eastern Europe	Gert von Bally
13	Israel	Israel Gannot
14	Russia	Valery Tuchin
15	Taiwan	Arthur Chiou
16	Singapore	Colin Sheppard Zhiwei Huang
17	Hong Kong	Jianan Qu

19	Korea	Woong Shik Ahn
20	Australia/New Zealand	Halina Rubinzstein-Dunlop David Sampson

1.3.4
Current Activities of the BP4Life Consortium

The Consortium's Chairs and node leaders coordinate the activities listed below, which benefit faculty, students, and other members of the biophotonics community. Most of these activities and programs are implemented via the www.biophotonics-world.org portal.

1) Research opportunities:
   a) Collaborative projects.
   b) Exchange opportunities for students, faculty, researchers, and so on to spend time in another laboratory (in the same or different country); funding opportunities for exchange programs.

   c) Webinars delivered live via the Internet and recorded for offline use.
   d) Information sharing on how biophotonics is funded in each region.
   e) Focus on medical needs that may have biophotonics-based solutions.
2) Education opportunities:
   a) Curricula for different educational levels, from beginners to advanced.
   b) Courses.
   c) Review articles.
   d) Other resources (computer codes, movies, tutorials, etc.).
3) Knowledge transfer:
   a) Overview of activities and biophotonics strengths and resources (equipment, skills, and capabilities) for each node.
   b) Brokering knowledge of needs and biophotonics tools.
   c) Information sharing on companies active in biophotonics in each region.
   d) Current and developing biophotonics industry clusters.
   e) News: local, regional, national, international.
4) Industry participation:
   a) Membership.
   b) White papers.
   c) Advertising.
5) Roadmapping to guide research and development, commercialization, and policy in applications of photonics-enabled technologies to medicine and the life sciences.

The Chairs and Node Leaders meet via web conferences once per month, and in person 2–3 times per year, during existing conferences, and discuss the Consortium's activities. For example, the Consortium's leaders met in January 2010, during the Photonics West Conference, in April 2010, during Photonics Europe, and will meet again in Quebec, Canada, in September 2010, during the BiophotonicsWeek series of events. Many of the BP4Life Node Leaders will be active participants in the 2nd International Congress on Biophotonics (part of BiophotonicsWeek), where they will update the roadmaps of biophotonics generated during the first Congress, and generate new content for this year's areas of focus: biophotonics in neurosciences, infectious diseases, and point-of-care, and drug discovery and development.

Perhaps one of the most important activities of the Consortium is to chart and monitor trends in how much biophotonics research funding is being provided in different areas of the world. We illustrate a very preliminary (and not yet validated) example of this in Figure 1.16. As we accumulate more data, these will be updated and published on the web portal, but it serves to illustrate that many regions are beginning to provide substantial research funding for the field, albeit far short of the actual revenues being generated by the biophotonics industry marketplace [10].

1.3.5
Medical Fellows

One of the many important recommendations of the Node Leaders has been the creation of voluntary positions known as Medical Fellows. These are physicians who

Figure 1.16 Government funding levels in 2009 for biophotonics research for three different regions of the world: North/South America, Europe, and Asia/Australia/New Zealand. These are lowest level estimates based on a partial survey of researchers in a given region, but the arrows indicate the trends, either constant or increasing support.

help our Consortium members understand medical needs that could, in particular, benefit from biophotonics devices or methods. The Medical Fellows are asked to address the Consortium regularly through webinars and blogs to help create lists of medical challenges. They are also encouraged to be early adopters of any new technology created and, if applicable, to assist or even lead clinical trials. The identities of the Medical Fellows will be changing regularly and can be viewed on the www.biophotonicsworld.org portal.

1.3.6
Anticipated Role of Industry

The Consortium is still determining the role(s) for biophotonics industry players, but it is planned to be substantial. Clearly, just as with Medical Fellows, it will be important for industry to voice their needs and challenges through webinars and blogs so that Consortium members can provide assistance. We would also anticipate that private companies will be interested in knowing who is doing what type of research and has what type of technology in their immediate region. We also believe that the web portal will be an excellent place for industry to advertise positions and, of course, their products. We are also considering an entrepreneur-in-readiness program, whereby CEOs could advertise their availability to lead startup companies that may be the outcome of research technology applied to medical needs and leading to medical devices.

1.3.7
Potential Future Activities of the Consortium

Our vision for the BP4Life Consortium is that it will grow into a thriving and productive science and technology social network that will be the knowledge source

for the field of biophotonics. It will also become the forum to discuss end-user needs and further where industry finds its new technologies and employees and vets its products. Ultimately, it has potential to become a "self-assembling" model for how science, industry, students and end-users can convene and network on a global basis.

2
Short Introduction to Atomic and Molecular Configuration

Dirk Bender, Leticia González, and Stefanie Gräfe

In this chapter, we introduce the basic ideas and concepts of computational chemistry. We have tried to avoid using equations as much as possible; however, for better understanding, we provide some mathematical expressions. For the mathematically more interested reader, literature is cited where derivations and exact expressions can be found. We start with some basic ideas of quantum mechanics, as much as will be needed in the following. Next, we introduce some model systems frequently used in spectroscopy, and illustrate fundamental approximations used for chemical applications. We conclude by describing quantum chemical methods used for calculating the electronic structure of molecules.

2.1
Introduction

Today, we are aware of the fact that molecules (and atoms) can only be described properly on the foundations of quantum mechanics. Historically, however, chemists (and also alchemists) for a long time did not know of the existence of chemical bonds. What was known was that substances can be transformed into each other, thereby changing their properties – nowadays we call this a *chemical reaction*. In the beginning, a more phenomenological approach led to the idea that all substances consist of small building blocks – *atoms*. These atoms are stuck together by *chemical bonds*.

Later, physicists started to experiment with atoms. At the beginning of the twentieth century, the *electron* was discovered. It was found that atoms are not the smallest possible units but that they consist of building blocks. For chemical purposes, the most relevant units are the negatively charged electrons which surround in a classical picture a heavy positive charge – the *nucleus*. Very soon it was clear that the number of electrons that each atom possesses can be used to classify them in the so-called periodic system of the elements. By this means, a categorization of different atoms was put on a more quantitative footing. Each

Handbook of Biophotonics. Vol.1: Basics and Techniques, First Edition.
Edited by Jürgen Popp, Valery V. Tuchin, Arthur Chiou, and Stefan H. Heinemann.

element has a certain atomic number, that is, a certain number of electrons equals to the atomic number.

Subsequently, chemists realized that the chemical bonds that hold the atoms together are composed in most cases of *two electrons*. A picture of a molecule built up by atoms connected by bars should exactly symbolize this: each stick contains two electrons representing a chemical bond. This very intuitive picture is able to explain many properties and reactivity of the molecules but does not suffice to describe the molecule or chemical substance more quantitatively. For this purpose, a quantum mechanical description is required.

The basic difficulty in this quantum mechanical description is that many-body problems (more than three particles) cannot be solved exactly. However, atoms and molecules are intrinsically many-body problems with many electrons (according to the atomic number) involved. To describe the realm of chemistry, we are therefore left to seek approximations and numerical solutions, which unfortunately can be computationally very demanding.

2.2 Basics of Quantum Mechanics

Physicists assumed for a very long time that light is an (electromagnetic) wave. Huygens showed that from a light source, light spreads out circularly – the same behavior can be observed on throwing a stone into water. However, in contradiction to classical physics, Planck showed in 1900 that light cannot have all energies but only discrete values occur, all separated by a very small constant number h, nowadays known as *Planck's constant*. This constant takes the value 6.634×10^{-34} Js – a very tiny number indeed. Despite being small, this means that the energies are not continuous but *quantized* (discrete). To exemplify this fact, let us take a lamp with a rotary switch with which we can dim the light. By turning the switch we can obtain all possible values of brightness of the lamp. This is *not*, however, what we find in the quantum world: the energy is *quantized*, that is, we find only discrete values of energy (Figure 2.1). This is similar to what we would have with an electric fan – we can only access speeds 1, 2, and 3 but nothing in between. The *quantum numbers* (speeds 1, 2, 3 in the fan example) indicate on which energy level we are situated. The lowest level indicates the ground state, the others are excited states. Planck described the connection between the frequency of the light radiation ν and its energy E by the equation

$$E = h\nu. \tag{2.1}$$

By explaining the photoelectric effect in 1905, Einstein could demonstrate that light consists of tiny particles, called *photons*. This discovery caused a serious dilemma: is light a wave or a particle? The solution to this problem was to assign both – wave *and* particle character – to the light. This we call the *wave–particle duality*. De Broglie was able to establish a direct connection between the particle and the wave character of the light with the equation

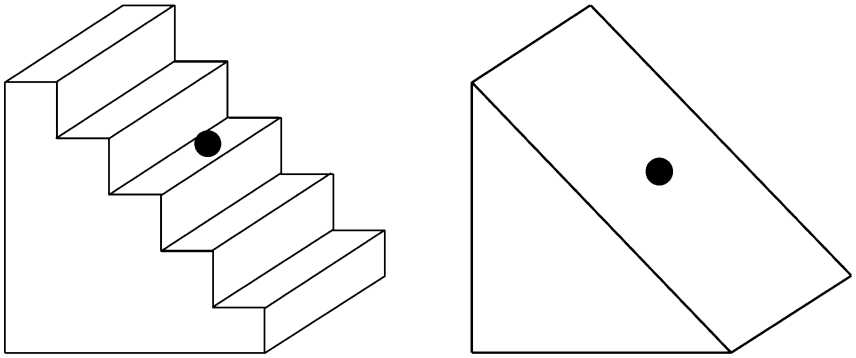

Figure 2.1 Quantization of the energy. The ball in (a) can have only discrete potential energies, represented by the steps. The ball in (b) can have *any* energy on the plane; this is the macroscopic behavior.

$$\lambda = \frac{h}{p} \tag{2.2}$$

where the wavelength λ refers to the wave character, the momentum p to the particle character of the photon, and h is again Planck's constant. De Broglie stated that his simple equation should be universally valid, applying to *all* particles: electrons, nuclei, atoms, and even macroscopic "particles" such as humans. (Due to the macroscopic size and weight of humans, the "wave character" does not affect much every day life, however.) In 1925, Davisson and Germer demonstrated that the electron also possesses wave character. Nowadays, the wave character of larger particles, even as large as the fullerenes, has also been proven. Inspired by all these new discoveries, Heisenberg and Schrödinger formulated their equations to describe a new form of mechanics, applicable to such microscopic particles: *the quantum mechanics*.

In quantum mechanics, the keynote to memorize is the following: *everything we want to know about a system is incorporated in its wavefunction* Ψ. Hence, whether we are interested in spectra, geometries, or other properties of a molecule, all we need to know is its state or its state vector – the wavefunction Ψ. The only problem is that calculating the wavefunction Ψ is very difficult and except for a few examples it is not possible to obtain Ψ exactly. Calculating the wavefunction and extracting its molecular properties by approximated methods is the aim of computational chemistry.

2.2.1
Wavefunctions and Operators

Let us first become more familiar with the concept of a wavefunction and describe some of its properties. The wavefunction Ψ is typically a complex function which depends on all spatial coordinates of all particles in the system, and on the time. For N

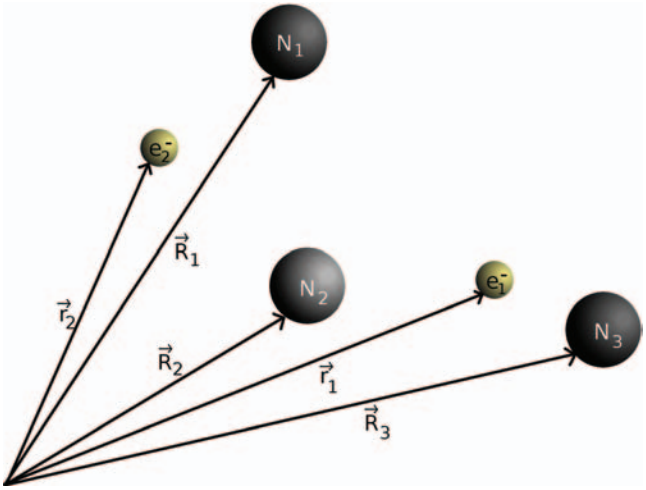

Figure 2.2 Visualization of the coordinates of two electrons (e^-, $\vec{r}_1, \vec{r}_2$) and three nuclei (N, $\vec{R}_1, \vec{R}_2, \vec{R}_3$).

electrons and M nuclei we therefore write $\Psi(\vec{r}_1, \vec{r}_2, \vec{r}_3 \ldots \vec{r}_N, \vec{R}_1, \vec{R}_2 \ldots \vec{R}_M, t)$. We denote all electronic coordinates with lowercase letters, $\vec{r}_1, \vec{r}_2 \ldots \vec{r}_N$, and the coordinates of the nuclei with capital letters, $\vec{R}_1, \vec{R}_2 \ldots \vec{R}_M$. The distances r_i, R_j we are referring to are on the sub-nanometer scale. Typical interatomic distances are $\sim 0.1\,\text{nm}$ (or $10^{-10}\,\text{m} = 1$ Å). Figure 2.2 displays the definition of coordinates of a sample system of two electrons and three nuclei.

The Probability Density

The value $|\Psi|^2 = \Psi^*\Psi$ is called the probability density; Ψ^* is the complex conjugate of Ψ. In the one-dimensional case, the value $|\Psi(x)|^2 \mathrm{d}x$ is proportional to the probability of finding the particle described by Ψ in the interval $x \ldots x + \mathrm{d}x$. Because Ψ and $c\Psi$ describe for any complex number c the same state, it is possible to normalize the wavefunction, that is, to find a factor c such the integral

$$\int_{-\infty}^{\infty} |c\Psi|^2 \mathrm{d}x \tag{2.3}$$

gives 1. If we include this factor in Ψ, we can interpret $|\Psi(x)|^2 \mathrm{d}x$ directly as the probability of finding the particle in the interval $x \ldots x + \mathrm{d}x$.

In the three-dimensional case, the probability of finding the particle at the position $\vec{r}$ in the infinitesimal volume element $\mathrm{d}V$ (see Figure 2.3) is proportional to (or after normalization equal to) $|\Psi(\vec{r})|^2 \mathrm{dV}$.

Although it is not intuitive to visualize the wavefunction itself as it is normally complex, one very important interpretation suggested by Bohr is based on its absolute

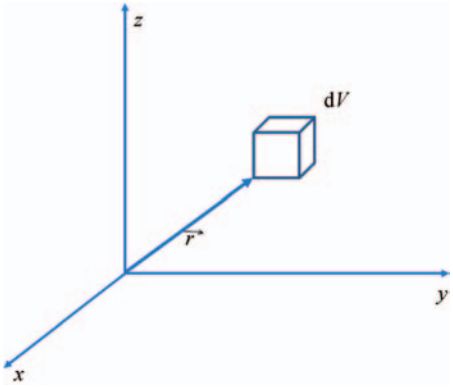

Figure 2.3 In a three-dimensional space, the probability of finding the particle described by Ψ at position $\vec{r}$ in the infinitesimal volume $dV = dxdydz$ is proportional to $|\Psi|^2 dV$.

squared, $\left|\Psi\left(\vec{r}_i, \vec{R}_j\right)\right|^2$, the so-called *probability density* ρ. The probability density gives a measure of the probability of finding a particle at the position in a small given volume (see Figure 2.3). The larger the number, the higher is the probability that the particle is there. Small values denote a low probability of finding the particle. The concept of probability density means that we have to bid farewell to the picture that we know exactly where a particle is: in the quantum world, we can only state where the highest probability of the particle position is. This probability is represented by the probability density ρ. Figure 2.4 shows an arbitrary function $\Psi(\vec{r}_1)$ for one electron depending on the coordinate $\vec{r}_1$, and its probability density $\rho(\vec{r}_1) = |\Psi(\vec{r}_1)|^2$. Here, for example, the probability of finding the particle is highest around $r = -2$ and $r = +2$, while the probability is zero at three values of $\vec{r}$. These zeros in the probability ρ are exactly the roots (nodes) of the wavefunction $\Psi(\vec{r}_1)$. By convention, the probability of finding a particle anywhere in space is 100% or, mathematically speaking: the probability density $\rho(r)$ is normalized to 1. Figure 2.4 clearly illustrates that quantum mechanics offers a more statistical description with probabilities than classical mechanics.

One fundamental implication of quantum mechanics is the Heisenberg *uncertainty principle*. In brief, it says that it is not possible to determine simultaneously the exact position and the exact velocity (or the momentum) of a particle. Although there is no one-to-one correspondence to the classical world, we can exemplify this with a runner on a racetrack: we can at one time either determine the position where he/she is *or* the speed he/she has at that moment. In the macroscopic world, we can measure both; in the quantum world, we can determine both properties at the same time only with a certain accuracy. It is important to stress that this incapability has nothing to do with the measuring devices but with the quantum system itself: the accuracy with which we can measure the position $\vec{r}$ immediately limits the accuracy with which the momentum $\vec{p}$ can be measured see (Figure 2.5). Figure 2.5d shows two probabilities with the same coordinate but with different "precision": the more narrow the distribution is, the more accurately the position can be determined. When, for example, the coordinate r is fairly accurately known, then the distribution

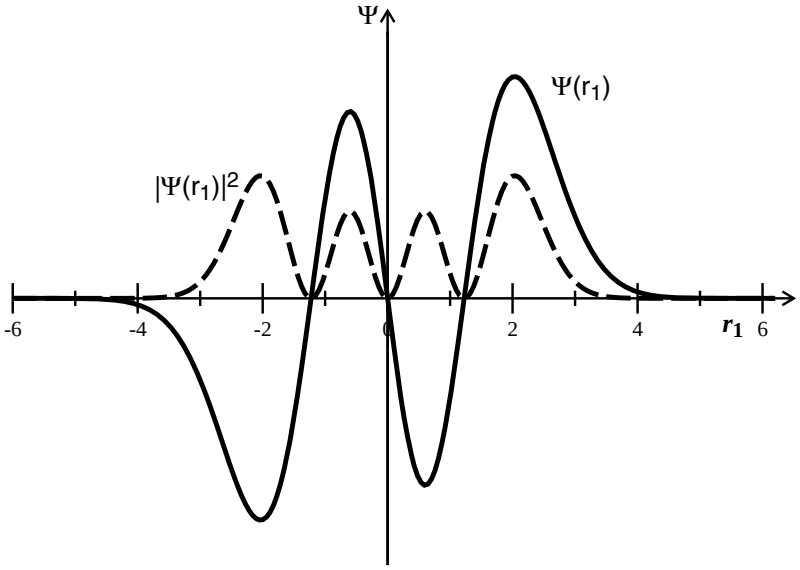

Figure 2.4 A wavefunction $\Psi(\vec{r}_1)$ depending on one electronic coordinate $(\vec{r}_1)$ and the corresponding probability density $|\Psi(\vec{r}_1)|^2$ (dashed line). The probability of finding the electron is zero on several values of $\vec{r}_1$, whereas it is most probable to find the electron around $r_1 = -2$ or $r_1 = +2$.

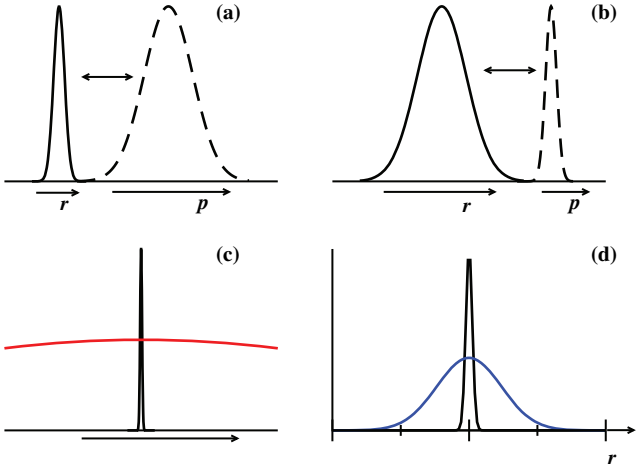

Figure 2.5 Visualization of the uncertainty principle. (a) A narrow distribution (solid line) in coordinate representation has a smeared momentum distribution. (b) Vice versa: a narrow momentum distribution has a smeared coordinate representation. (c) In the limit of a very precise distribution of one property, no information about the other property can be obtained. (d) Two distributions with the same value of coordinate but with a different width.

of the momentum p (the velocity) is smeared (Figure 2.5a), and vice versa (Figure 2.5b). In the limit of a highly accurately known coordinate (or momentum) distribution, virtually no information of the other respective property can be gathered (Figure 2.5c). Mathematically, the uncertainty relation is expressed by the inequality

$$\Delta x \cdot \Delta p \geq h/2. \tag{2.4}$$

The product of uncertainties of coordinate and momentum is always larger than (or equal to) Planck's constant divided by 2. Other properties of the wavefunction $\Psi(\vec{r}_i, \vec{R}_j)$ can be found in quantum mechanics textbooks (see, for example, [1–4]). We will restrict ourselves here to the necessary properties to deal with basic theoretical chemistry.

As we stated before, all necessary information on any system is in its wavefunction. In addition to the probability interpretation, how do we extract this desired information? For this purpose, we introduce the concept of a mathematical operator, represented by $\hat{A}$ (we will denote all operators in this chapter by the "hat" ^). The operator $\hat{A}$ can represent different physical properties; it can be, for example, the momentum operator $\hat{\vec{p}}$, the operator of coordinate $\hat{\vec{r}}$, or the operator of energy $\hat{H}$. Mathematically, they can have different forms: it can be a derivation, an integral, or just a multiplication. Generally, when an operator $\hat{A}$ *acts* on a wavefunction Ψ, it might modify the function and yield another function, which we call, for example, Φ:

$$\hat{A}\Psi = \Phi. \tag{2.5}$$

This can be visualized by thinking of an example function, say $\Psi = f(x) = x^2$. If the operator is a derivative, $\mathrm{d}/\mathrm{d}x$, we evaluate the derivative of $f(x)$ and obtain the new function $\Phi = f'(x)$:

$$\hat{A} = \frac{\mathrm{d}}{\mathrm{d}x} \qquad \Psi = f(x) = x^2$$

$$\hat{A}\Psi = \frac{\mathrm{d}}{\mathrm{d}x} x^2 = 2 \cdot x = \Phi.$$

The desired information about an observable A can be extracted by calculating from the operator $\hat{A}$ the *expectation value* $\langle \hat{A} \rangle$, which represents the mean value that one obtains in an experimental measurement. Mathematically, the expectation value $\langle \hat{A} \rangle$ is calculated by acting the operator on the wavefunction, subsequently multiplying by the complex conjugate of the wavefunction, and integrating over the space. This yields a number which is the mean value that one would obtain by an experimental measurement:

$$\int \Psi^*(\vec{r})\, \hat{A}\, \Psi(\vec{r}) \mathrm{d}V = \langle \hat{A} \rangle. \tag{2.6}$$

Let us assume we are interested in the momentum that a particle has. For this, we act the momentum operator $\hat{\vec{p}}$ on the wavefunction Ψ and evaluate the integral. The number we obtain is the momentum expectation value $\langle \hat{\vec{p}} \rangle$ – or the average

momentum we would measure in an experiment. The same holds if we are interested in the position (or the energy) of the system – we then evaluate the coordinate expectation value $\langle\hat{\vec{r}}\rangle$ (or the energy expectation value $\langle\hat{H}\rangle$).

In some special cases, the action of an operator $\hat{A}$ on a function Ψ yields the wavefunction itself, just multiplied by a factor, some number a[1)]:

$$\hat{A}\Psi = a\Psi. \tag{2.7}$$

We call such equations, where an operator acting on a function does not change the function but just multiplies it by some number a, an *eigenvalue equation*. One of the most famous examples for such an eigenvalue equation is the *time-independent Schrödinger equation*:

$$\hat{H}\Psi = E\Psi. \tag{2.8}$$

We see that this equation is an eigenvalue equation for the energy, defined by the energy operator $\hat{H}$, which is called the *Hamilton operator* of a system. The action of the Hamilton operator $\hat{H}$ on the wavefunction yields the wavefunction itself and a value E, which is the energy of the system. This is the central equation for calculating the energy of a molecule and, as we will see later, also for obtaining the wavefunction itself.

The Hamilton operator $\hat{H}$ consists of two terms: the *kinetic energy operator* $\hat{T}$ and the *potential energy operator* $\hat{V}$ (which describes in many cases the electrostatic interaction between the particles):

$$\hat{H} = \hat{T} + \hat{V}. \tag{2.9}$$

The Hamilton operator (or the Hamiltonian) has to be specified for each problem we want to solve. For a molecule, the kinetic energy operator $\hat{T}$ contains the kinetic energy of the electrons and of the nuclei. The potential energy operator $\hat{V}$ has the nuclear–nuclear repulsion (all nuclei are positively charged), electron–electron repulsion (all electrons are negatively charged), and the nuclear–electron attraction. In total, $\hat{H}$ can be written as

$$\hat{H} = \hat{T}_{\text{el}} + \hat{T}_{\text{nuc}} + \hat{V}_{\text{el–nuc}} + \hat{V}_{\text{nuc–nuc}} + \hat{V}_{\text{el–el}}. \tag{2.10}$$

As we see immediately, the actual form of the Hamilton operator $\hat{H}$ depends on the system: how many electrons, how many nuclei are we dealing with? Which charge do the nuclei have? How far are the nuclei apart? ...

At this point, we know that the fundamental equation (the Schrödinger equation) can describe microscopic particles but unfortunately, except for a few model systems, this equation cannot be solved exactly at all. In the following, we will describe these model systems, as they are of special importance.

1) In most cases a is not just a number, but a physical quantity, characterized by a *value* and a *unit*.

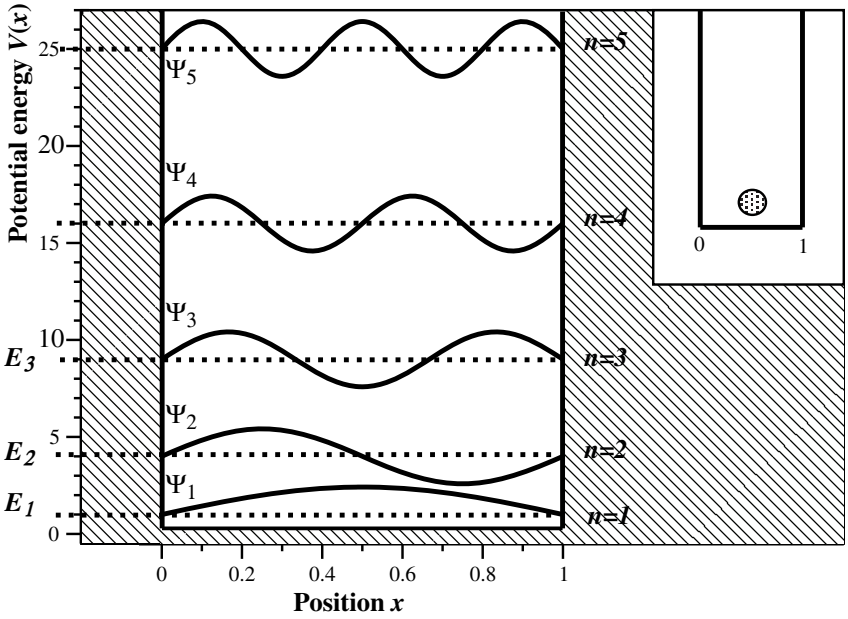

Figure 2.6 The quantum mechanical particle in a box model with infinitely high walls. Wavefunctions and energies are shown, depending on the quantum number *n*.

2.2.2 Particle in a Box

One of the model systems which can be solved exactly is the "particle in a box" (see Figure 2.6). Assuming infinitely high walls on both sides, we can set up the Hamilton operator for this system, which is just the kinetic part since the potential contribution is zero inside the box and infinite outside the wall.

Particle in a Box

We have a box of length L. A particle with mass m is confined between the two walls at $x = 0$ an $x = L$. Inside the well, the potential is zero, but rises abruptly to infinity at the walls. Defining the potential as

$$V = \begin{cases} 0 & 0 \leq x \leq L \\ \infty & \text{else} \end{cases} \tag{2.11}$$

the total Hamiltonian becomes

$$\hat{H} = -\frac{\hbar^2}{2m}\frac{\mathrm{d}^2}{\mathrm{d}x^2} + V. \tag{2.12}$$

Inside the box we have a free particle. The Schrödinger equation is

$$-\frac{\hbar^2}{2m}\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} = E\Psi. \tag{2.13}$$

The wavefunction must vanish on both ends of the box. With these boundary conditions, we obtain the energy eigenvalues:

$$E_n = \frac{\hbar^2\pi^2 n^2}{2mL^2} \tag{2.14}$$

and after normalization the wavefunction is

$$\Psi_n(x) = \sqrt{\frac{2}{L}}\sin\frac{n\pi}{L}x \tag{2.15}$$

with the quantum number $n = 1, 2, 3, \ldots$.

The probability of finding the particle outside the box is therefore zero. Solving the Schrödinger equation (see Box), we obtain the solutions and energies depicted in Figure 2.6. Note that the probability of finding the particle directly on the wall is also zero. With increasing quantum number, the number of nodes increases (the number of nodes is one less than the quantum number) and, therefore, with increasing quantum number also the nodes come closer to each other. In the limit of very high quantum number, the probability is more or less equally distributed in the box – as we would expect it intuitively: classically, the probability of finding the particle somewhere in the box should be everywhere the same. This extrapolation to high quantum numbers reaching the classical values and probabilities is called *Bohr's correspondence principle*.

The energy spacing (the energies are quantized) is not equal: it grows with increasing quantum number. Another special feature is that there is no state with zero energy. Even for the lowest possible state ($n = 1$), there is an associated energy.

Let us next consider a small extension to this model. Assume that the walls are not infinitely high, but have a height V_0 (Figure 2.7). Now the situation is peculiar: taking a closer look at the tails of the wavefunctions, we can see that the probability of finding the particle on the wall is *not* zero any longer but there is a small probability of finding the particle *outside the wall*. How far the particle may enter the wall depends on its mass. For electrons, this is very probable, and electrons can reach far into the walls (this is an important property to describe processes on surfaces of electrodes in batteries, for example). For protons this is still probable, but for almost all heavier systems this effect is negligible.

Another difference to observe in Figure 2.7 is in the energies: above the wall, the energies are truly continuous – the particle can have all possible energies. We say, for energies below the wall height ($E < V_0$), the particle is bound, whereas for the opposite case the particle is unbound – or free.

We can further extend this model and put a small potential barrier in the middle of the box (Figure 2.8). If we locate the particle initially on one side of the barrier, there is a small probability (again depending on the mass of the particle) of finding it after

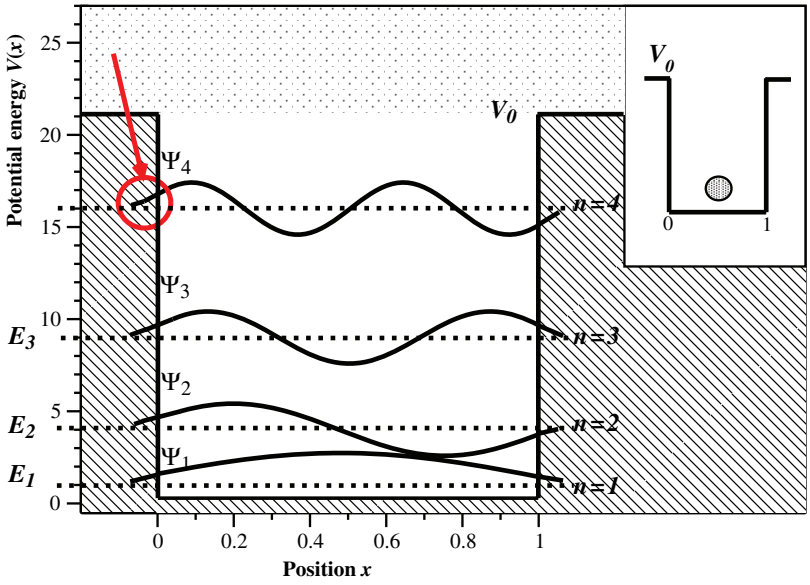

Figure 2.7 The quantum mechanical particle in a well model with finite high walls. Wavefunctions and energies are shown, depending on the quantum number *n*. Note that the wavefunctions here enter the wall. Energies above the potential well are continuous – only four levels are bound in this example.

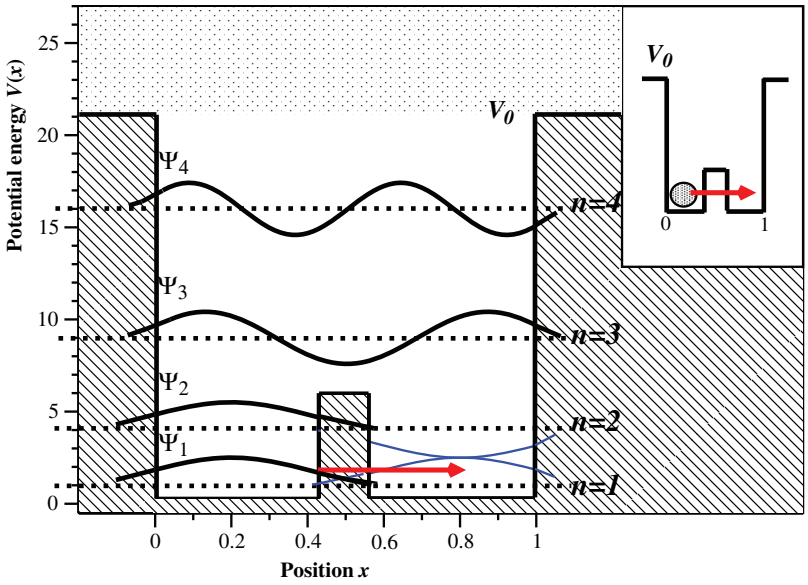

Figure 2.8 Same as before, particle in a potential well, now with a small barrier inside the well. There is a probability that the particle, initially located on the left-hand side of the potential barrier, will tunnel to the right-hand side.

some time on the *other side* of the barrier – also due to the non-zero tail of the wavefunction. This process is called *tunneling*. Although tunneling may sound rather exotic, it plays an important role in, for example, vibrational spectroscopy; the tunneling time can even be measured experimentally by analyzing the spectral linewidth.

2.2.3 Harmonic Oscillator – Vibrations

The *harmonic oscillator* is another very important model system which can be solved exactly. The harmonic oscillator serves in classical mechanics to describe the potential energy of springs or the pendulum motion: on deflecting a pendulum to one side, it will swing back (oscillate) exactly to the same height on the other side and back (in the absence of friction). Classically, any deflection is possible – quantum mechanically not.

The One-Dimensional Harmonic Oscillator

The problem of a one-dimensional harmonic oscillator is described by the following potential energy:

$$\hat{V} = \frac{k}{2}x^2 \tag{2.16}$$

where the constant k in the classical interpretation describes the strength of the spring (force constant). The Hamiltonian is then

$$\begin{aligned}\hat{H} &= \hat{T} + \hat{V} \\ &= -\frac{\hbar^2}{2m}\frac{\mathrm{d}^2}{\mathrm{d}x^2} + \frac{k}{2}x^2\end{aligned} \tag{2.17}$$

where x is the displacement from equilibrium. The Schrödinger equation is

$$-\frac{\hbar^2}{2m}\frac{\mathrm{d}^2\Psi(x)}{\mathrm{d}x^2} + \frac{k}{2}x^2\Psi(x) = E\Psi(x). \tag{2.18}$$

After some steps we obtain the solutions

$$E_n = h\nu\left(n + \frac{1}{2}\right) \tag{2.19}$$

$$\Psi_n(x) = \frac{1}{\sqrt{2^n n!}}\sqrt[4]{\frac{4\pi m\nu}{h}}\exp\left(-\frac{2\pi^2 m\nu}{h}\mathrm{x}^2\right)H_n\left(2\pi\sqrt{\frac{\mathrm{m}\nu}{\mathrm{h}}}\mathrm{x}\right) \tag{2.20}$$

with the quantum number $n = 0, 1, 2, \ldots$ and the frequency $\nu = \frac{1}{2\pi}\sqrt{\frac{k}{m}}$. The H_n are the so-called *Hermite polynomials*.

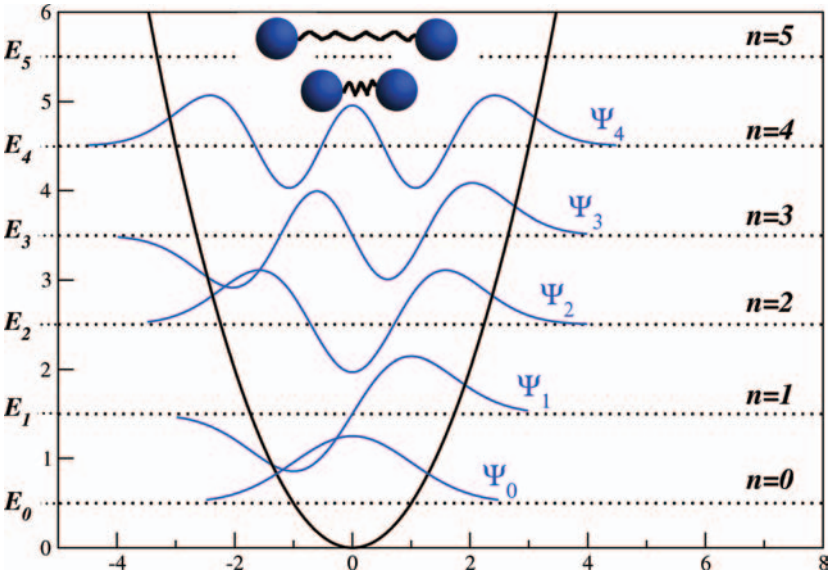

Figure 2.9 The quantum mechanical harmonic oscillator with its wavefunctions (blue) and energies (dotted), depending on the quantum number *n*. The black curve is the potential energy.

Solving the Schrödinger equation for the harmonic oscillator (see Box) will give the wavefunctions and energies shown in Figure 2.9. Although at first glance the probabilities may look similar to those of the particle in a box, there is one very important difference here: the energies are quantized but *equally spaced*.

The quantum mechanical harmonic oscillator serves as a model system to describe chemical bonds: a chemical bond can to some approximation be expressed by two atoms held together by a spring (the bond). Pushing the atoms closer together increases the potential, as the spring is squeezed. Stretching the bond also increases the potential, as now the spring is stretched. There is a certain distance where the potential is lowest: this is the *equilibrium internuclear distance*. The strength of a spring represents the bond strength (see Figure 2.10). The harmonic oscillator therefore serves in spectroscopy as a model to analyze vibrational spectra – the excitation of vibrational motion between atoms. It works reasonably well as a model system for small deviations from equilibrium but becomes poor for larger deviations (and therefore larger quantum numbers). The reason for this poor description for larger quantum numbers is that the description of atoms held together by a spring is not adequate for long, stretched bonds: it is intuitive that a bond may break if the atoms are pulled too far apart. Such a situation is not contemplated in the harmonic oscillator and is better described by an anharmonic one – or a *Morse potential* (see Figure 2.11). However, we will not discuss details of this potential and its solutions here.

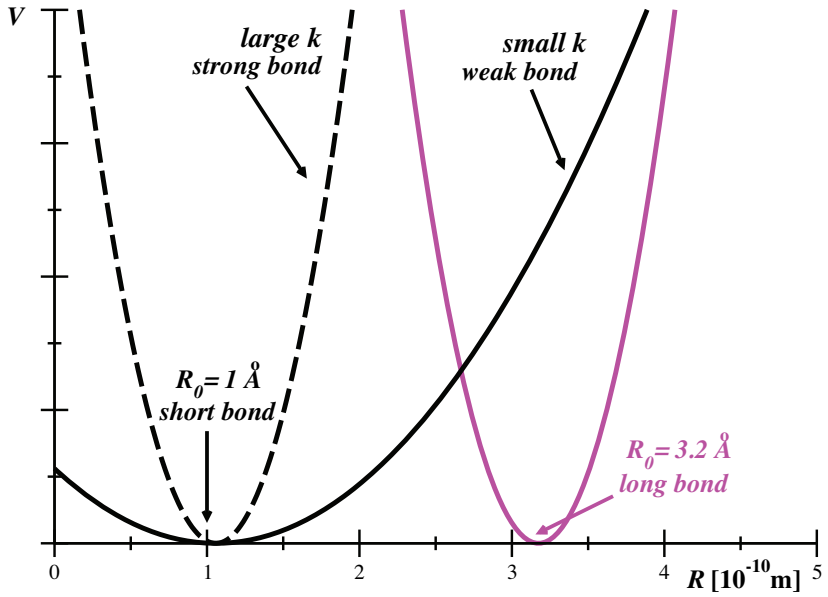

Figure 2.10 Quadratic (harmonic) potential describing the stretching of a bond. The figure visualizes the effect of the equilibrium internuclear distance R_0 and the bond strength k, parameters describing a chemical bond.

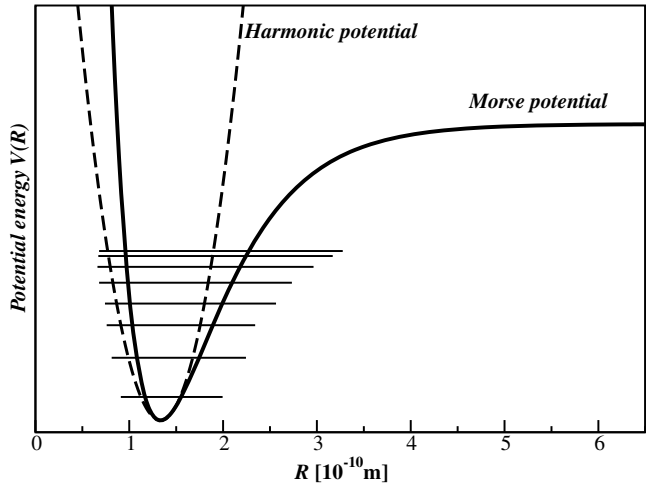

Figure 2.11 Morse potential and harmonic potential describing the stretching of a bond. For small deviations from equilibrium, the harmonic potential describes the vibration reasonably well, whereas it becomes a poor model for larger deflection.

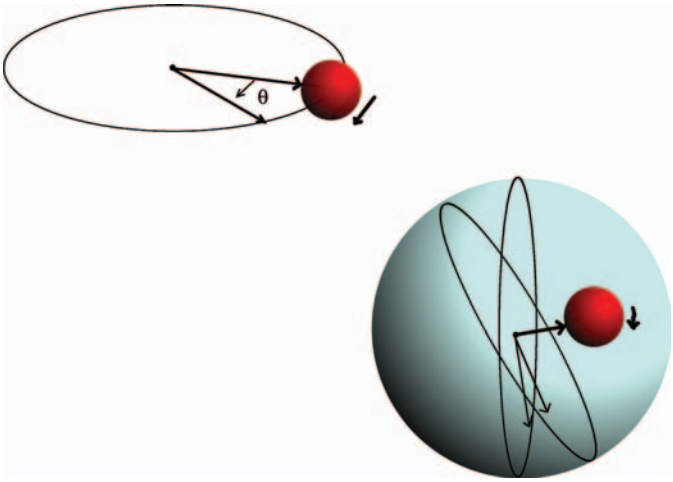

Figure 2.12 Particle on a ring and particle on a sphere as model systems for rotational motion.

2.2.4
Particle on a Sphere, Rigid Rotor – Rotations

The *rigid rotor* is used to describe rotational motion. It is a special case of the model system of a particle on a ring (or on a sphere). For visualization, imagine a carousel or a gyroscope, as shown in Figure 2.12.`

Particle on a Sphere

The Schrödinger equation for a three-dimensional rotation – or the motion of a particle with mass m on a sphere with radius r – is

$$-\frac{\hbar^2}{2mr^2}\left\{\frac{1}{\sin^2\theta}\frac{\partial^2\Psi(\theta,\phi)}{\partial\phi^2}+\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left[\sin\theta\frac{\partial\Psi(\theta,\phi)}{\partial\theta}\right]\right\}=E\Psi(\theta,\phi) \tag{2.21}$$

where θ and ϕ are the inclination and azimuth – the two angles from the spherical coordinate system.

The solution involves two quantum numbers:

$$l=0,1,2,\ldots \tag{2.22}$$

and

$$m_l=-l,-l+1,\ldots,l-1,l. \tag{2.23}$$

The energy depends only on the quantum number l:

$$E = l(l+1)\frac{\hbar^2}{2mr^2}. \tag{2.24}$$

The normalized wavefunctions are called *spherical harmonics* – denoted Y_{lm_l}. They depend on both quantum numbers l and m_l.

The quantum mechanical solutions of this problem (see Box) are represented by a class of functions, the so-called *spherical harmonics*, often denoted Y_{l,m_l}, which depend on *two* quantum numbers, l and m_l. The quantum number l counts as $l = 0, 1, 2, \ldots$; for a given value of l, m_l can assume the values $-l, -(l+1), \ldots, -1, 0, 1, \ldots, l-1, l$. For $l = 0$, there is only one value of m_l, namely $m_l = 0$. The spherical harmonic Y_{00} is a sphere, commonly denoted an *s*-function. For $l = 1$, m_l can assume three values, $m_l = -1, 0, 1$, and we are dealing with three functions, the *p*-functions. In a coordinate system, these dumb-bell-type functions are oriented along the three axes, x, y, z. For $l = 2$, there are five values for m_l, $-2, -1, 0, 1, 2$, the *d*-functions. All these functions are displayed in Figure 2.13.

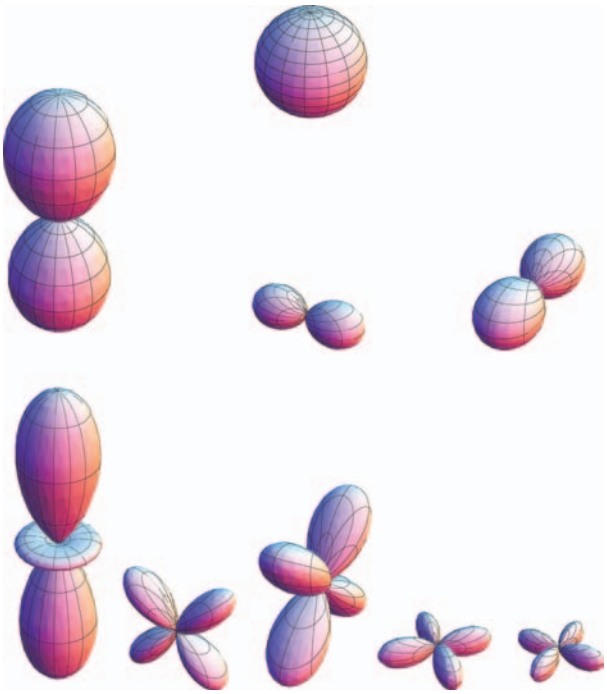

Figure 2.13 The spherical harmonics, the solutions of a particle on a sphere model. The top one is the Y_{00} (the one for $l = 0$), the next row shows the three functions for $l = 1$, and the bottom row the five for $l = 2$. Note that the spherical harmonics are complex-valued functions. Therefore, real-valued linear combinations are shown here.

We will meet these functions again in the following subsections. The energies increase quadratically with l. The rigid rotor is a special case of the particle on a sphere model. The functions and energies of the rigid rotor show the same behavior as discussed before. The rigid rotor is commonly used as a model system in rotational spectroscopy, where the quantum numbers are typically denoted j, m_j instead of l, m_l.

2.2.5 The Hydrogen Atom

The lightest of all atoms, the hydrogen atom, consisting of one proton and one electron, is the only one which can be calculated exactly. Its Hamilton operator can be decomposed into two parts: a radial part, describing the distance r of the electron to the nucleus, and an angular part, which is described by the particle on a sphere model. The solution of the radial part is an exponential function, $\exp(-\zeta r)$, multiplied by a polynomial, the *Laguerre polynomial*. The radial part has a dependence on the quantum number n, and its energies increase with $1/n^2$. (This dependence of the energy on the quantum number n had earlier been found empirically by Rydberg.) Above $V = 0$, there is again a continuum of states for the electron.

The Hydrogen Atom

The wavefunctions of the hydrogen atom are products of a radial part and the spherical harmonics:

$$\Psi_{nlm_l} = R_{nl}(r)\, Y_{lm_l}(\theta, \phi). \tag{2.25}$$

Therefore, they depend on *three* quantum numbers: n, l, m_l. These quantum numbers can take the following values:

$$\begin{aligned} &n = 1, 2, 3 \ldots && \text{(principal or main quantum number)} \\ &l = 0, 1, 2, \ldots, (n-1) && \text{(angular momentum quantum number)} \\ &m_l = -l, \ldots, 0, \ldots, l && \text{(magnetic quantum number).} \end{aligned} \tag{2.26}$$

The radial part R_{nl} of the wavefunction contains the so-called *associated Laguerre polynomials* L:

$$R_{nl}(r) = N \exp\left(-\frac{r}{a_0 n}\right)\left(\frac{2r}{a_0 n}\right)^l L_{n-l-1}^{(2l+1)}\left(\frac{2r}{a_0 n}\right) \tag{2.27}$$

where N is the normalization factor and a_0 is the Bohr radius.

The energy is related to the principal quantum number n:

$$E_n = -\frac{m e_0^4}{2\hbar^2 (4\pi\varepsilon_0)^2}\,\frac{1}{n^2}. \tag{2.28}$$

Each energy level is n^2-fold degenerate.

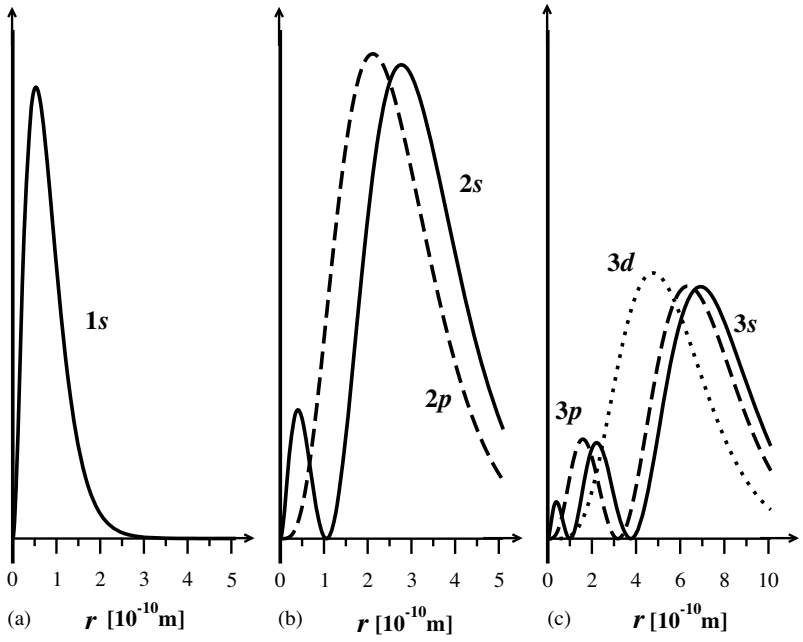

Figure 2.14 The radial part of the atomic orbitals of the hydrogen atom, sorted by the quantum number *n*. (a) $n = 1$; (b) $n = 2$; (c) $n = 3$.

The total state of the electron is given by the product of the radial part and the spherical harmonics, and therefore depends on *three* quantum numbers: n, l, m_l. The quantum numbers take the values $n = 1, 2, 3, \ldots; l = 0, 1, 2, \ldots, (n-1)$; $m_l = -l, \ldots, 0, \ldots, l$. The resulting solutions are labeled according to these quantum numbers, giving 1 *s* ($n = 1,\ l = 0,\ m_l = 0$), 2 *s* ($n = 2,\ l = 0,\ m_l = 0$), three times 2 *p* ($n = 2,\ l = 1,\ m_l = -1, 0, +1$), 3 *s* ($n = 3,\ l = 0,\ m_l = 0$), three times 3 *p* ($n = 3,\ l = 1,\ m_l = -1, 0, +1$), five times 3 *d* ($n = 3,\ l = 2,\ m_l = -2, -1, 0, +1, +2$), and so on. These functions are the *atomic orbitals* of the hydrogen atom. The radial dependence is depicted in Figure 2.14; for the angular dependence, we refer to Figure 2.13. In Figure 2.14 the orbitals are sorted by the quantum number *n*, which is also called the main quantum number. Often, it is also referred to as a *shell*. The first shell includes all orbitals with $n = 1$, which is the 1*s* orbital only. The second shell, $n = 2$, includes the 2 *s* and the 2 *p* orbitals. Each atomic orbital offers space for up to two electrons of different spin.

An orbital without electrons inside is empty or unoccupied; orbitals containing one or two electrons are called singly and doubly occupied orbitals, respectively. The electronic ground state of the hydrogen atom contains just one electron in the orbital with the lowest energy – the 1 *s* orbital.

Heavier atoms with more electrons have more occupied atomic orbitals, thereby occupying first the 1 *s* orbital twice (this would be the case for the helium atom), and subsequently the 2 *s* and 2 *p* orbitals, and so on. As every atomic orbital may contain

two electrons, the first shell (with only the 1*s* orbital) offers space for two electrons, the second shell with the 2*s* and three 2*p* orbitals has space for eight electrons, and so on. Remember that atoms with more than one electron cannot be exactly calculated any longer, and thus some approximations are required.

2.3 Approximations

We have seen in the previous subsections that the Schrödinger equation (Equation 2.8) can only be solved for a few problems and the simplest atom, the hydrogen atom. For all other atoms or even molecules, the Schrödinger equation cannot be solved exactly. Although we know the form of the Hamilton operator $\hat{H}$ (defined by the molecule in which we are interested), we do not know either the wavefunction Ψ or the energies E. Because we are interested in both, we are left with making some approximations to obtain these quantities.

2.3.1 Variational Principle

As we have seen, in order to calculate the energy E of a system (from the energy expectation value, see Equation 2.6), one has to know the wavefunction Ψ describing the system. As we do not know the wavefunction, we may guess it, using a test wavefunction $\tilde{\Psi}$. Of course, when choosing just any guess wavefunction, we will obtain just some arbitrary energy of our system.

However, here the *variational principle* comes to help: it states that the true and exact wavefunction yields the lowest energy. Or, differently formulated: if we have obtained by variation the lowest possible energy, then the corresponding wavefunction is the exact wavefunction Ψ. No other test-wavefunction can possibly yield a lower energy than the exact wavefunction. This can be expressed as

$$\left\langle \hat{H} \right\rangle = \left\langle \tilde{\Psi} \middle| \hat{H} \middle| \tilde{\Psi} \right\rangle \geq \left\langle \Psi \middle| \hat{H} \middle| \Psi \right\rangle = E_0 \tag{2.29}$$

where E_0 is the true ground-state energy of the system. In practice, we start with a test wavefunction $\tilde{\Psi}$, calculate the corresponding energy expectation value $\left\langle \hat{H} \right\rangle$, and vary the test function iteratively until the energy does not decrease any more (upon definition of a threshold value that determines the accuracy). Depending on the choice of the test wavefunction, the variational wavefunction will more or less well describe the exact wavefunction.

2.3.2 Perturbation Theory

A second avenue to find approximations to the wavefunction is the so-called *perturbation theory*. The starting point here is that if we cannot solve the system exactly at least a similar problem can be solved and taken as a reference. Then, we

declare any deviance from the reference system as a *perturbation*. By taking higher and higher orders of corrections, we approach the exact solution to our system. The order of correction that we consider is called the order of the perturbation.

We start by solving the Schrödinger equation for the reference system, obtaining the wavefunctions $\Psi^{(0)}$ and energies $E^{(0)}$. The superscript (0) denotes the reference system. Then, we calculate the contribution of perturbation – this will give an additional energy $E^{\text{pert},(1)}$ and an additional part to the wavefunction, $\Psi^{\text{pert},(1)}$. We now have a new wavefunction consisting of the reference part $\Psi^{(0)}$, and the contribution of the perturbation, $\Psi^{\text{pert},(1)}$, and correspondingly, the same for the energy, $E^{(0)}$ and $E^{\text{pert},(1)}$. We can then use the new wavefunctions to calculate the next higher order of the perturbation, $\Psi^{\text{pert},(2)}$, and so on. In principle, if all orders of perturbation are included, we would obtain the exact solution. In practice, one normally does not go to higher than the fourth order of perturbation. It is fair to mention that perturbation theory only works if the reference system is reasonably similar to the exact one. If this is not the case, the problem might arise that higher order corrections do not converge to the exact solution or, even worse, that they diverge.

2.3.3
Born–Oppenheimer Approximation

The Born–Oppenheimer approximation is the most basic approximation underlying all quantum chemical calculations for molecules. We recall that for molecules, the total wavefunction $\Psi(r_i, R_j)$ depends on both the electronic and nuclear coordinates. Within the Born–Oppenheimer approximation, one separates the nuclear motion from the electronic motion:

$$\Psi(r_i, R_j) \approx \psi^{\text{el}}(r_i, \bar{R})\chi^{\text{nuc}}(R_j). \tag{2.30}$$

Now $\bar{R}$ is no longer a variable, but a parameter which we can fix beforehand. As the nuclei are at least 1823 times heavier (depending on the atom) than the electron, they do not move as fast as the electrons, and therefore the separation into an electronic and a nuclear part is reasonable. Equation 2.30 says that we separate the total wavefunction Ψ into two parts: one which describes the state of the electrons ψ^{el} for a fixed nuclear geometry $\bar{R}$, and another which describes the nuclear part χ. This separation automatically implies that we shall be dealing with *two* Schrödinger equations, one for the electrons, and one for the nuclei:

$$\hat{H}_{\text{el}}\psi_{\text{el}} = E_{\text{el}}\psi_{\text{el}} \tag{2.31}$$

and

$$\hat{H}_{\text{nuc}}\chi_{\text{nuc}} = E_{\text{nuc}}\,\chi_{\text{nuc}}. \tag{2.32}$$

Figure 2.15 visualizes the two systems which we are now considering. The *electronic Schrödinger equation* is of particular interest for quantum chemistry. The *nuclear Schrödinger equation* is relevant for vibrational spectroscopy and reaction dynamics. We will concentrate here only on the former one. Note that as the

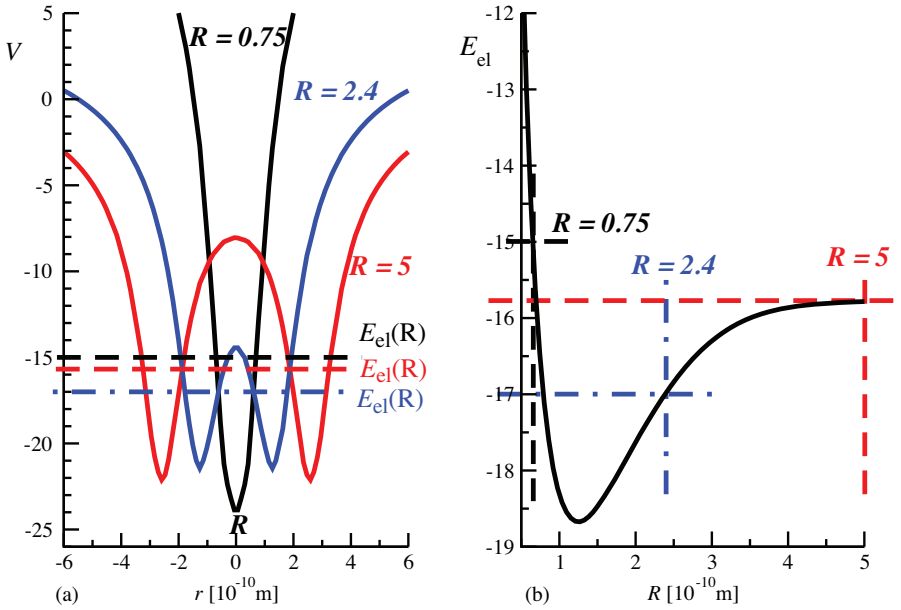

Figure 2.15 Visualization of the Born–Oppenheimer equation and its implications. Panel (a) shows that varying the nuclear geometry leads to different electronic wavefunctions ψ^{el}, the energies $E_{el}(\bar{R})$ of which correspond to the potential energy curves shown in (b). (b) Potential energy curves and nuclear motion on these curves.

electronic part depends parametrically on R ($\bar{R}$), also the energies E_{el} depend on the nuclear geometry $\bar{R}$. We therefore write $E_{el}(\bar{R})$ – these energies are the potential energy curves (or potential energy surfaces PESs). In general, these energies are potential energy hypersurfaces depending on $3M-6$ degrees of freedom, where M is the number of atoms in the system. Such PESs are evaluated by solving the electronic Schrödinger equation for single points at a particular nuclear configuration. Because these PESs are a direct consequence of the Born–Oppenheimer or adiabatic approximation, the resulting PESs are also called adiabatic potentials. As the energies of the electronic system depend on the geometry, we can find a point where the energy is lowest – this is the most stable geometry – the *equilibrium geometry*. This is one of the important pieces of information that we want to know about the system! Often, there are different possible geometries but the one with the lowest energy is the most stable and therefore the most probable geometry of the molecule. This is of particular interest when looking at chemical reactions, but also for protein and enzyme structures. The concept of a PES is fundamental to chemistry, since it allows us to understand chemical reactions. For large molecules, however, one does not compute a total hypersurface in all degrees of freedom. Normally, it is sufficient to find critical points, such as minima and saddle points of first order (associated with the chemical concept of a transition state), which correspond to optimal structures that define the most important regions of the PES that the system can visit in a particular chemical reaction (e.g., reactants, intermediates, and products). The

optimization of such points can be routinely performed at different levels of theory, i.e. with different levels of approximation (see Section 2.5 and 2.7).

We just mention that the second equation, the nuclear Schrödinger equation (Equation 2.32), is of special importance for the motion (dynamics) of the nuclei in a molecule (e.g., to analyze and calculate vibrational and rotational motion). The calculated vibrational spectra (infrared and Raman spectra) help to characterize a substance (see Chapter 3).

The Born–Oppenheimer or adiabatic approximation is usually a good approximation, provided that two (or more) solutions of the electronic Schrödinger equation (Equation 2.31) are energetically far from each other. At points where two states are close or even cross, the Born–Oppenheimer approximation breaks down, and nonadiabatic corrections, which are far off the scope of this introductory chapter, need to be evaluated.

The next section deals with methods to obtain solutions of the electronic Schrödinger equation (Equation 2.31).

2.3.4
Linear Combination of Atomic Orbitals

So far, we have intuitively seen how chemical bonds are constructed. But which conditions have to be fulfilled to obtain stable molecules? One very simple rule is based on the stability of a fully completed shell: the most fundamental way to construct stable molecules is to ensure that every atom in the molecule has a fully occupied shell. Recall Section 2.2.5, where we have seen that each atomic orbital offers space for up to two electrons, and that the first shell (with the 1*s* orbital), and the second shell (including the 2*s* and 2*p* orbitals) offers space for two or eight electrons, respectively: the rule now simply states that atoms in the first row (hydrogen and helium) are especially stable, if they contain two electrons. For helium, being the second element in the periodic system of the elements, and therefore possessing two electrons, this is already the case – helium does not need any other atom to reach a completed shell. In fact, helium does not make any stable molecule with any other atom, or with itself. We say that helium is chemically inert. For hydrogen, the situation is different. We have seen that it has only one electron, and therefore it needs one more electron to complete the shell. This is why it forms a molecule, consisting of two hydrogen atoms, each contributing with one electron. The two electrons form the chemical bond and are shared by the two hydrogen atoms.

Looking at the other atoms of the periodic system of the elements, this rule explains why all noble gases, such as helium, neon, argon, krypton, and xenon (all found in the last column of the periodic system of elements), do not form molecules or chemical bonds with other atoms: they all already have a full shell. Hence they all are chemically inert.

All other atoms do not have a completed outer shell and therefore need to form chemical bonds with other atoms to reach an octet, sharing the electron pairs of the chemical bond with their neighbors. Molecules in which all atoms have a completed shell (always including the shared electrons into the count of outer electrons) are

Figure 2.16 Formation of a chemical bond in hydrochloric acid, H–Cl. The hydrogen atom contributes one electron and the chlorine atom seven electrons, all indicated by the dots (left-hand side). The bond is formed by two electrons shared by both atoms, middle part. Two electrons forming an electron pair (two dots) are replaced by a bar, right-hand part.

especially stable. Molecules in which this is not the case are typically highly reactive – such as radicals, where at least one orbital is occupied by only one electron. Radicals try to form other molecules where the full shell rule is fulfilled, and are therefore highly reactive.

Consider as an example the chlorine atom (Cl) (number 17 in the periodic system of the elements, column number 7) with seven outer valence electrons; it needs one more electron to complete the outer shell. Therefore, chlorine forms bonds with, for example, the hydrogen atom (with one electron), creating the H–Cl (hydrochloric acid) molecule, where the hydrogen and the chlorine share one electron pair. In the molecule Hydrogen has again two electrons, and chlorine is surrounded by eight electrons (see Figure 2.16).

This also applies for larger molecules, such as CH_4: the carbon atom (C) (number 6, column 4) has four outer electrons, and the four hydrogen contribute one electron each. Together they form the methane molecule, in which each hydrogen is surrounded by two electrons and the carbon atom by eight molecules, yielding a full shell for all atoms (see Figure 2.17).

2.4
Solving the Electronic Schrödinger Equation

Methods which solve the electronic Schrödinger equation without including empirical parameters are called *ab initio* methods. *Ab initio* methods are restricted to small and medium size molecules, as they need substantial computer power. We introduce the different *ab initio* methods in Sections 2.5 and 2.7. In contrast, semiempirical methods contain empirical parameters that might have been derived from experiment or parameterized from *ab initio* information. In general, in the semiempirical methods several calculation steps are omitted and, to compensate for these errors,

Figure 2.17 Formation of chemical bonds in methane, CH_4. Each hydrogen atom contributes one electron and the carbon atom four electrons, all indicated by the dots (left-hand side). The bond is formed by two electrons shared by both atoms, middle part. Two electrons forming an electron pair (two dots) are replaced by a bar, right-hand part.

other values are parameterized. Semiempirical methods are valuable for larger molecules, say around 100–1000 atoms, and are discussed in more detail in Section 2.9.

So far, we have separated the nuclear motion from the electronic motion. However, we are still dealing with the coordinates of all N electrons. It would be highly convenient if we could describe each electron separately, for example, in the following form:

$$\begin{aligned}\psi^{\mathrm{el}}(\vec{r}_1, \vec{r}_2, \vec{r}_3, \ldots, \vec{r}_N) &= u_1(\vec{r}_1) \cdot u_2(\vec{r}_2) \cdot u_3(\vec{r}_3) \ldots u_N(\vec{r}_N) \\ &= u_1(1) \cdot u_2(2) \cdot u_3(3) \ldots u_N(N).\end{aligned} \tag{2.33}$$

The above form is called the *Hartree ansatz*. In general, this is not a good approach as it violates some basic principles of quantum mechanics: first the indistinguishability of identical particles. We can imagine this principle by a swarm of mosquitoes: as all mosquitoes look the same when looking at a cloud of them we cannot trace the motion of one particular insect. Quantum mechanics goes one step further: even if there are only two mosquitoes, we are not able to distinguish them. However, Equation 2.33 assumes that we know exactly which is electron 1 and it is located in $\vec{r}_1$, and so on. The second principle that is violated is the *Pauli principle*: when interchanging two particles, the state has to change its sign (it has to be antisymmetric). Let us exemplify this by means of a battery: on changing the two poles, the current runs in the opposite direction – the direction changes its sign. Writing the wavefunction as a Hartree product violates both the indistinguishability and the Pauli principle.

A better approach is to write the wavefunction as a *Slater determinant*, which, for two electrons, has the following form:

$$\psi^{\mathrm{el}}(\vec{r}_1, \vec{r}_2) = \frac{1}{\sqrt{2}} \begin{vmatrix} u_1(\vec{r}_1) & u_2(\vec{r}_1) \\ u_1(\vec{r}_2) & u_2(\vec{r}_2) \end{vmatrix} \tag{2.34}$$

$$= \frac{1}{\sqrt{2}} [u_1(1)u_2(2) - u_2(1)u_1(2)]. \tag{2.35}$$

Now it can be easily seen that changing the numbering of the electrons will invert the sign of $\psi^{\mathrm{el}}(\vec{r}_1, \vec{r}_2)$ and, simultaneously, the electrons are indistinguishable, since each of the electrons can be at $\vec{r}_1$ and $\vec{r}_2$. What are the functions $u_i(j)$? They are the so-called *spin orbitals*, wavefunctions consisting of a spin part and a spatial wavefunction. The spin also appears when throwing a baseball – in addition to the forward direction which you targeted, the ball additionally has an intrinsic rotation around itself. Similarly, we can understand the spin of an electron – however, as we have seen already with the energies, the spin cannot have all values, but it is restricted to two values, which we call *up* and *down*, or mark by arrows, $\uparrow, \downarrow$. The total spin of the system is then just the sum of the individual spins of the electrons. By writing the wavefunction ψ^{el} as a Slater determinant, it is an antisymmetric combination of individual functions and the spin of each electron. Now we are in the position to ask: What is the energy of ψ^{el}, written as a Slater determinant?

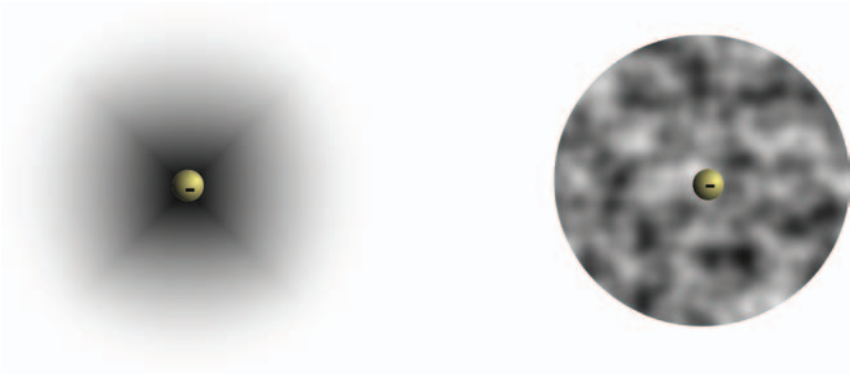

Figure 2.18 Schematic diagrams contrasting the average potential that an electron feels with the explicit interaction.

2.5 The Hartree–Fock Method

With the Hartree–Fock method, the energy and a wavefunction being represented by a Slater determinant can be calculated. Recalling the explicit form of the Hamilton operator (Equation 2.10), the term of the electron–electron repulsion term prevents us from solving the Schrödinger equation. The other terms in the Hamilton operator – the kinetic energy and the electron–nuclear attraction – depend only on one electron (for all but each individually). However, the electron–electron repulsion depends on at least two electrons repelling each other. We therefore can expect that the energy of the wavefunction also depends partially on one electron, and partially on two electrons.

This is indeed what we find. One part $\hat{h}$ depends on one-electron terms (and this N times for all N electrons). The second part gives the two-electron parts, the Coulomb term J, and the exchange term K. The former is the electrostatic repulsion between the electrons, and the latter arises from the explicit form of the wavefunction as a Slater determinant.

Calculating the energy of a single Slater determinant – using the variational principle – leads to the Hartree–Fock equations:

$$\hat{f}^{\mathrm{HF}} u_i = \varepsilon_i u_i \tag{2.36}$$

where $\hat{f}^{\mathrm{HF}}$ is the Hartree–Fock operator, consisting of the above-mentioned one-electron operators $\hat{h}$, and the Coulomb and exchange operators $\hat{J}$ and $\hat{K}$, respectively, and ε_i is the orbital energy. Note the formal similarity to the Schrödinger equation.[2)]

One important approximation used here is that the electron–electron interaction is only accounted for in an average way: each electron moves in the average potential of all other electrons (Figure 2.18). As an example in every-day life, imagine you are

2) Despite this formal similarity, the Hartree–Fock equations are *no* eigenvalue equations, because the Hartree–Fock operator depends on all of the u_i.

walking into a perfume shop: people shopping inside test different fragrances. As soon as you have entered into the shop, you will not be able to distinguish the different smells any longer. This is how in the Hartree–Fock method the electron–electron interaction is described. The approximation is quite fair, however, coming back to the perfume example: when you walk around the shop you will approach a person who has tested an unpleasant smell. You try to avoid him/her and do not approach further. This also happens similarly to the electrons – they try to avoid each other and not come closer. This is the so-called *dynamic electron correlation* and it is not accounted for within the Hartree–Fock approximation. The Hartree–Fock equations have to be solved iteratively. One starts with a trial spin-orbital $\tilde{u}_i$, calculates the energy, modifies the trial function, re-calculates the energy, and so on until the energy does not change any longer (upon the predefined threshold value). Then we have reached *self-consistency*. The Hartree–Fock method is therefore often called the Hartree–Fock self-consistent field (HF-SCF) method. The variational principle thereby ensures that the spin-orbital giving the lowest energy will be closest to the true solution. Recall that when applying the variational principle we can never obtain energies lower than the true energy.

The energies ε_i of each spin orbital can be interpreted according to *Koopmans' theorem*: The orbital energies ε_i are the negative value of the ionization energy – the energy which is necessary to remove one electron from the molecule or, in different terms, to ionize the molecule.

In practice, we do not vary the orbitals themselves in every iteration step – this is computationally too demanding – but represent them by a set of *basis functions*:

$$u_i = \sum_j c_j \varphi_j. \tag{2.37}$$

The orbital u_i is expressed by a sum of known, predefined functions φ_j, the *basis set*. Then, we keep the known functions and vary only the coefficients c_j, the weight of each basis function. The variational principle also applies when using the basis set expression instead of the wavefunction itself. Now, by variation of the coefficients c_j, we need to find the lowest possible energy. Varying only numbers instead of the wavefunction is much faster. Therefore, in computational chemistry, we mainly work with basis sets.

2.6 Basis Sets

As shown above, every function (every orbital) can be expressed as a sum of basis functions. The idea is to represent the molecular orbitals as a sum of basis functions which can be, for example, atomic orbitals. If the sum is up to infinity, the expression in Equation 2.37 would be exact, and we would have a complete basis; the (extrapolated) energy is called the energy in the *basis set limit*. Calculating with infinities is

always challenging. Truncating the summation leads to additional error, the basis set truncation error.

It is intuitive to see that the largest possible basis leads to most exact results. On the other side, the larger the basis, the more computational effort we have to do. We therefore have to find some compromise concerning the basis set size. In what follows, we will introduce the most common basis sets and provide some explanations.

2.6.1
Slater Versus Gaussian Functions

A common discrimination of basis functions is between Slater and Gaussian functions. Both functions are used in computational chemistry; we will use the acronyms STO for Slater-type orbitals and GTO for Gaussian-type orbitals. The two different types have mathematically different expressions. The STOs are exponential functions:

$$\varphi^{\mathrm{STO}}(r) \propto \mathrm{e}^{-\zeta r} \tag{2.38}$$

as they occur in the analytical solutions of the hydrogen atom. The GTOs are of the form

$$\varphi^{\mathrm{GTO}}(r) \propto \mathrm{e}^{-\zeta r^2}. \tag{2.39}$$

The STO and GTO functions are centered around $r = 0$, the position of the nucleus. The factor ζ occurring in the exponent is called the *orbital coefficient* as it describes the spatial extent of the function (of the orbital). Large values of ζ describe compact functions, whereas small values of ζ yield functions which are spread over space and are more diffuse. Figure 2.19 demonstrates the behavior of GTOs for different values of ζ. Comparing the STO and GTO functions, they show similar behavior but differ in some important details. As already mentioned, Slater functions

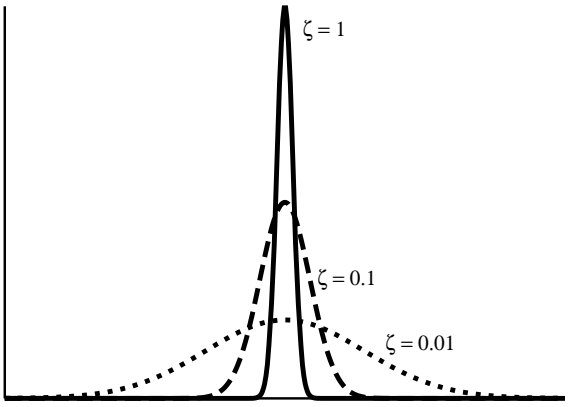

Figure 2.19 Gauss functions (GTOs) for different values of the orbital coefficient ζ. Large values of ζ yields compact functions, whereas small values produce diffuse functions.

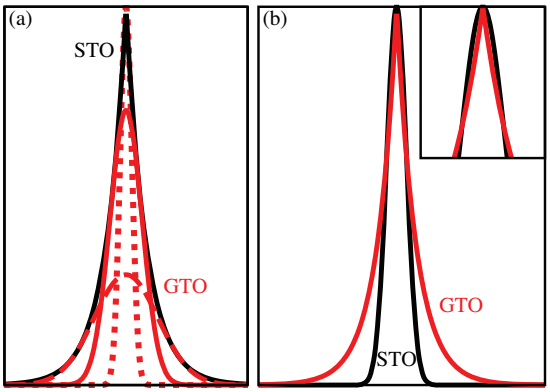

Figure 2.20 (a) Slater function (STO) being represented by 3 Gauss functions (GTOs); (b) Quantitative difference between GTO and STO.

are analytical solutions of the hydrogen atom, meaning that they should be a good starting point to describe other atoms also. Since we are interested in basis functions representing atomic functions that we would like to combine to form molecular orbitals, Slater functions should be very well suited. This is indeed the case. However, they are computationally difficult to handle.

In contrast, GTOs are not functions representing solutions to any atomic problem, but they are computationally much easier to handle. The aforementioned two-electron integrals are faster to calculate using GTOs. Additionally, we can represent any STO by a clever combination of GTOs. Figure 2.20a demonstrates how a Slater function can be approximated by three GTOs. Figure 2.20b illustrates the qualitative difference between STOs and GTOs. The Slater functions have a cusp around the position of the nuclei and fall off less rapidly than the GTOs. Despite the fact that we need more GTOs to represent one STO, most quantum chemical programs use Gaussian functions due to faster processing. If not indicated differently, we will from now on concentrate on Gaussian basis functions.

2.6.2 Number of Basis Functions

Recall that the basis set is constructed from a certain number of atomic orbitals φ_j. How many functions do we need to include? The smallest number of basis functions possible to describe an atom is called a *minimum basis*. For the hydrogen and the helium atoms, this simply corresponds to a single *s* orbital. The atoms in the second row, starting from lithium to neon, are represented by two *s* functions, and three *p* functions. We need two *s* functions, as one *s* function is needed to describe the inner 1*s* orbital, and the other one to represent the valence 2*s* orbital.

The next step in complexity would be just to double the number of basis functions from the minimum basis. Such a basis is called a double zeta (DZ) basis. The zeta originates from the orbital exponent ζ which we have introduced before. In practice,

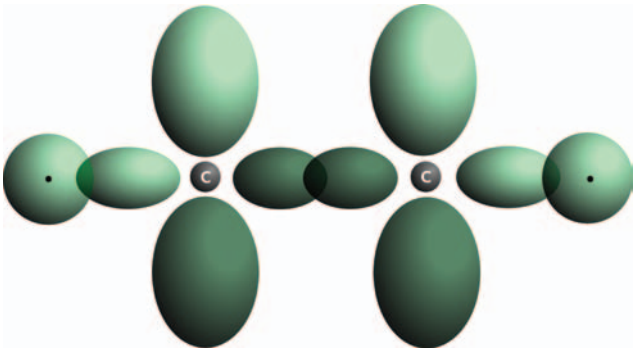

Figure 2.21 Molecule with two different bond types (σ and π) including *p* orbitals. The two different bonds may have different spatial distributions.

this means for the elements hydrogen and helium each is now described by two *s* functions, and for the elements lithium to neon by four *s* and six *p* functions. Such a basis is already much better suited to represent an atom. Why is this the case? We exemplify this by a simple example, illustrated in Figure 2.21. This molecule has two different C−C bond types with two different neighbors. Most probably the spatial distribution of electrons in each of the neighbors is different. By using only one set of *p* functions, as done in the minimum basis, we have to make a compromise between the two different bonds, resulting in an average value for the orbital exponent ζ. In doubling the number of functions, we account for two different bonding types, allowing two different values of ζ, and enable a better (and more individual) description of the two different bonds. Naturally, this leads to much more realistic wavefunctions and energies closer to the experimental value.

Nothing prevents us from tripling the minimum basis, thereby creating a triple zeta (TZ) basis, or quadrupling (QZ), or even quintupling (5Z) the minimum basis. In practice, however, a 5Z basis is in most cases too expensive.

By multiplying all basis functions, we create a huge basis set. In order to describe chemical bonds, we especially need to describe the outer electrons (the valence electrons) properly. Therefore, instead of multiplying the complete minimum basis, we can solely multiply the basis functions for the outer electrons. Such a multiplication of a chopped basis is called a *split valence basis*. They are denoted VDZ (for a basis where the valence basis set is doubled), VTZ (denoting a tripling of the valence basis set), VQZ, and so on.

Very often, we need to add *polarization functions*. As the name indicates, polarization functions contribute with higher angular momentum, thereby polarizing other functions. A *p* function polarizes an *s* function, a *d* function polarizes a *p* function, and so on. Typically, adding polarization functions improves the description of chemical bonds. Also, polarization functions allow for a certain degree of asymmetry of the bond. This is important to describe bonds where the two atoms are not the same. Adding a set of polarization functions (that is, *p* orbitals to the hydrogen atom and *d* orbitals to the heavier atoms) is commonly denoted DZP (double zeta plus polarization) basis, and analogously one can have TZP, QZP basis set, and so on.

2.6.3
Contracted Basis Sets

The disadvantage of basis sets is very often that the inner electrons make the largest contribution to the total energy. Applying the variational principle, we are iterating to achieve the lowest possible energy. This, in turn, means that many basis functions are used to describe the core with the inner electrons properly, as they make the largest contribution to the energy, as shown in Figure 2.22a. However, we are interested in describing the chemical bond as accurate as possible, implying that the valence electrons have to be represented properly. Unfortunately, describing the outer electrons accurately does not change as much in the total energy as representing the inner electrons properly (see Figure 2.22b). By taking a large basis, we can account for both types of electrons, the inner and the valence electrons. This, however, is computationally inefficient. A common solution to this problem is to contract basis sets: a certain number of functions describing the core (the inner electrons) are combined into one function describing the whole core. Often, three, four, or six basis functions are combined into one. The rest of the basis set is used to describe the chemically more relevant valence electrons. In common quantum chemical programs, we find already a pre-built variety of contracted basis sets. A well-known class was introduced by John Pople and co-workers. In the following we describe some of the most common Pople types of basis sets.

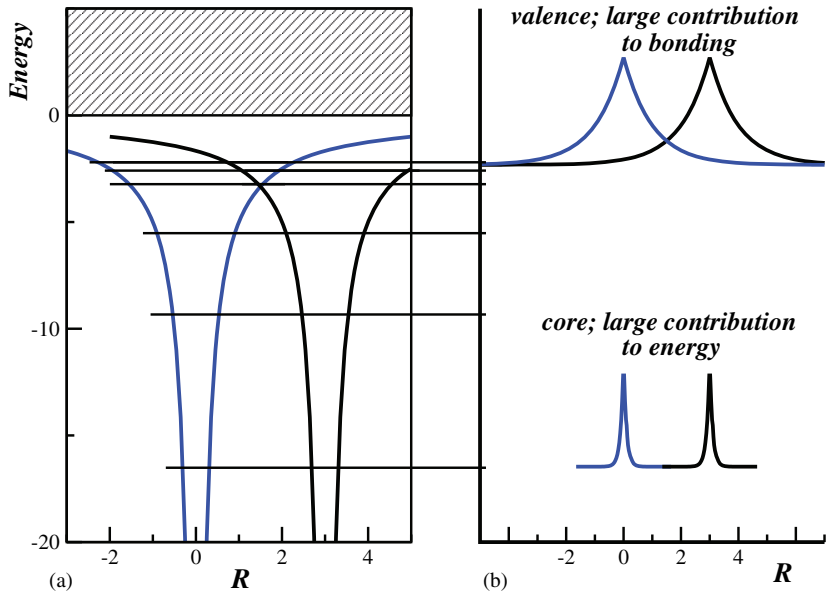

Figure 2.22 Inner electrons make the largest contribution to the energy, but are not so important in describing the chemical bond, and vice versa. (a) Energetic picture; (b) the wavefunctions.

STO-nG basis sets represent a minimum basis set of one Slater orbital (STO) consisting of *n* Gaussian orbitals (GTO). The exponents of the Gaussians are fitted to describe an STO. The best known member of this class is the STO-3G basis set, where one Slater orbital is described by three Gaussian orbitals. As an example of the hydrogen atom, out of three *s* GTO functions, one STO function is constructed. Similarly, for any element between lithium and neon, out of six *s* functions and three *p* functions, two *s* functions and one *p* function are constructed to describe the 1*s*, 2*s*, and 2*p* orbitals.

The *k-nlmG* class of basis functions consist of Gaussian functions split by the valence shell, which we call "split valence." The coding by the letters representing numbers can be interpreted as follows. The letter *k* denotes how many Gaussians functions are contracted to one core orbital. The *nlm* codings contains several pieces of information. First, when only two numbers are present, this indicates a double split valence, whereas three numbers indicate a triple split valence. Then, the numbers themselves specify the contraction scheme.

A common basis set of this type is the *3-21G basis set*. This is a split valence basis set. Here, out of three functions, one core function is constructed, whereas for the inner valence two basis functions are contracted to one function and the outer valence is not contracted, consisting of one basis function. Similarly, the common *6-31G basis set* can be interpreted as follows. The core is constructed from six orbitals, the inner valence from three orbitals, and the outer valence is again uncontracted. Although both the 3-21G and the 6-31G basis sets result in the same number of basis functions, the 6-31G basis set typically performs better, as more functions (called primitives) are used to construct this basis set. Another representative of this class of basis sets is the *6-311G basis set*, being a triple split valence basis set. The core again consists of six functions contracted to one, the inner valence is contracted from three functions, and additionally there are two more valence functions being not contracted.

If additionally diffuse functions (*s* or *p* orbitals with a very small orbital coefficient ζ) are present, these are typically marked by adding a $+$ or $++$ before the letter G. One $+$ indicates a set of diffuse functions on the heavy atoms, whereas $++$ denotes diffuse functions on both the heavy functions and the hydrogen atom. Adding polarization functions is denoted by a * or **, where analogously one * indicates a set of polarization functions on the heavy atoms, whereas ** denotes polarization functions on the hydrogen also. Often, we find explicit notation where the specific functions are written, that is, 6-31G** is equivalent to 6-31G(d,p). The largest standard basis of this style is the 6-311$++$G(2df,2pd), a triple split valence basis with a set of diffuse *s* and *p* functions on the heavy atoms and the hydrogen, two *d* and one *f* polarization functions on the heavy atoms, and two *p* and one *d* polarization function on the hydrogen atom.

A different class of contracted basis sets is the so-called *correlation consistent* basis sets developed by Dunning and co-workers, denoted cc-pVDZ, cc-pVTZ, cc-pVQZ, cc-pV5Z, and so on. They have the advantage that they build a sequence of basis sets where each step of increasing the basis size converges to the basis set limit. For this reason, they are slightly more expensive than the counterparts of

Pople. In the sequence of these functions, always one more function is added, thereby increasing the basis set size in a stepwise manner. As an example, let us consider the sequence from cc-pVDZ, cc-pVTZ to cc-pVQZ: while the smallest basis cc-pVDZ from this sequence consists of 3*s*, 2*p*, and 1*d* orbital for the heavy atoms (we will omit the explicit form for the hydrogen atoms, which is always one function and one polarization function less than the heavy atom), the basis for the next larger basis, cc-pVTZ, has one more function of each type, therefore consisting of 4*s*, 3*p*, 2*d*, and as a new function with higher angular momentum: 1*f* function. Correspondingly, the cc-pVQZ basis has 5*s*, 4*p*, 3*d*, 2*f* and 1*g* function, and so on. The functions can be augmented by additional diffuse functions, which is denoted by the prefix *aug-*.

Of course, for special tasks, self-made basis sets can be constructed. However, there are some general rules to obey which we cannot mention here. Instead, we refer the interested reader to the computational chemistry literature [1–4].

2.7 Electron Correlation

Assuming a complete basis set, the calculated energies with the Hartree–Fock–procedure still do not agree fully with the experimentally measured values. In the ideal case, we obtain up to 99% of the experimentally exact energy – but the chemistry often is very well hidden in the remaining 1%. Which contributions are behind this 1% (or more)?

This 1% (or more) is the so-called *electron correlation*. The electron correlation energy is commonly defined by the difference between the exact energy and the Hartree–Fock energy in the limit of a complete basis set:

$$E_{\text{corr}} = E^{\text{exact}} - E_0^{\text{HF}}. \tag{2.40}$$

This energy is the sum of different contributions, which can be grouped into two different types of electron correlation:

1) **Dynamic electron correlation:** We recall that in the Hartree–Fock method, we made the explicit assumption that an electron moves in the average potential of all other electrons. This does not correspond to reality since the electrons try to avoid each other due to their charges – they do not come close but swerve, as sketched in Figure 2.23. There is a reduced probability of finding an electron in the close neighborhood of another electron. This implies that the dynamics of each electron are not independent of the motion of the other electrons but is correlated with the dynamics of all other electron.
2) **Static electron correlation:** Unfortunately, there is no common definition of static electron correlation; we therefore try to approach its meaning by exemplifying typical occurrences. Static electron correlation occurs close to degeneracy or, generally, when several electronic configurations are important. We often

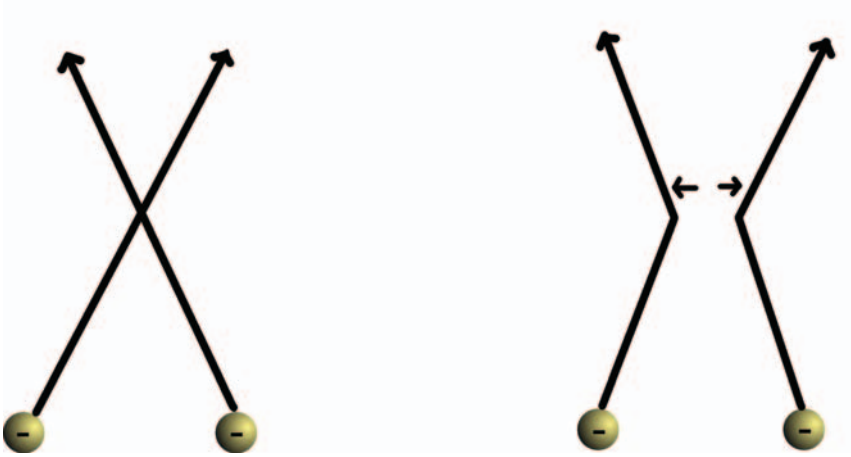

Figure 2.23 Dynamic electron correlation: Electronic motion is not independent of the motion of all other electrons but depends explicitly on the motion of the other electrons, thereby avoiding each other.

encounter static electron correlation, for example, when transition metals are involved, as there are many electronic energies lying close together, or in homolytic dissociation. The reason for the latter might not be so obvious, hence we would like to address this problem briefly.

For simplicity, let us imagine the hydrogen molecule, which consists of two nuclei and two electrons. Applying a single Slater determinant with a minimal basis of two spin orbitals in the Hartree–Fock method, we obtain different contributions describing the hydrogen–hydrogen bond, as depicted in Figure 2.24. As a result of a Hartree–Fock calculation, we obtain four wavefunctions. Two of them are of ionic character, meaning that the two electrons are located around one nucleus (formally negatively charged) whereas the other one has no electrons (formally positively charged). The other two wavefunctions are of covalent character, where each nucleus has one electron around it. This is an appropriate description for the bond around the equilibrium internuclear distance.

However, how is the bond described in the limit of infinite internuclear distance? For homolytic dissociation, the system should be described by two (infinitely) separated hydrogen atoms, having one electron each. Hence, in the dissociation limit, the wavefunction has 100% pure covalent character. Then it is clear that the character of the bond changes during dissociation: whereas it is 50% covalent and 50% ionic around the equilibrium internuclear distance, it is 100% covalent and 0% ionic at large internuclear distances. Unfortunately, this change of the character of the wavefunction cannot be described by the Hartree–Fock method, which uses one determinant only. This error in the Hartree–Fock description is known as static correlation and requires more than one determinant.

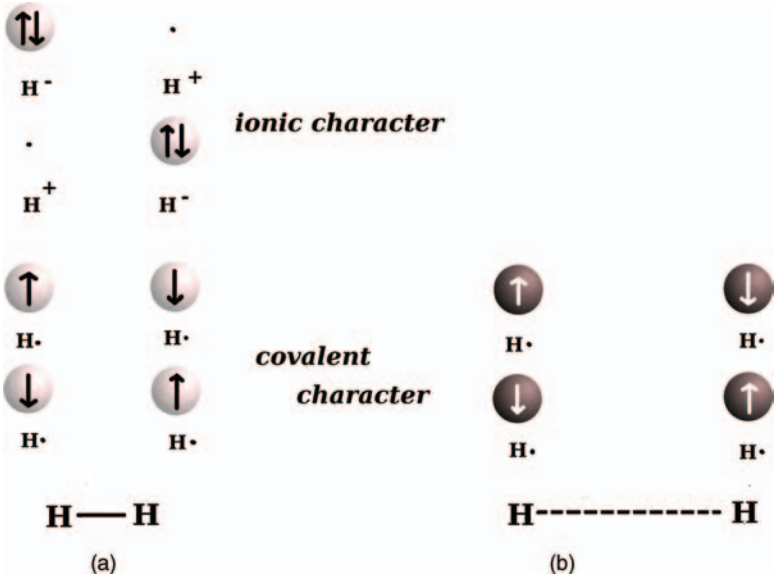

Figure 2.24 (a) Hartree–Fock wavefunction describing the hydrogen molecule around its equilibrium internuclear distance. The bond has 50% ionic (both electrons on one nucleus) and 50% covalent character (each nucleus has one electron). Part (b) shows that in the limit of infinite internuclear distance (dissociation limit), the wavefunction should be exclusively described as covalent.

In order to describe such problems where several electronic configurations or other determinants are important, quantum chemical methods including (static or dynamic) electron correlations have to be employed.

The lack of additional determinants in Hartree–Fock calculations results in the following errors:

- The bond energies for stretched bonds are too high. This is crucial for transition states, which often are described by stretching and breaking/making of different bonds. Consequentially, the energies of transition states are typically too high at the Hartree–Fock level of theory.
- As the energies increase too rapidly on stretching the bonds slightly, it often appears that the minimum on the potential energy surface is at too short internuclear distances and the curvature is too strong. This is important for vibrations, which are for this reason too high.
- The opposite is true for complexes involving metals or for charge-transfer systems. Here, within the Hartree–Fock approach the ionic character during dissociation is correctly described but the equilibrium distance is too long.

In general, the main sources of error in quantum chemical calculations are (a) insufficient treatment of electron correlation and (b) a limited basis set. (Minor errors are due to relativistic and non-Born–Oppenheimer effects.) We have introduced the different forms of electron correlation, namely dynamic and static electron

correlation. As a next step, we introduce quantum chemical methods accounting for electron correlation in the calculation.

2.7.1 Configuration Interaction

The conceptually easiest method to recover electron correlation is the so-called *configuration interaction* (CI) method. As we have seen before, a description of the wavefunction by only one Slater determinant is not capable of incorporating electron correlation effects. The next logical step is to include more determinants (more configurations) in the wavefunction. If we include all of the possible ones, this is called a full-CI wavefunction:

$$\Phi^{\text{full-CI}} = \sum_{i}^{\infty} a_i \psi_i^{\text{el}} \tag{2.41}$$

$$= a_0 \psi_{\text{HF}}^{\text{el}} + a_1 \psi_1^{\text{el}} + a_2 \psi_2^{\text{el}} + \cdots . \tag{2.42}$$

The different determinants ψ_i^{el} are the different configurations. What is the physical meaning of these configurations? Figure 2.25 sketches different determinants occurring in Equation 2.42. The different configurations can be categorized by their excitation level. Whereas the Hartree–Fock determinant corresponds to the ground-state configuration where no electron is excited, there are different configurations which can be classified as single excitations, as double excitations, and so on. We can see immediately that the number of configurations of a system contributing to, for instance, single excitations depends on the size of the chosen basis, as the electrons sitting in the occupied orbitals can be excited to all virtual orbitals. The number of virtual orbitals, in turn, depends on the basis set size. Including all possible excitations (full-CI) within the chosen basis leads to an exact wavefunction including the full electron correlation.

The problem of including all possible configurations in a sufficiently large basis lies at hand: except for very small systems, accounting for all possible configurations

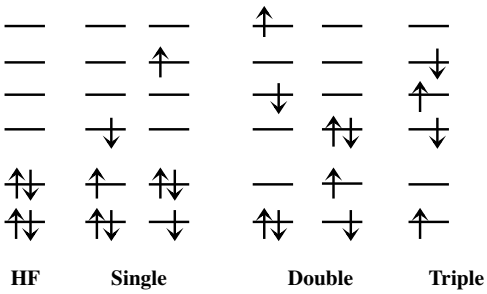

Figure 2.25 Different configurations contributing to the full-CI wavefunction. The configurations can be categorized according to their excitation level as single, double, triple, and so on excitations.

is computationally too expensive, if not even impossible. For typical systems, we can analyze the importance of the particular excitation. On doing so, it was found that double excitations provide the most important contribution to the electron correlation energy, much more important than single or triple excitations. In order to reduce computational effort, truncated CI methods have been implemented. Single configuration interaction (CIS) means that in addition to the Hartree–Fock determinant wavefunction, all kinds of single excitations contribute. Analogously, for double configuration interaction (CID), the Hartree–Fock wavefunction and all different kinds of double excitations contribute. In the CISD method, the Hartree–Fock determinant, single and double excitation contribute. Not considering all excitations but just excitations up to a certain level reduces the computational effort substantially, but introduces a different problem: the calculations are not size consistent (Figure 2.26).

Size-consistent calculations are calculations where the relative errors scale proportionally to the size of the system. Consider a molecule consisting of two atoms; a size-consistent calculation (e.g., HF or full-CI) yields a certain energy. Now we double the system size, that is, treating four atoms, where two are building one molecule, and we separate the two molecular entities. In the limit of infinite separation of the monomer units, there would be no interactions between these subunits, and the system's energy would be just twice the energy of the single molecule, as to be expected. Non-size-consistent calculations, such as the truncated-CI methods (e.g., CISD), would yield an energy for the two molecules different from the correct value of twice the one-molecule energy. Even worse: in the limit of very large systems, as the energy does not scale with the system size, the correlation energy is not recovered at all any longer. The reason for this deficiency lies in the truncation itself: consider a hydrogen molecule with two electrons being described by CISD calculations. For a chosen basis (for simplicity let it be even the minimal basis of one *s* function on each nucleus), the wavefunction contains besides the Hartree–Fock part all single and double excitations. On adding a second hydrogen molecule at large

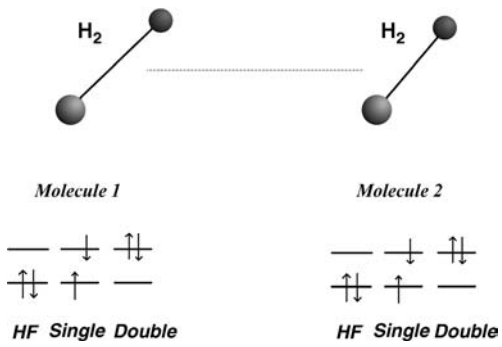

Figure 2.26 Visualization of the size consistency problem using two hydrogen molecules as an example. Each hydrogen molecule has two electrons and can therefore be maximally doubly excited. Two hydrogen molecules, being both doubly excited, correspond to a quadruply excited system.

distances to our calculation, the second hydrogen molecule can be described by the same excitations, the Hartree–Fock determinant, as well as all single and double excitations. However, as each of the two hydrogen molecules can have double excitations, this would correspond to all four electrons (two on each molecule) to be excited – this is formally a quadruple excitation, which is not included in the CISD series, as we truncate after double excitation and explicitly omit triple, quadruple, and all higher excitations. Therefore, on doubling the system size, the degree to which electron correlation is accounted for shrinks and the description becomes worse for larger systems. The problem of size consistency has led to a reduced disposal of truncated-CI methods. Instead, the conceptually similar *coupled cluster* methods, the subject of the next subsection, have gained in importance.

2.7.2 Coupled Cluster Method

The message of the last subsection is that in order to permit electron correlation in the calculation, we need to include different configurations in the wavefunction. However, a full-CI calculation (being size consistent) is for most of the systems not possible, and truncating the series of configurations causes size-consistency errors. Within the coupled cluster (CC) approximation, the concept of expanding the wavefunction to higher excitations is retained, while the problem of the size consistency is eliminated. The ansatz for a CC wavefunction is to introduce the CC operator e^{T} so that

$$\Phi^{\mathrm{CC}} = \mathrm{e}^{\hat{T}}\psi_{\mathrm{HF}}^{\mathrm{el}}. \tag{2.43}$$

As in the case of full-CI, a full-CC calculation is exact but computationally not feasible. The truncated-CC wavefunctions are similarly built according to the level of excitation in which they are truncated. For instance, CCSD indicates the inclusion of single and double excitations.

Recall that the problem of the size inconsistency occurred because higher excitations were omitted. The CC wavefunction accounts for the contribution of higher excitation by approximating their contribution from lower excitations: the probabilities (the coefficients) with which the lower excitations appear are used to describe the probabilities in which the higher excitations would occur. Consider as an example the CCSD method; here we include single and double excitations. Remember the example of the hydrogen dimer for the CISD method: we stated that we did not account for the quadruple excitations which caused the size inconsistency. Within the CCSD method, we also account for the quadruple excitations approximately by describing the quadruple excitations as products of double excitations. Although not including the quadruple excitations explicitly, we approximate their contribution to be about the product of the corresponding double excitations. By doing so, the CC method is size consistent.

The CC theory is probably the most accurate method to compute electronic energies to date, but it is also one of the most expensive.

2.7.3 Multi-Configurational Self-Consistent Field Theory

In chemistry, we often encounter situations where not only one configuration is important and contributes to approximately 99% of the energy. Typical examples are molecules where chemists draw mesomeric structures – structures where different charge distributions play a role. One of the textbook examples is the ozone molecule, O_3, which can exist as a zwitterionic structure or a biradical structure (Figure 2.27). In the case of ozone, the wavefunction has approximately 60% zwitterionic character and about 40% biradical character. It is straightforward to see that we introduce large errors if we consider only the zwitterionic character as the Hartree–Fock approach would do. We therefore need a theoretical description in which we account for different configurations. The *multi-configurational self-consistent field* (MCSCF) method is such a theory: in a conceptually similar manner to the CI method, the total wavefunction is likewise written as a linear combination of different configurations (see Equation 2.42), but with the important difference that the coefficients from which the configurations (the molecular orbitals) are built are also varied. Choosing the hydrogen molecule as an example, we are dealing with two configurations, as shown in Figure 2.28. Note that the single excitation does not contribute for symmetry reasons. These configurations correspond to the Hartree–Fock ground state (a) and a doubly excited configuration (b). In analogy with the CI approach, the MCSCF wavefunction for this case is written as

$$\Phi^{\mathrm{MCSCF}} = a_A \psi_A^{\mathrm{el}} + a_B \psi_B^{\mathrm{el}} \tag{2.44}$$

$$\psi_A^{\mathrm{el}} = \sum_i b_{iA} \varphi_i \qquad \psi_B^{\mathrm{el}} = \sum_i b_{iB} \varphi_i \tag{2.45}$$

where the φ_i are basis functions. Then, the coefficients a_A, a_B, b_{iA}, b_{iB} are varied until self-consistency is reached. However, in general, the problem is to know of which configurations have to be chosen. One very common approach is the complete active space self-consistent field (CASSCF) method. Here, the choice of configurations is made by defining a so-called active space, consisting of n electrons and m orbitals ($[n,m]$-CASSCF). Inside this active space, a full-CI is performed. Figure 2.29 visualizes a typical partitioning of a set of orbitals (wavefunctions) into active and inactive spaces. The active space consists of the relevant occupied and unoccupied (virtual) orbitals; typically, the highest occupied molecular orbital (HOMO), in addition to the lowest unoccupied molecular orbital (LUMO), should be at least contained in the active space. As inside the active space a full-CI is calculated, the size of the

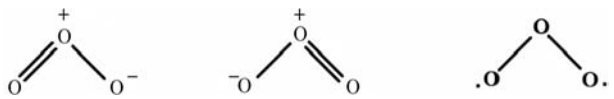

Figure 2.27 Different mesomeric structures of ozone. The first two structures are zwitterionic, whereas the last structure has biradical character.

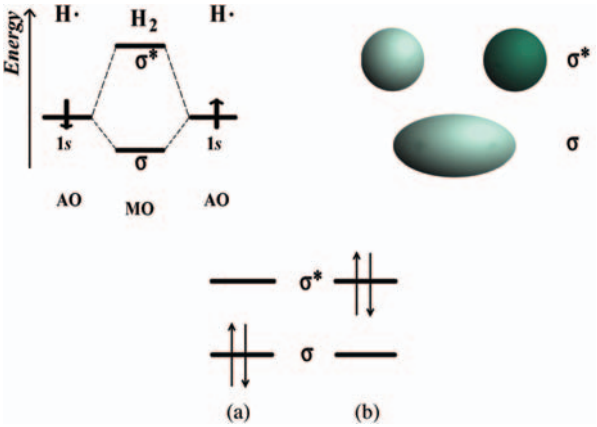

Figure 2.28 Two configurations in the hydrogen molecule: (a) is the Hartree–Fock ground state and (b) is a doubly excited configuration.

active space cannot be large. The biggest CASSCF calculations up to date contain 18 electrons/orbitals.

The main disadvantage with the CASSCF method is that it can lead to an "unbalanced" description: as electron correlation is only accounted for in the active space and not, for example, the inactive core electrons. Further, the CASSCF method tends to overestimate the biradical character of chemical compounds.

2.7.4
Møller–Plesset Perturbation Theory

Recall that the idea behind perturbation theory is that the problem to be handled differs only slightly from a known problem. Then the Hamiltonian operator can be defined as the sum of two parts, a reference Hamiltonian $\hat{H}^{(0)}$ and a perturbation $\hat{H}'$.

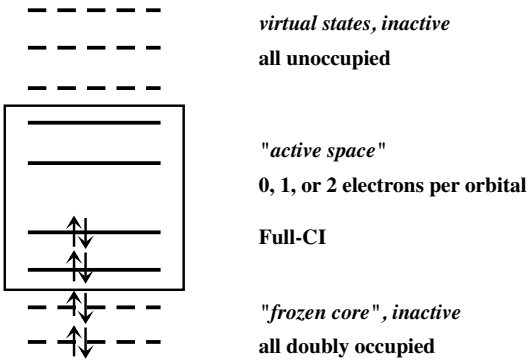

Figure 2.29 Partitioning of the orbitals into active and inactive spaces. The inactive spaces are either doubly occupied (frozen core) or empty (virtual). Inside the active space, the orbitals are either singly, doubly or not occupied, and a full-CI is performed.

The perturbation has to be small compared with the reference Hamiltonian. The n solutions of $\hat{H}^{(0)}$ are assumed to be known and given. In 1934, Møller and Plesset [5] proposed to partition the Hamiltonian operator such that the unperturbed Hamiltonian is $\hat{f}$, the Fock operator defined in Equation 2.36. With this definition of $\hat{H}^{(0)}$, the zeroth-order energy $E^{(0)}$ is the sum of the energies ε_i.

The perturbation $\hat{H}'$ is the difference between $\hat{H}$ and $\hat{H}^{(0)}$, that is, everything in the electron–electron interaction which has not been accounted for by the smeared Hartree–Fock average potential of all other electrons.

In this so-called Møller–Plesset or MP partition, one can realize that the Hartree–Fock energy already corresponds to the zeroth- and first-order corrections. Hence it is just the second-order correction that allows an estimate of the correlation energy. The essence of the MP2 method is then to calculate the energy correction for the ground state. A detailed analysis shows that the second-order correction to the energy in the MP2 theory involves all possible double excitations.

MP2 typically accounts for 80–90% of the correlation energy, and as it is computationally highly efficient, it is a popular *ab initio* method for including electron correlation. It should be noted that although not variational, the MPn perturbation method is size consistent. Beyond MP2, the only MPn methods implemented in standard codes are MP3 and MP4. Whereas MP3 is very often divergent, MP4 can be very accurate, recovering up to 98% of the correlation energy, but of course at a higher computational cost than MP2.

2.8 Density Functional Theory

The electronic wavefunction has been the central key to quantum chemistry so far. If ψ – or a good approximation to it – is known, all information about our target system can be calculated. This approach, however, has a series of disadvantages. First, this wavefunction is very complicated. It depends on $4N$ variables (three spatial and one spin coordinate) and its complexity grows with increasing number of electrons. Second, there is no observable for the wavefunction which can be easily probed experimentally. On the other hand, one can consider the electron density or, strictly, $\rho(r)$, the probability density, that we introduced at the beginning. We will follow the common practice of calling it electron density.

The electron density ρ depends on three spatial coordinates regardless of how many electrons our system includes; moreover, it can be measured via X-ray experiments. But is the electron density sufficient to obtain the energy and all the other properties of interest? The first hint about this is that the expectation value of a (multiplicative) operator $\hat{A}$ can be calculated analogously using the electron density.

Furthermore, the electron density has the following interesting properties:

- Integrating the electron density gives the number of electrons.
- The cusps of the density match the positions of the nuclei.
- The density at the nucleus position contains information about the nuclear charge.

Hence it seems that the electron density provides all information to set up the system-specific Hamiltonian and to determine all molecular properties. Therefore, it is the electron density which is used in density functional theory (DFT).

2.8.1 The Hohenberg–Kohn Theorems

DFT is based on two basic pillars, the two *Hohenberg–Kohn theorems*, which are exposed in the following.

The first Hohenberg–Kohn theorem [6] provides a proof that the electron density can be used in quantum chemistry calculations instead of the wavefunction. It states that the electron density is uniquely determined by the external potential, that is, the electron–nuclear interaction potential. In other words, it means that the ground-state electron density uniquely specifies the external potential or that there is a one-to-one correspondence between the external potential and the electron density.

A semantic note is in order here. A *function* is an instruction on how to obtain a number from a set of variables (e.g., coordinates). A *functional* is in this context an instruction on how to obtain a number from a function which itself depends on variables; it is a "function of a function". To denote functionals depending on a function, square brackets, $F[f]$, will be used instead of parentheses, $f(x)$.

The ground-state energy E_0 is a unique functional of the ground-state density ρ_0 and so are its individual parts. Hence we can write

$$E[\rho_0] = T[\rho_0] + E_{\text{el}-\text{el}}[\rho_0] + E_{\text{el}-\text{nuc}}[\rho_0]. \tag{2.46}$$

We can split this expression into parts which depend on the actual system determined by the external potential – that is, the potential of the electron–nuclei interaction $E_{\text{el}-\text{nuc}}[\rho_0]$ – and those which are universal, meaning that the form of the functional is independent of the actual system:

$$E[\rho_0] = \underbrace{E_{\text{el}-\text{nuc}}[\rho_0]}_{\text{system dependent}} + \underbrace{T[\rho_0] + E_{\text{el}-\text{el}}[\rho_0]}_{\text{system independent}}. \tag{2.47}$$

The system-independent parts can be gathered in the *Hohenberg–Kohn functional* $F_{\text{HK}}[\rho_0]$:

$$E[\rho_0] = E_{\text{el}-\text{nuc}}[\rho_0] + F_{\text{HK}}[\rho_0]. \tag{2.48}$$

This functional $F_{\text{HK}}[\rho_0]$ can be considered as the holy grail of DFT. Knowledge of it would allow us to solve exactly the Schrödinger equation. Also, since this is a universal functional, this would be valid for all systems, independent of the number of atoms or electrons. Unfortunately, the explicit form of $F_{\text{HK}}[\rho_0]$ lies completely in the dark. In an effort to simplify the problem, F_{HK} is divided into parts:

$$\begin{aligned} F_{\text{HK}}[\rho_0] &= T[\rho_0] + E_{\text{el}-\text{el}}[\rho_0] \\ &= \underbrace{T[\rho_0]}_{\text{unknown}} + \underbrace{J[\rho_0]}_{\text{known}} + \underbrace{E_{\text{ncl}}[\rho_0]}_{\text{unknown}} \end{aligned} \tag{2.49}$$

where $J[\rho_0]$ is the classical Coulomb part and $E_{\mathrm{ncl}}[\rho_0]$ represents the non-classical contribution to the electron–electron interaction. This includes self-interaction and correlation.

Finding explicit expressions for the yet unknown parts of the Hohenberg–Kohn functional represents the major challenge in DFT.

Up to now it has been demonstrated that the ground-state density suffices to obtain all properties of interest. But how one can be sure that a given density is the ground-state density we are looking for? Fortunately, the second Hohenberg–Kohn theorem provides a way. This theorem is nothing else than the variational principle for densities. In plain words, it states that $F_{\mathrm{HK}}[\tilde{\rho}]$ – with an arbitrary test density $\tilde{\rho}$ – delivers the lowest energy if, and only if, the input density is the true ground-state density ρ_0, that is,

$$E_0[\tilde{\rho}] = \langle \tilde{\psi} | \hat{H} | \tilde{\psi} \rangle \geq \langle \psi | \hat{H} | \psi \rangle = E_0[\rho_0] \tag{2.50}$$

with the equals sign valid only if $\tilde{\rho} = \rho_0$. A consequence of this variational principle is that DFT is formally only a ground-state theory.

2.8.2 The Kohn–Sham Approach

The main problem with DFT (besides the unknown Hohenberg–Kohn functional) is related to the way in which the density is expressed to put the theory to work. Kohn and Sham [7] proposed to replace the density ρ of the *full-interacting* electron system with the density ρ_{KS} of a reference system of *non-interacting* quasi-particles with $\rho = \rho_{\mathrm{KS}}$. For this system we can write a Hamiltonian $\hat{H}_{\mathrm{KS}}$ analogously to what we did for the Schrödinger equation earlier. Since this Hamiltonian does not contain any electron–electron interactions, the Slater determinant is the exact wavefunction for the system and its kinetic energy can be calculated.

The spin orbitals in the latter determinant are the so-called *Kohn–Sham orbitals* u_i^{KS} and are one-particle wavefunctions which satisfy, in analogy with the Hartree–Fock Equation 2.36, the *Kohn–Sham equations*:

$$\hat{f}^{\mathrm{KS}} u_i^{\mathrm{KS}} = \varepsilon_i u_i^{\mathrm{KS}} \tag{2.51}$$

with the Kohn–Sham operator

$$\hat{f}^{\mathrm{KS}} = \hat{T}_{\mathrm{KS}} + \hat{V}_{\mathrm{KS}} \tag{2.52}$$

which resembles the Fock operator. Due to this similarity, one can solve the Kohn–Sham equations using the same algorithms as in the Hartree–Fock theory, that is, the same self-consistent field approach. Note that the Kohn–Sham orbitals u_i^{KS} are *not* the same as the Hartree–Fock orbitals u_i^{HF}, as we require the Kohn–Sham density to be the same as the ground-state density of our real target system ρ_0.

Of course, the kinetic energy of the non-interacting system T_{KS} is not equal to the true kinetic energy T of our real target system. Keeping this in mind, the functional $F_{\mathrm{HK}}[\rho]$ can be written split into the following parts:

$$F_{HK}[\rho] = T_{KS}[\rho] + J[\rho] + E_{XC}[\rho] \tag{2.53}$$

with the so called exchange-correlation functional

$$\begin{aligned} E_{XC} &= (T[\rho] - T_{KS}[\rho]) + (E_{el-el}[\rho] - J[\rho]) \\ &= (T[\rho] - T_{KS}[\rho]) + E_{ncl}[\rho]. \end{aligned} \tag{2.54}$$

The residual part of the true kinetic energy is added to the non-classical electrostatic contributions. In this way, the exchange-correlation functional contains everything that is unknown. Often this functional is split into an exchange part and a correlation part:

$$E_{XC}[\rho] = E_X[\rho] + E_C[\rho] \tag{2.55}$$

both of which are approximated independently.

The remaining quest is to obtain the exchange-correlation functionals. The explicit form of the functionals is often very complicated because they are developed in a more or less systematic way using empirical models[3)].

The corresponding correlation functionals have even more complicated analytical forms and therefore they will not be explicitly written here. Currently the most popular are hybrid functionals such as B3LYP with three optimized parameters [8].

2.8.2.1 **Advantages**

DFT is able to consider electron correlation at the computational cost of Hartree–Fock. In most cases, it delivers reliable molecular geometries, good values for H-bond distances and good values for binding energies (hybrid functionals). The DFT method is universally applicable (i.e., for the solid state, surfaces, and molecules and for all elements). At the same accuracy, it is more efficient than correlated Hartree–Fock methods.

2.8.2.2 **Disadvantages**

The main disadvantage of DFT is that, unlike wavefunction-based methods that are hierarchical, there is no systematic way to improve the accuracy of the DFT results. It is not necessarily true that larger basis sets deliver better energies or better properties. Due to the variational principle (second Hohenberg–Kohn theorem) DFT can only describe the ground state; however, as will be shown in Section 2.8.3, an extension to treat electronic excited states is possible.

2.8.3
Time-Dependent Density Functional Theory

DFT is formally a ground-state theory. To describe the interaction with time-dependent potentials such as electric or magnetic fields and to extract

3) In this sense DFT is not a clean *ab initio* method, but more a semiempirical method.

information such as excitation energies or (resonance) Raman spectra, it has to be extended to the so-called time-dependent density functional theory (TDDFT). The concepts and computational foundations of TDDFT are analogous to those of the pure DFT.

The formal foundation of TDDFT is the Runge–Gross theorem [9]. It shows that, for a given initial wavefunction, there is a unique one-to-one relation between the time-dependent external potential of a system and its time-dependent density. Unlike DFT, there is (unfortunately) no general variational principle in time-dependent quantum mechanics.

The Runge–Gross theorem was originally derived for electrons moving in an external field.

Two external potentials differing only by an additive time-dependent, spatially independent function, $c(t)$, give rise to the same electronic density. The Runge–Gross theorem [9] shows that there is a unique mapping from an external potential to the electronic density. The proof is done in the following steps:

1) It is shown that two external potentials differing by more than an additive constant generate different current densities. This is done via the expansion of the external potential in a Taylor series about a given time.
2) Using the continuity equation, it is then shown that for finite systems, different current densities correspond to different electron densities.

For a given interaction potential, the Runge–Gross theorem shows that the external potential uniquely determines the density. The Kohn–Sham approach chooses the density of the interacting system as that of the non-interacting one for all times. The wavefunction of a non-interacting system can be represented as a Slater determinant and the kinetic energy of the non-interacting system can be expressed exactly in terms of those orbitals. The problem is therefore to find a potential, denoted $V_{\mathrm{KS}}(\vec{r}, t)$, that sets up a non-interacting Hamiltonian, $\hat{H}_{\mathrm{KS}}$, which in turn specifies a determinantal wavefunction which is constructed in terms of a set of orbitals and generates a time-dependent density $\rho_{\mathrm{KS}}(\vec{r}, t)$ such that ρ_{KS} is equal to the density of the interacting system at all times.

The problem of obtaining approximations to the Kohn–Sham potential is challenging. Analogously to DFT, the time-dependent Kohn–Sham potential is decomposed to extract the external potential of the system, the time-dependent Coulomb interaction and the exchange-correlation potential.

Linear response TDDFT can be used if the external perturbation is small. That means that it does not completely destroy the ground-state structure of the system. In this case one can analyze the linear response of the system. This is a great advantage as, to first order, the variation of the system will depend only on the ground-state wavefunction so that we can simply use all the properties of DFT. Consider a small time-dependent external perturbation $\delta V^{\mathrm{ext}}(t)$. Looking at the linear response of the density, one can obtain an equation from which it is possible to derive the excitation energies of the system, as these are simply the poles of the response function.

2.9 Semiempirical Methods

Semiempirical methods come into play when molecules cannot be calculated *ab initio* any longer due to computational insufficiencies, i.e. the system is too big. For all semiempirical methods, we can summarize the following general properties:

- Use of a minimal basis, typically STOs are applied.
- Explicit consideration of the outer valence electrons only; the inner electrons are modeled by changing the effective nuclear charge acting on the outer electrons.
- Compared with the Hartree–Fock approximation, several types of integrals involving the electron–electron interaction are neglected. This is a consequence of the so-called *zero differential overlap* (ZDO) approximation.
- To compensate for the errors made by the approximations above, several other integrals are parameterized.

The particular semiempirical methods differ on the one hand in the types of integrals being neglected, and on the other hand in the parameters chosen to represent the remaining integrals.

Some semiempirical methods, such as the method proposed by Hückel and the Pariser–Parr–Pople (PPP) method, can treat only a subset of the valence electrons orthogonal to the molecular plane – the p_π electrons (see Figure 2.30). Other methods are able to treat all valence electrons of different atoms. Especially the Hückel method provides a fundamental qualitative understanding of organic compounds containing conjugated (alternating) π-electrons. Although making crude approximations such as neglecting the overlap of orbitals between different atoms and ignoring interactions between atoms that are not bonded to each other, it qualitatively predicts excitation energies between electronic states and stabilization energies correctly. The Hamiltonian is not specified as its corresponding energy expectation value is never calculated directly but just parameters are added. Let us consider an example of a simple model system consisting of a certain number of electrons and nuclei. The energy expectation values (Equation 2.6) are *all* set to the same value α if they describe contributions from one atom *A* only, and set to a second value β if they describe interactions between two neighboring atoms *A* and *B*. Otherwise, the integrals are set to zero:

$$\int \phi_A^* \hat{H} \phi_A \mathrm{d}V = \alpha \tag{2.56}$$

$$\int \phi_A^* \hat{H} \phi_B \mathrm{d}V = \beta \qquad \text{if } A \text{ and } B \text{ neighbors} \tag{2.57}$$

$$\int \phi_A^* \hat{H} \phi_B \mathrm{d}V = 0 \qquad \text{if } A \text{ and } B \text{ not neighbors.} \tag{2.58}$$

The parameters α and β are chosen such that the resulting energies match experiments. From the above equations, it is clear that the Hamilton operator does not have

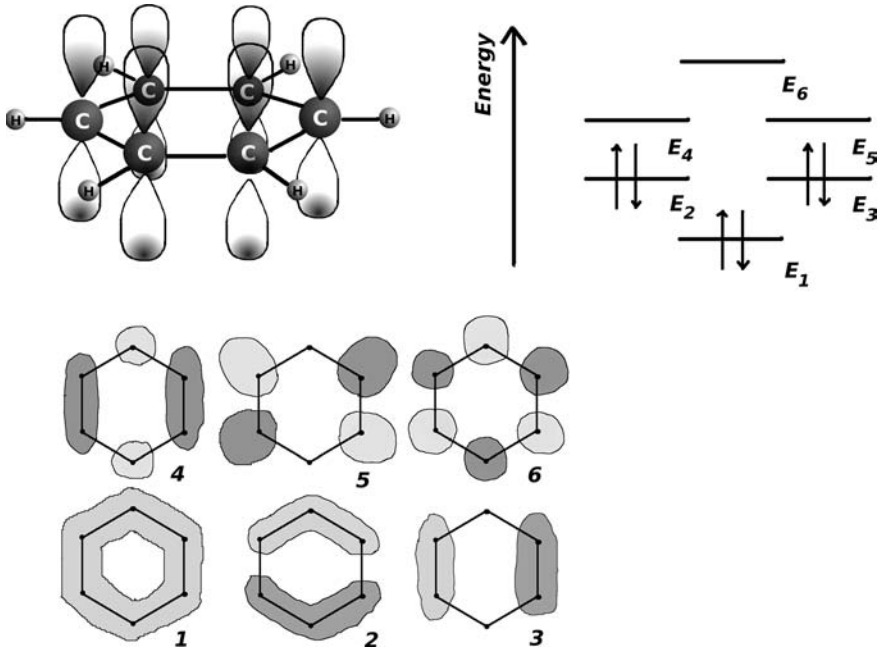

Figure 2.30 Visualization of p_π electrons (in the orbitals above and below the molecular plane) within the Hückel picture and resulting π-bond combinations using the benzene molecule (C_6H_6) as an example. There are six different combinations, corresponding to six different molecular orbitals. As for the simple systems, the higher the number of nodes (nodal planes), the higher is the energy of the system. Molecular orbitals 2 and 3, and also 4 and 5, have the same number of nodal planes (one and two, respectively) and have the same energies ($E_2 = E_3$ and $E_4 = E_5$).

to be specified, as the integrals are anyway never calculated and just the parameters are considered. Later, Roald Hoffmann, extended the Hückel method to include more than just π-electrons. This *extended Hückel method* was and still is extremely successful in elucidating reaction mechanisms in chemistry (e.g., the Woodward–-Hoffmann rules).

As already mentioned, there are several semiempirical methods that can be distinguished according to the integrals neglected and parameterized. We will not specify these approximations in detail. Instead, we mention two of the most commonly used semiempirical methods – the AM1 and the PM3 methods developed by Dewar and co-workers. Here, too, we are dealing with energy expectation values and a minimal basis. Minimal basis means that for most of the light atoms with which we are dealing, only *s* and *p* orbitals are included. From combinatorics, we can easily understand that different electron–electron interaction integrals have to be parameterized, depending on whether both electron are in *s* orbitals or in *p* orbitals, or each in different orbitals. It is also clear that these parameters differ for different atoms. All together, at least 12 parameters for each atom have to be considered.

The advantage of the semiempirical methods is that larger systems with up to a few thousand atoms can be calculated. As the parameters for the integrals are typically averaged or fitted to match known species, semiempirical methods provide good results for molecules or groups of similar molecules that have been considered during the fitting procedure. Known problems for all semiempirical methods are that weakly bound systems (e.g., including van der Waals interactions) are very poorly described. Further, molecules including metal atoms are not well described. Additionally, other more specific problems arise. We refer the interested reader to more specific literature here [10].

2.10 Force Field Methods

The last type of method that we introduce here is *not* a quantum chemical method. We neither have a Hamilton operator, nor a wavefunction, nor an electron density in these methods. Instead, the method is based on classical mechanics; therefore, it is often called *molecular mechanics* (MM) method. Simply speaking, within the *force field methods*, the atoms in a molecule are held together by bonds which are described by potentials V representing bending, stretching, torsion, and so on. Then, the total potential is minimized (mathematically, this is performed by calculating the derivative: in classical mechanics, the derivative of the potential is the force, hence the name of this method). With the force field method, equilibrium geometries and relative energies can be obtained. The absolute values of the energy obtained within the MM methods are meaningless; the most obvious reason is the neglect of kinetic energy. However, on comparing different possible arrangements of atoms in a molecule, the energy differences (the relative energies between the possible isomers) can be considered to find the one lowest in energy (the most stable one). Using force field methods, systems with more than 10 000 atoms (and therefore biologically relevant systems such as small proteins and enzymes) can be calculated.

In more detail, the total potential is given by the sum of different potentials, describing stretching, bending, out-of-plane bending, torsion, cross-terms, van der Waals interactions, and electrostatic interactions:

$$V_{\text{tot}} = V_{\text{stretch}} + V_{\text{bend}} + V_{\text{out-of-plane bend}} + V_{\text{torsion}} + V_{\text{cross}} + V_{\text{van der Waals}} + V_{\text{electrostatic}}. \tag{2.59}$$

The total potential gives the force field acting on the atoms. For all individual potentials, there are analytic expressions and parameterized values. Take as an example the stretching of a bond: the potential energy is described by a harmonic potential (parabola), $k \cdot (R - R_0)$ (see Section 2.2.3), As parameters, the equilibrium internuclear distance R_0 (where the potential energy is zero), and a constant k describing the strength of the bond (the inclination of the parabola) are fitted (see Figure 2.10).

Similar expressions and parameterizations can be found for all the other potentials. The basic idea here is that atoms in molecules often behave very similarly; considering the C−H bond as an example, we find values for the equilibrium bond length varying between 0.6 and 1.1 Å, and vibrational frequencies also in a similar range. Further diversifying into C−H bonds, where the carbon atom is bonded to three, two, or one more atoms, will yield even closer values for these subclasses. Therefore, atom "types" are classified (71 different atom types), representing atoms and their subclasses. For these atom types, the parameters used for the potentials describing a chemical bond are listed.

The information that we can obtain with the force field methods, in addition to the aforementioned equilibrium geometries and the relative energies, is very accurate values for the heat of formation, dipole moments, gas-phase entropies, and vibrational frequencies. It is clear that the results of the MM method are most accurate for common molecules where parameter sets are available.

As an extension to this section, we would like to mention that hybrid methods between molecular mechanical and quantum mechanical methods exist. These *QM/MM methods* are applied to chemical reactions, enzymes, solvent effects, and so on – or generally to larger systems, where one small part of the whole system is of special importance (such as the active center of an enzyme). QM/MM methods treat the large system with MM methods, whereas the small, important part is calculated with quantum mechanical methods. This partitioning allows for efficient treatment of such systems; the trick, however, is to couple these two methods efficiently.

3
Light–Matter Interaction

Michael Schmitt, Thomas Mayerhöfer, and Jürgen Popp

3.1
Electrical Properties of Matter

Biophotonics deals with the interaction of light with biological systems such as cells, tissue which consist of molecules such as lipids, DNA, amino acids, and so on. This chapter aims to provide a basic description of the physical foundation of the manifold interplay (e.g., absorption, emission, scattering, reflection, diffraction, dispersion) between light and matter. Light can exhibit properties of both waves and particles, a phenomenon known as wave particle dualism. Here, the description of light as electromagnetic waves is mostly employed to describe light–matter interaction. Thus, electromagnetic radiation is a wave-like perturbation recurring periodically over a certain distance called the wavelength. Light waves are described as oscillating electric (E) and magnetic fields (B) being perpendicular to each other. Matter, for example molecules, consists of positively charged nuclei held together by negatively charged electrons. In a very simple theory, matter can be described as an aggregation of oscillating nucleus–electron dipoles. On an atomic scale, light–matter interactions are governed by the quantum mechanical nature of matter and light, but many are adequately explained by the interactions of classical electromagnetic radiation with charged particles, that is, nucleus–electron dipoles. That means that when an electric field is applied to matter it causes the charges to move. Thus the interaction of electromagnetic radiation with matter can polarize matter and induce molecular dipole moments. In other words, positive and negative charges are driven in opposite directions and the matter acquires a frequency-dependent electric polarization. Since the electric polarization of molecules induced by electromagnetic radiation (light) is one of the central quantities for understanding light–matter interactions, this chapter presents an introduction to the electric properties of matter.

Detailed descriptions of electromagnetism and the electric properties of matter can be found in [1–4].

Handbook of Biophotonics. Vol.1: Basics and Techniques, First Edition.

3.1.1 Polar Molecules

To understand light–matter interactions, it is necessary to obtain a basic understanding of both the nature of light and the structure of matter. This section aims at presenting the reader with an introduction to the properties of matter that determine the way in which matter interacts with light.

Assuming that matter appears homogeneous to light (this supposes that any inhomogeneities, which are always present since there is always a scale in which matter is discontinuous, albeit on the scale of molecules and atoms, are much smaller than the wavelength of light; since the wavelength of light has not yet been introduced we will come back to this point at a later stage), the mode of interaction is determined by its properties on an atomic and molecular scale.

Assuming that matter is generally composed of molecules (as we are nearly exclusively interested in biological matter, this assumption is generally true), it is the structure and the atomic composition of these molecules, and also their mutual alignment, that are vital for further discussion. The most frequent atoms in organic matter are carbon, hydrogen, oxygen, and nitrogen. As described in Chapter 2, the different atoms share common electron pairs in molecules, which leads to chemical bonding between these atoms. If the atoms that share an electron pair are chemically identical, for example, two carbon atoms, the common electron pair is usually located between both atoms, on average symmetrically. This is no longer true if two chemically different atoms share an electron pair, for example, a carbon and an oxygen atom. In this particular example, the common electron pair is displaced towards the oxygen, meaning that the electrons have a higher sojourn probability close to the oxygen compared with the carbon. The oxygen is therefore said to have a higher electronegativity, a property that quantifies the attraction of the common electrons. Important for the following discussion is that because the common electron pair is on average closer to the oxygen than to the carbon, a dipole exists. Such a dipole is quantified by the size of the dipole moment, μ, which is given by the product of the charge difference Q and the distance l between the negative and the positive charges (see Figure 3.1):[1)]

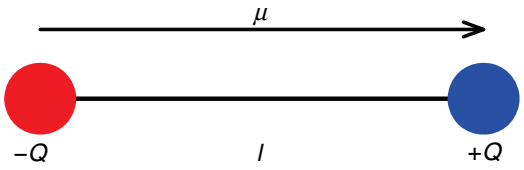

Figure 3.1 A dipole is characterized by two charges $+Q$ and $-Q$ at a distance l.

1) Note that μ and l are vector quantities. Keeping this in mind, vector notation is dropped from now on if not mentioned explicitly.

$$\mu = Q \cdot l. \tag{3.1}$$

A molecule with such a permanent dipole moment is also said to be a polar molecule. Molecules without a permanent dipole moment can nevertheless also adopt a (temporary) dipole moment if an electrical field interacts with them, since this field can either distort the electron distribution around the molecule or dislocate the cores of the atoms, or both. The dipole moment that is generated by the distortion or dislocation is called an induced dipole moment, μ_{ind}. For comparably small strengths of the electric field, this dipole moment is proportional to the electric field, E. The proportionality constant, α, is called the polarizability of the molecule:[2)]

$$\mu_{ind} = \alpha \cdot E. \tag{3.2}$$

By its nature μ_{ind} is a microscopic quantity. The corresponding macroscopic quantity is the so-called polarization, P, which is the average electrical dipole moment per unit volume of a sample or material (the "density of the dipole moments").

3.1.2 Induced Dipole moments by External Electrical Fields

To obtain a more elaborate understanding of the polarization and the macroscopic situation, it is instructive to discuss the properties of a plate capacitor. A plate capacitor consists of two metallic plates with a surface area A and a distance between them d, which have a different potential U by feeding a voltage. As a consequence, an electrical field E results given by (Figure 3.2)

$$E = \frac{U}{d}. \tag{3.3}$$

One of the plates is depleted of electrons and carries a positive charge Q, whereas the other plate is enriched with electrons and carries a negative charge $-Q$. If we divide the charge Q by the area of the plates, we obtain the electric surface density $\sigma = Q/A$, which we also obtain by definition if we multiply the electric field by the permittivity of vacuum, ε_0:

$$\sigma = \frac{Q}{A} = \varepsilon_0 \cdot E. \tag{3.4}$$

Another characteristic property of a plate capacitor is its capacity, C:

$$C = \frac{Q}{U}. \tag{3.5}$$

If matter is placed between the plates, the electric fields acts on it and induces dipole moments. The capacity depends on the material in the volume which is enclosed by the plates (see Figure 3.3). The dipole moments introduce surface

2) Note that α represents a third-rank tensor. Keeping this in mind, tensor notation is dropped from now on if not mentioned explicitly.

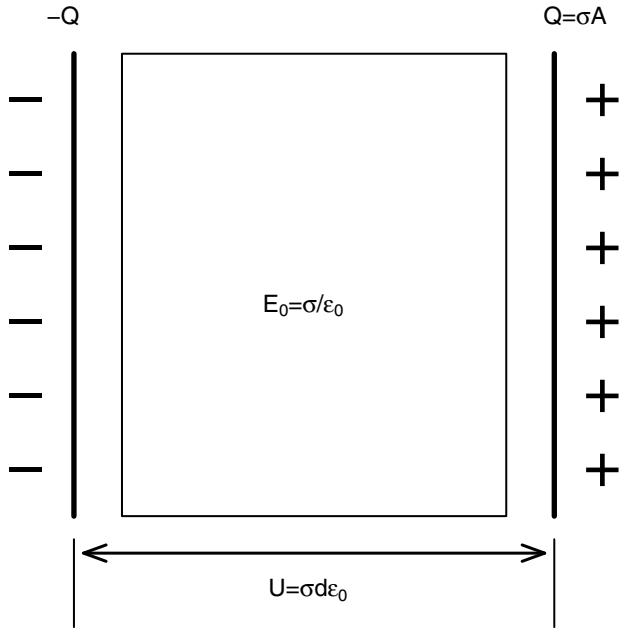

Figure 3.2 Plate capacitor.

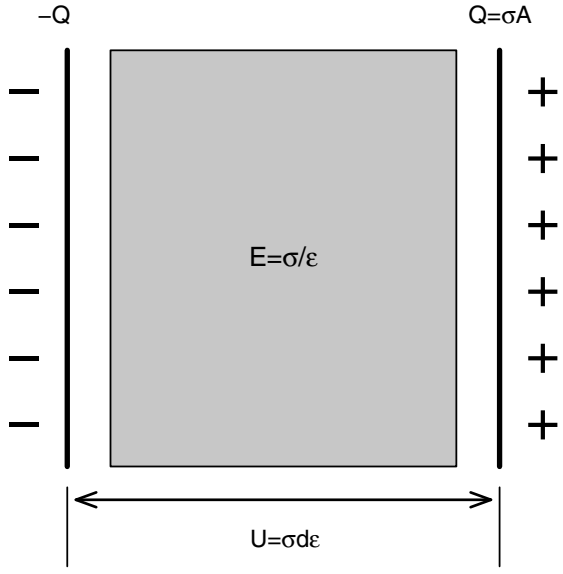

Figure 3.3 Plate capacitor filled with a material characterized by a dielectric constant ε.

charges which partly compensate the charges on the plates. If the voltage is kept constant, the charge Q and with it the surface density σ increase. From Equation 3.5, it follows that C increases.

The ratio between the capacity of an empty capacitor, C_V, and the capacity with a material between the plates, C_M, defines a new quantity called the relative dielectric constant, ε_r:

$$\frac{C_M}{C_V} = \frac{\varepsilon}{\varepsilon_0} = \varepsilon_r \tag{3.6}$$

which, when multiplied by the permittivity of vacuum, ε_0, gives the dielectric constant ε, both being macroscopic properties of a material.

How can these results be explained and what is happening on a microscopic scale? The material that is brought into the capacitor consists of atoms and molecules or molecular entities. The electric field within the capacitor exerts forces on the molecules, which on the one hand try to orient dipoles if a permanent dipole moment is present and/or on the other hand induce dipoles within the material parallel to field lines. Whereas in the volume of the material the charges neutralize each other since positive and negative charges are adjacent to each other (Figure 3.4), the surface of the material neighboring the negatively charged plate is positively charged and vice versa, leading to partial neutralization of the charges on the plates. If the capacitor is not separated from the voltage source, the source consequently increases the charge of the plates compensating the surface charge of the material inserted into the capacitor. The relation between the polarization P and the electric field E depending on the relative dielectric constant is found to be

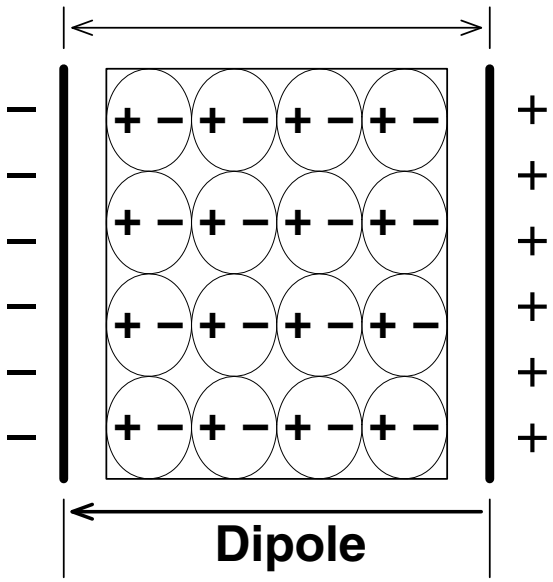

Figure 3.4 Plate capacitor filled with a material: microscopic picture.

$$P = \underbrace{(\varepsilon_r - 1)}_{\chi_{el}} \varepsilon_0 E \tag{3.7}$$

where the quantity χ_{el} is referred to as the electric susceptibility, which can be seen as the receptivity of the electric field strength of the particular material of interest. By employing P and E a new field quantity D can be defined, which is given by

$$D = \varepsilon_0 E + P = \varepsilon_0 \varepsilon_r E = \varepsilon E. \tag{3.8}$$

D is called the electric flux density and, in contrast to E, is not defined by the potential drop over distance, but by the charge per unit surface area.

Anisotropic Materials

For anisotropic materials (anisotropy: dependence of the properties on direction), χ_{el} becomes a so-called tensor (a 3×3 matrix) χ_{el}. This is due to the fact that both P and E are vector quantities, $\vec{P} = \chi_{el}\varepsilon_0 \vec{E}$, and the direction of $\vec{P}$ is only in isotropic materials always parallel to the field $\vec{E}$, which induces the polarization, whereas in case of anisotropy, χ_{el} accounts for both a change of length and a change of direction. In anisotropic materials, also the direction of the electric field $\vec{E}$ and the electric flux density $\vec{D}$ differ in general. Consequently, the dielectric constant also becomes a tensor.

3.2 Classical Dispersion Theory

It is well known that the interaction of light[3)] with matter depends strongly on the frequency (i.e., color) of light. Hence the general form of the polarization and with it the dielectric constant depend on the frequency of the applied electric field. In other words, the dielectric constant is constant only for a given frequency. Otherwise, the dielectric constant is transformed into a dielectric function, which reflects the fact that at certain frequencies matter is more strongly polarized than at others. The overall trend is that matter is more strongly polarized at lower frequencies than for higher frequencies as there are several mechanisms which introduce polarization in matter. Some of these, such as the displacement of atoms, need more time than the displacement of the relatively light electrons. However, there exist certain frequencies, called eigenfrequencies, at which the polarization can be extraordinarily large. These results can be understood to a first approximation by applying a comparably simple model, where we assume that an applied electric field displaces charges, for example, the electrons from the

3) Note that light refers to electromagnetic radiation of any frequency (or wavelength), whether visible or not.

nucleus of an atom, and there exists a restoring force, which is the attracting force between two opposite charges. A modification of the model, where we introduce a third force, which is proportional to the speed of the electron and leads to damping, allows us to describe quantitatively the variation of the dielectric constant with frequency, which is very important to understand the frequency (i.e., color) dependence of light–matter interactions discussed in the following sections.

More complex models for the dielectric function can be found in [2–4].

Employing the plate capacitor from Section 3.1.2, we could also apply an alternating voltage instead of direct voltage (in fact, we did not make any statement about that in Section 3.1.2). Would that leave the response of a medium inside the capacitor, that is, the polarization of the material, unchanged or would we detect differences that probably could depend on the number of voltage direction changes per unit time (i.e., the frequency)? Indeed, the response of the medium to an electric field applied to it depends critically on the frequency if it is an alternating field. This phenomenon is called dispersion.

What happens on the microscopic level if the voltage and therefore the electric field change their direction? Since the permanent dipoles orient themselves according to the applied electric field of the plate-type capacitor, they have to reorient with every directional change of the field. One can easily imagine that such a reorientation is not instantaneous, but takes some time to be completed. In fact, there exists an upper limit of frequency above which it is no longer possible for the dipoles to follow the electric field changes. Therefore, the orientation of permanent dipoles no longer takes place and adds to the polarization. This frequency limit depends on the material. Usually, a rotation happens within picoseconds. Therefore, the frequency limit usually lies within the microwave region, that is, around 10^{11} Hz.

As already mentioned, there are two kinds of induced polarizations; one is due to dislocations of the cores (distortion polarization), whereas the other is caused by distortions of the electron shell (electronic polarization). It is easy to imagine that the much heavier cores are more inert compared with the lightweight electrons. As a consequence, the electrons are able to follow the electric field changes up to much higher frequencies than the cores. In fact, distortion polarization is no longer able to contribute beyond the infrared (IR) region (10^{14} Hz), whereas the electronic polarization usually ceases to exist somewhere in the ultraviolet (UV) region, well above 10^{15} Hz. (see Figure 3.5).

In the following, these findings will be quantified by assuming a comparably simple atomic picture known as Lorentz atom (see Figure 3.6).

The atomic core is

- positively charged
- non-mobile (heavy, fixed within the crystal lattice)
- with the center of charge at $x = 0$.

For the electrons the following assumptions are made:

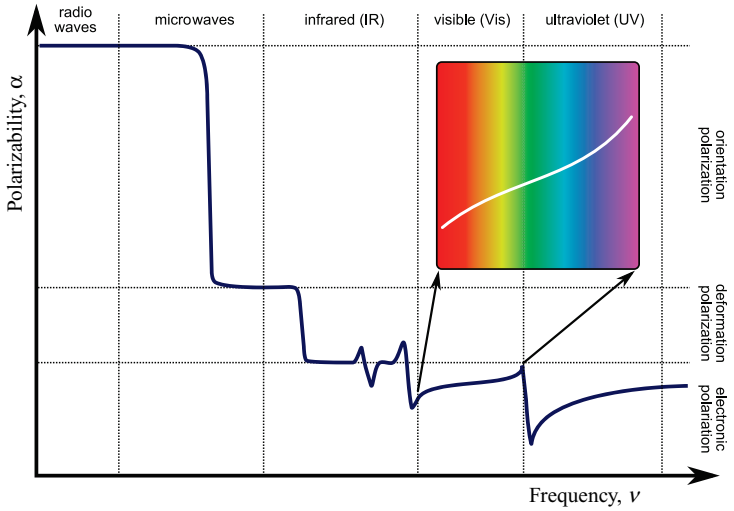

Figure 3.5 Changes of the polarizability α with frequency (adapted from [1]).

- lightweight (mass = m_e)
- elastically bound by a massless spring with spring constant k
- equilibrium position x_{eq} at $x = 0$
- carrying out a damped movement, that is, after removing the force, which led to the acceleration of the electrons (i.e., the electric field), with the movement decreasing and finally ending.

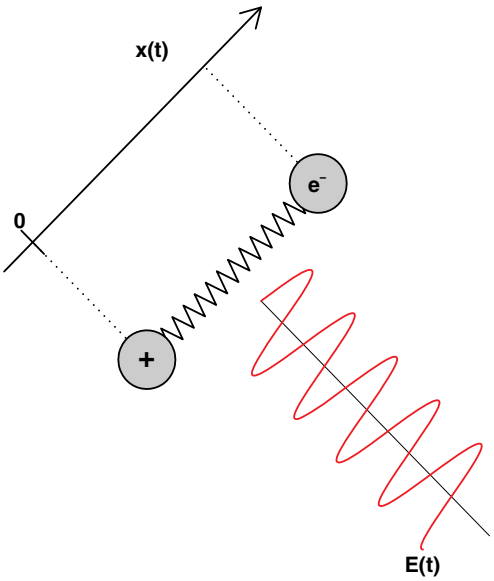

Figure 3.6 Illustration of the Lorentz atom.

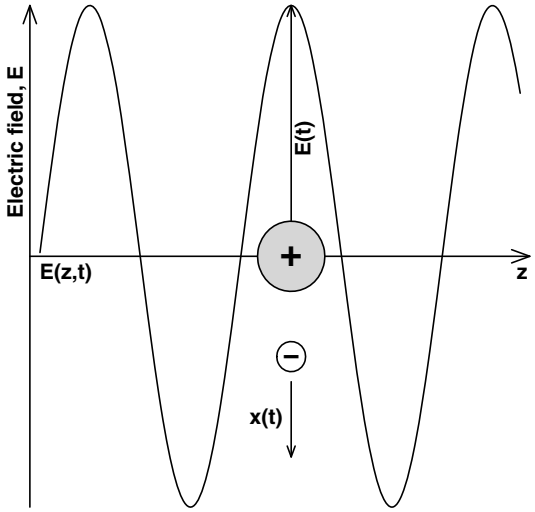

Figure 3.7 An oscillating electric field $E(t)$ induces an oscillating dipole.

Without an applied field, the centers of the negative and the positive charges coincide. Therefore, the dipole moment is zero. If a field constant in time is applied, the electrons are displaced relative to their position in the absence of an external field. As a consequence, the centers of the positive and negative charges no longer coincide and a static dipole moment is induced.

If we now assume that a time-dependent electric field $E(t) = E_0 \cos(2\pi\nu t)$ interacts with the atom, where ν is the frequency[4)] and t the time, then the electron starts to oscillate with frequency ν around its equilibrium position ($x = 0$), that is, the position of the electron becomes time dependent: $x(t) = x_0 \cos(2\pi\nu t)$. As a consequence, an oscillating dipole $\mu(t) = -e \cdot x(t)$ results, where e is the charge of the electron (see Figure 3.7). However, an oscillating dipole corresponds to an accelerated charge and therefore an electromagnetic wave will be emitted.

The forces acting on an electron are due to

- the electric field $E(t) = E_0 \cos(2\pi\nu t)$, which drives the electron away from its equilibrium position by a force $F_E = -e \cdot E(t)$ (driving force)
- the "spring," which tries to push the electron back to its equilibrium position with a force that is proportional to the deflection $x(t)$ from the equilibrium position ($x = 0$): $F_x = -k \cdot x(t)$ (restoring force).

According to Newton's second law, the sum of all forces acting on a body (in this case the electron) is equal to the body's mass m multiplied by its acceleration a, which is the second derivative of the position [in this case the displacement from the equilibrium position $x(t)$] with respect to time t: $a = d^2x(t)/dt^2$. If we put this together, it results in the following equation of motion:

4) Very often instead of the frequency ν the angular frequency $\omega = 2\pi\nu$ is used.

$$m_e \frac{d^2x(t)}{dt^2} = F_E(t) + F_x(t) = -e \cdot E(t) - k \cdot x(t) \tag{3.9}$$

where m_e represents the electron mass. In this equation, both the function $x(t)$and one of its derivatives (in this case the second derivative) is present. We write Equation 3.9 in the following form, where we have divided the left- and right-hand sides by m_e and where all terms containing $x(t)$ are on the left-hand side:

$$\frac{d^2x(t)}{dt^2} + \frac{k}{m_e} \cdot x(t) = -\frac{e}{m_e} \cdot E(t). \tag{3.10}$$

Before solving Equation 3.10 it is instructive to solve the somewhat simpler problem of the vibration of the electron without being forced by the external electric field $E(t)$. In this particular case Equation 3.10 reduces to the simplest possible form:

$$\frac{d^2x(t)}{dt^2} + \frac{k}{m_e} \cdot x(t) = 0. \tag{3.11}$$

What does the solution for $x(t)$ looks like? We see from Equation 3.11 that the sum of the function $x(t)$ multiplied by k/m_e and its second derivative must be zero. Consequently, $x(t)$ and its second derivative differ only in a constant $\omega_0^2 = k/m_e$ such that

$$\frac{d^2x(t)}{dt^2} = -\omega_0^2 \cdot x(t). \tag{3.12}$$

This equation is fulfilled if $x(t)$ equals, for example, $x_0 \sin(\omega_0 t)$, since $d\sin(\omega_0 t)/dt = \omega_0 \cos(\omega_0 t)$ and $d^2\sin(\omega_0 t)/dt^2 = -\omega_0^2 \sin(\omega_0 t)$. Therefore, without external force, the electron carries out vibrations with angular frequency ω_0, which is called its eigenfrequency. The eigenfrequency depends only on the spring constant k, which is a measure of the bond strength and consequently depends on the material, and the electron mass m_e. From this result, we can already suspect that the interaction of the electron with an external field is especially strong if this external field varies also with ω_0. This brings us back to Equation 3.10. Mathematically, Equation 3.10 is an inhomogeneous differential equation, in contrast to Equation 3.11, which is the related homogeneous differential equation. To solve Equation 3.10, we assume that the inhomogeneous differential equation has also a solution of the form $x(t) = x_0 \cos(\omega t)$, like its homogeneous counterpart. Setting $x(t) = x_0 \cos(\omega t)$ in Equation 3.10, we obtain

$$-\omega^2 \cdot x_0 \cos(\omega t) + \frac{k}{m_e} x_0 \cos(\omega t) = \frac{-e}{m_e} \cdot E_0 \cos(\omega t) \tag{3.13}$$

and after dividing by $\cos(\omega t)$ and solving for x_0 we have

$$x_0 = \frac{-e \cdot E_0}{\left(\frac{k}{m_e} - \omega^2\right) m_e}. \tag{3.14}$$

Using ${\omega_0}^2 = k/m_e$, we finally obtain

$$x_0 = \frac{-e \cdot E_0}{\left(\omega_0^2 - \omega^2\right) m_e} \tag{3.15}$$

After some consideration, it can be recognized that Equation 3.15 must be an unphysical result since the displacement $x(t)$ becomes infinite if the frequency ω of the external field approaches the eigenfrequency ω_0 of the electron. This is a consequence of having neglected damping of the vibration of the electron. For damping, we assume an additional force F_{damp}, which is proportional to the velocity of the electron $\mathrm{d}x(t)/\mathrm{d}t$ with a proportionality constant $-\Gamma$, so that $F_{\text{damp}} = -\Gamma \cdot \mathrm{d}x(t)/\mathrm{d}t$. Accordingly, the equation of motion Equation 3.10 becomes

$$\frac{\mathrm{d}^2x(t)}{\mathrm{d}t^2} + \frac{\Gamma}{m_e} \cdot \frac{\mathrm{d}x(t)}{\mathrm{d}t} + \frac{k}{m_e} \cdot x(t) = -\frac{e}{m_e} \cdot E(t). \tag{3.16}$$

We are now looking for a function $x(t)$ which differs from its first and second derivative only by a constant factor. This excludes sine and cosine functions and we have to rely on an exponential function of the form $x(t) = x_0 \exp(i\omega t)$, where i is the imaginary unit with $i^2 = -1$.[5)]

Setting $x(t) = x_0 \cdot \exp(i\omega t)$ in Equation 3.16, we obtain

$$-\omega^2 \cdot x_0 \exp(i\omega t) + \frac{\Gamma}{m_e}\omega \cdot i \cdot x_0 \exp(i\omega t) + \frac{k}{m_e} \cdot x_0 \exp(i\omega t) = -\frac{e \cdot E_0 \cdot \exp(i\omega t)}{m_e}. \tag{3.17}$$

Setting $\Gamma/m_e = \gamma$ and recapitulating that $k/m_e = {\omega_0}^2$, we obtain after some algebraic manipulation the solution

$$x_0 = -\frac{e}{m_e} \frac{1}{\omega_0^2 - \omega^2 + i\gamma\omega} E_0. \tag{3.18}$$

Through the forced oscillation of the electron with charge $Q = -e$, a microscopic dipole moment is induced. The macroscopic polarization, which is the sum of the induced dipole moments per unit volume, is then given by the product of electron charge, microscopic deflection, and the number of oscillators per unit volume N:

$$P(t) = -e \cdot x(t) \cdot N = \frac{Ne^2}{m_e} \frac{1}{\omega_0^2 - \omega^2 + i\gamma\omega} E(t). \tag{3.19}$$

If we compare this result with Equation 3.7, we find that

$$(\varepsilon_r - 1)\varepsilon_0 = \frac{Ne^2}{m_e} \frac{1}{\omega_0^2 - \omega^2 + i\gamma\omega} \tag{3.20}$$

and consequently

5) The function $x(t) = x_0 \exp(i\omega t)$ is also a potential solution of Equation 3.12, which is a consequence of Euler's equation $\exp(i\omega t) = \cos(\omega t) + i\sin(\omega t)$ and the fact that any linear combination of solutions of a differential equation again generates a solution to this equation. The exponential function is often preferred, especially because multiplication and division are very easily carried out. Therefore, time-dependent electric fields $E(t) = E_0 \cos(2\pi\nu t)$ are also often written as an exponential function: $E(t) = E_0 \exp(i \cdot 2\pi\nu t)$. One has to keep in mind, however, that the real electric field is then represented by the real part $\mathrm{Re}[E(t) = E_0 \exp(i \cdot 2\pi\nu t)] = E_0 \cos(2\pi\nu t)$.

$$\varepsilon_r(\omega) = 1 + \frac{Ne^2}{\varepsilon_0 m_e} \frac{1}{\omega_0^2 - \omega^2 + i\gamma\omega}. \tag{3.21}$$

The obvious conclusion is that the relative dielectric constant depends on the frequency and should henceforth better be called dielectric function. According to Equation 3.21, the dielectric function $\varepsilon_r(\omega)$ consists of a real part $\varepsilon_{r,1}(\omega)$ and an imaginary part $\varepsilon_{r,2}(\omega)$: $\varepsilon_r(\omega) = \varepsilon_{r,1}(\omega) + i \cdot \varepsilon_{r,2}(\omega)$. If we separate these two parts in Equation 3.21, we obtain

$$\begin{aligned} \varepsilon_{r,1}(\omega) &= 1 + \frac{Ne^2}{\varepsilon_0 m_e} \frac{\omega_0^2 - \omega^2}{\left(\omega_0^2 - \omega^2\right)^2 + \gamma^2\omega^2} \\ \varepsilon_{r,2}(\omega) &= \frac{Ne^2}{\varepsilon_0 m_e} \frac{-\gamma\omega}{\left(\omega_0^2 - \omega^2\right)^2 + \gamma^2\omega^2}. \end{aligned} \tag{3.22}$$

The resulting functions are displayed in Figure 3.8. $\varepsilon_{r,1}$ is unity at frequencies high compared with the eigenfrequency ω_0, which was set to $1600\,\mathrm{cm}^{-1}$ ($\tilde{\nu} = 1/\lambda = \nu = \omega/2\pi\omega$, where $\tilde{\nu}$ is the wavenumber, λ the wavelength, ν the frequency, and ω the angular frequency), then decreases until it reaches a minimum close to the eigenfrequency before it increases steeply. After a maximum it reaches

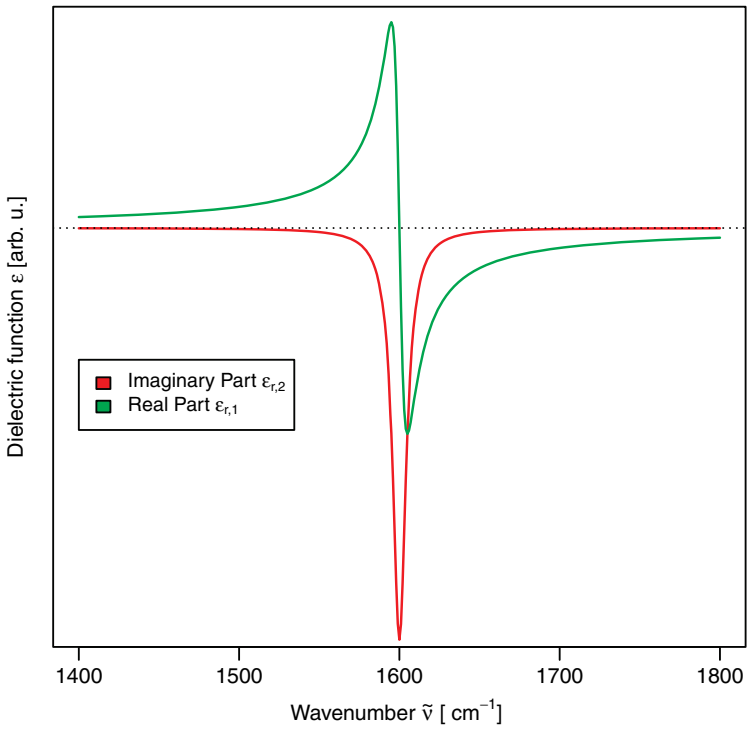

Figure 3.8 Dependence of the real $\varepsilon_{r,1}$ and the imaginary part $\varepsilon_{r,2}$ of the dielectric function for $\omega_0 = 1600\,\mathrm{cm}^{-1}$ and $\gamma = 10$.

a nearly constant value for low frequencies, which is higher than its nearly constant value at high frequencies. $\varepsilon_{r,2}$, on the other hand, is close to zero for frequencies well below and above the eigenfrequency, at which it reaches its maximum. This frequency dependence of the dielectric function will be very important for understanding or explaining the different light–matter interaction phenomena such as absorption (see Section 3.4) and its dependence on the light frequency, that is, color.

3.3
Electromagnetic Waves in Matter

In the preceding section, it has been shown that the interaction of electromagnetic radiation with matter can polarize matter and induce on an atomic scale a dipole moment or a macroscopic polarization in the molecular ensemble. Furthermore, we have seen that the general form of the polarization depends on the frequency of the applied field: radiofrequency radiation (10 GHz) leads to an alignment of polar molecules according to the external electric field, that is, a reorientation of the complete molecules (orientation polarization) takes place. The same is true for the electrons, which can follow the changing electric field much more easily due to their low mass. However, higher frequencies lead to a distortion polarization of the electrons (induced electric dipole moment), since molecules exhibiting a permanent dipole cannot follow such rapidly oscillating fields any longer. The induced dipole moment oscillates with the same frequency as the exciting oscillating electric field. Since the oscillating induced dipole moment is nothing else than an oscillating charge, matter radiates light of the same frequency. This is in total analogy with a Hertzian dipole acting as a broadcasting and receiving antenna which is based on the radiation of electromagnetic waves from a dipole. In an antenna, electrons are driven by a generator to the top or the bottom, respectively. This generates a charge distribution similar to a dipole.

Hence the interplay of molecules with light, in particular with visible light which polarizes molecules, leads to the emission of a secondary radiation of the same frequency as the polarizing field. This section aims to describe the physical foundation of the generation of this secondary radiation, that is, how the induced polarization acts as a source of the radiation of a secondary electromagnetic field. In doing so, a set of equations known as Maxwell's equations are needed. These equations relate the electric and magnetic fields that constitute electromagnetic waves. Here we examine how Maxwell's equations describe the generation of this secondary radiation. This approach results in so-called wave equations, which, when solved, lead to sinusoidal functions containing the frequency and the wavelength as variables and providing the amplitude of the electromagnetic waves.

The major difference between waves in vacuum and waves in matter is that the speed in matter is reduced by a factor n, which is called the refractive index, and is usually given by the square root of the dielectric function. As the dielectric

function is dependent on frequency, the same is valid for the refractive index. The frequency dependence of the refractive index is the basis to describe quantitatively the absorption of light, as will be shown in the next section.

For the less mathematically inclined reader, this section can be skipped. Interested readers are referred to [2, 3].

The aim of this section is the calculation of the electromagnetic wave which is caused by the oscillating electric dipole density $\vec{P}$ distributed in matter. In the following we have to introduce the fields in vector form. In a field, at least in the case of such fields as we are interested in, each position in space is assigned a vector. For example, in case of the electric field $\vec{E}$ is explained by the force that acts on a charge. The amount of the vector is proportional to the magnitude of the force and its direction is oriented parallel to that of the force. Since we are dealing with a three-dimensional space, each vector can be split into its x, y, and z components; for example, in the case of $\vec{E}$ these are E_x, E_y, and,E_z each being a scalar quantity. Therefore, the calculation with vectors can be easily traced back to calculations with scalars, except that we have to carry out three calculations per vector. In the following we give the equations for both the component and the short vector form.

Since electromagnetic radiation (light) consists of electric and magnetic fields, oriented perpendicular to each other, we also have to introduce the magnetic field $\vec{B}$ (historically referred to as magnetic induction). However, since the force induced by the magnetic field of an electromagnetic wave on charged particles is much smaller than that induced by the electric field, it can be neglected for most light–matter interaction phenomena. This means that we will not explain $\vec{B}$ in detail, since it will be eliminated from the equations below and will not be of importance for the majority of light–matter interaction phenomena treated within this book.[6)]

The starting point of this calculation is the Maxwell equations in differential form. The physical meaning of these equations will also be explained in detail:

1) The source of the electric flux density is charges (the field lines begin at positive and end at negative charges). These charges, which are represented by the charge density $\rho = Q/V$, where V is a unit volume, cause the existence of the electric flux density and the electric field, the latter being the origin of the force that acts on other charges.

$$\vec{\nabla} \cdot \vec{D} = \frac{\partial D_x}{\partial x} + \frac{\partial D_y}{\partial y} + \frac{\partial D_z}{\partial z} = \rho. \tag{3.23}$$

2) Unlike with electric fields, there are no sources of the magnetic field (a magnetic monopole, the magnetic equivalent of a charge, has not been observed so far; if a magnet is separated between its south and north poles, two magnets, each with its own south and north poles, result). Also, unlike electric fields, magnetic field

6) However, the magnetic field component is of importance for the interaction of polarized light with chiral molecules such as proteins and amino acids, which will be treated in Section 3.10.

lines are closed loops without beginning or end.

$$\vec{\nabla} \cdot \vec{B} = \frac{\partial B_x}{\partial x} + \frac{\partial B_y}{\partial y} + \frac{\partial B_z}{\partial z} = 0. \tag{3.24}$$

3) **Law of induction:** Every change of the magnetic induction in time leads to a response and a related change in the shape of the electric field. In particular, the electric field tends to oppose the changes of the magnetic field.

$$\begin{aligned}
\left(\frac{\partial E_z}{\partial y} - \frac{\partial E_y}{\partial z}\right) &= -\frac{\partial B_x}{\partial t} \\
\left(\frac{\partial E_x}{\partial z} - \frac{\partial E_z}{\partial x}\right) &= -\frac{\partial B_y}{\partial t} \\
\left(\frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y}\right) &= -\frac{\partial B_z}{\partial t} \\
\vec{\nabla} \times \vec{E} &= -\frac{\partial \vec{B}}{\partial t}.
\end{aligned} \tag{3.25}$$

4) Magnetic fields can be generated in two ways, either by an electrical current or by a changing electromagnetic field. If we assume that there are no free charges moving inside the medium, the following equation results:

$$\begin{aligned}
&\left(\frac{\partial B_z}{\partial y} - \frac{\partial B_y}{\partial z}\right) = \mu_0 \frac{\partial D_x}{\partial t}, \left(\frac{\partial B_x}{\partial z} - \frac{\partial B_z}{\partial x}\right) = \mu_0 \frac{\partial D_y}{\partial t}, \left(\frac{\partial B_y}{\partial x} - \frac{\partial B_x}{\partial y}\right) = \mu_0 \frac{\partial D_z}{\partial t} \\
&\vec{\nabla} \times \vec{B} = \mu_0 \frac{\partial \vec{D}}{\partial t}
\end{aligned} \tag{3.26}$$

where μ_0 represents the permeability of free space and is therefore the magnetic counterpart of ε_0.

Together with the so-called constitutive relations or material equations, one of which we already know (Equation 3.8), and the second, which is already implicitly contained in Equation 3.26, the Maxwell relations establish a system of equations the solution of which eventually leads to the concept of electromagnetic waves. To derive the wave equation, we differentiate first the left- and the right-hand side of Equation 3.26 with respect to time

$$\vec{\nabla} \times \frac{\partial \vec{B}}{\partial t} = \mu_0 \frac{\partial^2 \vec{D}}{\partial t^2} \tag{3.27}$$

and subsequently employ Equation 3.25 to replace $\partial\vec{B}/\partial t$. This yields

$$-\vec{\nabla}\times\vec{\nabla}\times\vec{E}=\mu_0\frac{\partial^2\vec{D}}{\partial t^2} \tag{3.28}$$

in which we replace $\vec{D}$ by using Equation 3.8[7)]

$$\begin{aligned}&\frac{\partial^2 E}{\partial x^2}+\frac{\partial^2 E}{\partial y^2}+\frac{\partial^2 E}{\partial z^2}-\varepsilon_r\varepsilon_0\mu_0\frac{\partial^2 E}{\partial t^2}=0\\&\Delta\vec{E}-\varepsilon_r\varepsilon_0\mu_0\frac{\partial^2\vec{E}}{\partial t^2}=0.\end{aligned} \tag{3.29}$$

For one dimension (e.g., the electric field travels along the z-direction and, additionally, has only a component in the x-direction), Equation 3.29 reduces to

$$\frac{\partial^2 E_x}{\partial z^2}-\varepsilon_r\,\varepsilon_0\mu_0\frac{\partial^2 E_x}{\partial t^2}=0. \tag{3.30}$$

Equations which link the second derivative of a quantity with respect to position with the second derivative of the same quantity with respect to time are called wave equations, since their solutions have wave character. A wave equation for a wave traveling in the z-direction with only an x-component is usually of the form

$$\frac{\partial^2 E_x}{\partial z^2}-\frac{1}{\upsilon^2}\frac{\partial^2 E_x}{\partial t^2}=0 \tag{3.31}$$

where υ represents the speed of the wave (the phase velocity) inside the medium. Therefore, we find that the velocity υ of an electromagnetic wave inside a medium is generally given by

$$\upsilon=\frac{1}{\sqrt{\varepsilon_r\varepsilon_0\mu_0}}=c\frac{1}{\sqrt{\varepsilon_r}} \tag{3.32}$$

since, if we had made the same derivatization for a wave in vacuum (no free charges, therefore $\vec{\nabla}\cdot\vec{D}=0$), we would have found that $\upsilon=1/\sqrt{\varepsilon_0\mu_0}=c$, where c is consequently the speed of light in vacuum. Therefore, the influence of the medium and its polarization is to decrease the velocity of the wave by a factor $\sqrt{\varepsilon_r}$, which, as we will see later, corresponds to the refractive index n inside the medium.

The simplest solution of the wave equation (Equation 3.29) is the plane wave given by

$$\vec{E}(\vec{r},t)=\vec{E}_0\cos(\omega t-\vec{k}\cdot\vec{r}+\varphi). \tag{3.33}$$

This plane wave, the form of which is depicted in Figure 3.9, moves in the direction of the wavevector $\vec{k}$; φ represents the phase of the wave and is employed to adapt the plane wave to certain initial or boundary conditions. If we feed Equation 3.33 into Equation 3.30, assuming thereby that the wave travels in the z-direction ($\vec{k}$ has

7) Here, also the identity: $\vec{\nabla}\times\vec{\nabla}\times\vec{E}=\vec{\nabla}\cdot(\vec{\nabla}\cdot\vec{E})-(\vec{\nabla}\cdot\vec{\nabla})\vec{E}$ with $\vec{\nabla}\cdot\vec{E}=0$ (for nonconducting matter where ρ vanishes) and $\vec{\nabla}\cdot\vec{\nabla}=\Delta=\partial^2/\partial x^2+\partial^2/\partial y^2+\partial^2/\partial z^2$ has been used.

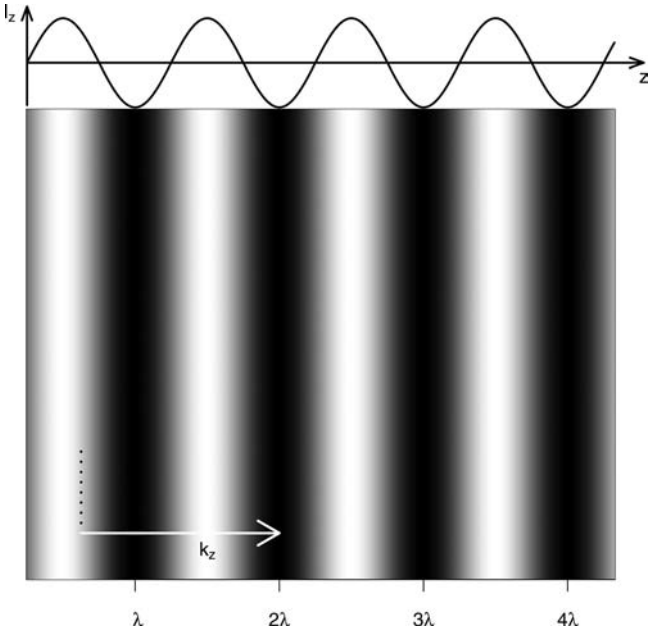

Figure 3.9 Plane wave traveling along $\vec{k}$.

a component only in the z-direction and is therefore given by $\vec{k} = (0, 0, k_z)^T$ and, additionally, that the electric field has a component only in the x-direction, that is, $E_0 = E_{0,x}$. Therefore, $E_x(z,t) = E_{0,x} \cdot \cos(\omega t - k_z \cdot z + \varphi)$ and

$$\begin{aligned} &\frac{\partial^2 E_x(z,t)}{\partial z^2} - \varepsilon_r \varepsilon_0 \mu_0 \frac{\partial^2 E_x(z,t)}{\partial t^2} = 0 \\ &-k_z^2 E_x(z,t) + \varepsilon_r \varepsilon_0 \mu_0 E_x(z,t) \omega^2 = 0 \\ &k_z^2 = \varepsilon_r \frac{\omega^2}{c^2} = n^2 \frac{\omega^2}{c^2} \\ &k_z = n \frac{\omega}{c} \end{aligned} \tag{3.34}$$

which is the dispersion relation for light inside matter with n being the refractive index. In Figure 3.9, the distance between two maxima or minima is the wavelength λ. Considering that the angular frequency $\omega = 2\pi \cdot \nu = 2\pi c/\lambda$, one obtains for the relation between wavevector and wavelength the following equation:

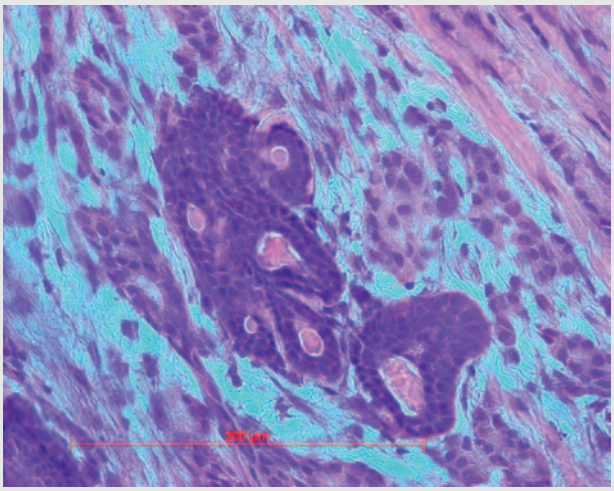
$$k_z = n \frac{2\pi}{\lambda}. \tag{3.35}$$

Since the refractive index is a dimensionless quantity and the dimension of the wavelength is length, the dimension of the wavevector is that of an inverse length, for

example, the number of maxima of the wave per unit length. Traditionally, one "counts" the number of maxima per centimeter, leading to the dimension cm^{-1} for the wavevector, which is especially popular among vibrational spectroscopists (also called wavenumber if the directional property is less important for the problem at hand). For deriving the relations above, we have implicitly also assumed that the medium of interest is microscopically and macroscopically isotropic, meaning that for light traveling through the medium in an arbitrary direction ε_r always remains the same. If this is not the case, ε_r becomes a tensor, as already mentioned in Section 3.1.2. In anisotropic materials, the dispersion relations become much more complex and generally two different refractive indices exist, depending on the direction of the light wave and its polarization. This important term will be explained in Section 3.5.3. The next section focuses on the very important quantity refractive index and its significance for the description of light absorption.

3.4 Absorption of Light

The simplest form of microscopy, bright field microscopy, relies on white light absorption changes of the microscopic sample. White light is composed of various wavelengths. If we see them separately, they appear as colors, and each color has a different wavelength. Substances appear colored because they absorb (i.e., filter out) some wavelengths and reflect or transmit others out of the broad white light spectrum. A very prominent example commonly used in histology where white light absorption changes are utilized for medical diagnosis is H&E (hematoxylin and eosin) staining. The following image displays such an H&E image of a breast cancer tissue section:



Here, the blue dye hematoxylin is applied to color basophilic structures, which are usually the ones containing nucleic acids, such as the cell nucleus, whereas eosin is used to color eosinophilic structures, which are generally composed of intracellular or extracellular protein, bright pink.

Thus, absorption of electromagnetic radiation is the way in which the energy of electromagnetic radiation is taken up by matter. This section combines all the topics treated in the preceding sections to characterize the very important phenomena of light absorption.

In the preceding sections, it has been shown that light traveling through matter induces oscillating dipoles. These vibrations of the electrons against the core or vibrations of one atom against another are usually damped, as we learnt in Section 3.2, which means on the one hand that vibrations forced by radiation at an eigenfrequency finally end when the excitation is removed, and on the other hand that the amplitude will not reach infinite values. The reason for the damping is energy dissipation, which means that the exciting radiation looses intensity while traveling through the medium, that is, absorption takes place. In addition to scattering, which will be discussed later, absorption is one reason for a medium not to be transparent. The damping manifests itself in the dielectric function by an additional imaginary part. Due to the relation between dielectric function and refractive index function through the wave equation, the refractive index also becomes a complex property where the imaginary part is responsible for the absorption of light. At the same time, the wavenumber of the wave, which is linearly dependent on the refractive index, also becomes a complex number. As a consequence, the relation describing the amplitude of the wave as a function of time and place, can be split up in two parts, one of which is dependent only on the place. This latter part is an exponential function and is the reason for an exponential decay of the intensity of a wave in an absorbing medium, which is known as the Lambert–Beer law. The absorption index is especially high in the vicinity of an eigenfrequency and tends to decrease rapidly when the frequency is increased or decreased. In contrast, the refractive index decreases when the eigenfrequency is approached from higher frequencies, whereas it increases steeply at the eigenfrequency. After reaching a maximum, it decreases again until the next eigenfrequency. This decrease between two eigenfrequencies is called normal dispersion. Local changes in the absorption index cause contrast in a sample, which can be exploited to investigate the sample under a bright field microscope. Corresponding changes in the refractive index allow one to investigate a sample with a dark field, phase contrast, or differential interference contrast microscope. They are also exploited in optical coherence tomography (OCT).

As further reading for this section, two books [5, 6] are recommended.

In Section 3.2, we have already touched upon the fact that the dielectric function (or the individual components of the dielectric tensor function in the case of anisotropic media) consists of a real and an imaginary part, $\varepsilon_r(\omega) = \varepsilon_{r,1}(\omega) + i\varepsilon_{r,2}(\omega)$, as a result

of damping of the vibrations of electrons against the core (or, equivalently, the vibrations of atoms against each other). The question that we want to tackle in this section is "how does the damping act upon a light wave passing through the medium?" Since $\varepsilon_r = n^2$ (for cubic or isotropic media), the refractive index also becomes a complex function: $n = \mathrm{n} + i\kappa$. For diluted media such as gases, where the refractive index is close to unity, the refractive index can be calculated from Equation 3.21

$$
\begin{aligned}
&(\varepsilon_r - 1) = (n^2 - 1) = (n+1)(n-1) \cong 2(n-1) \\
&(n-1) \cong \frac{1}{2}[\varepsilon(\omega) - 1] = \frac{e^2 N}{2\varepsilon_0 m} \frac{1}{\omega_0^2 - \omega^2 + i\gamma\omega} \\
&\mathrm{n} = 1 + \frac{e^2 N}{2\varepsilon_0 m} \frac{\omega_0^2 - \omega^2}{\left(\omega_0^2 - \omega^2\right)^2 + \gamma^2\omega^2} \\
&\kappa = \frac{e^2 N}{2\varepsilon_0 m} \frac{-\gamma\omega}{\left(\omega_0^2 - \omega^2\right)^2 + \gamma^2\omega^2}.
\end{aligned}
\tag{3.36}
$$

The corresponding frequency dependence of the real part n and imaginary part κ of the refractive index are displayed in Figure 3.10 (compare the changes in the dielectric function displayed in Section 3.2). The real part of the refractive index n starts for small frequencies $\omega \to 0$ at $n_0 = 1 + e^2 N / 2\varepsilon_0 m\omega_0^2$ and increases for higher frequencies. Only in direct vicinity of the eigenfrequency ω_0 does n decrease. For high frequencies $\omega \gg \omega_0$, n approaches 1. For diluted media such as gases which are considered here, to simplify matters the imaginary part κ is always negative

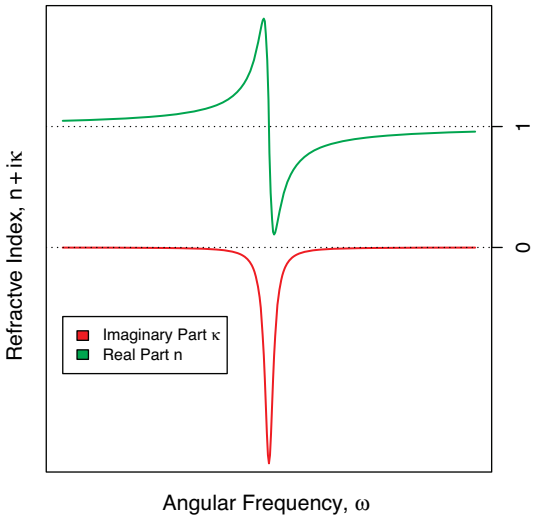


Figure 3.10 Dependence of the refractive indices and absorption in the vicinity of an eigenfrequency.

(further below dense matter will also be considered). In general, κ is very small and differs from 0 only in close vicinity to the eigenfrequency ω_0. The frequency dependence of κ exhibits a Lorentzian lineshape.

To understand the relevance of the complex refractive index, we use the result of Equation 3.34, $k_z = n \cdot \omega/c$, in combination with the exponential notation of the electric wave $\vec{E}(\vec{r}, t) = E_x(z, t) = E_{0,x} \cdot \exp[i(\omega t - k_z \cdot z)]$:

$$\begin{aligned} k_z = n\frac{\omega}{c} &= \frac{\omega}{c}(\mathrm{n} + i\kappa) \\ E_x(z,t) &= E_{0,x} \cdot \exp[i(\omega t - k_z \cdot z)] \\ &= E_{0,x} \cdot \exp\left\{ i\left[\omega t - \frac{\omega}{c}(\mathrm{n} + i\kappa) \cdot z\right]\right\} \\ &= E_{0,x} \cdot \exp\left[i\left(\omega t - \frac{\omega}{c}\mathrm{n} \cdot z - \frac{\omega}{c} i\kappa \cdot z\right)\right] \\ &= E_{0,x} \cdot \exp\left(\frac{\omega}{c}\kappa \cdot z\right) \cdot \exp\left[i\left(\omega t - \frac{\omega}{c}\mathrm{n} \cdot z\right)\right]. \end{aligned} \tag{3.37}$$

It can be seen that the electric field $E_x(z, t)$ exhibits a rapidly oscillating contribution whose wavelength is determined by the real part n of the refractive index. However, the initial amplitude of the wave $E_{0,x}$ will decrease exponentially with increasing travel distance along the z-direction because the factor $\exp[(\omega/c)\kappa \cdot z]$ is real and $\kappa < 0$ (see Figure 3.10). Hence κ is called the absorption index, since it causes the wave to weaken as a consequence of the damping of the vibrations inside the medium. As the light intensity I is given by E^2, it follows that also the intensity is weakened as the wave travels along the z-direction:

$$I(z) = I_0 \exp\left(\frac{2\omega}{c}\kappa \cdot z\right) = I_0 \exp(-a \cdot z) \tag{3.38}$$

where a is the extinction coefficient

$$a = \frac{e^2 N}{\varepsilon_0 mc} \frac{\gamma\omega^2}{\left(\omega_0^2 - \omega^2\right)^2 + \gamma^2\omega^2}. \tag{3.39}$$

Equation 3.38 is known as the Lambert–Beer law. The absorption A is then given by[8)]

$$A = 1 - \frac{I(z)}{I_0} = \exp(a \cdot z). \tag{3.40}$$

8) Note that fairly often in the literature also a quantity named absorbance or extinction A is referred to, which is given by $A = a \cdot z$. Since the terms are also not consistently used in the literature (the terms absorption and absorbance, for example, are switched), one has to deduce from the context what is actually meant.

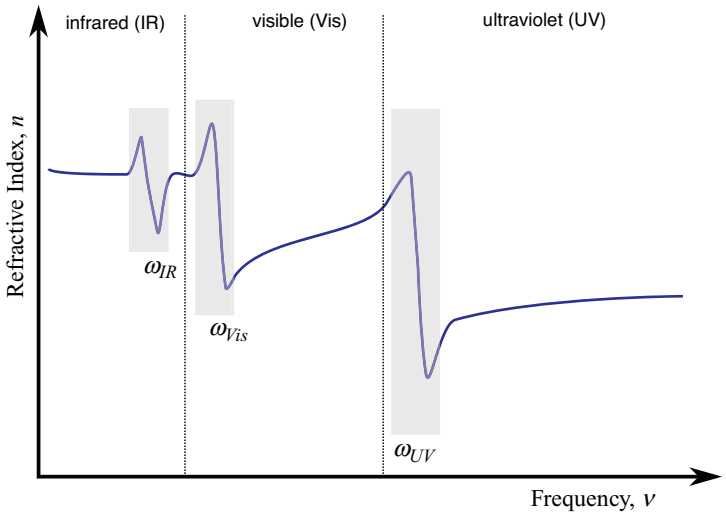

Figure 3.11 Schematic diagram displaying the frequency dependence of the real part of the refractive index for eigenfrequencies in the IR (ω_{IR}) and UV–Vis regions (ω_{UV} and ω_{Vis}). Abnormal dispersion ($dn/d\lambda > 0$) can be only found close to an eigenfrequency. In these regions of abnormal dispersion, absorption also takes place (adapted from [4]).

The absorption index and also the extinction coefficient are both macroscopic quantities. To relate the properties of single atoms or molecules, the number of atoms or molecules N per unit volume can be extracted from the extinction coefficient according to $a = \sigma \cdot N$, were σ represents the separated cross-section. Equation 3.40 then reads

$$I(z) = I_0 \exp(-\sigma \cdot N \cdot z). \tag{3.41}$$

Equation 3.41 remains valid in the case of solutions. Instead of using the number of entities N per unit volume, usually concentrations c in moles per liter ($\mathrm{mol\,l^{-1}}$) are introduced (1 mol corresponds to 6.0225×10^{23} entities). The equivalent to Equation 3.40 then reads

$$I(z) = I_0 \exp(-\alpha_\omega \cdot c \cdot z) \tag{3.42}$$

where $-\alpha_\omega$ is the molar natural extinction coefficient.[9)]

So far, it has been assumed that the refractive index n is close to unity, for which its frequency dependence can be expressed by Equation 3.36 (see also Figure 3.10). For dense media, the most significant difference from Equation 3.36 is that the maximum of the absorption index is slightly shifted from the eigenfrequency ω_0 towards higher wavenumbers and the band is no longer symmetric around ω_0. Figure 3.11 displays the frequency dependence of the real part of the refractive index n for the case of different eigenfrequencies. It can be seen that in the spectral ranges

9) The Lambert-Beer law is often written in the form: $I(z) = I_0 10^{-\epsilon \cdot c \cdot z}$ where ϵ is the molar decadic extinction or absorption coefficient. ϵ and α_ω are related to each other by: $\epsilon = \alpha_\omega / \ln 10 = \alpha_\omega / 2.302$. The molar decadic absorption coefficient ϵ must not be confused with the dielectric function ε.

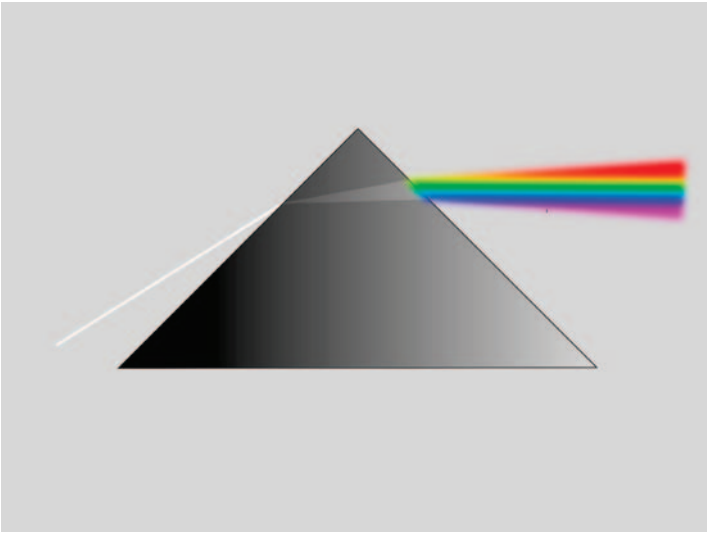

Figure 3.12 Normal dispersion: white light refracted by a prism is split up into its components as the refractive index increases with frequency.

where absorption is close to zero (i.e., outside hatched areas of Figure 3.11), the refractive index increases with increasing frequency, and as a consequence blue light is refracted more strongly than red light (see also Figure 3.12). These areas with $dn/d\omega > 0$ or $dn/d\lambda < 0$ are called areas of "normal dispersion." Only in the close vicinity of the eigenfrequencies where the imaginary part of the refractive index κ (absorption index) differs from zero does $dn/d\lambda > 0$ apply. In these areas of "abnormal dispersion," electromagnetic waves are absorbed. The resonances in the IR region are determined by molecular vibrations whereas those in the UV–Vis range result from electronic absorption. IR absorption is treated in detail in Section 3.8 and UV–Vis spectroscopy is covered in Section 3.9.

Equation 3.37 is also fundamental for the understanding of some of the most important contrast modalities in conventional microscopy, namely bright field, dark field, phase contrast and differential interference contrast microscopy (Figure 3.13).

Bright field microscopy is the simplest and most basic light microscopy method and is based on the absorption of light within the microscopic specimen. Here, the sample is illuminated from below with white light and the sample becomes visible because it is contrasted from its environment by its color or by its lack of color. Such an object is called an amplitude object because its recognizability is based on amplitude variations of the light wave. In other words, an object keeping the phase of an incoming wave constant and retarding the amplitude is called an amplitude object (see the left side of Figure 3.13). Decreasing an amplitude contrast by different light transmissions is directly visible. Unfortunately, the differences in the absorption index are comparably low for most biological samples, resulting in a low contrast. Therefore, bright field microscopy is not practical for transparent and thin objects since these objects absorb no light. This means that most cell compartments are not

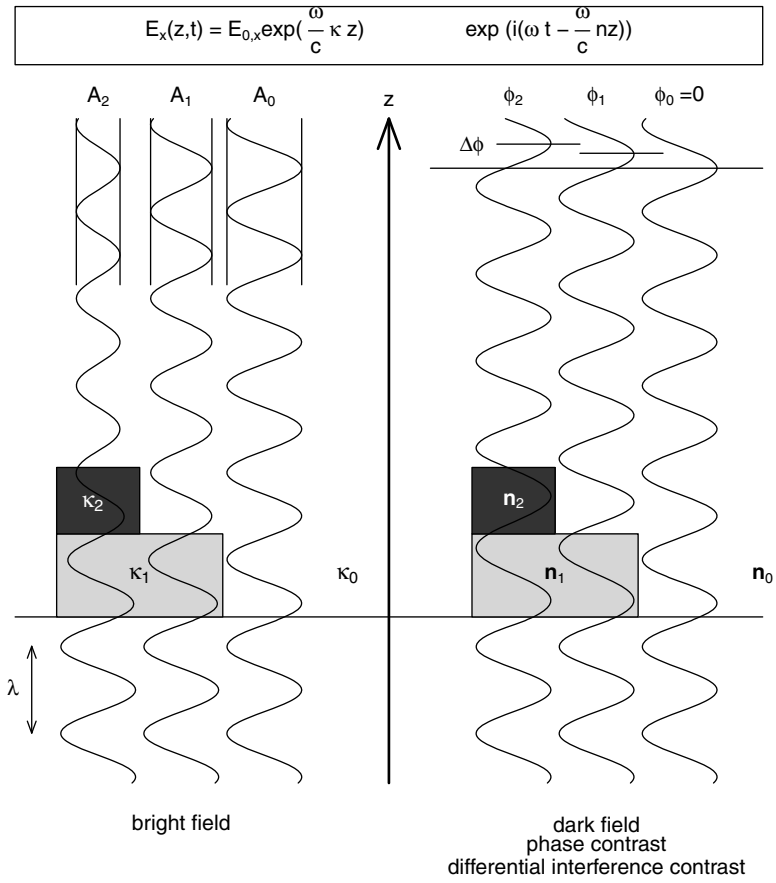

Figure 3.13 Significance of absorption and dispersion for light microscopy.

amplitude objects. Practically, the contrast can be increased by bright field staining (chemical contrasting), where the samples are stained with dyes to visualize and mark certain cell and tissue structures. Most dyes are selectively accumulated within cells due to special chemical or physical properties. Bright field staining is commonly used to dye histological cross-sections such as H&E stain for morphological inspection of biopsy specimens to identify malignant changes or Gram staining to differentiate bacterial species into two large groups based on the chemical and physical properties of their cell walls. Most bright field dyes require cell fixation prior to staining in order to be able to work with high dye concentrations, which is why the investigation of living cells becomes difficult.

In addition to chemical contrasting light microscopy with instrumental contrast enhancement (optical contrasting) such as dark field, phase contrast, and differential interference contrast (DIC) microscopy is possible. Dark field microscopy, which also requires transparent samples, utilizes light refracted at phase boundaries, that is, between structures with different refractive indices to visualize phase boundaries.

This is achieved by illuminating the sample with special microscopic condenser units in such a way that without a specimen the light rays do not arrive at the microscope objective, that is, the field of view is dark, whereas with a specimen the light rays will be refracted at sample edges and arrive at the microscope objective, that is, bright sample edges are seen on a dark background. The reason for light being refracted is the inhomogeneities of the sample leading to an inhomogeneous refractive index (see also Section 3.5).

An inhomogeneous distribution of the refractive index also leads to a phase change of the light waves, which travel through areas of the sample with different refractive indices. Many cell organelles exhibit different refractive indices and therefore diffract light beams differently, leading to a phase shift compared with an undisturbed reference beam. Such specimens are called phase objects (see the right side of Figure 3.13). Phase objects are not visible in the bright field. Phase contrast visualizes these phase shifts by converting them into amplitude differences. In this way, light passing through the sample and which is phase shifted is combined with a reference beam [i.e., unshifted (undeviated) light passing through or around the sample] in such a way that the resulting wave interference reveals the phase structure of the sample. This is achieved by introducing a phase plate, which introduces a phase difference between the sample and reference beam to produce interference between these two beams such that an amplitude-modulated wave results where the phase shift induced by the specimen appears as an intensity variation.

DIC microscopy works by separating a polarized light source (see Section 3.5) into two beams which take slightly different paths through the sample. Where the lengths of each optical path (i.e., the product of refractive index and geometric pathlength) differ, the beams interfere when they are recombined after leaving the sample.

Figure 3.14 shows some microscopic images of biological specimens summarizing the different contrast mechanisms which are based on absorption and dispersion.

OCT is also based on inhomogeneities of the refractive index in biological samples such as tissue. OCT is a method in which light is used to measure distances in a highly scattering medium such as tissue where the scattering of light (see Section 3.12) is due to changes in the refractive index within the tissue because of cell membranes or organelles. OCT contrast is achieved by utilizing the interference between backscattered light and a reference beam. As shown above, interference between two light waves occurs only when the two waves have a well-defined phase relation within a certain region. In contrast to light microscopy, OCT uses light with longer wavelengths than visible light, namely near-IR light. In addition, the light used is coherent, which means that all waves emitted from the light source have the same phase (see Section 3.7). This coherence becomes partly lost when the light is scattered inside the sample. For OCT, only the part of the light which is ballistically backscattered (i.e., unscattered or coherently scattered) is detected and evaluated. This means that ballistic scattered light propagates in the direction of the incoming light and therefore travels the shortest path and carries the maximum information on the internal structure of the tissue. A displacement of the reference beam produces the pathlength difference between the light reflected from the reference mirror and the backscattered ballistic light from the scattering sample, generating an

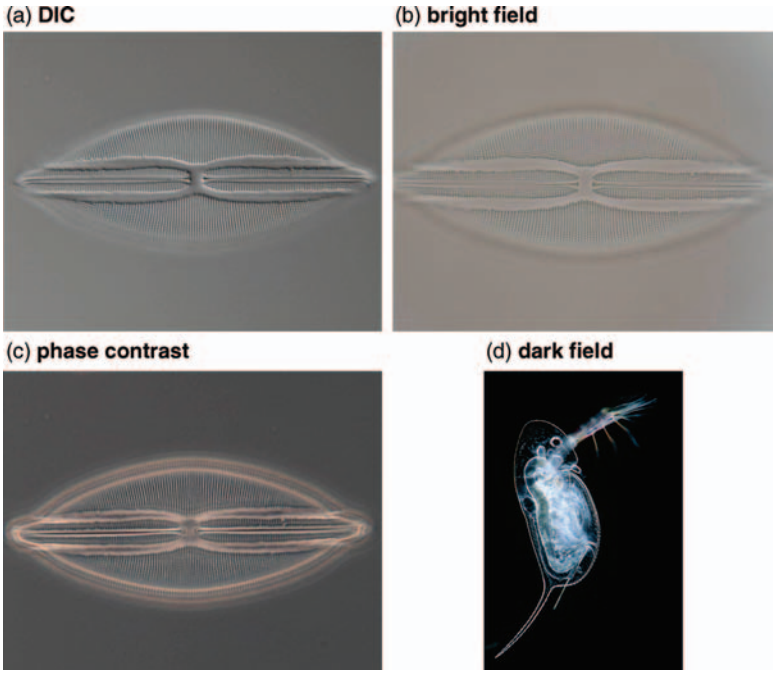

Figure 3.14 Comparison of the different contrast modalities based on absorption and dispersion. (images courtesy of Carl Zeiss MicroImaging GmbH, Jena).

interference pattern containing information about the refractive index variation of the tissue, which thus provides an optical image. OCT allows the non-coherent part of the scattered light, which usually carries little information about the sample under investigation, to be suppressed.

3.5 Reflection and Transmission

In the previous section, it was detailed how absorption originates and how useful it can be to determine this quantity. Unfortunately, absorption cannot be measured directly. Instead, absorption can be determined by measuring transmission (the quantity of light that remains after light has traveled through the sample) and reflection (the part of light that is sent back without entering the sample). Absorption is then the remaining part which is neither reflected nor transmitted (if the sample is inhomogeneous, which most biological materials are, scattering may also have to be taken into account; see Section 3.12). As a further

consequence, for example, microscopes can be operated in either the transmission or reflection mode.

When a light wave hits a smooth interface that separates two media with different dielectric properties, part of the light is unable to penetrate the interface and is reflected back into the medium from which the light wave was approaching the interface. If the incidence of the light is not perpendicular to the interface, the angle of incidence, which is measured from the perpendicular, has the same magnitude as the angle of reflectance. The part of the light, which is reflected, depends on the angle of incidence, on the dielectric functions of both media, and on the polarization direction. The other part of the light wave permeates the interface and travels through the second medium, while its intensity may decrease due to absorption. The quantity of both parts can be calculated from the boundary conditions, which state that an electric field tangential to the interface remains unchanged whereas the perpendicular part is either decreased or increased depending on whether the dielectric constant of the second medium is larger or smaller than that of the first medium. To calculate the quantities, it is of advantage to calculate separately the cases where the electric field vector is either perpendicular or parallel to the plane of incidence, which is defined by the incoming, reflected, and transmitted beams. From the results of the calculation we find that if the dielectric constant of the first medium is smaller than that of the second medium, the reflectance of perpendicular polarized light increases monotonically with increasing angle of incidence, whereas the reflectance of parallel polarized incoming light is zero (minimum if the second medium is absorptive) at a certain angle of incidence. Both reach the value of unity when the angle of incidence reaches its maximum value of 90°. If the dielectric constant of the first medium is larger than that of the second medium, the principal behavior of the reflectance is the same except that it reaches unity at an angle of incidence smaller than 90°. This is called total reflection. If the second medium is absorptive, the total reflection is weakened. This effect is called attenuated total reflection (ATR); it is very sensitive and is exploited in a number of different microscopic and spectroscopic methods. If the interface between two media is not smooth, part of the light is not reflected in one particular direction but scattered in all directions. This is called diffuse reflection. The higher the surface roughness is, the higher becomes the proportion of diffusely reflected light. The interpretation of diffuse reflectance spectra is not straightforward. Spectra also become more complicated if the simple optical model isotropic medium/interface/isotropic medium is not applicable. One possibility is that the second medium has such a small thickness and such a low absorption that light is able to reach its back side, which is then again an interface. This means that part of the light leaves the medium, whereas another part of the light is reflected and travels backwards. While traveling backwards it interferes with the forward traveling light. Depending on the thickness, this generates regular minima and maxima in spectra. If the second medium is anisotropic, light absorption and reflection depend on the orientation of the medium. In the case of inhomogeneous media, absorption and reflection depend strongly on the size of the inhomogeneities relative to the

wavelength of light. In the latter case, scattering may not be negligible, which is another optical quantity in addition to absorption that can provide most useful insights into the nature of biological matter.

A full description of reflection and transmission of light can be found in [6–9].

In vacuum (and also in optically isotropic media such as glass or cubic crystals but not generally in isotropic materials), each electromagnetic wave is purely transversal. This means that the electric field vector (and also the magnetic field vector) is always oriented perpendicular to the direction of the wave (to the wavevector). For illustration, let us assume that an electromagnetic wave is traveling along the z-direction. Therefore, the electric field vector $\vec{E}$ is confined to the $x-y$ plane

$$\vec{E} = \begin{pmatrix} E_x \\ E_y \\ 0 \end{pmatrix}. \tag{3.43}$$

If the electromagnetic wave has its origin in a conventional light source (see Chapter 4), then all possible directions of the $\vec{E}$ vector in the $x-y$ plane will be realized, as illustrated in the Figure 3.15. Such light is said to be unpolarized or naturally polarized. With the help of so-called (linear) polarizers, it is possible to extract a single polarization direction. Such a polarizer can consist, for example, of a wire grid that is embedded in a transparent material, which can be a polymer. In the example above, the resulting wave is polarized along the y-axis. Therefore, the resulting electric field vector has only one component, E_y, and is said to be linearly polarized in the y-direction

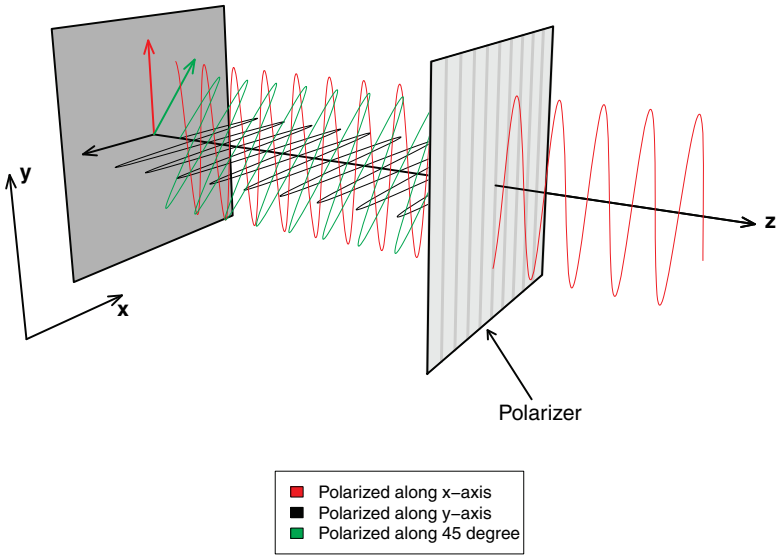

Figure 3.15 A linear polarizer acts on unpolarized light resulting in linearly polarized light.

$$\vec{E} = \begin{pmatrix} 0 \\ E_y \\ 0 \end{pmatrix}. \tag{3.44}$$

The superposition of two linearly polarized waves of the same wavelength with mutually perpendicular polarization directions, which are traveling in the same direction and have the same amplitudes E_0 and phases, always leads to unpolarized waves since the superposition of two electromagnetic waves is purely additive. If the amplitudes are not equal, elliptically polarized light results. On the other hand, we are allowed to split unpolarized waves into two linearly polarized waves, the linear combination of which again produces the unpolarized wave. This is of great importance, for example, for the calculation of reflection and transmission: if the light wave does not come in perpendicular to an interface, light that is polarized parallel to the plane of incidence behaves differently from that which is polarized perpendicular to that plane. Further, linearly polarized light usually experiences different refractive indices and is absorbed differently when traveling through anisotropic materials depending on their orientation.

To obtain information about the molecular structure, the resonance frequencies of a medium (a sample) can be studied, by measuring either the transmission or the reflection. From both of these the dielectric function in which this information is contained can be regained. If we denote the intensity of the incident light I_0, as was done in the previous section, the conservation of energy leads to the following relation:

$$I_0 = I_R + I_T + I_A \tag{3.45}$$

where I_R, I_T and I_A are the intensity of the reflected, the transmitted, and the absorbed light, respectively (see Figure 3.16). If we divide these quantities by I_0 we obtain

$$1 = \frac{I_0}{I_0} = \frac{I_R}{I_0} + \frac{I_T}{I_0} + \frac{I_A}{I_0} = R + T + A \tag{3.46}$$

by which the quantities reflection R, transmission T, and absorption A are defined. If we rearrange Equation 3.46, we obtain

$$1 - R - T = A \tag{3.47}$$

which shows that we have actually disregarded reflection in Equation 3.40 as is often done in the literature. Since, as we will see, reflection is especially strong in spectral regions with strong absorption, this can lead to considerable errors. For Equation 3.45, we have implicitly assumed that the medium of interest is homogeneous. In the case of samples where this assumption is incorrect, scattering also has to be taken into account. We will come back to scattering in Sections 3.12 and 3.13.

Figure 3.17 illustrates the optical model of reflection and refraction. We assume a plane wave $\vec{E}_e = \vec{E}_{0,e}\cos(\omega t - \vec{k}_e \cdot \vec{r})$ that is incident from a medium 0 with a refractive index n_0 (usually air, therefore $n_0 \approx 1$) under an incidence angle α_e on to an interface that separates the incidence medium from medium 1 (usually the sample) with an in

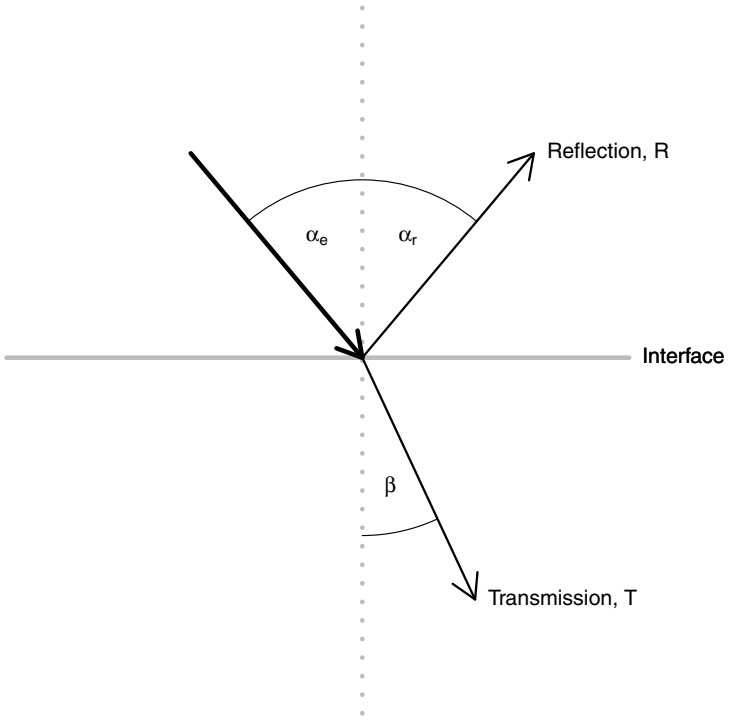

Figure 3.16 Reflection and transmission.

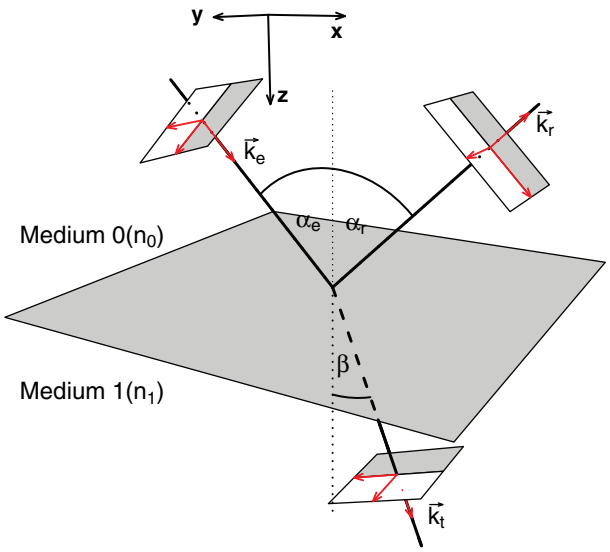

Figure 3.17 Reflection and refraction at a single interface.

general complex refractive index $n_1 = \mathrm{n}_1 + i\kappa_1$. The interface is perfectly smooth and the media are assumed to be so-called semi-infinite media (in practice, this means that the extent of medium 1 along the z-direction is large enough that the wave is not again reflected and refracted at the back side of the sample, since this considerably complicates the situation; we come back to this problem later). We choose a coordinate system in such a way that the interface is lying in the $x-y$ plane, whereas the plane of incidence is the $x-z$ plane. The wavevector $\vec{k}_\mathrm{e}$ therefore has components along both the x and z directions according to

$$\vec{k}_\mathrm{e} = n_0 \frac{\omega}{c} \begin{pmatrix} \sin\alpha_\mathrm{e} \\ 0 \\ \cos\alpha_\mathrm{e} \end{pmatrix}. \tag{3.48}$$

At the interface, the incident, the reflected, and the refracted (transmitted) waves must at all times have the same phase, that is, if the incident wave has a maximum of the amplitude at the interface, the same holds for the reflected and the refracted waves. As a consequence, it can be derived from

$$\begin{aligned} \vec{E}_\mathrm{e} &= \vec{E}_{0,\mathrm{e}} \cos\left(\omega t - \vec{k}_\mathrm{e} \cdot \vec{r}\right) \\ \vec{E}_\mathrm{r} &= \vec{E}_{0,\mathrm{r}} \cos\left(\omega t - \vec{k}_\mathrm{r} \cdot \vec{r}\right) \\ \vec{E}_\mathrm{t} &= \vec{E}_{0,\mathrm{t}} \cos\left(\omega t - \vec{k}_\mathrm{t} \cdot \vec{r}\right) \end{aligned} \tag{3.49}$$

that the following condition must be valid:

$$\vec{k}_\mathrm{e} = \vec{k}_\mathrm{t} = \vec{k}_\mathrm{r}. \tag{3.50}$$

Therefore, the y-component of all three vectors is zero and all lie in the plane of incidence. Accordingly, $\vec{k}_\mathrm{r}$ and $\vec{k}_\mathrm{t}$ are given by

$$\vec{k}_\mathrm{r} = n_0 \frac{\omega}{c} \begin{pmatrix} \sin\alpha_\mathrm{r} \\ 0 \\ -\cos\alpha_\mathrm{r} \end{pmatrix}, \; \vec{k}_\mathrm{t} = n_1 \frac{\omega}{c} \begin{pmatrix} \sin\beta \\ 0 \\ -\cos\beta \end{pmatrix} \tag{3.51}$$

where β is the angle of refraction. As a consequence, from Equations 3.48 and 3.51 the so-called Snell's law can be derived focusing on the x-components

$$\begin{aligned} \sin\alpha_\mathrm{e} &= \sin\alpha_\mathrm{r} \\ \sin\alpha_\mathrm{e} &= \frac{n_1}{n_0} \sin\beta. \end{aligned} \tag{3.52}$$

Therefore, the angle of incidence equals the angle of reflection: $\alpha_\mathrm{e} = \alpha_\mathrm{r}$. As already mentioned, in media that can be characterized by a single refractive index, the electric fields are perpendicular to the wavevector.

Due to the so-called boundary conditions, the relations are simplified if we consider two cases separately (see below). In the first case, the electric field vector is oriented perpendicular to the plane of incidence and therefore has only a component $E_{\mathrm{e},y}$ in the y-direction tangential to the interface (often this case is called

"transverse electric"). In the second case, the electric field has components in both the x- and z-directions and is given by

$$\vec{E}_{\mathrm{e}} = E_{\mathrm{e}} \begin{pmatrix} \cos\alpha_{\mathrm{r}} \\ 0 \\ \sin\alpha_{\mathrm{r}} \end{pmatrix}. \tag{3.53}$$

As a consequence, it possesses one component $E_{\mathrm{e},x}$ that is also tangential to the interface and a second component $E_{\mathrm{e},z}$ that is oriented perpendicular to the interface (often this case is called "transverse magnetic" in the literature). The electric fields are accompanied by magnetic fields $\vec{B}$. Employing Equation 3.25 and inserting a plane wave of the form $\vec{E} = \vec{E}_0 \cos\left(\omega t - \vec{k}\cdot\vec{r}\right)$, one obtains for the magnetic field $\vec{B}$ the following relation:

$$\begin{gathered} \vec{k} \times \vec{E} = \frac{\vec{B}}{\mu_0} \\ \begin{pmatrix} k_y E_z - k_z E_y \\ k_z E_x - k_x E_z \\ k_x E_y - k_y E_x \end{pmatrix} = \begin{pmatrix} -k_z E_y \\ k_z E_x - k_x E_z \\ k_x E_y \end{pmatrix} = \frac{1}{\mu_0} \begin{pmatrix} B_x \\ B_y \\ B_z \end{pmatrix} \end{gathered} \tag{3.54}$$

since $k_y = 0$. According to the boundary conditions, the tangential component of the electric field remains unchanged:

$$E_x(\text{medium } 0) = E_x(\text{medium } 1),\ E_y(\text{medium } 0) = E_y(\text{medium } 1). \tag{3.55}$$

Similar relations apply to magnetic fields. Again, the tangential components are not altered:

$$B_x(\text{medium } 0) = B_x(\text{medium } 1),\ B_y(\text{medium } 0) = B_y(\text{medium } 1). \tag{3.56}$$

Case I: Electric field polarized perpendicular to the plane of incidence

In medium 0, the existing electric fields are those of the incident and reflected waves. Therefore, their sum must be equal to the field of the transmitted wave

$$E_y(\text{medium}0) = E_y(\text{medium}1) \rightarrow E_{\mathrm{e},y} + E_{\mathrm{r},y} = E_{\mathrm{t},y.} \tag{3.57}$$

An equivalent relation can also be derived for the x-components of the magnetic fields

$$B_{\mathrm{e},x} + B_{\mathrm{r},x} = B_{\mathrm{t},x}. \tag{3.58}$$

Employing Equation 3.54 together with Equations 3.48 and 3.51 to replace the components of $\vec{k}$ (see Equation 3.54), we obtain

$$E_{\mathrm{e},y}\cos\alpha - E_{\mathrm{r},y}\cos\alpha = E_{\mathrm{t},y} n_1 \cos\beta \tag{3.59}$$

using $\alpha_e = \alpha_t = \alpha$. Solving Equation 3.59 for $E_{\mathrm{r},y}$ and $E_{\mathrm{t},y}$ in terms of $E_{\mathrm{e},y}$, we find that

$$E_{r,\gamma} = \frac{\cos\alpha - n_1\cos\beta}{\cos\alpha + n_1\cos\beta} E_{e,\gamma}$$
$$E_{t,\gamma} = \frac{2\cos\alpha}{\cos\alpha + n_1\cos\beta} E_{e,\gamma}. \tag{3.60}$$

The next step is to replace the complex angle β. To that end, we employ Snell's law, $\sin\alpha = n_1 \sin\beta$ ($n_0 = 1$); taking into account that $\sin^2\beta + \cos^2\beta = 1$ and, therefore, $\cos\beta = \sqrt{1-\sin^2\beta} = \sqrt{1-\frac{1}{n_1^2}\sin^2\alpha}$, we obtain

$$E_{r,\gamma} = \frac{\cos\alpha - \sqrt{n_1^2 - \sin^2\alpha}}{\cos\alpha + \sqrt{n_1^2 - \sin^2\alpha}} E_{e,\gamma}$$
$$E_{t,\gamma} = \frac{2\cos\alpha}{\cos\alpha + \sqrt{n_1^2 - \sin^2\alpha}} E_{e,\gamma}. \tag{3.61}$$

The ratios $E_{r,\gamma}/E_{e,\gamma}$ and $E_{t,\gamma}/E_{e,\gamma}$ are the reflection and the transmission coefficients r_γ and t_γ, respectively. To indicate the polarization relative to the plane of incidence, it is common to denote them as t_s (from the German "*senkrecht*") and r_t.

Case II: Electric field polarized parallel to the plane of incidence:

Again the tangential components of the electric and the magnetic field vectors $\vec{E}$ and $\vec{B}$ must be continuous at the interface. These components are $E_{i,x} = E_{i,p}\cos\vartheta$ (Equation 3.53) and $\mu_0 B_{i,\gamma} = -\cos\vartheta \cdot E_{i,x} - \sin\vartheta \cdot E_{i,z} = E_{i,p}$, wherein $i = e,\ r,\ t$ and ϑ stands either for α or β. Therefore, we obtain the following equations

$$E_{e,p}\cos\alpha + E_{r,p}\cos\alpha = E_{t,p}\cos\beta$$
$$B_{e,p} + B_{r,p} = B_{t,p}. \tag{3.62}$$

Solving Equation 3.59 for $E_{r,p}$ and $E_{t,p}$ in terms of $E_{e,p}$, we find that

$$E_{r,p} = \frac{\cos\beta - n_1\cos\alpha}{\cos\beta + n_1\cos\alpha} E_{e,p}$$
$$E_{t,p} = \frac{2\cos\alpha}{\cos\beta + n_1\cos\alpha} E_{e,p}. \tag{3.63}$$

After replacing the complex angle β $\left[\cos\beta = \sqrt{1-\sin^2\beta} = \sqrt{1-(1/n_1)\sin^2\alpha}\right]$, we obtain

$$E_{r,p} = \frac{\sqrt{n_1^2 - \sin^2\alpha} - n_1\cos\alpha}{\sqrt{n_1^2 - \sin^2\alpha} - n_1\cos\alpha} E_{e,p}$$
$$E_{t,p} = \frac{2\cos\alpha}{\sqrt{n_1^2 - \sin^2\alpha} - n_1\cos\alpha} E_{e,p}. \tag{3.64}$$

The ratios $E_{r,p}/E_{e,p}$ and $E_{t,p}/E_{e,p}$ are the reflection and the transmission coefficient r_p and t_p, respectively.

Equations 3.58 and 3.63 are known as the Fresnel equations. From the reflection and transmission coefficients, we obtain the reflectance and transmittance by considering the time-averaged energy flow through the interface. To that end, we have to invoke the so-called Poynting vector $\vec{S}$, which is given by

$$\vec{S} = \frac{\vec{k}}{2\omega}\left|\vec{E}\right|^2 \tag{3.65}$$

provided that the media are nonmagnetic ($\mu = 1$). Its magnitude is simply the intensity of the plane wave. The reflectance is then given by the intensity I_r of the reflected wave in the direction perpendicular to the interface (the z-direction) divided by the intensity of the incident wave I_0:

$$R_i = \frac{I_{r,i}}{I_0} = \frac{S_{z,r,i}}{S_{z,e,i}}, \quad i = s,\ p. \tag{3.66}$$

In case of transmission the component of the wavevector in the z-direction is different. Therefore the transmission is not simply the square of the value of the transmittance coefficients but obtained as

$$T_i = \frac{I_{t,i}}{I_0} = \frac{S_{z,t,i}}{S_{z,e,i}} = \frac{\sqrt{n_1^2 - \sin^2\alpha}}{\cos\alpha}|t_i|^2, \quad i = s, p. \tag{3.67}$$

Figure 3.18 shows the dependence of the reflectance on the angle of incidence for $n_0 = 1$ and $n_1 = 2$. At $\alpha = 0^\circ$ (normal incidence), the polarization of R_p has only a component parallel to the interface, as has R_s. Therefore, $R_s = R_p$. With increasing angle of incidence, R_s increases monotonically, whereas R_p possesses not only a minimum at 63°, but actually reaches zero. This angle is called the Brewster angle. After the Brewster angle, R_p also increases monotonically and reaches unity together with R_s at 90°, which actually simply means that the wave is traveling parallel to the interface and therefore reflection no longer occurs.

If we allow the medium to be absorptive, then the reflectance at normal incidence increases with increasing absorption index κ (see Figure 3.19). R_s is still a monotonically increasing function of the angle of incidence and R_p still shows a minimum, at which, however, R_p no longer reaches zero. This minimum shifts with increasing absorption index to higher angles of incidence.

An important peculiarity occurs if the refractive index of the incidence medium is higher than that of the exit medium. In this case, Equations 3.61 and 3.64 have to be modified to allow for a refractive index of the incidence medium that does not equal unity

$$\begin{aligned} r_s &= \frac{n_0\cos\alpha - \sqrt{n_1^2 - \sin^2\alpha}}{n_0\cos\alpha + \sqrt{n_1^2 - \sin^2\alpha}} r_p \\ E_{t,p} &= \frac{2\cos\alpha}{\sqrt{n_1^2 - \sin^2\alpha} - n_1\cos\alpha} E_{e,p}. \end{aligned} \tag{3.68}$$

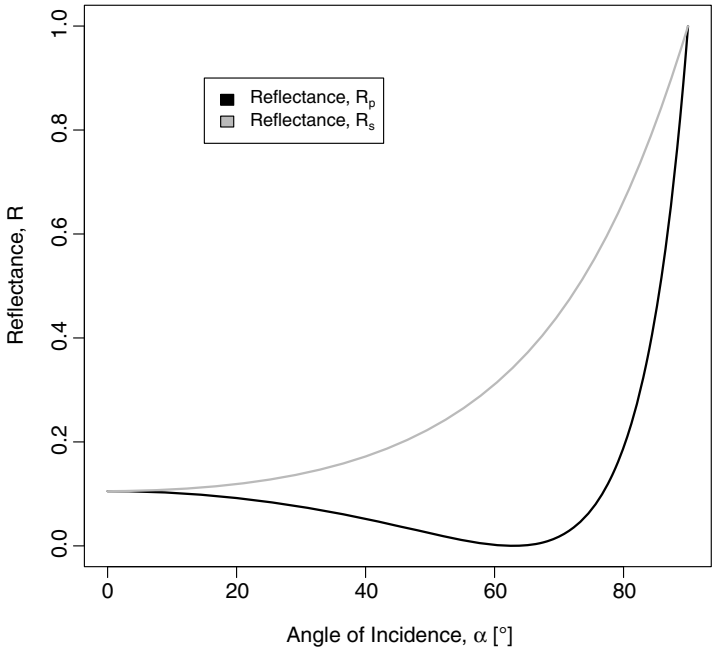

Figure 3.18 Dependence of the reflectance of the angle of incidence.

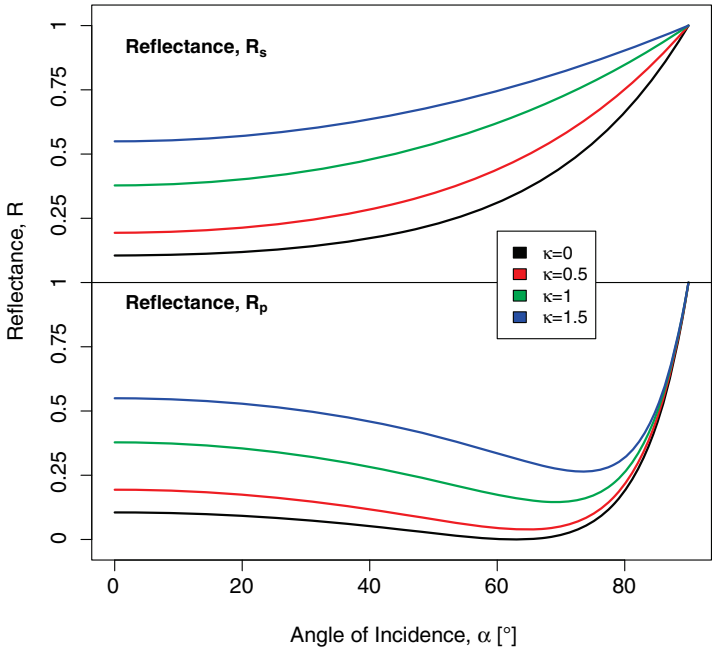

Figure 3.19 Variation of the reflectance with increase in absorption.

If we now set, for example, $n_0 = 3$ and keep $n_1 = 2$, the reflectance reaches unity already at 41°. The reason for this is comparably simple. As long as $n_0 < n_1$ holds, it follows from Equation 3.52 that $\alpha > \beta$. If this is inverted ($n_1 < n_0$) the consequence is that $\alpha < \beta$. The maximum β that can exist, however, is $\beta = 90°$. Based on Equation 3.52, the corresponding α_c is given by

$$\alpha_c = \arcsin\left(\frac{n_1}{n_0}\right) \tag{3.69}$$

and is called the critical angle. If the angle of incidence is chosen above the critical angle $\alpha > \alpha_c$, no energy is transferred into medium 1. As a consequence, the reflectance must reach unity independent of the incoming light's polarization. Again as a consequence, the transmittance must be zero (note that so far we have assumed that n_1 is real!) Despite the fact that no energy is transferred into the second medium, the wave nevertheless penetrates the interface; however, since cosβ is a purely imaginary quantity, the wave decays exponentially. Such a wave is called evanescent. The penetration distance is in the order of several wavelengths except close to the critical angle.

It is instructive to investigate what happens if the medium with the lower refractive index is absorptive. As can be seen from Figure 3.20, even an absorption index as low as $\kappa = 0.06$ has a strong influence on the reflectance and considerably weakens it. This phenomenon, ATR (see earlier), constitutes the basis of a number of different

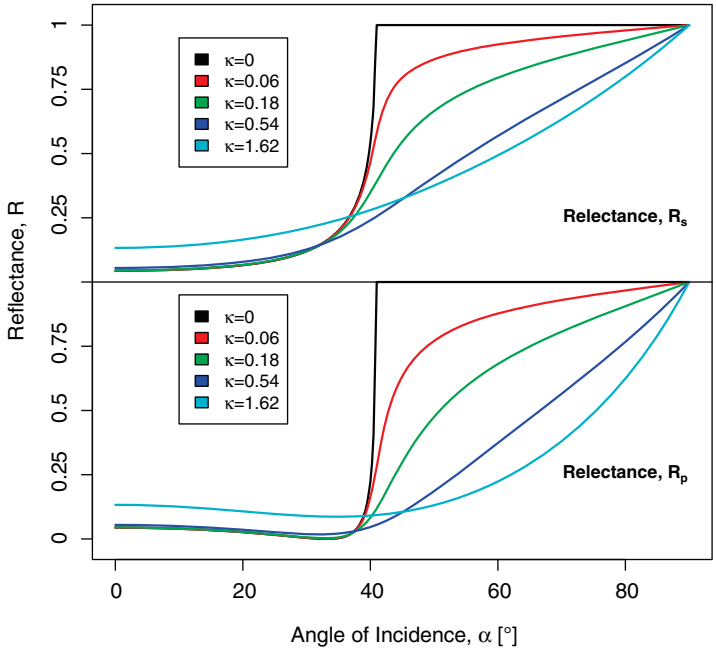

Figure 3.20 Reflectance from a medium that has a lower refractive index than the incidence medium.

spectroscopy and microscopy methods. If the medium is not absorptive, but inhomogeneous, total reflection may also become attenuated, since inhomogeneities close to the interface may distort the evanescent field. As a consequence of this distortion, a wave may be emitted, which receives its energy from the evanescent wave, leading to the attenuation of the total reflection. This phenomenon is called evanescent wave scattering.

It must be emphasized that so far we have treated the simplest optical model that one can think of (for example, we have assumed the media to be semi-infinite, characterized by a scalar dielectric function, homogeneous, etc.). If we remove one or more of the conditions of the model, the situation becomes considerably more complicated. Even taking into account that in the case of biological matter nearly all of the complications are present, we will abstain from treating the theory in detail. Instead, we will describe the effects, with some exceptions, in only a qualitative manner.

3.5.1
Diffuse Reflection

Diffuse reflection occurs whenever the interface is not perfectly smooth and is uneven or granular or possesses holes (see Figure 3.21). Part of the light is then scattered in all directions. As a consequence, the measured specular reflection is smaller, which can often be corrected by applying a factor to the measured spectrum. The larger the diffusely reflected portion of light is, however, the more problematic is

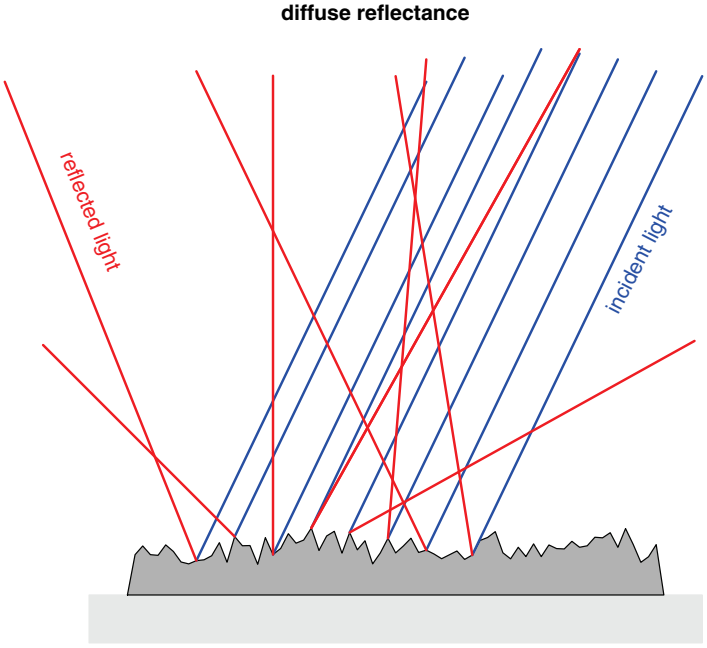

Figure 3.21 Illustration of diffuse reflectance.

such a simple correction. In the extreme case of a powdered sample, all of the light is diffusely reflected. Using a so-called integrating sphere (often also called Ulbricht sphere), which collects the light that is spread over the whole hemisphere, spectra can also be recorded. An interpretation of such spectra, however, is not straightforward. One possibility to evaluate such spectra quantitatively is to employ the so-called Kubelka–Munk theory or one of its various forms, which assumes that scattering is dominant compared with absorption (and compared with specular reflection). It requires a powder that is evenly spread in a surplus of a nonabsorbing powder, for example, KBr. Due to many simplifying assumptions, the results are usually of comparably poor quality.

3.5.2
Layered Media

If a medium cannot be considered as semi-infinite, it must be treated as a layer. A simple realization of this situation is a glass plate. In the spectral region where absorption is weak, the light that is transmitted through the first surface reaches the back side of the sample. Assuming that the sample surfaces are smooth and that it has a uniform thickness, part of the transmitted light is reflected back to the first surface where again a portion is reflected. Depending of the wavelength of the light and the thickness of the sample, interference peaks occur, that is, the reflectance shows periodically, as a function of both wavelength and layer thickness, minima and maxima caused by destructive and constructive interference since in the equations for transmission and reflection a phase factor occurs, which is given by

$$\exp\left(-i\frac{2\pi}{\lambda}n_1\cos\beta\right). \tag{3.70}$$

The underlying physical principle is the principle of superposition of waves (in this case, the waves traveling forwards and backwards inside the sample), which states that the resulting displacement at a point is equal to the vector sum of displacements of all waves present. Exact equations to interpret the resulting spectra quantitatively are somewhat cumbersome, but have been derived for an arbitrary number of layers and even for anisotropic media.

3.5.3
Anisotropic Media

A characteristic feature of biological tissues is that they consist of both amorphous and well-ordered crystalline regions. Typical examples are collagen fiber bundles, which consist of bundles of fibrils. In most cases these crystalline regions form anisotropic media.

Whereas in isotropic media, for example, the electric flux density and the electric field are vectors with equal direction which can be related to each other by a scalar factor (the dielectric function), this is no longer true for anisotropic media. As a consequence, the dielectric function becomes a 3×3 tensor function. In general, the

wave Equation 3.29 becomes much more complex and its solutions indicate that depending on the polarization of the wave and its direction, two different refractive indices exist. Consequently, a wave upon entering an anisotropic medium generally decomposes into two waves with mutual perpendicular polarization directions and traveling with different velocities. This behavior can be exploited in a manifold of optical techniques to detect changes in tissues which change into malignant forms.

From general experience, it seems that anisotropic media are somehow exotic whereas isotropy is what is usually encountered. Indeed, most of the volume of the universe is made up of isotropic media, that is, vacuum, gases, and liquids. The last state of matter, however, has at least one class of liquids that already belong to anisotropic media, namely liquid crystals. In the case of solid matter, which also includes soft matter such as biological material, anisotropy nearly always plays a role. In almost all kinds of solid matter ordered regions exist, which are in most cases anisotropic. Even if these ordered regions are randomly oriented and form a macroscopically isotropic medium, the anisotropy of the ordered regions makes the properties of such a medium differ from those of an original isotropic medium such as a cubic crystal. Unfortunately, the relationships can become complicated and it is far beyond the scope of this book to give an exhaustive introduction to optics and anisotropy. Nevertheless, the reader should be able to grasp some basic aspects after reading this section.

In an anisotropic medium, the polarization $\vec{P}$ is in general not parallel to the electric field $\vec{E}$ that causes it. As a consequence, the dependence between electric field $\vec{E}$ and dielectric displacement $\vec{D}$ must in general be written as

$$\begin{pmatrix} D_x \\ D_y \\ D_z \end{pmatrix} = \begin{pmatrix} \varepsilon_{xx} & \varepsilon_{xy} & \varepsilon_{xz} \\ \varepsilon_{yx} & \varepsilon_{yy} & \varepsilon_{yz} \\ \varepsilon_{zx} & \varepsilon_{zy} & \varepsilon_{zz} \end{pmatrix} \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix}. \tag{3.71}$$

The tensor generally consists of nine independent components. In the absence of optical activity, however, the tensor possesses only six independent components, since $\varepsilon_{ji} = \varepsilon_{ij}$ and the tensor is symmetric. Since the tensor transforms one vector into another, it can be seen as being fixed within a medium or a region of order to which it belongs. Usually the ordered region or the medium as a whole (e.g., a crystal) has a certain symmetry which can simplify the tensor considerably. To illustrate this, let us assume that the medium of interest has a mirror plane and perpendicular to the plane an axis of rotation. If we align the x, y, z coordinate system in such a way that the axes of the coordinate system are all parallel and perpendicular to the axis of rotation and the mirror plane, then the tensor takes on the diagonal form:

$$\begin{pmatrix} D_x \\ D_y \\ D_z \end{pmatrix} = \begin{pmatrix} \varepsilon_x & 0 & 0 \\ 0 & \varepsilon_y & 0 \\ 0 & 0 & \varepsilon_z \end{pmatrix} \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix}. \tag{3.72}$$

Now we can distinguish the following three cases:

1) The medium is of cubic symmetry; this means that $\varepsilon_x = \varepsilon_y = \varepsilon_z$ and the tensor reduces to a scalar. This is the case that we have discussed in detail in the preceding sections.

2) The medium is of hexagonal, trigonal, or tetragonal symmetry and the axis of rotation is oriented along the z-axis. Accordingly, $\varepsilon_x = \varepsilon_y$ and the tensor has only two independent components, ε_x and ε_z. The medium is then said to be optically uniaxial. As a consequence, each wave entering the medium is split into two waves with mutually perpendicular polarization directions and two different traveling speeds. One wave, which is called the ordinary wave, experiences a refractive index n_o, which is given by $n_o = \sqrt{\varepsilon_x} = \sqrt{\varepsilon_y}$. The other wave is called the extraordinary wave, and its refractive index n_e depends on the angle ϑ between the direction of the wave and the z-axis, which is called the optical axis

$$n_e = \sqrt{\frac{\varepsilon_x \varepsilon_y}{\varepsilon_x \sin^2\vartheta + \varepsilon_z \cos^2\vartheta}}. \tag{3.73}$$

3) The medium is of orthogonal, monoclinic, or triclinic symmetry. These are the optically biaxial media, since now two axes exist which, when the waves travel along them, behave like isotropic media. For a general direction, each wave is still split into two waves with mutually perpendicular oriented polarization directions. However, unlike in the uniaxial case, both waves are now extraordinary in the sense that the refractive indices generally depend on all elements of the dielectric tensor. The case of biaxial media can be further subdivided according to their symmetry:
   a) **Orthogonal media:** The dielectric tensor takes on the diagonal form whenever an incoming wave is aligned with one of the symmetry axes or, in case of crystals equivalently, with one of its crystal axes, and is polarized along another principal axis of the tensor. The principal axes of the tensor are independent of frequency (The principal axes of the tensor are those belonging to the coordinate system in which it takes on the diagonal form.) The refractive indices can be stated to depend on the three diagonal elements $\varepsilon_x = \varepsilon_y = \varepsilon_z$.
   b) **Monoclinic media:** Only one of the principal axes of the tensor is fixed; the orientations of the other principal axes depend on the frequency of the incoming wave. Usually the y-axis is chosen as the fixed axis. Accordingly, the refractive indices depend on one diagonal element ε_y and the elements ε_{xx}, ε_{xz}, ε_{zz}.
   c) **Triclinic symmetry:** The orientations of all principal axes of the tensor depend on the frequency of the incoming wave. As a consequence, the refractive indices depend on all six tensor elements ε_{xx}, ε_{xy}, ε_{yy}, ε_{yz}, ε_{xz}, ε_{zz}.

      For general directions inside biaxial media, the two refractive indices are obtained by solving the following equation:

$$\left| \begin{pmatrix} \varepsilon_{XX} - n^2 & \varepsilon_{XY} & \varepsilon_{XZ} \\ \varepsilon_{YX} & \varepsilon_{YY} - n^2 & \varepsilon_{YZ} \\ \varepsilon_{ZX} & \varepsilon_{ZY} & \varepsilon_{ZZ} \end{pmatrix} \right| = 0 \tag{3.74}$$

      where X, Y, Z is an external coordinate system (i.e., the coordinate system is not fixed inside the medium and is some kind of laboratory coordinate system, where the light wave is traveling along the Z-axis).

The derivation of reflection from and transmission through anisotropic media follows the procedure outlined in this section. The complexity increases with decreasing symmetry. Especially for monoclinic and triclinic symmetry, the solutions can no longer be given in closed form even in the case of normal incidence. The most important consequence of anisotropy is that upon reflection from and transmission through an anisotropic medium, a linearly polarized wave generally decomposes into two waves, which are mutually orthogonally polarized and each of which has a different speed. Therefore, a linear polarized wave becomes in general elliptically polarized inside the anisotropic medium (see Figure 3.22). Due to the boundary conditions at the interface, it is usually nearly impossible to determine the component of the dielectric tensor that is oriented perpendicular to the interface (consider, e.g., a uniaxial medium with the optical axis perpendicular to its surface) even for parallel polarized light and large angles of incidence. Exact solutions for the reflectance and transmittance can be found in the literature even for layered samples consisting of anisotropic layers.

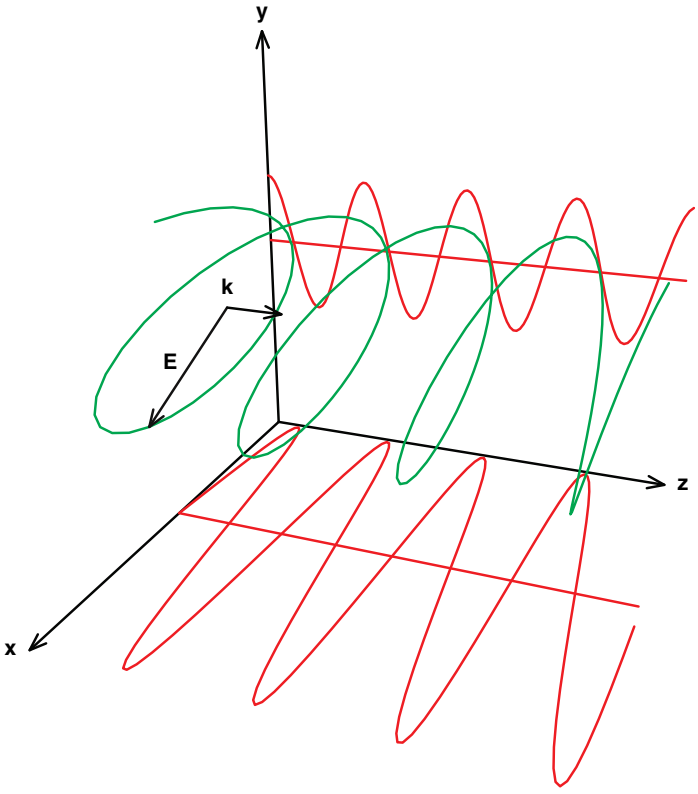

Figure 3.22 Illustration of elliptically polarized light.

3.5.4 Inhomogeneous Media

The simplest case is given by spheres in a matrix or a mixture of two kinds of spheres. The general problem consists in finding the appropriate optical constants (either the dielectric function or the refractive index) that optically characterizes the medium. This is possible only if the inclusions or the particles can be considered small compared with the wavelength (usually smaller than one-tenth of the wavelength). In principle, there are two different approaches. The first consists in constructing an averaged dielectric function starting from calculations of the local electric field (a simple average with the volumes as weighting factors does not work in this case!), for example, the so-called Lorentz–Lorentz relation. The second approach consists in averaging the refractive indices according to

$$\langle n \rangle = \sum_i f_i n_i \tag{3.75}$$

where n_i represent the refractive indices of the individual materials and f_i the part of the volume that is occupied by the medium i inside the sample. Both approaches have their merits and their drawbacks, so that it is not possible to decide *a priori* which method should be used for a problem at hand.

If particles or ordered regions in a heterogeneous sample are large compared with the wavelength, then the reflectance has to be averaged directly according to

$$\begin{aligned} \langle R \rangle &= \sum_i f_i R_i \\ \langle T \rangle &= \sum_i f_i T_i \end{aligned} \tag{3.76}$$

where R_i and T_i are the reflectances and transmittance of the corresponding homogeneous media.

The same applies to samples that consist of one sort of particles or ordered regions if the ordered regions are anisotropic. If the ordered regions are randomly oriented, the resulting medium is optically isotropic. If the ordered regions are small compared with the wavelength, the medium can be characterized by an averaged refractive index or an averaged dielectric function. As a consequence, such a medium no longer converts linear polarized light into elliptically polarized light. Such a conversion, however, still takes place if the medium consists of large ordered regions. This can be easily verified with, for example, a microscope. If linear polarized light is used and a second polarizer oriented perpendicular to the first is employed, usually no light should be transmitted. However, since the ordered regions are large enough to be optically resolved in the microscope, they convert linear polarized into elliptically polarized light, the ellipticity depending on the dielectric tensor and the orientation of the ordered region.

In addition to the discussed deviations from the simple optical model of two semi-infinite media separated by a smooth interface, numerous further deviations are possible, for example, a quasi-continuous change of the refractive index, a

non-homogeneous layer thickness, and so on. Fairly often such aberrations lead to changes in the spectra such as band shifts and intensity and shape changes, which can easily lead to the conclusion that the sample has different properties on a molecular level compared with a reference sample. Therefore, if a spectrum is to be interpreted quantitatively, it is important to model correctly the "optical influences" in order to obtain and interpret the optical constants with regard to the molecular level.

3.6
Nonlinear Optics

3.6.1
Nonlinear Polarization

The recent progress in the development of high-intensity ultrashort lasers (see Section 3.7) made it possible to utilize nonlinear optical phenomena in microscopy to create a higher microscopic/imaging contrast. Nonlinear microscopy methods have been successfully applied for the investigation of biological samples and have revolutionized many areas of biophotonics research. Nonlinear microscopy spans a multitude of different technologies from, for example, multi-photon fluorescence microscopy to label-free methods such as the generation of the second or third harmonics and also coherent anti-Stokes Raman scattering (CARS) microscopy. The application of these nonlinear microscopy techniques opened up exciting new possibilities for studying important biomedical processes. This section aims to provide a general introduction to the basic physical principles of nonlinear light–matter interaction phenomena.

So far we have only considered the case where the polarization responds linearly to the electric field, which is the case for normal light intensities. Here an incoming electromagnetic wave induces a dipole oscillating at the same frequency ω as the exciting wave. This oscillating dipole acts as a source for the emission of a secondary wave with frequency ω, that is, it must radiate and produce light with a frequency equal to the oscillation frequency. Such linear light–matter interactions are characterized by a linear dependence between the signal intensity and the irradiating light intensity and by the fact that no new frequencies are generated in a linear regime. This linear regime has been described in Section 3.2 by a harmonic approximation where the displacement of an electron attached to a spring from its equilibrium position is considered to be small. This harmonic representation is expressed by employing Hook's law, which states that the displacement of a spring is directly proportional to the applied force. In the equilibrium the external force of the electromagnetic wave is balanced by the force of the spring. It is well known that Hook's law is no longer valid when a

large force or displacement is applied to the spring. A large oscillating force acting on the electron spring corresponds to large electric fields and thus to high light intensities. Hence for high light intensities, the electron movement becomes nonlinear and has to be described by an anharmonic potential. As a consequence, the emitted light is no longer identical with the incident light and new frequencies are generated. On illumination of matter with intense light, the polarization of a molecule is no longer linearly proportional to the applied electric field and we have to consider the polarization by a power series expansion in the applied electric field resulting in a nonlinear polarization.

The interested reader is referred to [3, 10–12] for further details.

The mathematical description of the nonlinearity between polarization $\vec{P}(t)$ and electric field strength $\vec{E}(t)$ is expressed by a power series:

$$\vec{P}(t)/\varepsilon_0 = \chi^{(1)} \cdot \vec{E}(t) + \chi^{(2)} : \vec{E}(t) \cdot \vec{E}(t) + \chi^{(3)} \vdots \vec{E}(t) \cdot \vec{E}(t) \cdot \vec{E}(t) + \ldots \qquad (3.77)$$

in which $\chi^{(i)}$ are $i+1$ rank susceptibility tensors, that is, $\chi^{(1)}$ is the linear susceptibility whereas the higher order terms $\chi^{(2)}$ (second-order susceptibility), $\chi^{(3)}$ (third-order susceptibility), and so on are the nonlinear susceptibilities. Since $|\chi^{(1)}| \gg |\chi^{(2)}| \gg |\chi^{(3)}|$, nonlinear polarization effects can be seen only for or high field strengths. The magnitude of the nonlinear susceptibility depends on the nature and symmetry of the matter and is a measure of the size of the nonlinear restoring force during the distortion of the electron cloud by the incoming light wave.

Under the assumption of a power series expansion in just one dimension (neglecting the tensor characteristics of the susceptibility and vector characteristics of the field strength), the polarization can be written as

$$P(t)/\varepsilon_0 = \chi^{(1)} \cdot E(t) + \chi^{(2)} \cdot E(t) \cdot E(t) + \chi^{(3)} \cdot E(t) \cdot E(t) \cdot E(t) + \cdots . \qquad (3.78)$$

Now we can separate the polarization $P(t)$ into a linear part $P_{\text{lin}}(t)$ and a nonlinear part $P_{\text{NL}}(t)$:

$$\begin{aligned} P_{\text{lin}}(t) &= \chi^{(1)} \cdot E(t) \\ P_{\text{NL}}(t) &= \chi^{(2)} E^2(t) + \chi^{(3)} E^3(t) + \cdots . \end{aligned} \qquad (3.79)$$

In the following we will discuss the consequences of the nonlinear polarization $P_{\text{NL}}(t)$ in light–matter interaction. We will start with a simple example and calculate the polarization with a plane wave approach, that is, inserting $E(t) = E_0 \cos \omega t$ into Equation 3.78 resulting in

$$|P(t)| = \varepsilon_0 \cdot \chi^{(1)} E_0 \cos(\omega t) + \varepsilon_0 \cdot \chi^{(2)} E_0^2 \cos^2(\omega t) + \varepsilon_0 \cdot \chi^{(3)} E_0^3 \cos^3(\omega t) + \cdots . \qquad (3.80)$$

By employing the trigonometric relations

$$\begin{aligned}\cos^2\alpha &= \frac{1}{2}(1+\cos 2\alpha)\\ \cos^3\alpha &= \frac{1}{4}(3\cos\alpha+\cos 3\alpha)\end{aligned} \tag{3.81}$$

the polarization can be rewritten as

$$\begin{aligned}|P(t)| = \varepsilon_0\chi^{(1)}E_0\cos(\omega t) + \frac{1}{2}\varepsilon_0\chi^{(2)}E_0^2[1+\cos(2\omega t)]\\ + \frac{1}{4}\varepsilon_0\chi^{(3)}E_0^3[3\cos(\omega t)+\cos(3\omega t)] + \ldots.\end{aligned} \tag{3.82}$$

It can be seen that the nonlinear terms in the expansion series of the polarization lead to polarization terms vibrating at different frequencies:

- $\chi^{(2)}$ induces a term oscillating with twice the frequency of the incoming wave 2ω and a temporally constant term called optical rectification.
- $\chi^{(3)}$ results among other terms in a polarization oscillating with the triple frequency 3ω.

In Section 3.3, we have seen that employing the linear polarization $\vec{P}_{\text{lin}}$ in $\vec{D} = \varepsilon_0\vec{E} + \vec{P}_{\text{lin}} = \varepsilon_0\varepsilon_r\vec{E} = \varepsilon\vec{E}$ as source term within the Maxwell equations leads to the irradiation of an electromagnetic wave of frequency ω. By following the same derivation as outlined in Section 3.3 (see Equations 3.23–3.26) and using the relation $\vec{D} = \varepsilon_0\vec{E} + \vec{P}_{\text{lin}} + \vec{P}_{\text{NL}} = \varepsilon_0\varepsilon_r\vec{E} = \varepsilon\vec{E}$ results in a nonlinear wave equation:

$$\frac{\partial^2\vec{E}}{\partial^2 z} - \left[\chi^{(1)}+1\right]\varepsilon_0\mu_0\frac{\partial^2\vec{E}}{\partial t^2} = \mu_0\frac{\partial^2\vec{P}_{\text{NL}}}{\partial t^2}. \tag{3.83}$$

Now we assume a medium where we have to consider only the lowest order nonlinearity, that is, $\chi^{(2)}$:

- For small electric field strength E, we can neglect P_{NL}. Thus we obtain the undisturbed propagation of an electromagnetic wave $E(z,t) = E_0\exp(i\omega t - ikz)$ according to its dispersion relation with the refractive index $n_0 = \sqrt{\chi^{(1)}+1}$ (see 3.4 + 3.6.3).
- However, if we increase the field strength $\vec{E}$, we have to consider the term $\mu_0\cdot\partial^2\vec{P}_{\text{NL}}/\partial t^2$ within the nonlinear wave Equation 3.83. If we choose a plane wave approach, $E(z,t) = E_0\exp(i\omega t - ikz)$, and assume that the field envelope E_0 varies slowly with z, we obtain

$$\mu_0\frac{\partial^2\vec{P}_{\text{NL}}}{\partial t^2} = \varepsilon_0\mu_0\chi^{(2)}\omega^2E_0^2[\exp(i2\omega t - i2kz)]. \tag{3.84}$$

The right side of Equation 3.84 contains a term oscillating with frequency 2ω. This term is responsible for the generation of light with a double frequency (half wavelength), which is called second harmonic generation (SHG) (see also

Section 3.6.2). Within the photon picture, one photon of frequency 2ω is generated from two photons of frequency ω.[10)]

Generally, the different frequency contributions of the nonlinear polarization will lead to an emission of electromagnetic waves with exactly these frequencies. The dipole moments induced under the influence of an incoming electromagnetic wave act as sources of new electromagnetic waves whose frequency spectrum is determined by that of $\vec{P} = \vec{P}_{\mathrm{lin}} + \vec{P}_{\mathrm{NL}}$.

Now we want to examine the frequency spectrum of the polarization induced by two plane waves with frequencies ω_1 and ω_2, that is

$$\text{wave 1}: \; E_1(z,t) = E_1^0 \cos(\omega_1 t - k_1 z)$$

$$\text{wave 2}: \; E_2(z,t) = E_2^0 \cos(\omega_2 t - k_2 z).$$

Superposition of both waves E_1 and E_2 in the medium and considering only the polarization at the lowest nonlinear order results in

$$P(t)/\varepsilon_0 = \chi^{(1)}(E_1 + E_2) + \chi^{(2)}(E_1 + E_2)^2 + \cdots . \tag{3.85}$$

The linear contribution of the polarization $P_{\mathrm{lin}}(t)/\varepsilon_0 = \chi^{(1)} E_1 + \chi^{(1)} E_2$ leads to two waves which will propagate independently of each other in the medium, that is, the two waves possess different propagation velocities. Now we want to evaluate the nonlinear part of the polarization, $P_{\mathrm{NL}}(t)/\varepsilon_0 = \chi^{(2)}(E_1^2 + 2E_1E_2 + E_2^2)$. By inserting the fields $E_1(z,t)$ and $E_2(z,t)$ and employing common trigonometric relations, the nonlinear polarization can be expressed by

10) Light shows the properties both of waves (electromagnetic waves) and of particles (photons). To understand its nature completely, both concepts are needed. According to the duality principle developed by de Broglie in 1923, electromagnetic radiation is both

- a current of particles named photons, which carry a measurable momentum, and
- a vibration (wave), which is a disturbance propagating in space and time carrying energy with it.

Both concepts are simultaneously needed, since it is not possible to explain all properties of light with only one model. According to de Broglie, photons have corresponding to their momentum an energy characteristic for their spectral range and the equivalent wave are characterized by

- the speed of light c, which is characteristic for all electromagnetic waves in vacuum and is given by approximately $3 \times 10^8\,\mathrm{m\,s^{-1}}$,
- the frequency ν ($\mathrm{Hz} = \mathrm{s^{-1}}$), and
- wavelength λ (m).

Between momentum p and frequency or wavelength and between energy and frequency or wavelength, the following relations hold:

$$p = \frac{h}{\lambda} = \frac{h\nu}{c}$$

$$E = h\nu = h\frac{c}{\lambda}$$

where h is the quantum of action according to Planck. Depending on the frequency of the radiation, the properties of either a wave or a particle dominate in light–matter interaction. However, in the frequency range in which we are most interested in this book, we can mostly focus on the wave properties, as these will allow us to understand most phenomena of light interaction with biological matter.

$$P_{NL}(t) = \frac{1}{2}\chi^{(2)} \cdot \begin{pmatrix} (E_1^0)^2\cos[2(\omega_1 t - k_1 z)] + \\ (E_2^0)^2\cos[2(\omega_2 t - k_2 z)] + \\ 2 \cdot E_1^0 E_2^0\{\cos[(\omega_1 + \omega_2)t - (k_1 + k_2)z]\} \\ 2 \cdot E_1^0 E_2^0\{\cos[(\omega_1 - \omega_2)t - (k_1 - k_2)z]\} \\ (E_1^0)^2 + (E_2^0)^2 \end{pmatrix} \begin{matrix} \rightarrow P_{2\omega_1}\ \text{SHG of}\ \omega_1 \\ \rightarrow P_{2\omega_2}\ \text{SHG of}\ \omega_2 \\ \rightarrow \text{Sum frequency}\ \omega_1 + \omega_2 \\ \rightarrow \text{Difference frequency}\ \omega_1 - \omega_2 \\ \rightarrow \text{Optical rectification.} \end{matrix}$$

Thus, already the first nonlinear term of the polarization leads to the emission of five different frequencies. In the next section we will see that which of these new frequency contributions is generated within the nonlinear medium with high efficiency depends on the so-called phase matching condition.

3.6.2 $\chi^{(2)}$ Processes

$\chi^{(2)}$ processes that are of significance to biophotonics are SHG (also called frequency doubling), sum frequency generation, difference frequency generation, and optical parametric generation. However, not all matter can support these kinds of nonlinear optical effects. In particular for susceptibilities of even order, such as for $\chi^{(2)}$, a very important symmetry relationship is valid: for materials possessing a center of inversion the even order susceptibilities are identically zero. This is the case for all gases, liquids, and amorphous solids. $\chi^{(2)}$ processes can be induced only in materials without inversion symmetry, such as optically anisotropic, that is, birefringence systems (see Section 3.5.3) or at the surface of a material where the inversion symmetry is always broken.

Thus, for example, SHG microscopy can be used to highlight the spatial distribution of highly ordered non-centrosymmetric structures. Collagen is the most prominent protein structure in mammalian tissue that is characterized by these prerequisites for efficient SHG. Generally, during the development of various diseases, collagen structures underlie alterations which are readily detectable by means of SHG imaging. SHG allows one to image selectively the distribution of ordered collagen.

Furthermore, $\chi^{(2)}$ processes and also many other nonlinear processes require phase matching to be efficient. Essentially this means that a proper phase relationship between the interacting waves (for optimum nonlinear frequency conversion) is maintained along the propagation direction. For phase-matched SHG, this means that a macroscopic frequency-doubled wave can be formed if the fundamental and frequency-doubled wave propagate with the same phase velocity, that is, the refractive index at the fundamental ω has to match the refractive index at the second harmonic 2ω: $n(\omega) = n(2\omega)$. This phase matching condition for $\chi^{(2)}$ processes can only be achieved in birefringence materials.

For this subsection, for further descriptions of $\chi^{(2)}$ processes [10, 13] can be used.

Let us assume that we have an isotropic medium with a center of inversion (e.g., cubic crystal or gas). If we apply an electric field in one direction, for example $+y$, the induced polarization also points in the same direction, that is, in the $+y$ direction. The application of an electric field in the opposite direction, that is, the $-y$ direction, has to lead to a polarization also pointing in the $-y$ direction. A crystal or a gas with inversion symmetry is isotropic and looks the same from all sides. This means that the respective forward and backward directions around the individual atoms are the same, that is, the material properties such as $\chi^{(1)}$ and $\chi^{(2)}$ must not be changed by space inversion, for example, $\chi^{(1)}(x,y,z) = \chi^{(1)}(-x,-y,-z)$ and $\chi^{(2)}(x,y,z) = \chi^{(2)}(-x,-y,-z)$ (see Figure 3.23).

Hence for linear polarization it follows that

$$+y \text{ direction} : P_{\text{lin}} = \chi^{(1)} E(t) \tag{3.86}$$

$$-y \text{ direction} : P_{\text{lin}} = \chi^{(1)}[-E(t)] \tag{3.87}$$

which is consistent. However, on changing the y direction from $+$ to $-$, a discrepancy for the second-order nonlinear polarization arises:

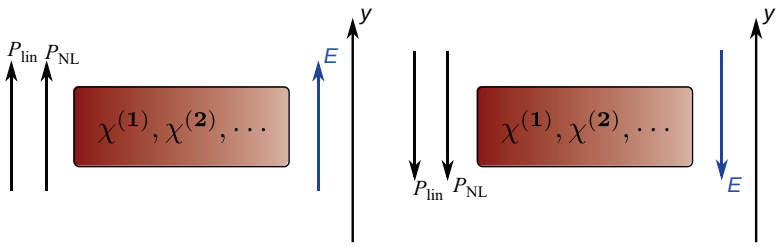
$$+y \text{ direction} : P_{\text{NL}} = \chi^{(2)} E^2(t) \tag{3.87a}$$

$$-y \text{ direction} : -P_{\text{NL}} = \chi^{(2)}[-E(t)]^2. \tag{3.87b}$$

Equation 3.87b can be only fulfilled if

- $\chi^{(2)}$ depends on the field direction ($+/-y$), which is impossible due to the center of inversion, that is, isotropic material.
- $E(t) = 0$, which represents a trivial case with no meaning for optics.
- $\chi^{(2)} = 0$.

This example shows that the second-order polarization vanishes in materials with inversion symmetry. The second-order polarization can only be induced in media without a center of inversion. Exceptions are surfaces or interfaces where the



(a) Case1: *E* field in *y* direction (b) Case 2: *E* field in −*y* direction

Figure 3.23 Illustration of vanishing $\chi^{(2)}$ for materials with center of inversion.

inversion symmetry is always broken. In general, second-order nonlinear effects (and all even-order nonlinear processes) can only be induced in materials without a symmetry center, surfaces, interfaces, or places where the symmetry is broken.

In the previous section, we have seen that the interaction of two waves with frequencies ω_1 and ω_2 leads to a second-order polarization which can oscillate at different frequencies and therefore can act as a source for the irradiation of electromagnetic waves with these different frequencies. According to these frequencies, the most important $\chi^{(2)}$ processes for biophotonics are (see also Figure 3.24):

- SHG, also called frequency doubling
- sum frequency generation
- difference frequency generation
- optical parametric generation.

Optical parametric generation (see Figure 3.24) is a special $\chi^{(2)}$ process where an incident photon of energy $\hbar\omega_1$ (called pump) is divided into two photons (called signal and idler) such that the sum of their energies $\hbar\omega_2 + \hbar\omega_3$ is equivalent to the incident photon energy $\hbar\omega_1$. More details about this process can be found further below.

These $\chi^{(2)}$ processes can be induced in materials where $\chi^{(2)} \neq 0$. However, the efficiency of a $\chi^{(2)}$ processes depends on the so-called phase matching condition. In the following, we attempt to explain this important phenomenon of nonlinear processes, phase matching condition, for the example of SHG.

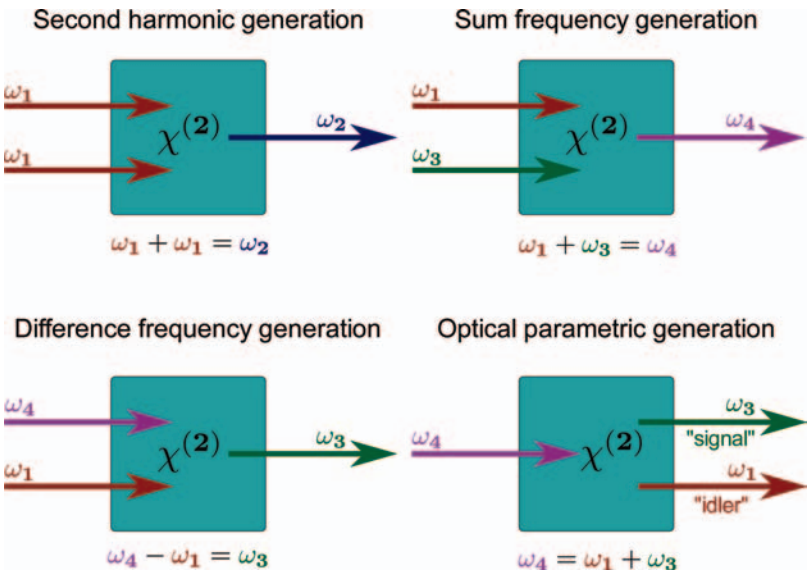


Figure 3.24 Illustration of important $\chi^{(2)}$ processes.

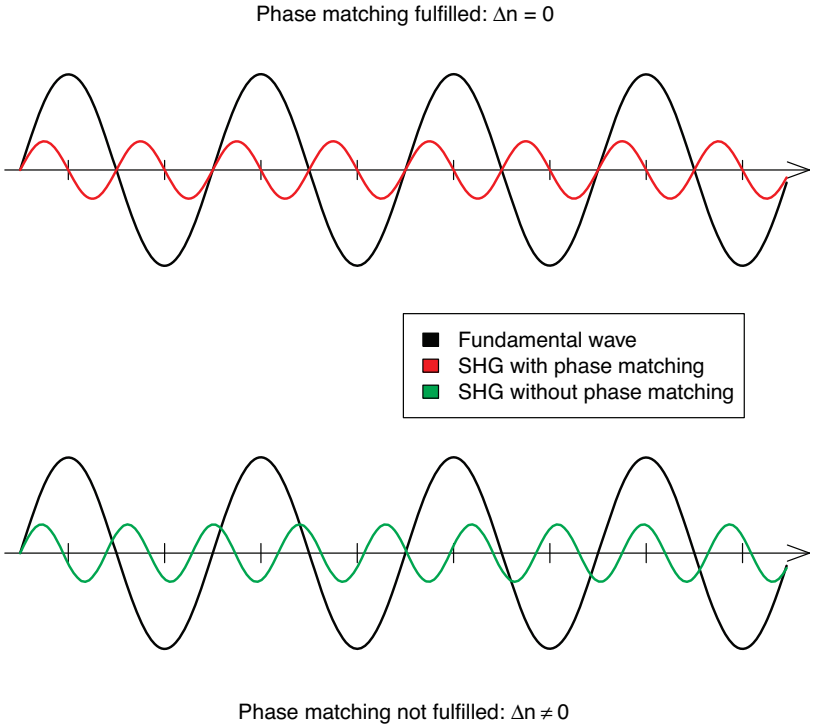

Figure 3.25 Illustration of phase-matching condition.

The incoming wave of frequency ω propagates through the $\chi^{(2)}$ medium with the phase velocity $\upsilon_{\mathrm{ph}}(\omega) = c/n(\omega)$ and generates light with the frequency 2ω anywhere in the medium. Due to dispersion, SHG light possesses a different phase velocity $\upsilon_{\mathrm{Ph}}(2\omega) = c/n(2\omega)$ than the fundamental wave. In order for a macroscopic frequency-doubled wave to build up, the fundamental and frequency-doubled wave have to propagate with the same phase velocity, that is, $n(\omega)$ must be equal to $n(2\omega)$ (see Figure 3.25).

Light at 2ω generated at the beginning of the material initially constructively interferes with light further inside the material, therefore increasing the overall intensity at 2ω. However, after a certain distance, l_{Ph} = coherence length, the light generation takes place out-of-phase and the SHG intensity decreases. The SHG intensity varies as a function of the propagating distance z within the material

$$I_{2\omega}(z) \sim \mathrm{sinc}^2\left(\frac{\pi z}{l_{Ph}}\right) \cdot z^2 \text{ with } l_{Ph} = \frac{\lambda_0}{2(n(\omega) - n(2\omega))}. \tag{3.88}$$

The sinc function is defined by $\mathrm{sinc}\,(x) = \sin x/x$ and has its maximum for $x = 0 : \mathrm{sinc}(0) = 1$. This means that in order to generate SHG light at 2ω efficiently, it has to be guaranteed that the SHG generation proceeds with phase matching, that

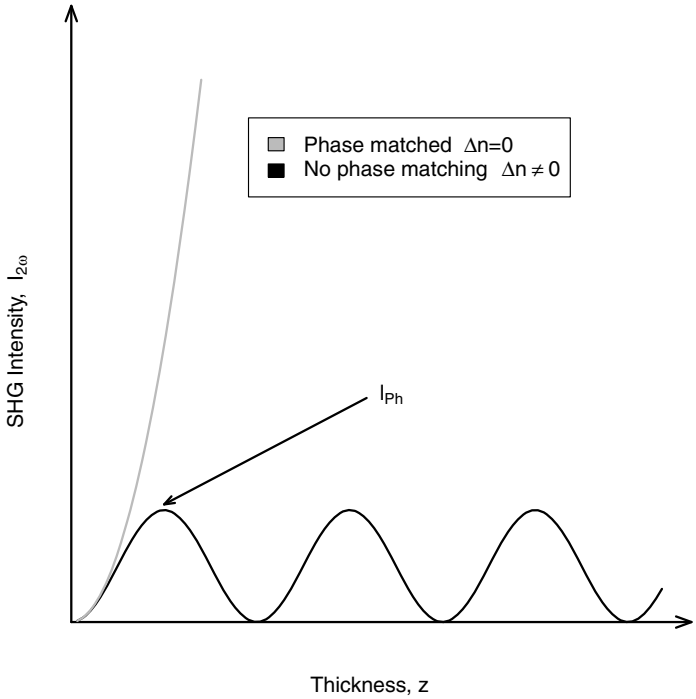

Figure 3.26 SHG intensity $I_{2\omega}$ as a function or material thickness for phase-matched ($\Delta n = 0$) and non-phase-matched ($\Delta n \neq 0$) conditions.

is, $\Delta n = n(\omega) - n(2\omega) = 0$ or $n(\omega) = n(2\omega)$. Figure 3.26 shows the SHG intensity as a function of the material thickness z for phase-matched and non-phase-matched conditions. It can be seen that if phase matching is fulfilled ($\Delta n = 0$), the SHG intensity increases quadratically with z. For non-phase-matched conditions ($\Delta n \neq 0$), the SHG intensity oscillates with the coherence length, $2l_{\mathrm{Ph}}$.

The phase matching condition $n(\omega) = n(2\omega)$ can be also seen as photon momentum conservation, that is, the momentum $\vec{k}$ of two photons of frequency ω("two red photons in") must be equal to the momentum $\vec{k}$ of one photon of frequency 2ω ("one blue photon out"):

$$\vec{k}(\omega) + \vec{k}(\omega) = \vec{k}(2\omega). \tag{3.89}$$

Equation 3.89 can be derived from Equation 3.35 by employing the phase matching condition $n(\omega) = n(2\omega)$. However, we have seen in Section 3.4 that normal dispersion prevents $n(\omega) = n(2\omega)$ from ever happening (see also Figure 3.27), hence special materials are needed to ensure phase matching. In Section 3.5.3 we learned that a wave, upon entering an anisotropic medium, decomposes into two waves with mutual perpendicular polarization directions and traveling with different velocities. In particular it is interesting to induce the $\chi^{(2)}$ processes depicted in Figure 3.24 for optically uniaxial crystals exhibiting two polarization directions:

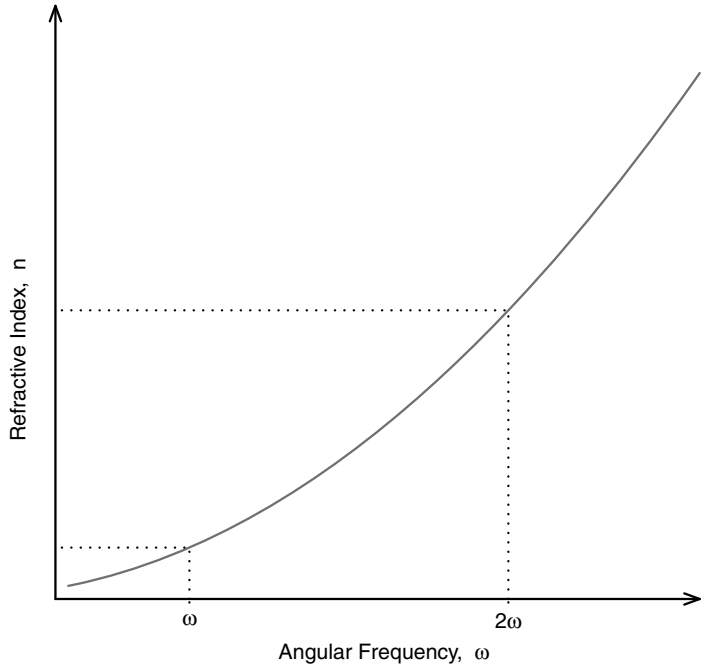

Figure 3.27 Normal dispersion curve.

- ordinary wave experiencing a refractive index n_o and obeying Snell's law (see Equation 3.52)
- extraordinary wave with a refractive index n_e depending on the angle ϑ between the direction of the wave and the z-axis, which is called the optical axis (see Equation 3.73).

Thus, uniaxial crystals can be used to ensure phase matching if for a wavelength λ and a certain direction ϑ the extraordinary refractive index $n_e(2\omega)$ for the SHG wave is equal to the ordinary one $n_o(\omega)$ for the fundamental wave. This means that for a fundamental wave with a propagation direction ϑ the phase matching condition for an SHG process $n_o(\omega) = n_e(2\omega)$ is achieved and a macroscopic SHG wave of frequency 2ω can build up (see Figure 3.28).

Since n_e depends on the propagation angle ϑ (see Figure 3.28a), by rotating the optical uniaxial crystal we can tune the phase matching condition precisely by moving the blue dispersion curve in Figure 3.28 up and down relative to the red curve. The phase matching conditions for the other $\chi^{(2)}$ processes depicted in Figure 3.24 are

- sum frequency generation: $k_4(\omega_4) = k_1(\omega_1) + k_3(\omega_3)$
- Difference frequency generation: $k_3(\omega_3) = k_4(\omega_4) - k_1(\omega_1)$
- Optical parametric generation: $k_4(\omega_4) = k_1(\omega_1) + k_3(\omega_3) = k_{\text{idler}} + k_{\text{signal}}$.

Technically relevant uniaxial crystals with large $\chi^{(2)}$-values are as follows:

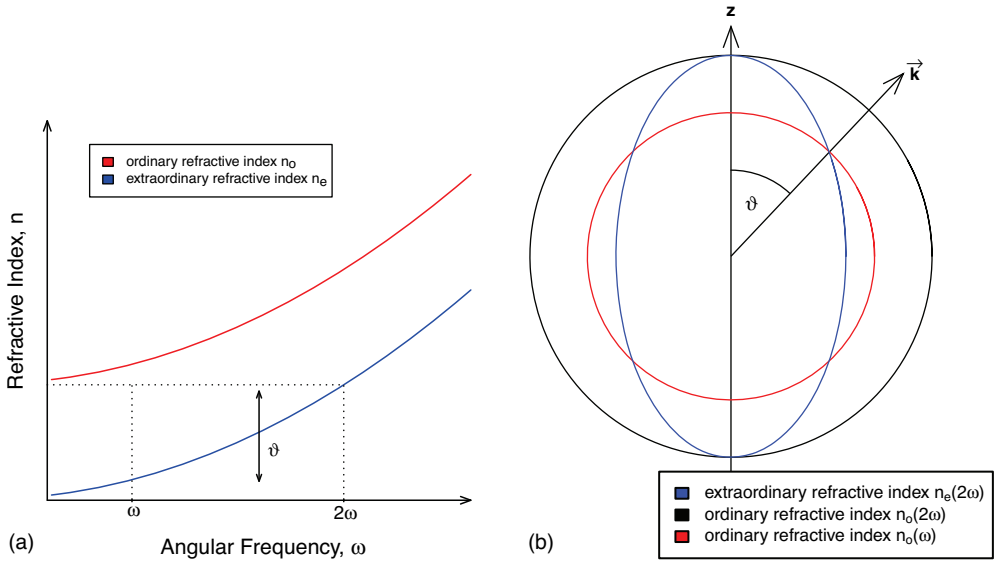

Figure 3.28 Phase matching in an optical uniaxial crystal. (a) Refractive index, ellipsoid, n_0 and $n_e(\theta)$ (adapted from [14]).

- KDP: potassium dihydrogenphosphate ($K_2H_2PO_4$)
- KD*P: potassium dideuteriumphosphate ($K_2D_2PO_4$)
- ADP: ammonium dihydrogenphosphate
- $LiNbO_3$: lithium niobate
- BBO: β-barium borate
- $AgGaS_2$: silver thiogallate.

These crystals can be used to induce all the $\chi^{(2)}$ frequency conversion processes sketched in Figure 3.24. By selecting the appropriate input beam or beams and by adjusting the required phase matching condition, a selective enhancement of one particular process is achieved. For optical parametric generation, a pump photon is divided into two photons by interaction with the crystal, that is, light with ordinary and extraordinary polarizations is generated. The ordinary polarized light is called the signal and the extraordinary light is called idler. The wavelength of signal and idler pulses is determined by the phase matching condition, which is changed by the angle ϑ between the pump light and the optical axis z of the crystal. Hence the wavelength of the signal and idler waves can be tuned by varying ϑ, that is, changing the phase matching condition. The signal and idler light can subsequently be frequency doubled or used for sum and difference frequency generation. Hence a wide range of different frequencies (wavelengths) can be generated by the above-mentioned $\chi^{(2)}$ frequency conversion crystals.

3.6.3 $\chi^{(3)}$ Processes

$\chi^{(3)}$ processes that are of particular relevance for biophotonics are two-photon absorption and the nonlinear Raman techniques stimulated Raman scattering (SRS) and CARS. $\chi^{(3)}$ phenomena, in contrast to $\chi^{(2)}$ processes, can be induced in all materials. As for $\chi^{(2)}$ processes, energy and momentum conservation (phase matching) must be also fulfilled for $\chi^{(3)}$ phenomena. In the following, we focus in particular on two-photon absorption, which is a consequence of the nonlinear refractive index (CARS and SRS will be treated in detail in Section 3.13). For sufficiently high intensities I, the refractive index contains, in addition to the linear dispersion term $n_0(\omega)$, also a nonlinear term $n_2(\omega)$, that is, $n(\omega, I) = n_0(\omega) + n_2(\omega)I$. The intensity-dependent refractive index $n_2(\omega)$ is determined by $\chi^{(3)}$ and is also a complex function like the linear dispersion term $n_0(\omega)$. The imaginary part of the nonlinear refractive index describes the two-photon absorption, which depends linearly on intensity. The real part of $n_2(\omega)$ is responsible for the nonlinear optical effects of self-focusing and self-phase modulation.

This section provides a general introduction to $\chi^{(3)}$ processes. The interested reader is referred to [10, 13].

Equation 3.82 reveals that the third-order polarization $P^{(3)}(t)$, that is, the terms of the power series expansion of the polarization depending on $\chi^{(3)}$ can be written as

$$\begin{aligned} \left|P^{(3)}(t)\right| &= \frac{1}{4}\varepsilon_0\chi^{(3)}E_0^3[3\cos(\omega t) + \cos(3\omega t)] \\ &= \frac{3}{4}\varepsilon_0\chi^{(3)}E_0^3\cos(\omega t) + \frac{1}{4}\varepsilon_0\chi^{(3)}E_0^3\cos(3\omega t). \end{aligned} \tag{3.90}$$

Then the third-order nonlinear wave equation appears as (see Section 3.6.1)

$$\mu_0\frac{\partial^2\vec{P}^{(3)}}{\partial t^2} = \frac{9}{8}\varepsilon_0\mu_0\chi^{(3)}\omega^2E_0^3\exp(i3\omega t - i3kz) + \frac{3}{8}\varepsilon_0\chi^{(3)}\omega^2E_0^3\exp(i\omega t - ikz). \tag{3.91}$$

Here the first part describes the third harmonic generation (THG) in analogy with the second harmonic generation (SHG) discussed above (see also Equation 3.84). However, in the following we focus on the second term of the right-hand side of Equation 3.91, which leads to an intensity-dependent refractive index. For the derivation of the intensity-dependent refractive index, we consider exclusively the terms of the polarization (see Equation 3.82) oscillating on ω:

$$\begin{aligned} |P(t)| &= \varepsilon_0\chi^{(1)}E_0\cos(\omega t) + \frac{3}{4}\varepsilon_0\chi^{(3)}E_0^3\cos(\omega t) \\ &= \varepsilon_0E_0\cos(\omega t)\left[\chi^{(1)} + \frac{3}{4}\chi^{(3)}E_0^2\right]. \end{aligned} \tag{3.92}$$

Now we follow the same procedure as outlined in Section 3.3 (Equations 3.23 – 3.30). This involves differentiation of the left- and right-hand sides of the Maxwell Equation 3.26 with respect to time, employing Maxwell Equation 3.25 to replace $\partial\vec{B}/\partial t$, replacing $\vec{D}$ by using $\vec{D} = \varepsilon_0\varepsilon_r\vec{E}$ and using Maxwell Equation 3.23 taking into account that for nonconducting materials $\rho = 0$, resulting in the following equation:

$$\Delta\vec{E} = \mu_0 \frac{\partial^2 \vec{D}}{\partial t^2} \tag{3.93}$$

Now we replace $\vec{D}$ by $\vec{D} = \varepsilon_0\vec{E} + \vec{P}$

$$\Delta\vec{E} = \mu_0 \left(\varepsilon_0 \frac{\partial^2 \vec{E}}{\partial t^2} + \frac{\partial^2 \vec{P}}{\partial t^2} \right) \tag{3.94}$$

and employ for the polarization Equation 3.92

$$\Delta\vec{E} = \mu_0\varepsilon_0 \left\{ 1 + \left[\chi^{(1)} + \frac{3}{4}\chi^{(3)} E_0^2 \right] \right\} \frac{\partial^2 \vec{E}}{\partial t^2}. \tag{3.95}$$

In Section 3.3 we have seen that equations where the second derivative of a quantity with respect to position is linked to its second derivative with respect to time have wave character. Thus Equation 3.95 is a wave equation with a velocity υ given by (see also Equation 3.31)

$$\upsilon = \frac{1}{\sqrt{1 + \chi^{(1)} + \frac{3}{4}\chi^{(3)} E_0^2}} \cdot c \tag{3.96}$$

where we used the relation $c = 1/\sqrt{\varepsilon_0\mu_0}$. From Equation 3.3, we know that the velocity of an electromagnetic wave inside a medium is given by $\upsilon = c/n$. Therefore, when considering the third-order nonlinear term of the polarization oscillating with frequency ω (see Equation 3.92), the refractive index n yields

$$n = \sqrt{1 + \chi^{(1)} + \frac{3}{4}\chi^{(3)} E_0^2}. \tag{3.97}$$

With $\chi^{(1)} = \varepsilon_r - 1$ and $n_0 = \sqrt{\varepsilon_r}$, it follows that the linear refractive index is given by $n_0^2 = \chi(\omega) + 1$. Hence we obtain for the refractive index n (Equation 3.97)

$$n = \sqrt{n_0^2 + \frac{3}{4}\chi^{(3)} E_0^2}. \tag{3.98}$$

Expanding the square root to first order yields

$$n = n_0 + \frac{\frac{3}{4}\chi^{(3)} E_0^2}{2n_0}. \tag{3.99}$$

The light intensity of a plane wave with linear polarization $E(t) = E_0 \cos \omega t$ is given by

$$I = \frac{1}{2}\varepsilon_0 n_0 c|E_0|^2. \tag{3.100}$$

Hence inserting Equation 3.100 into Equation 3.99 yields

$$n(\omega, I) = n_0 + \frac{3\chi^{(3)}}{4n_0^2\varepsilon_0 c} \cdot I. \tag{3.101}$$

Equation 3.101 shows that for sufficiently high intensities the refractive index contains, in addition to the linear dispersion term $n_0(\omega)$, also a nonlinear part $n_2(\omega)I$ that cannot be neglected:

$$n(\omega, I) = n_0(\omega) + n_2(\omega) \cdot I \quad \text{with} \quad n_2(\omega) = \frac{3\chi^{(3)}}{4n_0^2\varepsilon_0 c}. \tag{3.102}$$

If other higher order nonlinear polarization terms of odd order are also considered, the refractive index can be expressed by

$$n(\omega, I) = n_0(\omega) + n_2(\omega) \cdot I + n_3(\omega)I^2 + \cdots. \tag{3.103}$$

The linear refractive index n_0 refers to $\chi^{(1)}$ and is independent of the intensity. The nonlinear refractive indices n_2 and n_3 are related to $\chi^{(3)}$ and $\chi^{(5)}$, respectively, and depend on the incident intensity.

In the following, the influence of the nonlinear refractive index on light–matter interaction leading to important processes, the optical Kerr effect and two-photon absorption, will be discussed in more detail.

3.6.3.1 Optical Kerr Effect

Let us assume the interaction of a laser beam with a Gaussian intensity profile along the y-axis of sufficiently high intensity with a $\chi^{(3)}$) medium (see Figure 3.29).

The spatial intensity distribution of a Gaussian laser beam leads to a spatial variation of the refractive index over the beam profile within the medium. At the beam edges, where the light intensity is low, the refractive index is small. However, at the center of the light beam, where the intensity is highest, the refractive index is much larger than at the edges. This effect that an intense light pulse, when traveling in a medium, induces a varying refractive index of the medium is called the optical Kerr effect. The larger refractive index in the center as compared with the edges of the light beam leads to retardation of the light propagation. In other words, the wavefront is bent and delayed substantially in the center part of the wavefront, which means that the laser beam is being focused (see Figure 3.29). This phenomenon where a medium, whose refractive index increases with the electric field intensity, acts as a focusing lens for an electromagnetic wave is called Kerr-induced self-focusing. Self-focusing is often observed when radiation generated by femtosecond lasers (see Section 3.7) propagates through many solids, liquids, and gases.

A second effect that has its origin in the nonlinear refractive index is self-phase modulation. As we will see in Section 3.7, ultrashort laser pulses exhibit a broad frequency spectrum. We have seen above that the optical Kerr effect induces a varying

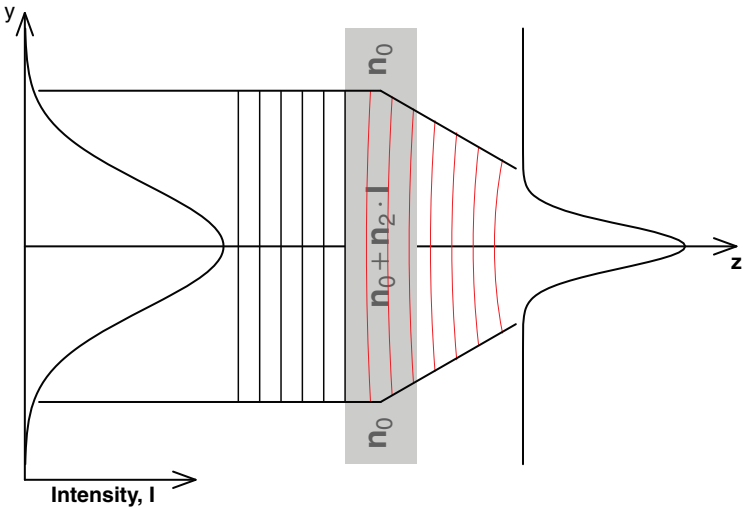

Figure 3.29 Illustration of Kerr-induced self-focusing: spatial intensity profile of a pulse traveling through a $\chi^{(3)}$ medium (adapted from [4]).

spatial refractive index distribution within a medium through which the ultrashort pulse is traveling. This variation in refractive index will produce a phase shift in the pulse, leading to a change of the pulse's frequency spectrum. The nonlinearity of the refractive index acts via the wavenumber $k = 2\pi n/\lambda$ on the phase of the light pulses. The field distribution of a Gaussian light pulse at position z in the medium can be expressed by

$$E(z,t) = E_0(t)\cos(-\varphi[t,z]) \quad \text{with} \quad \varphi[t,z] = -\omega_0 t + k \cdot z. \tag{3.104}$$

With $k = 2\pi n/\lambda$ and the intensity-dependent nonlinear refractive index $n = n_0 + n_2 \cdot I$, it follows for the phase:

$$\varphi[t,z] = -\omega_0 t + \left[\frac{2\pi n_2 I(t)}{\lambda_0} + \frac{2\pi n_0}{\lambda_0}\right] \cdot z. \tag{3.105}$$

This phase $\varphi[t,z]$ results in an instantaneous frequency $\omega(t)$:

$$\omega(t) = -\frac{\partial\varphi[t,z]}{\partial t} = \omega_0 - \frac{2\pi n_2 z}{\lambda_0} \cdot \frac{\partial I(t)}{\partial t} \tag{3.106}$$

leading to a frequency shift of

$$\delta\omega(t) = \omega(t) - \omega_0 = -\frac{2\pi n_2 z}{\lambda_0} \cdot \frac{\partial I(t)}{\partial t}. \tag{3.107}$$

Equation 3.107 shows that for the leading edge of the pulse ($\partial I/\partial t > 0$), the frequency is shifted to lower frequencies ("redder" wavelengths) whereas for the trailing edge of the pulse ($\partial I/\partial t < 0$), the frequency shifts to higher frequencies ("bluer") (see Figure 3.30). Hence the spectral profile of the pulse is increased. Such

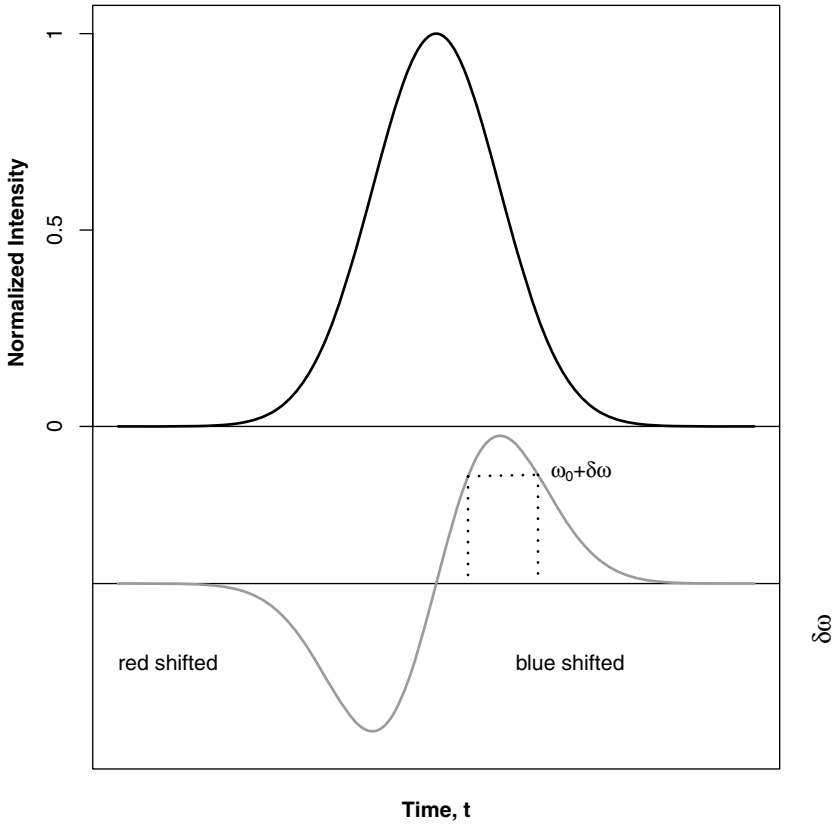

Figure 3.30 Illustration of self-phase modulation (SPM): the temporal intensity profile of the pulse is shown. Ultrashort laser pulse (top) traveling through a $\chi^{(3)}$ medium experiences a frequency shift $\delta\omega(t)$ because of SPM: the front of the pulse is shifted to lower frequencies whereas the back shifts to higher frequencies. The frequency shift within the center of the pulse is almost linear (adapted from [4]).

a generation of new frequencies by the optical Kerr effect is called self-phase modulation (SPM). The extra frequencies generated by the SPM broaden the spectrum of the pulse symmetrically. This spectral broadening is often utilized for the generation of ultrashort laser pulses or so-called coherent white light continua, which are very important for the realization of innovative nonlinear microscopic approaches discussed throughout this book.

3.6.3.2 **Two-Photon Absorption**

In Sections 3.2 and 3.4, it has been shown that the susceptibility and also the refractive index are complex quantities. This is also the case, of course, for the nonlinear susceptibilities and refractive indices. This means that $\chi^{(3)}$ and also the nonlinear refractive index can be separated into real and imaginary parts:

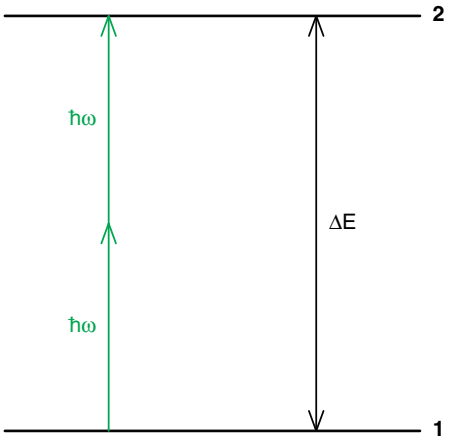

Figure 3.31 Illustration of two-photon absorption.

$$\chi^{(3)} = \chi_R^{(3)} + i\chi_I^{(3)}. \tag{3.108}$$

The real part of the third-order nonlinear susceptibility $\chi_R^{(3)}$ is responsible for the optical Kerr effect described above whereas the imaginary part $\chi_I^{(3)}$ is responsible for the two-photon absorption, which will be discussed in the following.

Two-photon absorption describes the simultaneous absorption of two photons by molecules to reach an excited state.[11)] Thereby the energies of the involved lower, 1, and upper, 2, molecular states are equal to the sum of the energies of the two photons: $\Delta E = E_2 - E_1 = 2 \cdot \hbar\omega$ (see Figure 3.31). Two-photon absorption is several orders of magnitude weaker than linear absorption.

The light attenuation for a two-photon absorption as the wave travels along the z-direction can be expressed by (see Equation 3.38 for one-photon absorption)

$$\frac{dI}{dz} = -\alpha_{2\omega} I^2 \tag{3.109}$$

where $\alpha_{2\omega}$ is the two-photon absorption coefficient

11) Section 3.4 reports the classical description of light absorption where we have seen that the imaginary part of the refractive index κ (called absorption index) causes an electromagnetic wave to weaken as a consequence of the damping of the vibrations of electrons against the core inside the medium. This description was based on the simple atomic picture known as the Lorentz atom. However, quantum mechanics associates with molecules discrete quantized energy levels (see Chapter 2). Later, in Sections 3.8 and 3.9, it will be shown that if the quantum energy of a photon matches the energy gap between two energy levels, the photon can elevate the molecular system from a lower to a higher state, that is, the transition between two molecular states is induced by the absorption of a photon.

$$\alpha_{2\omega} = \frac{3\omega\chi_I^{(3)}}{2\varepsilon_0 c^2 n_0^2(\omega)}. \tag{3.110}$$

In general, the simultaneous absorption of more than one photon is called multi-photon absorption. Thereby the imaginary parts of the nonlinear refractive indices n_2, $n_3, \ldots$ (see Equation 3.103), which depend on the nonlinear susceptibilities of odd order, are responsible for these multi-photon absorption processes, that is, for example, a three-photon absorption is described by the imaginary part of $\chi^{(5)}$. Since multi-photon processes require high excitation intensities, pulsed laser sources with high peak powers, such as femtosecond titanium–sapphire lasers (see Section 3.7), are required. The possibility of exploiting multi-photon absorption in multi-photon microscopy has attracted a great deal of interest across all fields of biophotonics. As we will see throughout this book, multi-photon microscopy has evolved from a photonic novelty into an indispensable tool in biological and biomedical research.

3.6.3.3 Other $\chi^{(3)}$ Processes

In addition to the optical Kerr effect and two-photon absorption, many other $\chi^{(3)}$ processes exist. This can be easily seen by analyzing the third-order polarization $P^{(3)}$ induced in a $\chi^{(3)}$ medium by three plane waves with the frequencies ω_1, ω_2, and ω_3:

$$\begin{aligned} P^{(3)}(t)/\varepsilon_0 &= \chi^{(3)}[E_1(t) + E_2(t) + E_3(t)]^3 \\ &= \chi^{(3)}\Big[E_1(t)^3 + E_2(t)^3 + E_3(t)^3 \\ &\quad + 3E_1(t)E_2(t)^2 + 3E_1(t)E_3(t)^2 + 3E_1(t)^2E_2(t) + 3E_1(t)^2E_3(t) \\ &\quad + 6E_1(t)E_2(t)E_3(t) + 3E_2(t)E_3(t)^2 + 3E_2(t)^2E_3(t)]. \end{aligned} \tag{3.111}$$

If we insert the three plane wave equations

$$\begin{aligned} E_1(t) &= E_1^0 \cos\omega_1 t, \\ E_2(t) &= E_2^0 \cos\omega_2 t, \\ E_3(t) &= E_3^0 \cos\omega_3 t \end{aligned}$$

and apply common trigonometric relations, the third-order polarization can be expressed by

$$\begin{aligned} P(t)^{(3)}/\varepsilon_0 = {} & P(\omega_1) + P(\omega_2) + P(\omega_3) \\ & + P(3\omega_1) + P(3\omega_2) - P(3\omega_3) \\ & + P(\omega_1 + \omega_2 + \omega_3) + P(\omega_1 + \omega_2 - \omega_3) \\ & + P(\omega_1 + \omega_3 - \omega_2) + P(\omega_2 + \omega_3 - \omega_1) \\ & + P(2\omega_2 \pm \omega_1) + P(2\omega_3 \pm \omega_1) + P(2\omega_1 \pm \omega_2) \\ & + P(2\omega_1 \pm \omega_3) + P(2\omega_3 \pm \omega_2) + P(2\omega_2 \pm \omega_3) \end{aligned} \tag{3.112}$$

with

$$
\begin{aligned}
P(\omega_1) &= \chi^{(3)}\left(\frac{3}{4}(E_1^0)^2+\frac{3}{2}(E_2^0)^2+\frac{3}{2}(E_3^0)^2\right)E_1^0\cos\omega_1 t\\
P(\omega_2) &= \chi^{(3)}\left(\frac{3}{4}(E_2^0)^2+\frac{3}{2}(E_1^0)^2+\frac{3}{2}(E_3^0)^2\right)E_2^0\cos\omega_2 t\\
P(\omega_3) &= \chi^{(3)}\left(\frac{3}{4}(E_3^0)^2+\frac{3}{2}(E_1^0)^2+\frac{3}{2}(E_2^0)^2\right)E_3^0\cos\omega_3 t\\
P(3\omega_1) &= \frac{1}{4}\chi^{(3)}(E_1^0)^3\cos 3\omega_1 t\\
P(3\omega_2) &= \frac{1}{4}\chi^{(3)}(E_2^0)^3\cos 3\omega_2 t\\
P(3\omega_3) &= \frac{1}{4}\chi^{(3)}(E_3^0)^3\cos 3\omega_3 t\\
P(\omega_1+\omega_2+\omega_3) &= \frac{6}{4}\chi^{(3)}E_1^0E_2^0E_3^0\cos(\omega_1+\omega_2+\omega_3)t\\
P(\omega_1+\omega_2-\omega_3) &= \frac{6}{4}\chi^{(3)}E_1^0E_2^0E_3^0\cos(\omega_1+\omega_2-\omega_3)t\\
P(\omega_1+\omega_3-\omega_2) &= \frac{6}{4}\chi^{(3)}E_1^0E_2^0E_3^0\cos(\omega_1+\omega_3-\omega_2)t\\
P(\omega_2+\omega_3-\omega_1) &= \frac{6}{4}\chi^{(3)}E_1^0E_2^0E_3^0\cos(\omega_2+\omega_3-\omega_1)t\\
P(2\omega_2\pm\omega_1) &= \frac{3}{4}\chi^{(3)}(E_2^0)^2E_1^0\cos(2\omega_2\pm\omega_1)t\\
P(2\omega_3\pm\omega_1) &= \frac{3}{4}\chi^{(3)}(E_3^0)^2E_1^0\cos(2\omega_3\pm\omega_1)t\\
P(2\omega_1\pm\omega_2) &= \frac{3}{4}\chi^{(3)}(E_1^0)^2E_2^0\cos(2\omega_1\pm\omega_2)t\\
P(2\omega_1\pm\omega_3) &= \frac{3}{4}\chi^{(3)}(E_1^0)^2E_3^0\cos(2\omega_1\pm\omega_3)t\\
P(2\omega_3\pm\omega_2) &= \frac{3}{4}\chi^{(3)}(E_3^0)^2E_2^0\cos(2\omega_3\pm\omega_2)t\\
P(2\omega_2\pm\omega_3) &= \frac{3}{4}\chi^{(3)}(E_2^0)^2E_3^0\cos(2\omega_2\pm\omega_3)t\,.
\end{aligned}
\tag{3.113}
$$

It can be seen that many different frequencies can be generated by $\chi^{(3)}$ processes. It is important to note that these processes can be induced in all materials since for $\chi^{(3)}$

phenomena no symmetry restrictions have to be fulfilled. However, the efficiency of these $\chi^{(3)}$ processes depends on the different phase matching conditions for every single frequency component. In Section 3.11 we will discuss with SRS and CARS two other important $\chi^{(3)}$ process for biophotonics.

3.7 Lasers

Modern biophotonic research is unthinkable without lasers. In particular, the development of ultrashort laser pulse sources revolutionized the microscopy sector by utilizing nonlinear optical phenomena as described in Section 3.6. These ultrashort lasers allow a moderate amount of energy to be generated within an extremely short time scale (pico- or femtoseconds). These ultrashort laser pulses can be focused down to generate extremely high light intensities.

The laser (light amplification by stimulated emission of radiation) is based on a process called stimulated emission, which occurs only in materials (so-called active media or gain media) that have quantum states in which a state with higher energy can become much more populated than a corresponding lower energy state. In this way, the emission occurs in a coordinated way in many atoms or molecules. Lasers are usually classified according to the nature of the active medium, that is, the medium that gives rise to the amplification of radiation by stimulated emission (gas, liquid, solid, photonic crystal, fiber).

This section aims to provide a short introduction to the basic principles of lasers with special emphasis on the generation of ultrashort laser pulses. Detailed information can be found in [14–16].

A laser is an apparatus which emits light by a process called stimulated emission. What renders the light of a laser so extraordinary is its unique properties:

1) Light from a laser is usually nearly monochromatic, which means that it has a very narrow wavelength spectrum, in contrast to white light or so-called blackbody radiation, which always consists of a very broad spectrum.
2) Laser light consists of a very narrow beam with a low beam divergence, meaning that the beam has a minimal tendency to spread while traveling through a (non-scattering) medium.
3) Laser light can reach a very high spectral energy density, which renders it a very valuable tool to investigate intrinsically weak processes such as Ramam scattering (see Section 3.13).
4) The individual waves possess a high temporal and spatial coherence, meaning that they are in-phase (see Figure 3.32) when they are emitted and even after some time due to their narrow wavelength spectrum. The propagation distance from a laser where the emitted wave maintains coherence, that is, a well-defined

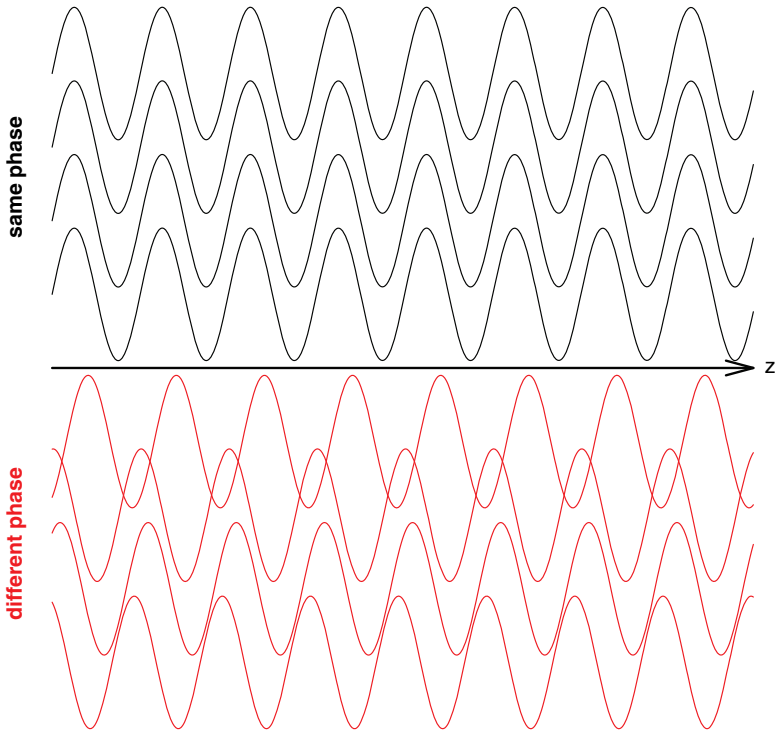

Figure 3.32 Sine waves that possess the same as compared with sine waves with different phase.

phase relation, is called coherence length. Within the coherence length the emitted light waves can interfere with each other.

To understand the lasing principle, it is necessary to investigate the connection between the processes absorption, induced emission, and spontaneous emission (note that absorption is always induced, therefore this is omitted from the term). Figure 3.33 illustrates these processes. In the case of absorption, a photon induces an atom or a molecule to step up from a ground state 1 to an excited state 2 (note that the photon must be of the same energy as the difference between the states 1 and 2, that is, $\Delta E = E_2 - E_1 = h\nu$). If the molecule is already in an excited state, there are two possibilities: either another photon of the same energy induces the molecule to fall back to the ground state by emitting a second photon, or the emission of a photon can be spontaneous. The spontaneous process is therefore obviously not dependent on the spectral energy density ρ of the electromagnetic field (see Figure 3.33) at the place where the molecule is sited. N_1 and N_2 represent the population density (of atoms or molecules) in the energy states 1 and 2 and B_{12}, B_{21}, and A_{21} are the so-called Einstein coefficients, which are a probability measure of the particular transition.

The precondition for laser activity is a population inversion: in thermodynamic equilibrium, the ground or energetically lower state is stronger occupied than its

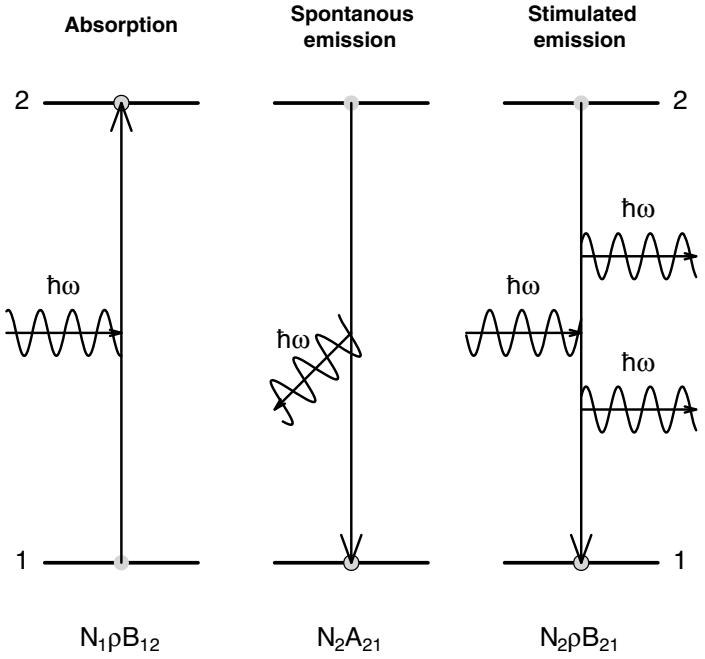

Figure 3.33 Illustration of absorption and induced and spontaneous emission.

energetically higher pendant according to Boltzmann if the degree of degeneracy g_i equals unity:

$$\frac{N_1}{N_2} = \frac{g_1}{g_2}\frac{\exp\left(-\frac{E_1}{kT}\right)}{\exp\left(-\frac{E_2}{kT}\right)} = \frac{g_1}{g_2}\exp\left(-\frac{\Delta E}{kT}\right) = \frac{g_1}{g_2}\exp\left(-\frac{h\nu}{kT}\right) \tag{3.114}$$

where, k denotes Boltzmann's constant and T represents the thermodynamic temperature. The energy difference between states 1 and 2 equals the photon energy $h\nu$. A laser is possible only if a population inversion can be caused by a pumping process so that the population of an excited state is higher than that of a ground state. This cannot be realized by optical pumping within two-state systems. Instead, a system with at least three or four states is necessary (see Figure 3.34). In the system displayed in Figure 3.34, the time constant A_{32} for a change from state 3 to 2 is much higher than that for a change from state 3 to the ground state 0 A_{30}. Therefore, most entities will use the right path. As, on the other hand, the transition from state 2 to 1 is slow, an inversion of the population will be established. If it is possible to preserve this inversion, then a continuous beam will be permanently intensified (continuous wave operation). Otherwise, an intensification can be achieved for only a short time, resulting in a pulsed operation mode which will also sometimes be desirable (e.g., for ablation of material).

To obtain as strong an inversion as possible, it is of advantage if state 2 in the system displayed in Figure 3.34 is depopulated only by induced emission and not by

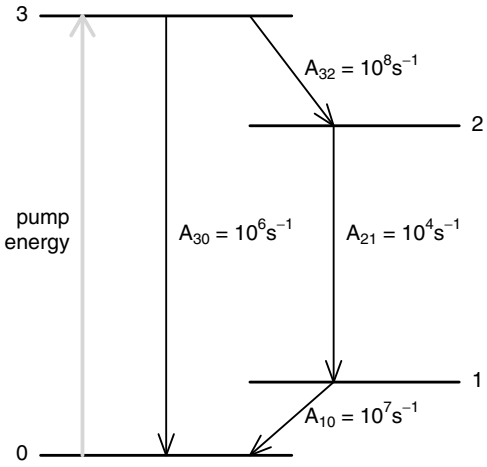

Figure 3.34 Four-state energy level diagram to achieve population inversion.

spontaneous emission or nonradiative processes. On the other hand, it is desirable if N_1 remains small, meaning that state 1 should be depopulated as fast as possible.

Most lasers are composed of the following three components: (1) an active medium (gain medium), (2) a means to deliver energy to the gain medium (energy medium), and (3) a highly reflecting optical cavity (resonator). The active medium is placed inside the resonator, which consists of a tube of length L with two highly reflecting mirrors at each end (see Figure 3.35). The resonator forms a standing wave cavity resonator for light waves. The resonator modes of a laser are characterized by radiation patterns which are reproduced on every round-trip of light in the resonator cavity. Two types of resonator modes exist: (1) longitudinal modes and (2) transverse modes. Longitudinal modes are axial standing waves and correspond to the wavelength of the wave. The frequency distance between two adjacent longitudinal modes q and $q+1$ (axial mode distance) is given by $\Delta\nu = c/2L$. Transverse modes are modes

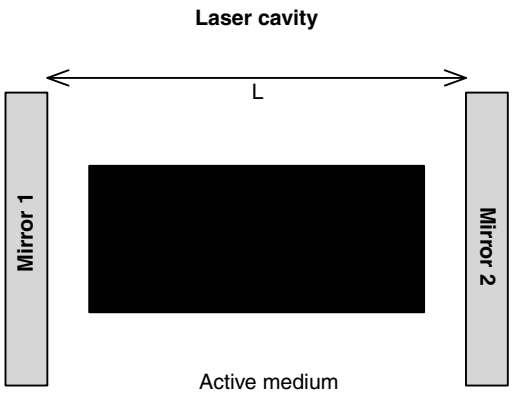

Figure 3.35 Active medium and resonator.

vibrating perpendicular to the long laser axis and are expressed by TEM_{mnq} where m and n are the number of nodes in the two directions perpendicular to the longitudinal optical axis and q is the longitudinal mode number. This means that for every transverse mode many longitudinal modes can exist. Transverse modes are determined by the geometry of the laser resonator. The TEM_{00} mode, for example, exhibits a Gaussian beam shape with its maximum intensity in the center of the beam. This TEM_{00} mode can be selected by placing an appropriately sized aperture in the laser cavity.

The lowest frequency ($q = 1$) is called the fundamental frequency. In the case of a laser it is not desirable that the power is distributed over all possible frequencies. Instead, the laser resonator is designed in such a way that the radiation energy will be concentrated in only a few modes (ideally only one, Figure 3.36), whereas the energy distributed by the gain medium to other modes will not be reflected but transmitted to the outside.

The energy pump, which consists of either an electric current or light of different frequency (pump laser), induces the stimulated emission inside the active medium. The resulting light bounces back and forth many times between the two mirrors and is increasingly (exponentially) amplified during the bouncing until saturation sets in and a certain equilibrium state is established. As one of the mirrors is partially transparent ($R > 99\%$), part of the light leaves the resonator and constitutes the laser beam. As certain losses occur within the resonator, for example, by absorption, scattering by imperfections within the active medium, and of course through the

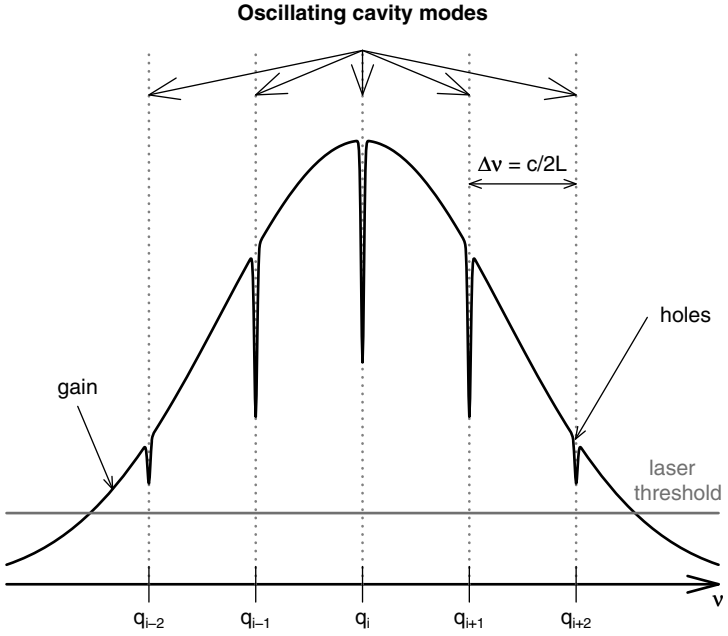

Figure 3.36 A laser cavity resonator restricts the number of oscillations to a few around discrete resonance frequencies (adapted from [14]).

leaving radiation, a minimum pump power is necessary to induce the laser, which is called the lasing threshold (see Figure 3.36).

Depending on the nature of the medium, certain types of lasers can be distinguished. In gas lasers, gases form the active medium, for example, the helium–neon laser, which emits at a variety of wavelengths of which the 633 nm line is very common, and the carbon dioxide laser, which is very efficient at the IR wavelengths 9.6 and 10.6 μm. Also fairly often employed, for example in Raman spectroscopy, is the argon ion laser with its most commonly used lines at 458, 488, and 514.5 nm.

Chemical lasers are powered by chemical reactions, for example, excimer lasers. Excimer lasers usually generate UV light and are therefore used for the photolithographic step in the production of microchips. Examples are the fluorine laser (emitting wavelength 157 nm), the argon fluoride laser (193 nm), and the krypton fluoride laser (248 nm).

Solid-state lasers involve a crystalline or glassy host doped with ions, for example, the ruby laser, which consists of corundum (crystalline Al_2O_3) doped with 0.05–0.1% chromium oxide (Cr_2O_3), which contributes the actual active ion. Another well-known dopant, neodynium, which is usually employed in yttrium-containing hosts such as yttrium aluminum garnet (YAG, $Y_3Al_5O_{12}$), constitutes high power lasers (Nd:YAG) in the NIR spectral region at 1064 nm, which is also often used in its frequency-doubled form at 532 nm. Also the titanium-doped sapphire laser should be mentioned, the frequency of which is highly tunable between 650 and 1100 nm, which is often-used in spectroscopy, especially as ultrashort pulses can be generated (see below). The advantage of solid state lasers is a much higher inversion density due to the higher material density compared with gases. As a consequence, the output power per unit volume is generally much higher, but requires efficient cooling as heat is generated by unconverted pump power. A solution to this problem is to use fiber lasers, in which the host medium consists of glass, which is drawn into fibers. A characteristic of fiber lasers is that the exciting light can be guided through long gain regions and an advantageous surface area-to-volume ratio is achieved, which easily allows efficient cooling. Another type of solid-state laser is semiconductor lasers, for example, laser diodes. They are often used to pump other lasers due to their high efficiency and due to the broad wavelength region that they cover (about 375–1800 nm).

Other types of lasers are photonic crystal lasers (consisting of well-ordered nanostructures leading to mode confinement), free electron lasers (widely tunable and with high output but with high cost and space considerations, hence not standard laboratory equipment), and also dye lasers in which organic dyes are employed as active media.

For more details concerning laser types, see Chapter 4.

3.7.1 Mode Locking

As outlined in Section 3.6, for inducing nonlinear optical effects [e.g., multi-photon absorption, SHG, THG, CARS, SRS (see Section 3.6)], pulsed lasers with high peak intensities are required. An ultrashort pulse of light is a laser pulse whose time duration τ_p is in the order of femtoseconds (10^{-15} s). Such pulses are characterized by

a broadband optical spectrum determined by the inverse pulse length τ_p. Ultrashort pulses are created by mode-locked oscillators.

In the following we briefly introduce the mode-locking technique used to generate ultrashort light pulses. A laser cavity playing the role of a frequency selector as described above allows oscillations in only a very few narrow-frequency domains and therefore cannot deliver ultrashort laser pulses. In other words, a laser operating in its free multimode regime oscillates simultaneously over all the longitudinal modes for which the gain is greater than the cavity losses. Lasers in a free-running regime produce waves with a mixture of longitudinal modes with a random mode-to-mode phase relationship. Since each longitudinal mode oscillates independently of the other modes, the output intensity of a laser operating in its free multimode regime is a chaotic sequence of fluctuations (see the upper part of Figure 3.37). Hence the intensity output of a free multimode regime laser results from the interference of longitudinal modes with random phase relationships. However, if it would be possible to lock the phases of the oscillating longitudinal modes, that is, to establish a fixed phase relationship the laser output would consist of a periodic sequence of pulses. In other words, the constructive interference of longitudinal modes generates

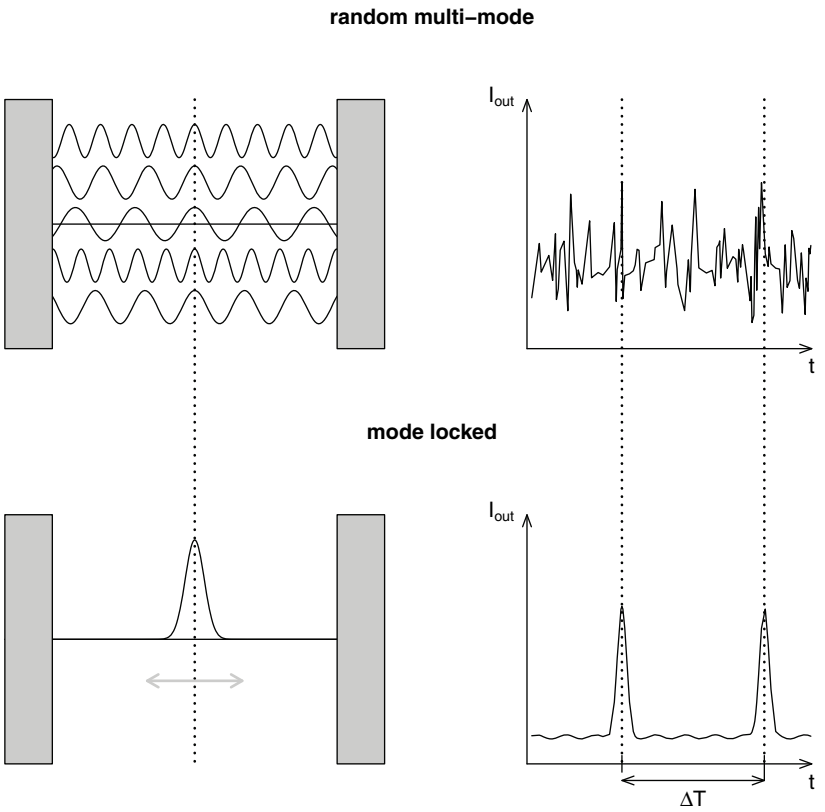

Figure 3.37 Illustration of the mode-locking principle (adapted from [16]).

a wave packet which oscillates back and forth within the laser cavity. This means that the laser beam consists of a periodic series of pulses with a repetition time $T = 2L/c$ (see the lower part of Figure 3.37). The width of the pulses (pulse duration $\Delta\tau_p$) depends on the number of modes N contributing to the wavepacket, that is, the number of phase-locked longitudinal modes: $\Delta\tau_p \sim N$. Pulses which are generated with identical initial phases are called Fourier transform limited. Figure 3.37 depicts schematically the mode locking principle to generate short laser pulses.

Now the question arises of how to produce mode locking, that is, a fixed phase relationship between the oscillating longitudinal modes. One method to achieve mode locking is to introduce a nonlinear medium inside the cavity, which is able to promote stronger intensities inside the cavity. By doing so, initial intensity maxima of a laser running in a free multimode regime (see Figure 3.37) will grow much stronger at the expense of less intense temporal features because of the competition within the gain medium. Eventually the situation arises where all the cavity energy is concentrated in a single pulse. However, the selection of a single starting intensity maximum in the time domain is totally equivalent to establishing a fixed phase relationship between the oscillating longitudinal modes in the frequency domain. In other words, the introduction of a nonlinear medium promoting stronger intensity starts mode locking out of normal intensity fluctuations. This means that one starting intensity fluctuation is slightly more intense than the others and is promoted by the nonlinear medium and therefore reduces its losses.

One of the most successful schemes of mode locking is Kerr lens mode locking (KLM). This scheme, which is also called self-mode locking, is based on the optical Kerr effect (self-focusing), which was described in Section 3.6.3. Here, the laser medium acts as a Kerr medium, that is, high-intensity light is focused differently to low-intensity light due to the intensity-dependent nonlinear refractive index. That means that the active laser medium decreases the losses of the initially stronger intensity peaks of the laser cavity by behaving like a lens (see Figure 3.38). Hence strong intensity maxima of the laser cavity are much more strongly focused than the weaker ones, for which focusing is negligible, and the transverse laser wave structure with respect to its intensity is modified. By carefully inserting an aperture or a slit in the laser cavity, the differences between the losses undergone by the weak intensities and those undergone by the intensity maxima can be increased. Most of the stronger intensity maxima can pass through the aperture whereas the weak intensity maxima are blocked.

This KLM principle exists in the most successful femtosecond laser in biophotonics, the titanium–sapphire (Ti:sapphire) laser. The active lasing medium consists of a sapphire crystal (Al_2O_3) which is doped with titanium atoms. The Ti:sapphire lasers are pumped by other lasers with a wavelength around 500 nm. The Ti:sapphire laser emit red and NIR light. Figure 3.39 depicts the configuration of a KLM Ti:sapphire laser.

Such KLM Ti:sapphire lasers routinely generate pulses of less than 100 fs at a repetition rate of 80 MHz with an average power of 1W. This corresponds to peak powers of close to 100 kW, which allows a great variety of nonlinear effects to be induced. Hence the KLM Ti:sapphire laser has become the most important light source for nonlinear microscopy in biophotonics.

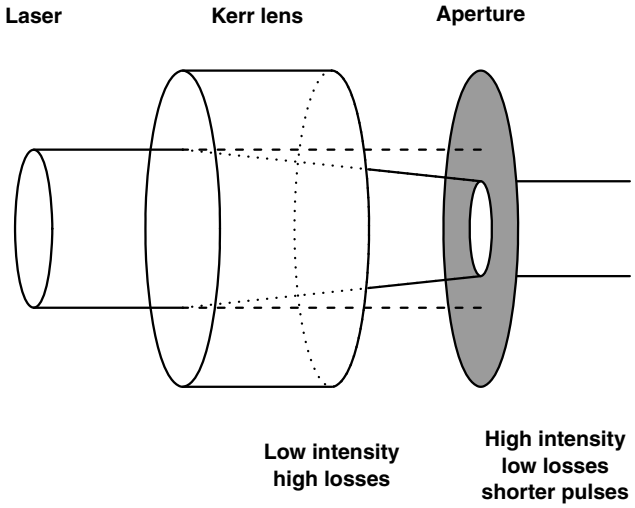

Figure 3.38 Illustration of the Kerr lens mode locking principle.

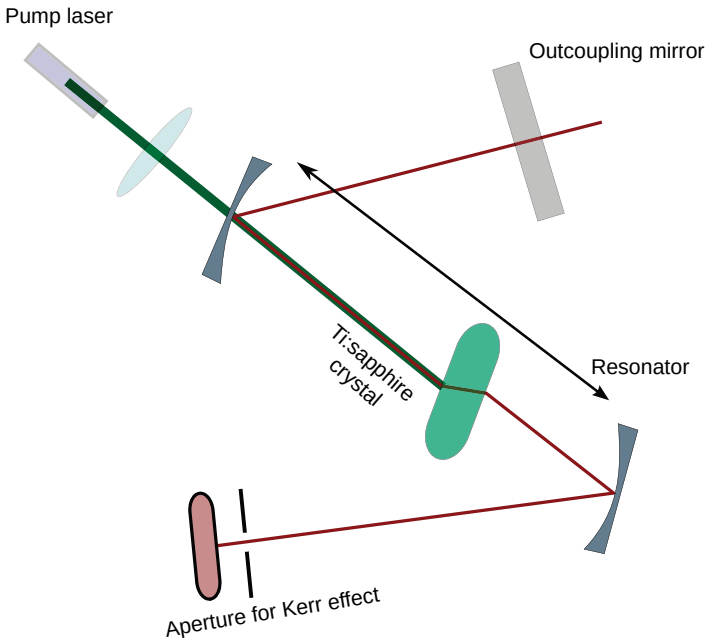

Figure 3.39 Cavity design of a KLM Ti:sapphire laser.

3.8 Infrared Spectroscopy

In Chapter 2, it was shown that for the description of molecular systems quantum effects need to be considered. This means that the energy of a microscopic system is quantized, that is, divided into well-defined energy portions. Molecules exhibit certain movement patterns, that is, the molecular degrees of freedom can be classified into translation, rotation, and vibration. The energy of all these degrees of freedom is quantized. Likewise, the electron energy in a molecule is quantized.

This section deals with molecular vibrations. A polyatomic molecule exhibits a multitude of vibrations. Of interest are the so-called normal mode vibrations. These vibrational motions differ from each other by different atomic displacements. One can differentiate between pure stretching (chemical bonds are stretched or compressed) and pure bending (bond angles are changed) vibrations, and mixed forms exhibiting both stretching and contraction of chemical bonds and extension and reduction of the bond angles. The easiest way to describe such a vibration is by approximating or describing the chemical bond as atoms held together by a spring. The vibrational frequency then depends on the atomic mass and the spring force constant. The atoms move during a vibrational period towards or away from each other. This movement is repeated periodically and can be easily described by a harmonic oscillator. A harmonic oscillator is a system performing periodic vibrations about its equilibrium position where the restoring force F is direct proportional to the displacement. According to quantum theory, the vibrational energy is also quantized. Light with the appropriate frequency can be absorbed by the ensemble of vibrating molecules, promoting them from the vibrational ground state into the first excited vibrational state. The light frequencies required to excite vibrational absorptions directly covers the spectral range from 2.5 to 1 mm or, in spectroscopic wavenumber units, from 400 to 4000 cm^{-1}. This frequency range is also called the mid-infrared (MIR) region.

Since the number and type of vibrations depend directly on the atoms present in the molecule and in particular how these atoms are chemically bonded to each other, IR absorption spectra can be considered as a molecular fingerprint of the molecules existing in a biological sample. Moreover, the energy of the vibrational transition depends on the chemical environment in which the molecules are embedded. Therefore, vibrational spectroscopy provides a key to learning about the molecular environment in which the molecules are located. However, the application of IR absorption spectroscopy or microscopy in biophotonics is often hindered by the presence of water, since water exhibits broad IR absorption bands, causing a large background.

This section provides a general introduction to IR absorption spectroscopy. A complete detailed description of IR absorption and IR spectroscopy is given in [5].

The energy of a molecule consists of translational energy (the center of gravity of the molecule moves), rotational energy (the molecule rotates around the center of

gravity), vibrational energy (the distances of the atoms vary), and electronic energy (electrons are in excited states). In this section we focus on the vibrations of a molecule, which are usually excited in the IR spectral range. This range extends from about 10 to 12 800 cm^{-1}, a unit which is the inverse of the wavelength and is generally preferred in IR (and in Raman) spectroscopy. In microns this range is from 1000 to 0.78 μm. Generally, the IR spectral range is further divided into the parts near-infrared (NIR, 4000–12 800 cm^{-1}), mid-infrared (MIR, 400−4000 cm^{-1}) and far-infrared (FIR, also called the terahertz regime, 10−400 cm^{-1}).

A polyatomic molecule exhibits a multitude of vibrations. However, of interest are the so called normal mode vibrations. Normal modes describe collective, independent, and synchronous vibrational displacements (motions) of atoms or groups of atoms within molecules. Since the normal modes of a molecular system are independent of each other, that is, they do not couple with each other, they can be excited without exciting another normal mode. A nonlinear N-atomic molecule exhibits $3N-6$ normal modes. This can be easily understood by analyzing the different molecular degrees of freedom, namely translation, rotation, and vibration. If we consider a molecule consisting of N atoms, the N atoms could move independently through the space by varying one of its three coordinates (x, y, and z) if they are not connected via chemical bonds. This independent motion would result in $3N$ translational degrees of freedom. However, the atoms in a molecule cannot move independently through the space but only the whole molecule as an entity. Hence the motion of the molecule through the space can be described by the three directions in space x, y, and z. Therefore, these three degrees of freedom describe the translational motion of the whole molecule in space from the the entirety of motions, that is, of the $3N$ degrees of freedom, only $3N-3$ remain. By taking into account that a molecule can rotate along the three axes of the coordinate system, we need to subtract three more degrees of freedom for the rotational motion. Of the original $3N$ degrees of freedom, only $3N-6$ remain.[12] These remaining degrees of freedom can be assigned to the vibrational degrees of freedom (displacements of the atoms against each other), that is, the normal modes of the molecule. The four normal modes of CO_2 are shown in Figure 3.40. These vibrational motions differ from each other by different atomic displacements. One can differentiate between pure stretching (chemical bonds are stretched or compressed) and pure bending (bond angles are changed) vibrations, and mixed forms exhibiting both stretching and contraction of chemical bonds and extension or reduction of the bond angles.

The easiest way to describe such a vibration is by approximating or describing the chemical bond as atoms hold together by a spring. In this view, we consider the atoms as mathematical points with masses that are connected by massless springs. These springs represent the bonds between the atoms. The vibrational frequency then depends on the atomic mass and the spring force constant. The atoms move during a

12) For nonlinear molecules, three coordinates are needed to describe their orientation in space. However, for linear molecules, two coordinates are sufficient since the moment of inertia for rotation around the molecular axis is vanishingly small (i.e., rotation only takes place around the two axes perpendicular to the molecular axis). This means that three or two degrees of freedom which remain after subtracting the three translational degrees of freedom belong to the rotation of the molecule.

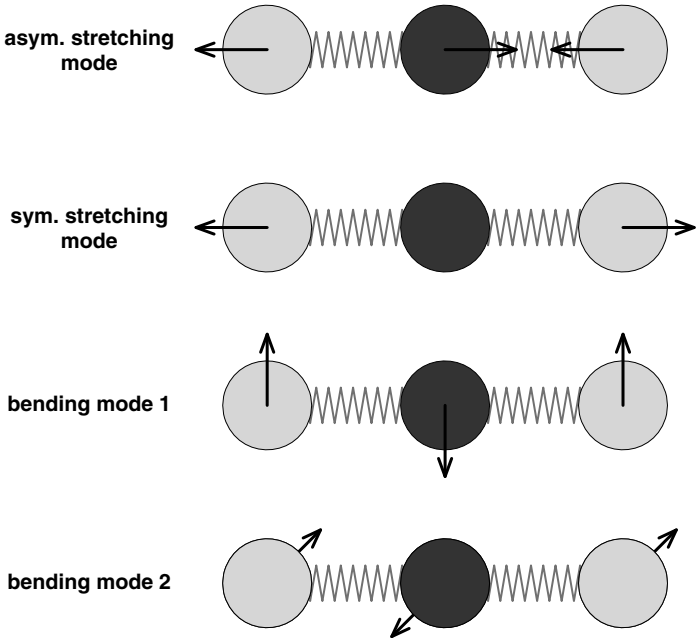

Figure 3.40 Four normal modes of CO_2. The atoms move along the arrows. These vibrational motions exhibit different vibrational frequencies and can be excited independently, bending mode 1 and 2 are identical but mutual perpendicular motions.

vibrational period towards or away from each other. This movement is repeated periodically and can be easily described by a harmonic oscillator. In the following we examine the resulting equations for a harmonic oscillator for the simplest case of a diatomic molecule (see Figure 3.41a).

Classically, the potential energy of a molecule depends on the distance R between the nuclei. A good approximation of this curve, at least around the equilibrium distance R_0, is given by a parabola which is represented by the equation $V = (1/2)k(R-R_0)^2 = (1/2)kx^2$, where $R-R_0 = x$ is the displacement from the

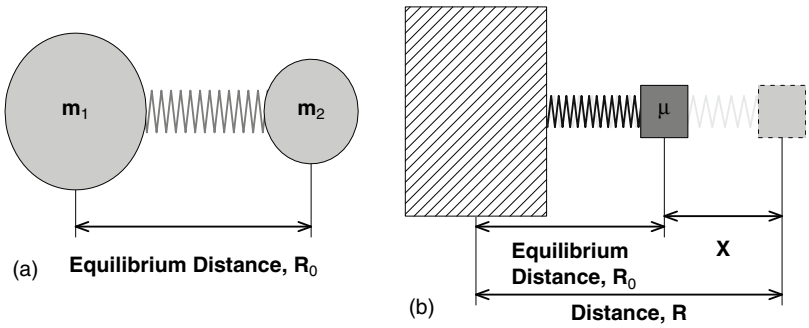

Figure 3.41 Illustration of the replacement of the molecule by an equivalent spring pendulum.

equilibrium position, k is the force constant, and V is the potential energy. Such a relation is the consequence of assuming a restoring force, which is proportional to $x = R - R_0$ with proportionality constant k, given by $F = -\mathrm{d}V/\mathrm{d}R = -k(R - R_0) = -kx$. It can be shown that the vibration of a diatomic molecule with two masses m_1 and m_2 is equivalent to that of a so-called reduced mass μ in a spring pendulum (see Figure 3.41b), with the reduced mass given by

$$\mu = \frac{m_1 \cdot m_2}{m_1 + m_2}. \tag{3.115}$$

Note that if one mass is much smaller than the other, than the small mass is to a good approximation the reduced mass. As a consequence, if H atoms are involved in a vibration, nearly exclusively these move, whereas the rest of the molecule remains stationary.

If we assume that the displacements from the equilibrium position of the spring is small, the force that tries to push or pull the mass is proportional to the displacement $x(t)$ from the equilibrium position ($x = 0$), $F_x(t) = -k \cdot x(t)$, where k is again the force (or the spring) constant. The situation is now equivalent to that of an electron bound to a nucleus which we treated in Section 3.2. Applying Newton's law, $F = \mu \cdot \mathrm{d}^2x/\mathrm{d}t^2$, we arrive at an equation similar to Equation 3.11:

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2} + \frac{k}{\mu} \cdot x(t) = 0 \tag{3.116}$$

where we have just replaced the mass of the electron m_e by the reduced mass μ. As a consequence, $x(t)$ and its second derivative again differ only in a constant ω_0:

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2} = -\omega_0^2 \cdot x(t) \tag{3.117}$$

with the solutions $x_0 \cdot \sin(\omega_0 t)$, and the only difference that the constant ω_0 is now given by $\omega_0 = \sqrt{k/\mu}$. This also shows that the dispersion relation that we derived in Section 3.2 for an electronic excitation still holds true in the IR spectral range in spite of the completely different nature of the excitation (see also Figure 3.11).

As ω_0 is directly proportional to the square root of the force constant k and indirectly proportional to the square root of the reduced mass μ, we can expect that the wavenumber of a particular vibration will rise if we increase the bond strength while keeping the masses constant or will decrease if the masses are increased while the bond strength remains constant. This finding is exemplarily illustrated in the following:

- In carbon monoxide, the oxygen and the carbon atoms are strongly bound by a partial triple bond. As a diatomic molecule it has only one vibration which can be found in the MIR region at 2143 cm^{-1}. In the case of a more weakly bound C = O double bond in $R_1R_2C = O$, as can be found, for example, in aldehydes (R_1 = H, R_2 = alkyl or aryl) or ketones (R_1/R_2 = alkyl/aryl), the wavenumber is downshifted to 1600–2000 cm^{-1}. A further downshift can be noticed for alcohols (R–OH) or ethers (R_1–O–R_2), where the C–O vibration appears between 1000 and 1200 cm^{-1} depending on the molecular groups R.

- C−H vibrations can usually be found between 2800 and 3000 cm^{-1} in alkanes, whereas in the deuterated species the C−D vibration usually shows up around 2100 cm^{-1} since the reduced mass has been almost doubled due to the atomic mass of the deuterium atom being double that of the hydrogen atom.

As biological matter consists nearly exclusively of comparably light atoms such as H, C, N, O, S, and so on, the fundamental vibrations of tissue can be found nearly exclusively in the MIR region with the stretching vibrations involving the movement of an H atom having the highest wavenumbers. A higher force is necessary to lengthen or shorten a spring than to bend it, and the same is valid for molecular vibrations. Accordingly, bending vibrations can be found at lower wavenumbers than their corresponding counterparts.

In Section 2.2.3, it was shown that according to quantum theory the vibrational energy of a molecule cannot be continuous but quantized. This means that the energy of a harmonic oscillator can only amount to

$$E_v = \left(v + \frac{1}{2}\right)\hbar \cdot \omega_0 \tag{3.118}$$

where v is the quantum number of the harmonic vibration, $\hbar$ is Planck's constant devided by 2π and ω_0 is the classically derived vibrational frequency (see above). This quantum harmonic oscillator can be symbolized by horizontal lines inside the parabolic harmonic potential (see Figure 3.42a). It can be seen that the energy levels form a uniform ladder with a spacing of $\hbar\omega_0$. Furthermore, the vibrating quantum

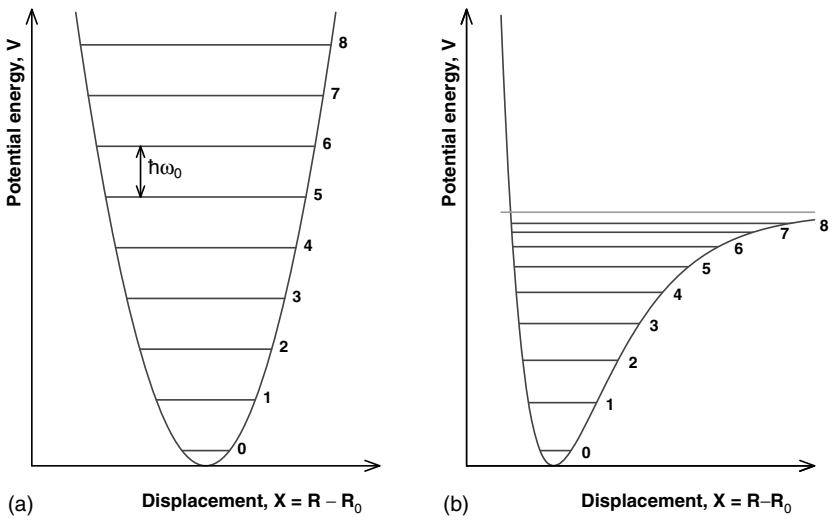

Figure 3.42 Comparison between (a) harmonic and (b) anharmonic oscillator. The anharmonic oscillator considers the fact that molecules can dissociate for high vibrational energies. Whereas for the harmonic oscillator the energy distance between the vibrational levels is constant, the corresponding energy difference decreases for the anharmonic oscillator with increasing energy until a continuum is reached where dissociation takes place.

mechanical system possesses a zero point energy of $^1/_2\hbar\omega_0$ because the smallest allowed value of v is 0. This means that molecules are always vibrating and are never at "rest."

Since normal modes can be excited independently (they are decoupled), every normal mode q is a harmonic oscillator independent of the rest of the molecule:

$$E_{q\mathrm{v}} = \left(\mathrm{v}_q + \frac{1}{2}\right)\hbar\omega_{0,q} \tag{3.119}$$

where v_q is the vibrational quantum number of the normal mode q, $\omega_{0,q} = \sqrt{k_q/\mu_q}$ is the vibrational frequency of the normal mode q with μ_q the effective mass of the vibration, that is, a measure of the mass which is moved during the vibration, and k_q is the force constant of the normal mode. Hence the total vibrational energy E_{vib} of polyatomic molecule is

$$E_{\mathrm{vib}} = \sum_{q=1}^{3N-6\ (\text{or } 3N-5)} \left(\mathrm{v}_q + \frac{1}{2}\right)\hbar\omega_{0,q}. \tag{3.120}$$

A normal mode q is excited when the molecule absorbs a quantum of energy $E = \hbar\omega_{0,q}$ corresponding to the normal mode's frequency $\omega_{0,q}$. It follows from the Boltzmann distribution (see Equation 3.114) that at room temperature most molecules will be in their vibrational ground state initially, that is, the vibrational quantum numbers of all normal modes v_q equals 0. Hence IR light in resonance with a particular normal mode (i.e., of frequency $\hbar\omega_{0,q}$) can be absorbed by the ensemble of vibrating molecules, promoting them from the vibrational ground state ($\mathrm{v}_q = 0$) into the first excited vibrational state ($\mathrm{v}_q = 1$).[13] During the course of the absorption process, only the amplitude of the normal mode out of equilibrium position changes while the vibrational frequency $\omega_{0,q}$ remains constant.

The absorption of IR radiation with the appropriate frequency promoting the molecule from its vibrational ground state into the first excited vibrational molecular state decreases the transmitted intensity with respect to the incident intensity (see also Section 3.4). A plot of the transmitted intensity versus the radiation frequency yields an IR absorbance spectrum. Figure 3.43 displays a typical IR absorbance spectrum of an organic molecule, propionamide.

As the molecules become more complex, so do their vibrational patterns, and vibrations (normal modes) often involve change of both the distance and angles. However, some of the vibrations are constrained on single molecular bonds or functional groups (localized vibrations) whereas other vibrations involve the complete molecule. The localized modes consist of valence (stretching), bending,

13) It can be shown in quantum mechanics that for the model of a harmonic oscillator the absorption of a photon can increase the vibrational quantum number only by one. That means that the so-called specific vibrational selection rule for the absorption of radiation by a molecular vibration for the model of a quantum mechanical harmonic oscillator can be expressed by $\Delta\mathrm{v}_q = 1$. This selection rule can be derived from an analysis of the expression for the transition dipole moment (see Equation 3.121) and the properties of integrals over harmonic oscillator wavefunctions (see Chapter 2).

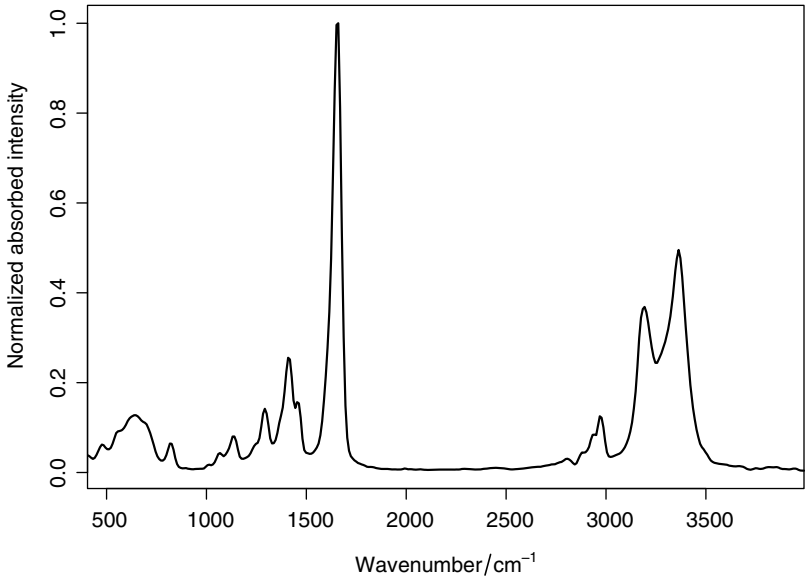

Figure 3.43 IR absorbance spectrum of propionamide.

rocking, twisting or wagging vibrations. Many of these localized normal modes can be used to identify functional groups such as $-C\equiv N-$, $-C\equiv C-$, $-C=C-$, and $-C=O-$. In complex molecules with atoms having mostly comparable masses such as the C, N, and O atoms in organic molecules, many vibrations involve not only some atoms but usually the complete backbone of the molecule. These backbone or skeletal motions lead to IR absorptions between 600 and 1500 cm^{-1}; this wavenumber range shows a more complex pattern the more complex the backbone of a molecule is. It is therefore a characteristic of the molecule and this range is called the fingerprint region. Thus, an IR spectrum can be divided into two regions: (1) above 1500 cm^{-1} absorption bands due to functional groups are present whereas (2) the wavenumber region below 1500 cm^{-1} is dominated by the presence of many absorption bands characterizing the complete molecular entity. The latter region is called the fingerprint area since it is characteristic of a particular molecule. This fingerprint region can be used to identify molecules.

In the solid state, free rotations and translations are not possible and the corresponding movements of the molecule as a whole, for example in a crystal lattice, constitute a third class of vibrations, the so-called lattice vibrations. Therefore, in the solid state all $3N$ degrees of freedom of a molecule are vibrations. As the interactions between molecules are usually much smaller than the interactions between atoms which lead to covalent bonding, the force constants for lattice vibrations are usually very small, so that the lattice vibrations can be found in the FIR spectral region. Therefore, especially in the FIR region, the more complex

organic molecules display interesting spectral patterns, especially if the interactions consist of intermolecular hydrogen bonding. The corresponding vibrational modes most probably are very sensitive to the intra- and intermolecular structure and should therefore also provide a fingerprint of the molecule like the backbone vibrations in the MIR region, but with emphasis on the conformational state of the molecule and interactions with the environment.

In addition to the transition from the vibrational ground state to the first excited vibrational state (fundamental transition), direct absorption processes into the second, third, or even higher vibrational states can also take place, but with much lower probability than the fundamental transition. These higher transitions are called overtones. The energy required to excite overtones lies mostly in the NIR region. The selection rule for a quantum mechanical harmonic oscillator ($\Delta v = \pm 1$) forbids the presence of overtones. However, the harmonic oscillator model, which is based on the parabolic potential energy curve, is a good approximation only around the equilibrium position. This means that for small displacements from the equilibrium position, which is true for small vibrational quantum numbers, the harmonic oscillator model is well suited to describe a vibrational absorption process. However, for large displacements, that is, for high vibrational states, the model of the harmonic oscillator model (parabolic potential) is problematic since it is impossible to put an arbitrary amount of energy into the system without destroying the molecule. However, it is well known that chemical bonds can break, that is, dissociate, or molecules can fall apart if they are heated too much. To allow for dissociation to take place, the harmonic oscillator model has been refined as the anharmonic oscillator model, which takes into account the fact that molecules at high vibrational energies dissociate, that is, the spring between the atoms breaks. Here, the vibrational motion becomes anharmonic in such a way that the restoring force F is no longer linearly related to the displacement, $x = R - R_0$. Whereas for the harmonic oscillator the energy difference between quantized vibrational states is always the same (see Figure 3.42b) this difference for the anharmonic oscillator decreases with increasing energy till one reaches a continuum where all vibrational states have almost the same energy (see right side of Figure 3.42). Anharmonicity accounts for the appearance of weak overtone absorptions in the NIR. That means when two quanta are absorbed the first overtone is excited, and so on to higher overtones (see Figure 3.42a). Since the spacing between the energy levels in an anaharmonic oscillator decreases with increasing vibrational quantum numbers, the first overtone appears at a wavenumber position slightly lower than twice that of the fundamental transition. Excitation of the higher overtones involves progressively less and less additional energy and eventually leads to dissociation of the molecule, when reaching the continuum where the atoms of the molecule can leave the molecules' force field. The anharmonic oscillator also accounts for so-called combination bands, which can occur at frequencies that correspond to a sum or a difference of the fundamental frequencies of two different normal mode frequencies. These bands, just as overtones, are comparably weak.

As molecules and especially biomolecules can be almost arbitrarily complex and consist of a large number of atoms (e.g., for proteins up to 10 000 and more), the

number of possible vibrations can be high. Accordingly, it is obvious that already comparably small molecules have a large number of different vibrations, which should render a spectrum very complicated. Fortunately, for a number of reasons the number of bands displayed in an IR spectrum is in many cases much smaller than the number of vibrations (i.e., $3N-6$ or $3N-5$). Unfortunately, the former is in general not true for biomolecules, but even if the number of bands is high, valuable information can nevertheless be gained. Since the frequencies of the vibrations depend on the geometry of the molecules and the masses of the atoms, whereas the intensity depends on the partial charges of the atoms, vibrational spectroscopy is very sensitive to structural changes of molecules and how and with what composition they form aggregates such as cells and tissue. Generally, not all vibrations cause a band in an IR spectrum. Since IR light is nothing else than a change of the electric field at the location of a molecule, a requirement for a vibration to be excited by IR light is that during the vibration the dipole moment of a molecule is changed. In other words, the change of the electric field needs to affect negative charges differently to positive charges so that the distance between the centers of the negative and the positive charges in a molecule changes. One consequence is that in a highly symmetric molecule such as benzene, usually only a few of the totality of vibrations are IR active.

Figure 3.44 displays two normal modes of benzene. Only the vibration illustrated in Figure 3.44b changes the dipole moment of the benzene molecule during the course of the vibration, that is, this vibration gives rise to an oscillating dipole and can therefore be excited by the absorption of an IR photon. The normal mode shown in Figure 3.44a does not lead to an oscillating dipole as it is impossible to excite this vibration through a direct IR absorption process.

Without going into all the details, which is impossible within this book, the following is true in general: the more complex a molecule is, the lower its symmetry

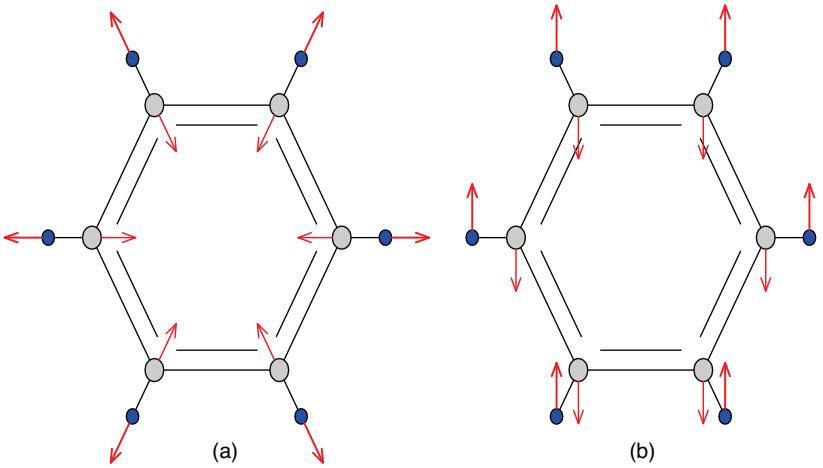

Figure 3.44 Two vibrational modes of benzene. The vibration illustrated in (a) is IR inactive as no dipole moment change occurs during the vibration.

usually is, which eventually renders all vibrations IR active. In many cases it is therefore very difficult, if not impossible, to reach the ultimate goal for every vibrational spectroscopist (the same is also true in Raman spectroscopy), namely to assign to each band in a spectrum a particular molecular vibration. Even if this ultimate goal cannot be achieved, vibrational spectroscopy is nevertheless an invaluable tool. Assuming that a spectrum of a pure substance was taken, a first inspection of it usually gives general hints about the class of substance, such as whether it is an aliphatic compound consisting only of single bonds between C atoms or if double bonds are present, which means that the compound is an alkene or an aromatic compound. Additional bands can reveal the presence of functional groups such as −OH and C=O groups, which have characteristic bands in distinct spectral ranges clearly separated from the C−C bands or C−H bands of pure hydrocarbons. This allows us to determine whether the compound is, for example, an alcohol, an organic acid, or an amine. This further enables us to distinguish proteins from fat as the former consists of amino acids and the latter of aliphatic or olefinic acids esterified to glycerol. It is even possible to distinguish the different amino acids and therefore different proteins as they consist of different quantities of amino acids. This example and other complex compounds, however, push IR spectroscopy and vibrational spectroscopy in general to their limits as the differences in the spectra become very subtle and eventually unrecognizable by visual inspection. To proceed and to permit the interpretation of spectra in such cases, usually different chemometric methods such as multivariate calibration, pattern recognition, cluster analysis, and multivariate curve resolution are employed. Such methods even allow the detection of the subtle changes in composition that healthy tissue undergoes when changing to precancerous and cancerous tissue.

In Section 3.13, it will be shown that there does not always need to be a direct absorption of radiation to promote a vibrational transition. Vibrational transitions can also take place via an inelastic light scattering process called Raman scattering. The two vibrational spectroscopic methods, Raman and IR absorption spectroscopy, are complementary methods based on two different light–matter interaction phenomenam thus exhibiting different selection rules. As has been shown above, selection rules determine which vibration of a molecule can be excited by what method. In the case of IR absorption, one photon directly promotes the molecule into a higher vibrational state whereas in the Raman scattering process two photons are involved. In Section 3.13, it will be demonstrated that in order for a molecular vibration to be Raman active, the polarizability α has to change during the vibration so that a molecular vibration can be promoted via an inelastic scattering process into a higher vibrational state. The benzene vibration displayed in Figure 3.44 which is IR inactive can be excited via a Raman scattering process, nicely demonstrating the complementarity of Raman and IR spectroscopy.

The important role of vibrational spectroscopy and in particular Raman spectroscopy in biophotonics (Raman spectroscopy, in contrast to IR spectroscopy, can be applied in aqueous environments) can be found in Section 3.13, where a detailed introduction to Raman spectroscopy is given.

3.9
UV–Vis Spectroscopy

Section 3.4 provided a classical introduction to the absorption of light. It was shown that the contrast in bright field microscopy is based on white light absorption changes of colored substances. This section aims to characterize the molecular origin of the absorption of visible and UV light by molecules based on quantized electron energies in molecules.

In the UV–Vis spectral range, the comparably high energy of the photons is able to excite electrons, which successively and in pairs fill up the energy levels of atoms or molecules, to higher energy states. Usually, the energy of the photons is only sufficient to excite those electrons which are in the highest occupied states (so-called valence electrons) to the lowest unoccupied states unaffected by being involved in bonding or not. Especially electrons involved in double bonding between C atoms can have low excitation energies, in particular if there is more than one double bond and the double and single bonds alternate. Then the excitation wavelength is shifted further to the red the more alternating single and double bonds are present in the molecule. Functional groups involving heteroatoms such as O, N, and S, which have free electron pairs (valence electrons that are not involved in bonding), can not only lead to a further red shift of excitation wavelengths but also cause intensification of the absorption. The intensity of an absorption in the UV–Vis is influenced by rules from quantum mechanics. Accordingly, the transition from a certain energy level to another may usually be forbidden or only "weakly" allowed due to a certain structural distortion of a molecule which breaks the rules. Such transitions are nevertheless weak and can be several orders of magnitude less intense than allowed transitions. An example of such a weakly allowed transition is the so-called $d{-}d$ transition in transition metal atoms such as Cu, Fe, and Ni, which renders many or their compounds colored. Electronic transition can be localized on an atom or a molecule but photons can also induce transitions of electrons from molecules to other molecules or to ions. Such charge transfers are often very strong transitions and play important roles in photochemistry and photobiology. In complex molecules, it is often a small part named a chromophore that is responsible for the color. Nevertheless, if the chromophore is separated from the rest of the molecule the properties of a mixture may be different from those of the compound due to interactions that may be due to secondary and ternary structure.

This section aims to present a short introduction to UV–Vis spectroscopy. Detailed information can be found in [17–20].

The UV–Vis spectral range can be subdivided into three different parts, namely the visible ranging from wavelengths of 700 to 400 nm, the near-UV covering the range from 400 to 200 nm, and the far-UV or vacuum UV extending from 200 down to 10 nm. Due to the higher energy of light in this spectral wavelength range, it is

possible to excite electrons from their ground state to higher energy levels. To understand the electronic excitations completely it would be necessary to have a detailed knowledge of quantum theory and bonding theories. As we cannot cover this topic fully here, we will just give a very general introduction and subsequently focus on different examples which are important in the context of this book.

In Chapter 2, it was shown that the quantum mechanical description of molecules allows only certain energy states of an electron. These quantized molecular energy states are described by many-electron wavefunctions. These many-electron wavefunctions are commonly approximated by an antisymmetrized product (Slater determinant) of one-electron wavefunctions called molecular orbitals (MOs). In other words, electronic states can be approximated by a single electronic configuration which is commonly displayed by a molecular orbital diagram where the MOs are represented by horizontal lines. The MOs are filled with electrons obeying the Pauli exclusion principle (the maximum number of electrons occupying an MO is two with opposite spins) and Hund's rule of maximum multiplicity (if there are several MOs with equal energy, the electrons fill one MO at a time). In a molecular orbital diagram (representing a single electronic configuration), the highest occupied molecular orbital is called HOMO and the lowest unoccupied molecular orbital LUMO.

MOs are most commonly represented as a linear combination of atomic orbitals. By doing so, bonding MOs result when the atomic orbitals enhance each other in the region of the nuclei. In contrast, antibonding MOs are formed when the atomic orbitals cancel each other in the region between the nuclei. Bonding MOs have lower energies than antibonding MOs. MOs are classified according to their symmetry: bonding MOs which are symmetrical with respect to rotation around the molecular axis are called σ-orbitals. The corresponding antibonding σ*-orbital is defined by a nodal plane within the molecular axis. A π-orbital results from the overlap of two lobes of one atomic orbital with the two lobes of the other atomic orbital. In addition to bonding and antibonding MOs, nonbonding molecular orbitals (n) also exist. These orbitals contain lone pairs of electrons which do not participate in bonding atoms together since they are unshared. They are localized on just a single atom. Nonbonding electrons usually possess higher energies than bonding orbitals.

The interaction of a molecule with light can promote an electron from an occupied MO into an empty MO. The electrons in single bonds, that is, σ-MOs, have the lowest energies and can be excited by light with wavelengths ranging between 120 and 130 nm into a σ*-MO. The π-bonds can be excited at about 170 nm into the π*-level when they are isolated. However, when the single and double bonds alternate and form so-called conjugate systems, the excitation wavelength depends on the extent of the system and can rise into the visible and NIR regions as in the case of, for example, β-carotene (see Figure 3.45).

The excitation energy can also or additionally be lowered if certain functional groups with nonbonding molecular orbitals are added to the molecule, such as $-$OH, $-$OR, and $-NH_2$, where the unshared electrons n are located on O and N, respectively. Here, another type of transition is possible involving the unshared (nonbonding) electron pairs n, which can also be excited into higher energy levels that belong to the molecule. As the unshared electron pairs are usually in energy levels

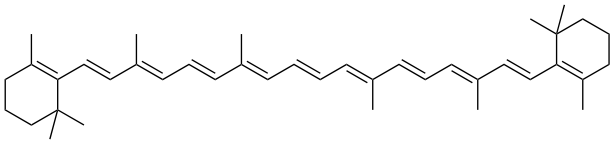

Figure 3.45 The large system of alternating single and double bonds in β-carotene.

with higher energy than electrons involved in σ-bonds or even in π-bonds, the energy required to transfer them into the unoccupied energy levels σ* and π* is usually smaller and varies in a broad range from about 200 to 665 nm. Figure 3.46 illustrates a $\pi \rightarrow \pi^*$ and an $n \rightarrow \pi^*$ transition by the respective boundary surfaces of the corresponding MOs displaying their spatial representation.

An overview of the different electronic transitions possible in organic molecules is given in Figure 3.47. This shows that the absorption of a photon can be attributed to

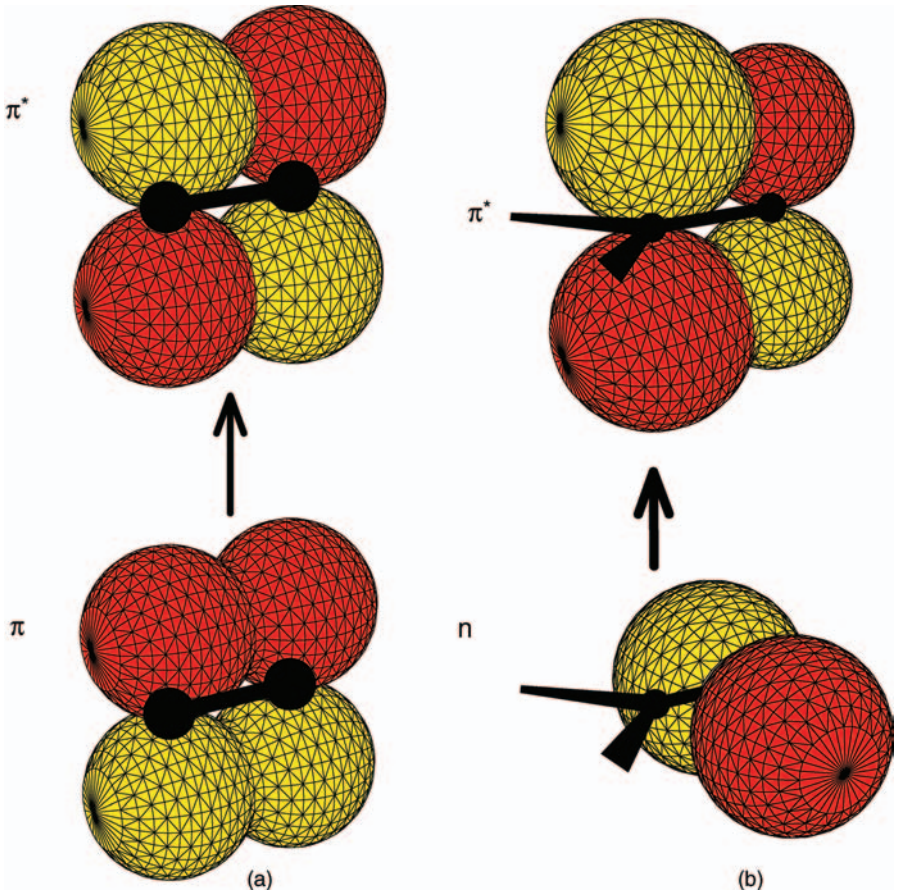

Figure 3.46 Illustration of the $\pi \rightarrow \pi^*$ and the $n \rightarrow \pi^*$ excitation with the boundary surfaces of the respective MOs (adapted from [18]).

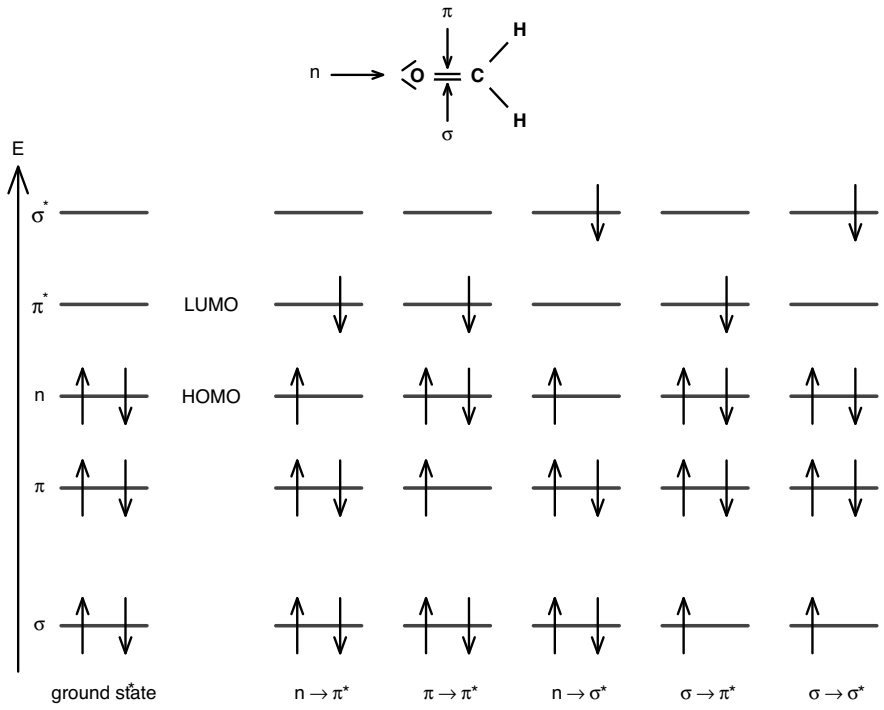

Figure 3.47 Overview of the electronic transitions in molecules exemplified with formaldehyde (H_2CO). Each horizontal line symbolizes a molecular orbital and each arrow an electron and its spin. HOMO stands for highest occupied molecular orbital and LUMO for lowest unoccupied molecular orbital. The order of excitation energy is mostly given by $(\sigma \rightarrow \sigma^*) > (\sigma \rightarrow \pi^*) > (n \rightarrow \sigma^*) > (\pi \rightarrow \pi^*) > (n \rightarrow \pi^*)$ (adapted from [17]).

certain electrons in a molecule or to certain electrons of characteristic functional groups of molecules. These moieties or parts of molecules which are responsible for the absorption of UV–Vis light are called chromophores.

The qualitative MO model also applies to metal complexes of the *d*-block elements, which play an important role in biology as natural chromophores, for example, chlorophyll and heme. In the free metals, all *d* atomic orbitals share the same energy. This degeneracy is lifted once the atom is surrounded by ligands (molecules) in complexes. The differences in energy are nevertheless small, and therefore visible light is generally able to excite a $d-d$ transition, which is the reason why many of the transition metal compounds are colored. Apart from $d-d$ transitions, the spectra of transition metal complexes also contain (1) bands from transitions localized in the ligands, called ligand-centered transitions between bonding and antibonding ligand-centered MOs, and (2) charge-transfer bands. In the latter case, an electron is transferred either from a bonding ligand-centered MO to an antibonding metal-centered MO (LMCT = ligand-to-metal charge transfer) or from a nonbonding metal-centered MO to an antibonding ligand centered MO (MLCT = metal-to-ligand charge transfer).

The MO diagrams allow the classification of electronic transitions and electronically excited configurations. The ground state of most molecules (i.e., closed-shell systems where all electrons are spin paired) has a total spin $S = 0$. The total spin S of a number of electrons is defined as the sum of the spin quantum numbers of the electrons involved. Usually an electronic state is specified by its spin multiplicity, which is defined as $2S + 1$. Thus, the ground state of a molecule has a spin multiplicity of 1, which is referred to as the ground state singlet state or S_0. However, as stated above, electronic excitation can promote an electron to an orbital of higher energy, resulting in excited electronic states. For such excited electronic states, usually two spin configurations exist: if the excited electron, for example a π^*-electron, and the residual electron, for example an n-electron, in the case of an $n \rightarrow \pi^*$ transition have opposite spins, the excited state has a spin multiplicity of 1 and is a singlet excited state. However, if the two electrons have parallel spins, the excited state has a spin multiplicity of 3 and is referred to as an excited triplet state. The excited singlet states are labeled S_1, S_2, and so on and the corresponding excited triplet states are denoted T_1, T_2, and so on depending on the underlying electronic transition, that is, excited electronic configuration (see Figure 3.48).

In order to visualize the energetic properties of a molecule – corresponding to the experimental UV–Vis absorption spectrum – instead of the molecular orbital diagram a Jablonski diagram is used (see Figure 3.49). In a Jablonski diagram, the electronic states of a molecule and the transitions between them are depicted. According to Hund's law the excited triplet states are always lower in energy than the corresponding excited singlet states of the same electronic configuration.

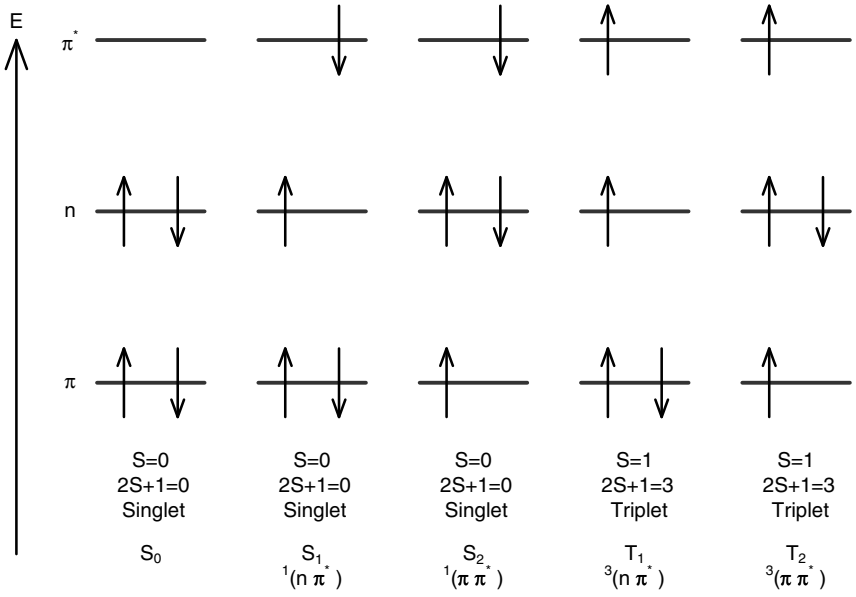

Figure 3.48 Ground and excited state electronic configurations and their spin multiplicity (adapted from [20]).

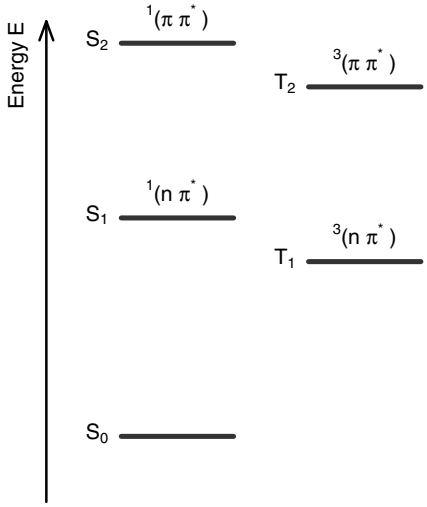

Figure 3.49 Energy state diagram (adapted from [20]).

3.9.1 Electronic Selection Rules

Electronic transitions between the energy levels in molecules are subject to certain constraints which are expressed by selection rules. When an oscillating electromagnetic field of appropriate energy interacts with a molecule, this molecule can be promoted from the ground state S_0 to a higher excited electronic state.

When an electronic transition occurs, the absorbing molecule undergoes an electric dipole transition and the intensity I of the electronic absorption is directly proportional to the square of the modulus of the transition dipole moment μ_{fi}:[14)]

14) The intensity of an absorption process (optical dipole transition) can be expressed by Fermi's golden rule, which is a way to express the transition rate $W_{i\to f}$ (probability of transition per unit time) between two quantum states ψ_i and ψ_f due to a perturbation $\hat{V}$:

$$W_{fi} = \frac{2\pi}{\hbar}\left|\int_{-\infty}^{\infty}\psi_f^*\,\hat{V}\,\psi_i \mathrm{d}x\mathrm{d}y\mathrm{d}z\right|^2 \rho$$

where ψ_i is the initial state and ψ_f the final state; ρ represents the density of final states. The integral within Fermi's golden rule is called matrix element in quantum mechanics and is very often expressed in "bracket" notation:

$$\int_{-\infty}^{\infty}\psi_f^*\,\hat{V}\,\psi_i \mathrm{d}x\mathrm{d}y\mathrm{d}z = \langle\psi_f|\,\hat{V}\,|\psi_i\rangle.$$

The intensity of a transition is proportional to $W_{i\to f}$ and therefore also to the square of the modulus of the perturbation matrix element $\left|\langle\psi_f|\hat{V}|\psi_i\rangle\right|^2$. For an electronic absorption process, the perturbation can be identified as the electric dipole moment interacting with the electric field of the incoming electromagnetic wave $E(t)$. Hence the perturbation can be expressed by

$$\hat{V}(t) = E(t)\cdot\hat{\mu}$$

$$I \sim |\mu_{fi}|^2 = |\langle \psi_f | \hat{\mu} | \psi_i \rangle|^2 \tag{3.121}$$

where ψ_i is the initial state, ψ_f the final state and $\hat{\mu}$ the dipole moment operator. The transition dipole moment arises due to the displacement of electron density during the electronic excitation. From Equation 3.121, it can be seen that the absorption intensity is theoretically determined by the transition dipole moment. As has been shown in Section 3.4, the absorption is experimentally determined by recording the transmittance, which is defined as $T = I(z)/I_0$, where $I(z)$ is the light intensity after it has passed through the sample and I_0 is the initial light intensity. The transmittance is expressed by the Lambert–Beer law (see Footnote 9 page 108):

$$T(\lambda) = \frac{I(z)}{I_0} = 10^{-(\epsilon(\lambda) \cdot zc)} \tag{3.122}$$

which expresses a logarithmic dependence between the transmittance of light T through a substance and the product of the molar absorption coefficient $\epsilon(\lambda)$, the concentration of absorbing molecules c, and the pathlength z that the molecule travels through the material. The absorbance A is defined as

$$A(\lambda) = \epsilon(\lambda) \cdot zc. \tag{3.123}$$

Usually, a plot of $\epsilon(\lambda)$ against the wavelength λ is called an absorption spectrum and the absorption maximum of a certain substance is characterized by its maximum value of ϵ_{max} ($l\,mol^{-1}\,cm^{-1}$).

The explicit treatment of optical dipole transitions by means of perturbation theory yields a relation between the integral of an absorption band of a transition of frequency ν_{fi} and the transition dipole moment:

$$\int \epsilon(\nu) d\nu = \frac{\pi \nu_{fi} N_L |\mu_{fi}|^2}{3\varepsilon_0 \hbar c} \tag{3.124}$$

which is a direct link between an experimentally measurable quantity $\int \epsilon(\nu) d\nu$ and a theoretical computable quantity μ_{fi}. Another useful way of expressing the absorption intensity is the introduction of the dimensionless oscillator strength f_o of a transition of frequency ν_{fi}:

$$f_o = \left(\frac{4\pi m_e \nu_{fi}}{3e^2\hbar}\right) |\mu_{fi}|^2. \tag{3.125}$$

The relation between the oscillator strength f_o and the integrated absorption $\int \epsilon(\nu) d\nu$ can be obtained by combining Equations 3.124 and 3.125:

$$f_o = \left(\frac{4m_e c\varepsilon_0}{N_L e^2}\right) \int \epsilon(\nu) d\nu \tag{3.126}$$

which can be expressed more practically as

$$f_o = 6.257 \cdot 10^{-19} \cdot \left(\frac{\int \epsilon(\nu) d\nu}{m^2 mol^{-1} \cdot s^{-1}}\right). \tag{3.127}$$

Hence the oscillator strength of a molecular transition can be determined experimentally from absorbance band intensities. Allowed dipole transitions are

characterized by an oscillator strength of $f_o \approx 1$ whereas for forbidden transitions $f_o \ll 1$.

In the following we evaluate the transition dipole moment μ_{fi} in more detail to obtain a deeper physical insight into the nature of electronic absorption transitions. As has been shown in Chapter 2, the total molecular wavefunction of a molecule can be divided into a nuclear $|\chi_v\rangle$ and an electronic component $|\psi_{el}\rangle$. This assumption is based on the Born–Oppenheimer approximation, which states that the electronic and nuclear motions within a molecule can be separated because the nuclear motion is usually much slower than the electron motion. As a consequence, the total energy of a molecule is made up of its electronic energy E_{el} and vibrational energy E_v discussed in Section 3.8. Hence the absorption of UV–V is light by molecules results in a combined electronic and vibrational transition, that is, both the electronic and vibrational states change. Such transitions are named vibronic transitions. The application of the Born–Oppenheimer approximation to express the transition dipole moment of a vibronic transition $|\psi_{el}\chi_v\rangle \rightarrow |\psi_{el'}\chi_{v'}\rangle$, that is, from the vibrational level χ_v in the electronic ground state ψ_{el} to the vibrational level $\chi_{v'}$ in the excited state $\psi_{el'}$ results in

$$\mu_{fi} = \langle\psi_f|\hat{\mu}|\psi_i\rangle \approx \langle\psi_{el'}\chi_{v'}|\hat{\mu}|\psi_{el}\chi_v\rangle = \langle\chi_{v'}\langle\psi_{el'}|\hat{\mu}|\psi_{el}\rangle\chi_v\rangle. \tag{3.128}$$

The electronic transition dipole moment, $\bar{\mu}_{\psi_{el'}\psi_{el}} = \langle\psi_{el'}|\hat{\mu}|\psi_{el}\rangle$, is assumed to be independent of small nuclear displacements (Condon approximation) and evaluated for the equilibrium nuclear geometry, that is, $\bar{\mu}_{\psi_{el'}\psi_{el}} \approx \bar{\mu}^{(0)}_{\psi_{el'}\psi_{el}}$. Thus, for the transition dipole moment it follows that

$$\mu_{fi} = \bar{\mu}^{(0)}_{\psi_{el'}\psi_{el}}\langle\chi_{v'}|\chi_v\rangle. \tag{3.129}$$

The electronic transition dipole moment at the equilibrium nuclear geometry, $\bar{\mu}^{(0)}_{\psi_{el'}\psi_{el}}$, is a measure of the degree of electron density redistribution during the electronic transition. The overlap integral $S_{v'v} = \langle\chi_v|\chi_{v'}\rangle$ is called the Franck–Condon integral and represents the degree of similarity of the nuclear configurations between vibrational wavefunctions of the initial and final states. Hence the intensity of a vibronic transition is directly proportional to the square modulus of the Franck–Condon integral, which is called the Franck–Condon factor: $|S_{v'v}|^2$. This is the quantum mechanical basis for the Franck–Condon principle, which is a rule to interpret electronic absorption spectra and their vibronic structure. The basis of this principle is that electronic transitions happen on a time scale ($\sim 10^{-16}$ s) that is significantly shorter than the vibrational period ($\sim 10^{-13}$ s) of a molecule and therefore the distance at which they occur can be assumed to be fixed during the transition. As a consequence, electronic transitions are vertical transitions. Hence transitions between vibrational levels in the lower v and upper electronic states v′ will be most intense when the two vibrational states have similar internuclear separations, that is, when the Franck–Condon overlap integral is greatest. This principle is illustrated in Figure 3.50 for a diatomic molecule.

The potential energy curves for a diatomic molecule can be expressed by Morse curves together with its quantized vibrational energy levels (see Section 3.8). Each

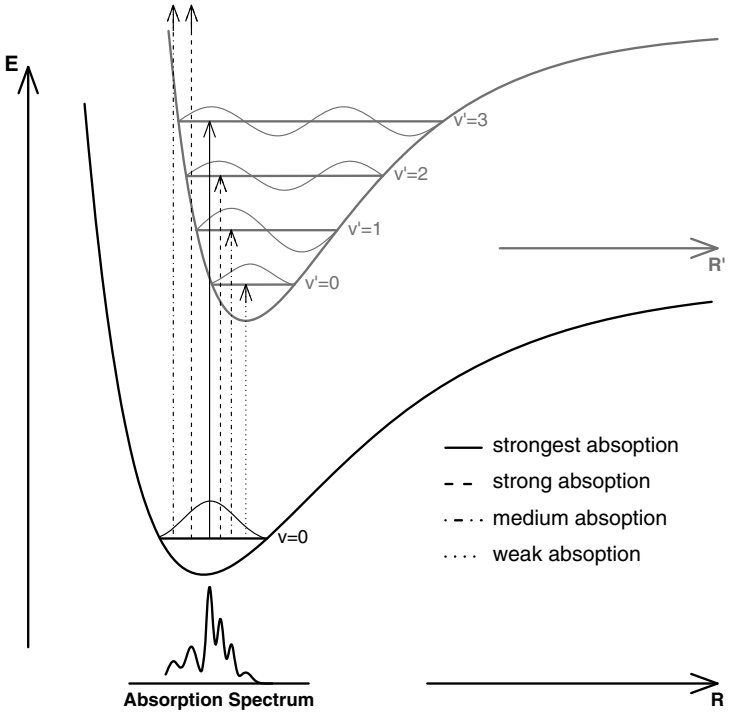

Figure 3.50 Illustration of the Franck–Condon principle (adapted from [19]).

vibrational level is expressed by its wavefunction or by its square modulus, which corresponds to the probability distribution of internuclear distances. At room temperature most molecules will be in the vibrational ground state ($v = 0$) of the electronic ground state ψ_{el} from where the absorption process starts. For the ground state vibrational level $v = 0$ the molecule spends most of the time at its equilibrium configuration. Thus, the most likely vibronic transition from $v = 0$ within the electronic ground state ψ_{el} at the equilibrium nuclear configuration to a vibrational level v' of the excited electronic state $\psi_{el'}$ corresponds to a transition for which the Franck–Condon factor $S_{v'v} = \langle \chi_{v'} | \chi_v \rangle$ is maximal, that is, where the vibrational wavefunctions for the ground and excited electronic states have a large overlap. In Figure 3.50 this corresponds to the $v = 0$ to $v' = 3$ transition. Other transitions from $v = 0$ away from the equilibrium nuclear configuration to vibrational levels v' of the electronic excited state will also occur, but with lower probability as shown in Figure 3.50. The resulting absorption spectrum and its vibronic structure is also shown in Figure 3.50.

The vibronic fine structure of absorption spectra of polyatomic molecules is more complex due to the larger number of vibrations (see Section 3.8). These vibrations, which lead to a vibronic structure in the absorption spectra of polyatomic molecules, are called Franck–Condon active modes. These are usually vibrations whose

equilibrium position is most greatly changed by the electronic transition. For example, during an $n\pi^*$ absorption of a ketone or an aldehyde the C=O stretch vibration is excited, that is, Franck–Condon active. However, very often the absorption spectra of organic molecules appear broad and featureless since the spectra are broadened by solvent interactions.

Now we have seen that the Franck–Condon factors determine the intensity of vibronic transitions. However, electronic transitions are only allowed if the electronic transition dipole moment $\bar{\mu}^{(0)}_{\psi_{el'}\psi_{el}}$ (see Equation 3.129) does not vanish. In practice, the integral itself does not need to be calculated to determine selection rules: it is sufficient to know if its value is not zero and the transition is allowed. This can be done with the help of molecular symmetry (group theory), which allows the analysis of integrals of the form of the electronic transition dipole moment $\langle\psi_{el}|\hat{\mu}|\psi_{el'}\rangle$ with respect to whether they vanish or not. Such a symmetry analysis leads to the orbital symmetry selection rules. It would go beyond the scope of this book to discuss the role of molecular symmetry in identifying vanishing electronic dipole matrix elements, that is, symmetry-forbidden transitions. In the following, the symmetry selection rules for the electronic transitions with which we shall be most concerned in biophotonics will be given. For organic molecules these are in particular $\pi\pi^*$ and $n\pi^*$ transitions. According to symmetry selection rules, $\pi\pi^*$ transitions are mostly allowed and $n\pi^*$ transitions are forbidden. However, in practice, $n\pi^*$ transitions are weakly allowed since the molecular symmetry is often distorted by molecular vibrations, that is, vibrations cause deviations from ideal molecular symmetry. These structural distortions can change a symmetry-forbidden transition into a weakly allowed transition. However, the different symmetry selection rules for these two transitions manifest themselves in the corresponding absorption coefficients. While the symmetry-allowed $\pi\pi^*$ transition is characterized by large absorption coefficients of 10^3-10^5 l mol^{-1} cm^{-1}, $n\pi^*$ transitions exhibit much weaker absorbance coefficients of 1–10^2 l mol^{-1} cm^{-1}.

We have learned above that $d-d$ transitions in metal complexes are very often the reason why many of the transition metal compounds are colored. However, for complexes with a center of inversion, $d-d$-transitions are symmetry forbidden. They can nevertheless be observed with small extinction coefficients since the ligands around the metal very often distort the perfect symmetry or vibrations remove the inversion symmetry. Other absorption processes within metal complexes have been identified above as charge-transfer transitions. These charge-transfer transitions are characterized by large electronic transition dipole moments.

Another selection rule is called the spin selection rule. It is especially impossible for light to alter the spin of an electronic state, that is, $\Delta S = 0$. This rule is a consequence of quantum mechanics. It is therefore also a forbidden transition to change a singlet state into a triplet state. Such a change can strictly speaking not be induced by light. However, spin-forbidden transitions can be weakly allowed by spin–orbit coupling, which is an interaction of the electron spin with the electron's motion. As a consequence of spin–orbit coupling, singlet and triplet states become mixed, making the spin selection rule no longer strictly applicable. Spin–orbit coupling is especially large for molecules containing heavy atoms.

We will come back to electronic transitions when we discuss fluorescence emission in Section 3.11.

3.10
Polarimetry, Optical Rotatory Dispersion, Circular Dichroism

Polarimetry, optical rotatory dispersion (ORD), and circular dichroism (CD) are based on a different response of chiral media to right- and left-circularly polarized light. Light is said to be circularly polarized if the polarization direction describes a circle around the direction of travel while the amplitude remains constant. On looking against the source of circular polarized light, the polarization direction rotates either clockwise or counterclockwise. A typical example of such a chiral medium is a solution of a molecule having a C atom with four different substituents. Such a molecule has two different forms, which are called enantiomers, one of which is the mirror image of the other. If the solution contains only one enantiomer, or one enantiomer in excess, then this medium is said to be optically active. As a consequence, it will rotate the tip of the *E*-vector of linearly polarized light in one direction, whereas if there is an excess of the other enantiomer, the *E*-vector is rotated in the opposite direction, and either light with right- or left-handed circular polarization will travel faster than the other form. If the rotation of the *E*-vector for linearly polarized light is measured at a fixed frequency, this method is called polarimetry. On the other hand, if the rotation is recorded as a function of the wavelength, then this method is named ORD.

Since a change in the refractive indices is always accompanied by a corresponding change in the absorption indices, there will always be a range in the spectrum of optically active media where the absorption indices are different for right- and left-circularly polarized light. Consequently, one form will be more strongly absorbed than the other. This effect is called CD.

Optical activity measurements are of great importance, since they are capable of determining the molecular stereochemistry of molecules in solution or even *in vivo*. An understanding of chirality is of the utmost importance in life since Nature itself is chiral. A lot of naturally occurring substances such as amino acids, terpenes, carbohydrates, and alkaloids are often enantiopure or at least enantioenriched, that is, one of the enantiomers predominates over the other. The occurrence of chirality in Nature usually results in totally different effects of the two enantiomers on cells, that is, only one enantiomer leads to the correct response in a living organism. As a consequence, normally only one enantiomer of a given drug has the desired activity. Hence understanding chirality is extremely important, for example, for the development of therapeutic drugs.

This section aims at a short introduction to the concept of polarimetry, ORD, and CD. The interested reader is referred to [6, 21].

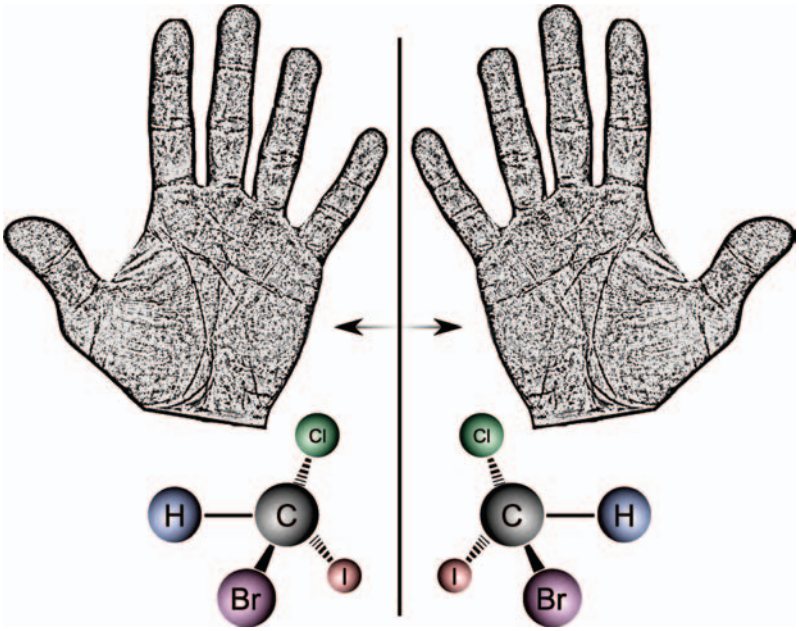

Figure 3.51 Two enantiomers.

3.10.1 Polarimetry

Polarimetry, optical rotation, and circular birefringence are based on the rotation of the *E*-vector of linearly polarized light at a fixed wavelength. The reason for the rotation lies in differences in the refractive index for circularly polarized light: $n_R \neq n_L$.[15] Such differences can be based on, for example, the presence of chiral molecules in a solution. Chirality or handedness can be best explained by employing the hands: the left hand is a mirror image of the right hand and even if one of the hands could be freely rotated in three dimensions it is impossible by an arbitrary series of rotations around different axes to superimpose the left hand on the right and vice versa. The same is true for chiral molecules. The two forms of a chiral molecule are called enantiomers (see Figure 3.51). If both forms are present in a solvent in

15) Circularly polarized light can be described as linearly polarized light where the direction of polarization is not fixed, for example, to the *x*-direction, but describes a circle in the plane perpendicular to the direction of propagation. Circularly polarized waves can also be described as a superposition of two waves that are mutually orthogonally polarized to each other. They also have the same wavelength and direction; however, they differ by 90° in phase, meaning that one wave has its maximum field strength when the field strength of the other wave is zero and vice versa. Looking against the source of the two superimposed waves, one can "see" the electrical vector rotating either clockwise or counterclockwise. The former is referred to as right (R) and the latter as left (L). Inversely linearly polarized light can be described a superposition of left and right circularly polarized light.

equal amounts, this solution is termed "optically inactive" as the *E*-vector of linearly polarized light is neither rotated to the left nor to the right. It needs one of the enantiomers to be present in excess to render the solution optically active. The observed rotation angle α_{obs} of the tip of the electric vector depends on the excess of one of the components, its total concentration c in the solution, and the length of the sample tube z.

The incoming linearly polarized light beam experiences in chiral materials different refractive indices for its left and right circular components. However, if $n_R \neq n_L$ then one component travels faster than the other (i.e., the phasing of left or right rotating component of exiting light beam is shifted while the absolute *E*-field vectors do not change) and finally, after leaving the sample tube, the addition of the components results again in linearly polarized light, but having a polarization direction that is rotated by an angle α_{obs} compared with the incoming polarization. This angle is given by

$$\alpha_{obs} = [\alpha]_\lambda^T \cdot z \cdot c \tag{3.130}$$

where $[\alpha]_\lambda^T$ is the specific angle of rotation characteristic of an optically active substance at a certain wavelength λ and at a certain temperature T. The molar rotation $[\Phi]_\lambda^T$, which is important for the ORD, is defined as

$$[\Phi]_\lambda^T = \frac{[\alpha]_\lambda^T \cdot M}{100} = \frac{\alpha_{obs} \cdot M}{100 \cdot z \cdot c} \tag{3.131}$$

where M is the relative molar mass.

3.10.2 Optical Rotatory Dispersion (ORD)

In ORD, the molar rotation $[\Phi]_\lambda^T$ is investigated as a function of the wavelength. If a compound does not absorb in the investigated wavelength range, a typical ORD spectrum is displayed as in Figure 3.52. Obviously, the ORD spectra of two enantiomers are not symmetric with the line $[\Phi]_\lambda^T = 0$. The reason for this observation is that the refractive indices for right- and left-circularly polarized light change differently with wavelength (i.e., the rotatory dispersion is proportional to the refractive index difference).

In the region of an absorption band, the indices both for right- and left-circularly polarized light show abnormal dispersion, with two possible developments of the molar rotation. For increasing wavelengths the molar rotation first becomes strongly negative, then increases, and crosses zero ORD for the wavelength of the absorption maximum. After reaching a maximum, the molar rotation finally decreases and approaches values close to zero. In the second case, the ORD develops as a mirror image (see Figure 3.53). This behavior of ORD spectra in the wavelength regions of an electronic absorption is called the Cotton effect after the French physicist Aimé Cotton, who discovered this effect in 1895. The Cotton effect is called positive if the ORD decreases with increasing wavelength, otherwise it is called negative.

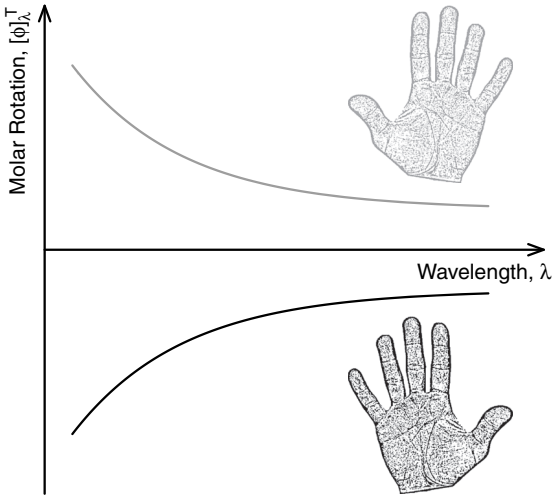

Figure 3.52 Typical ORD spectra for molecules showing no absorption band in the investigated wavelength region.

Quantitative theoretical correlations between molecular structure and ORD (Cotton effect) are difficult, if not impossible, to derive. Therefore, the investigations are mostly empirical. However, empirical investigations within this area have become important; for example, ORD has been successfully applied for constitution elucidation such as to find the position of carbonyl groups in complex optically active molecules.

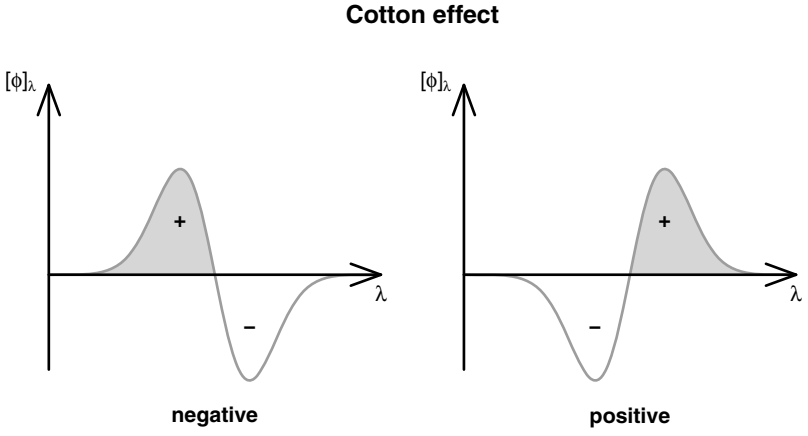

Figure 3.53 Positive and negative Cotton effect for a wavelength region of an absorption.

3.10.3
Circular Dichroism (CD)

As has been shown in Section 3.4, abnormal dispersion results from an absorption of electromagnetic waves, that is, in the close vicinity of an absorption the imaginary part of the refractive index (absorption index) differs from zero. Hence enantiomeric molecules exhibit, in addition to different refractive indices for left- and right-circularly polarized light, also different absorption indices for left- and right-circularly polarized light. Therefore, the extinction coefficients ϵ_L and ϵ_R are also different: $\Delta\epsilon = \epsilon_L - \epsilon_R$. However, compared with ϵ_L or ϵ_R, $\Delta\epsilon$ is rather small and lies in the range 10^{-3}–10^{-6}. Depending on the wavelength, the difference in absorbance for right- and left-circularly polarized light, $\Delta A(\lambda)$, is therefore given by

$$\Delta A(\lambda) = \Delta\epsilon(\lambda) \cdot z \cdot c = A_L(\lambda) - A_R(\lambda). \tag{3.132}$$

For pure ORD bands, left- and right-circularly polarized components have different velocities while traveling through the sample and combine with each other again to give linearly polarized light, but with a rotated plane of rotation. However, for a CD band one component of the circularly polarized light also becomes weaker due to stronger absorption. As a result, the amplitudes of left- and right-circularly polarized light are different, leading to elliptically polarized light. To quantify the ellipticity, the ratio between the short and the long elliptical axes is defined as tangent of an angle ϕ, the so-called ellipticity: $\tan\phi = b/a$ with $a = E_R + E_L$ and $b = |E_R - E_L|$ (see Figure 3.54). The specific ellipticity is then given by

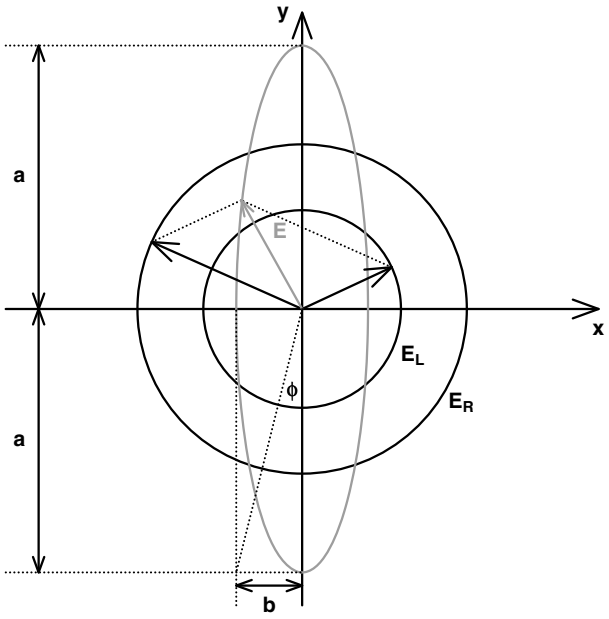

Figure 3.54 Definition of the ellipticity ϕ.

$$[\phi]_\lambda^T = \frac{\phi_{obs}}{z \cdot c} \tag{3.133}$$

where ϕ_{obs} is the experimentally determined ellipticity. Finally, as was the case for ORD, a molar ellipticity can be defined as

$$[\theta]_\lambda^T = [\phi]_\lambda^T \cdot \frac{M}{100}. \tag{3.134}$$

The peak height of CD bands can either be displayed as an absorption difference $\Delta\varepsilon$ or, equivalently, as molar ellipticity $[\theta]_\lambda^T$. Molar ellipticity and CD can be interconverted by the following relation:

$$[\theta]_\lambda^T = 3300 \cdot \Delta\epsilon. \tag{3.135}$$

For an electronic transition to be CD active, the product of the electronic transition moment $\mu_{el} = \langle\psi_f|\hat{\mu}_{el}|\psi_i\rangle$ (see Equation 3.121) and magnetic transition moment $\mu_{mag} = \langle\psi_f|\hat{\mu}_{mag}|\psi_i\rangle$ must be different from zero: $\mu_{el} \cdot \mu_{mag} \neq 0$. Here $\hat{\mu}_{el}$ and $\hat{\mu}_{mag}$ are operators for the electric and magnetic dipole, respectively. The electronic transition moment μ_{el} corresponds to a linear displacement of electrons upon transition from a ground state ψ_i into an excited state ψ_f. μ_{mag} is the magnetic transition moment and corresponds to a radial displacement of electrons upon excited state transition. Therefore, the scalar product $\mu_{el} \cdot \mu_{mag}$ is characterized by a helical electron displacement. Depending on the chirality of the helix, preferably more right- or left-circularly polarized light will be absorbed, respectively. A typical example of the application of CD is the determination of the relative quantities of the α-helix, β-strand, and random coil in proteins.

Of course, CD can also occur in the IR spectral region and is then often called vibrational circular dichroism (VCD). The advantage in this spectral region is that there is no electronic chromophore necessary and that an IR absorption spectrum (see Section 3.8) contains more characteristic absorption bands, making the identification of the stereo isomer easier.

3.11 Fluorescence

Fluorescence is the emission of light by molecules that have absorbed light of shorter wavelength. Fluorescence spectroscopy and in particular fluorescence microscopy have emerged as the most important technology in biophotonics since they allow a multitude of questions in the life sciences and medicine to be resolved. The detection of fluorescence instead of the weak absorption changes of white light in optical microscopy offers several advantages: the detection of fluorescence is virtually background free and extremely sensitive, so that even single molecules can be investigated. Fluorescence in biophotonics is generally used as a way of tracking biological molecules by means of the fluorescence emission. Its unique sensitivity, specificity, and versatility make fluorescence an

ideal diagnostic tool in biological and biomedical research. In fluorescence microscopy, naturally occurring autofluorescent biomolecules or introduced fluorescence labels selectively attached to another biomolecule such as a protein or nucleic acid or to certain cellular structures of interest are used. In particular, the selective fluorescence labeling allows for localization of a target within a cell or the identification of specific biostructures. Furthermore, elaborate fluorescence techniques such as FRET (Förster resonance energy transfer), FRAP (fluorescence recovery after photobleaching), FLIM (fluorescence lifetime imaging microscopy), and so on that allow the analysis of complex processes in biological specimens have been developed. More recently, the breakthrough from fluorescence microscopy to fluorescence nanoscopy was achieved by utilizing saturated optical transitions. Fluorescence nanoscopy paves the way for new, exciting insights into cellular processes. This section aims at providing insights into the underlying molecular processes and into basic theoretical concepts of fluorescence spectroscopy/microscopy.

A comprehensive introduction to fluorescence is given in [17, 19, 22], and the emerging concepts of fluorescence nanoscopy are described in [23–26].

3.11.1
The Fate of Electronically Excited States

In Section 3.9 it was shown that certain chromophores within molecules are able to absorb light, promoting the molecule into an electronically excited state. However, excited electronic states are usually energetically unstable and short-lived; what short means will be discussed later. Fluorescence is one pathway for a molecule to relax from an excited electronic state back to the ground state (nonexcited state). However, fluorescence is only one of numerous processes that can occur subsequent to an electronic absorption. These processes are usually represented in a Jablonski energy level diagram. A simple Jablonski diagram for an organic molecule is depicted in Figure 3.55.

The different electronic states together with their vibrational levels are plotted as horizontal lines. The processes taking place after absorption can be classified into radiative and radiationless (nonradiative) transitions. Radiative processes which involve the emission of light while the molecule relaxes back to the ground state are depicted as solid arrows pointing downwards, whereas radiationless processes are shown using wavy horizontal arrows. Radiationless means that the excited state deactivation is not accompanied by the emission of photons. Before we discuss fluorescence in detail, the different other deactivation processes which can occur subsequent to UV–Vis absorption should be briefly explained. As has been shown in Section 3.9, molecules can absorb light which populates excited electronic states S_1, S_2, and so on according to the orbital and spin selection rules.

Let us assume, as plotted in Figure 3.55, that the S_2 state is the first optically accessible state for UV–Vis absorption from the S_0 ground state, that is, the $S_0 \rightarrow S_2$

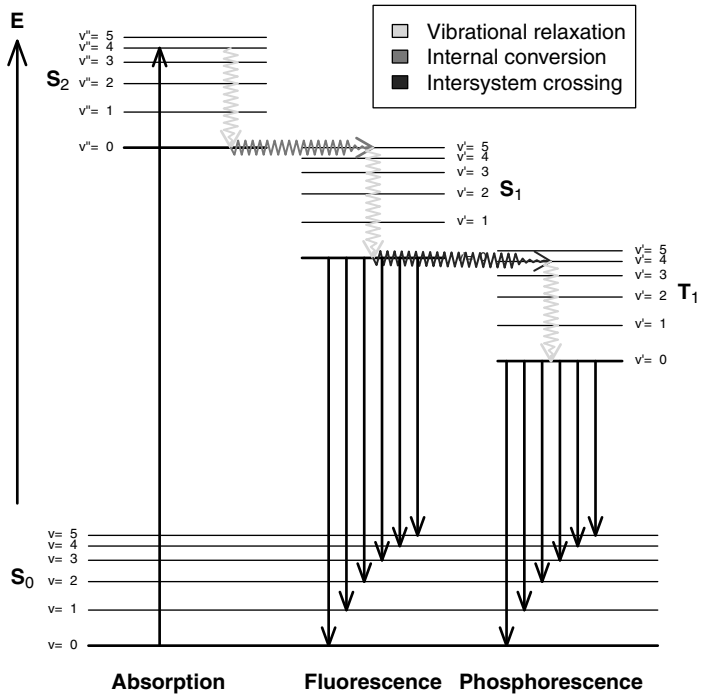

Figure 3.55 Jablonski term scheme for a polyatomic organic molecule (adapted from [20]).

transition is a fully allowed one. The absorption process proceeds according to the Franck–Condon principle and populates excited vibrational states ($v'' > 0$) of Franck–Condon-active modes within the S_2 state.[16] The excess vibrational energy of the S_2 state is dissipated as heat when the vibrationally excited S_2 molecules collide with solvent molecules. This relaxation process which populates the vibrational ground state ($v'' = 0$) of the S_2 state is called vibrational relaxation (vibrational cooling) and takes place on a typical time scale of 10^{-12} s.[17] The $v'' = 0$ level of the S_2 state is usually very close in energy to an excited vibrational level of the S_1 state, facilitating a rapid energy transfer between these two electronic states. Such a radiationless transition between isoenergetic vibronic levels of two different electronic states of the same multiplicity is called internal conversion. Internal conversion has its origin in the breakdown of the Born–Oppenheimer approximation. The Born–Oppenheimer approximation (or adiabatic approximation) is well justified for the ground state S_0 and the first excited state S_1 where the energy gap between these two electronic states is much larger than that between vibrational states. This allows the separate

16) Note that the electronic excitation populates excited vibrational states of Franck–Condon-active normal modes. This excess energy can also be redistributed among other modes that do not accompany the electronic transition, that is, populating vibrational excited states of dark modes.

17) Note that vibrational ground state means that the molecule exhibits in the excited electronic state in terms of all vibrational degrees of freedom q the vibrational quantum number $v_q = 0$.

treatment of electronic and nuclear motions. However, the energy gaps between higher excited electronic states (S_4, S_3, S_2) are relatively small, which means that electronic and nuclear motions cannot be treated independently of each other any longer since they take place on the same time scale and, as a consequence, nuclear motions can induce a radiationless transition between two isoenergetic vibronic levels of two higher excited electronic states. Typical time scales of internal conversion processes between higher excited electronic states are of the order of 10^{-13} s.

After the S_2/S_1 internal conversion process, vibrational relaxation again occurs, populating the vibrational ground state ($v' = 0$) of the lowest excited singlet state S_1. As has been stated above, the much larger energy difference between the S_1 and S_0 states than that between the higher excited electronic states means that internal conversion between S_1 and S_0 proceeds more slowly than that between the upper excited states. Therefore, no matter which upper excited singlet state is populated by the absorption of a UV–Vis photon, vibrational relaxation and internal conversion processes occurring in a matter of picoseconds lead to the population of the $v' = 0$ level of the S_1 state. From there, several relaxation channels can be accessed: (1) radiative transition by emission of a fluorescence photon, (2) S_1/S_0 internal conversion, or (3) intersystem crossing to the first triplet state T_1. This is the statement of Kasha's rule, which says that due to the very rapid depopulation of higher excited electronic states to the lowest vibrational level of the S_1 state, fluorescence emission of electronically excited molecules almost always happens from the lowest vibrational level of the lowest excited singlet state (S_1). In other words, fluorescence from higher excited electronic states is usually unable to compete with internal conversion from these states. Since the S_1/S_0 energy gap is much larger, $S_1 \rightarrow S_0$ fluorescence is able to compete with $S_1(v' = 0) \rightarrow S_0(v = n)$ internal conversion.

Intersystem crossing describes spin-forbidden radiationless transitions between isoenergetic vibrational levels of electronic states of different multiplicity. This spin-forbidden process is driven by spin–orbit coupling (see Section 3.9), which is why its rate can be enhanced by the presence of heavy atoms. Hence the intersystem crossing time scale is variable and depends strongly on the molecular systems. The two radiative excited state deactivation channels fluorescence and phosphorescence are called photoluminescence. Fluorescence involves a radiative decay between two electronic states of the same multiplicity. For most molecular systems, fluorescence starts from the vibrational ground state of the first excited state S_1 and ends in vibrational excited levels of the ground state S_0: $S_1(v' = 0) \rightarrow S_0(v = n) + h\nu$. The intensity of these vibronic fluorescence transitions is determined by the Franck–Condon principle (see also Section 3.9). The time scales of photon emission by fluorescence are in the order of nanoseconds (10^{-9} s). Phosphorescence is a spin-forbidden process which involves the emission of a photon due to a transition between two electronic states of different multiplicity, typically from the vibrational ground state of the first triplet sate T_1 to vibrationally excited levels of the electronic ground state: $T_1(v' = 0) \rightarrow S_0(v = n) + h\nu$. Just as for intersystem crossing, spin–orbit coupling is responsible for this forbidden spin flip process. Hence the time scale for phosphorescence depends on the molecular system (i.e., presence of heavy atoms) but can be really slow, in the order of 10^{-3}–10^{2} s.

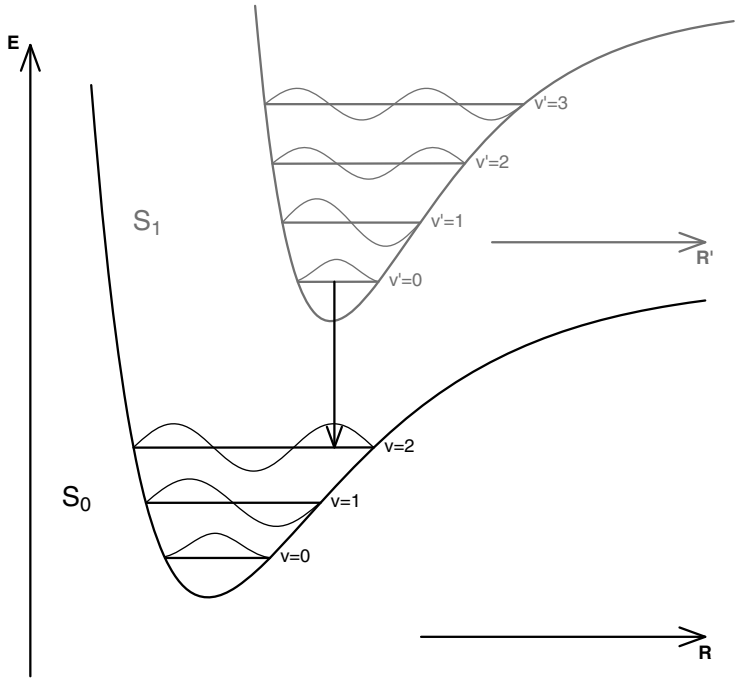

Figure 3.56 Illustration of the Franck–Condon principle for the most probable vibronic fluorescence transition (adapted from [17]).

In the following we characterize the fluorescence emission in more detail. It has been shown above that fluorescence usually originates from the vibrational ground state of the first excited singlet state S_1. Fluorescence transitions, just as absorption processes, are vertical transitions proceeding according to the Franck–Condon principle. Hence the intensities of the different vibronic $S_1(\mathrm{v}' = 0) \rightarrow S_0(\mathrm{v} = n)$ transitions are determined by the respective Franck–Condon integrals $\langle \chi_{\mathrm{v}} | \chi_{\mathrm{v}'} \rangle$ (see Figure 3.9). Figure 3.56 depicts this Franck–Condon principle for the most probable, that is, most intense, vibronic fluorescence transition exhibiting the largest Franck–Condon factor.

Figure 3.57 depicts the Jablonski diagram illustrating the vibronic transitions leading to the $S_0(\mathrm{v} = 0) \rightarrow S_1(\mathrm{v}' = n)$ absorption spectrum and to the $S_1(\mathrm{v}' = 0) \rightarrow S_0(\mathrm{v} = n)$ fluorescence spectrum for a typical organic molecule. The intensities of the vibronic absorption and fluorescence transitions within the absorption and fluorescence spectra (see upper part of Figure 3.57) are determined by the Franck–Condon factors. As has been stated in Section 3.9, the vibronic patterns are often washed out by interaction with the solvent environment and broad and structureless absorption and emission bands result.

The absorption and emission spectra plotted in Figure 3.57 look like mirror images. This is only the case if the vibrational spacings in the ground state S_0 and first excited state S_1 are similar, which occurs if the geometries of S_0 and S_1 states are

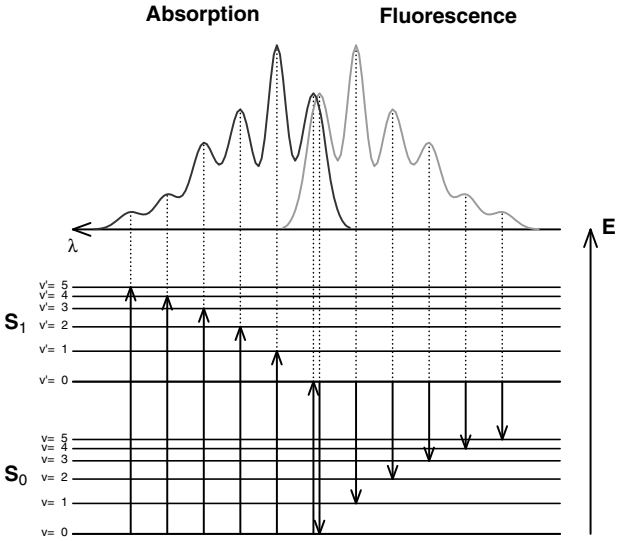

Figure 3.57 Illustration of the vibronic absorption and fluorescence transitions (adapted from [20]).

similar. Such a behavior can be observed for rigid aromatic molecules where there is almost no change in geometry upon electronic absorption. In general, the vibronic pattern of the absorption spectrum resembles the vibrational characteristics of the first excited state while the vibronic structure of the fluorescence spectrum is due to the vibrational level structure of the ground state S_0. According the Stokes rule, the fluorescence emission wavelengths are always red shifted compared with the absorption wavelengths. This phenomenon has its foundation in the rapid vibrational relaxation of vibrationally excited S_1 molecules generated by the absorption process. This means that the excess vibrational energy of the S_1 state is rapidly dissipated as heat to the surroundings prior to fluorescence emission originating from the vibrational ground state ($v = 0$) of the S_1 state. The gap between the intensity maximum of absorption spectrum and that of the fluorescence spectrum is called the Stokes shift.

3.11.2
Basic Concepts of Fluorescence Spectroscopy

In addition to this qualitative picture of fluorescence emission, we aim to establish in the following a quantitative description of fluorescence emission. We start with deriving an expression for the $S_1(v' = 0)$ excited state lifetime. Figure 3.58 recalls all the possible competing intramolecular S_1 deactivation processes with their rate constants:

- k_r^S: rate constant for radiative $S_1 \rightarrow S_0$ decay via fluorescence
- k_{ic}^S: rate constant for internal conversion ($S_1 \rightarrow S_0$)
- k_{isc}: rate constant for intersystem crossing ($S_1 \rightarrow T_1$)

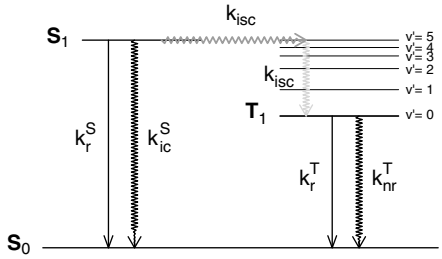

Figure 3.58 Photophysical processes occurring from the $S_1(v' = 0)$ state (adapted from [17]).

- k_r^T: rate constant for radiative decay via phosphorescence ($T_1 \rightarrow S_0$)
- k_{nr}^T: rate constant for nonradiative decay via intersystem crossing ($T_1 \rightarrow S_0$).

The radiationless transitions can be combined to result in an overall nonradiative rate constant $k_{nr}^S = k_{ic}^S + k_{isc}$. The application of standard first-order kinetics yields a rate of disappearance of S_1 excited state molecules $^1A^*$:

$$-\frac{d\left[{}^1A^*\right]}{dt} = \left(k_r^S + k_{nr}^S\right)\left[{}^1A^*\right] \tag{3.136}$$

where $\left[{}^1A^*\right]$ is the concentration of S_1 excited state molecules. Solution of this differential equation yields an expression for the transiently excited S_1 molecule concentration:

$$\left[{}^1A^*\right] = \left[{}^1A^*\right]_0 e^{-\frac{t}{\tau_S}} \tag{3.137}$$

where $\left[{}^1A^*\right]_0$ is the concentration of molecules A promoted to the excited state S_1 by a very short pulse (i.e., short with respect to the inverse of the rate constants listed in Figure 3.58) at time $t = 0$. The S_1 excited state lifetime τ_S is given by

$$\tau_S = \frac{1}{k_r^S + k_{nr}^S}. \tag{3.138}$$

In the following we derive an expression for how the observed fluorescence intensity decays subsequent to an ultrashort pulse excitation. The fluorescence intensity $I_F(t)$ at any time t after excitation is proportional to the concentration of S_1 excited state molecules, that is, $\left[{}^1A^*\right]$, in which the proportionality constant is the rate constant for the radiative decay via fluorescence k_r^S:

$$I_F(t) = k_r^S \cdot \left[{}^1A^*\right] = k_r^S \cdot \left[{}^1A^*\right]_0 \cdot e^{-\frac{t}{\tau_S}}. \tag{3.139}$$

Hence the fluorescence intensity decays monoexponentially with the fluorescence decay time τ_S, which is an important parameter to characterize fluorescent molecules.[18] As mentioned above, the fluorescence lifetime is in the order of nanoseconds.

18) In case that the S_1 state is exclusively deactivated by fluorescence emission, the lifetime is $\tau_r = 1/k_r^S$, which is called the radiative lifetime.

Another important characteristic of a fluorescent molecule is its fluorescence quantum yield, Φ_F, which is defined as the ratio of the number of photons emitted to the number of photons absorbed and can be expressed by

$$\Phi_F = \frac{k_r^S}{k_r^S + k_{nr}^S} = k_r^S \tau_S. \tag{3.140}$$

Integration of the monoexponential decay of the time-dependent fluorescence intensity yields the fluorescence quantum yield:

$$\frac{1}{[^1A^*]_0} \int_0^\infty I_F(t) dt = k_r^S \tau_S = \Phi_F. \tag{3.141}$$

If fluorescence is the only excited state relaxation pathway, then $\Phi_F = 1$, whereas $\Phi_F = 0$ if no fluorescence is observed. Thus the fluorescence quantum yield exhibits values between 0 and 1.

The above relations were deduced for time domain fluorescence experiments where the fluorescence intensity is recorded as a function of time after excitation with a very short light pulse. However, most commonly the fluorescence intensity is recorded under conditions of steady-state illumination where the excitation light source emits a constant amount of photons per unit time (e.g., a lamp). In the following, we derive a quantitative expression for the steady-state fluorescence intensity. The steady-state excitation process can be described as

$$^1A + h\nu \xrightarrow{k_a} {}^1A^* \tag{3.142}$$

where $k_a \approx 10^{15}\ s^{-1}$ is the absorption rate. The concentration of excited state molecules remains constant for such a steady excitation process:

$$\frac{d[^1A^*]}{dt} = 0 = k_a \alpha N_0 - (k_r^S + k_{nr}^S)[^1A^*] \tag{3.143}$$

where N_0 is the constant amount of incident photons under steady-state illumination and $k_a \alpha N_0$ characterizes the number of absorbed photons per unit volume and time (α denotes the fraction absorbed) and can be expressed by the intensity I_0 of the irradiated light, that is, $k_a \alpha N_0 = \alpha I_0$. The steady-state fluorescence intensity I_F is directly proportional to the constant concentration of S_1 excited molecules $[^1A^*]$:

$$[^1A^*] = \frac{\alpha I_0}{k_r^S + k_{nr}^S} \tag{3.144}$$

where the proportionality constant is the rate constant of fluorescence emission k_r^S:

$$I_F = k_r^S [^1A^*] = \alpha I_0 \frac{k_r^S}{k_r^S + k_{nr}^S} = \alpha I_0 \Phi_F. \tag{3.145}$$

Equation 3.145 shows that the ratio of steady-state emitted photons to absorbed photons yields the fluorescence quantum yield:

$$\frac{I_F}{\alpha I_0} = \Phi_F \tag{3.146}$$

All these relations have been derived for an integrated fluorescence intensity, that is, neglecting the different possible energies of the emitted fluorescence photons. Plotting the steady-state fluorescence intensity I_F as a function of the emission wavelength λ_F leads to the fluorescence emission spectra shown in Figure 3.57. This is done by expressing the steady-state fluorescence intensity per absorbed photon as a function of the fluorescence wavelength represented by $F_\lambda(\lambda_F)$. The fluorescence emission spectrum $F_\lambda(\lambda_F)$ mirrors the different vibronic $S_1(v' = 0) \rightarrow S_0(v = n)$ fluorescence transitions and is therefore determined by the corresponding Franck–Condon integrals. Hence the steady-state fluorescence intensity $I_F(\lambda_F)$ is proportional to $F_\lambda(\lambda_F)$ and also to the number of absorbed photons at the excitation wavelength λ_E, which can be expressed by the absorbed light intensity $I_A(\lambda_E)$:

$$I_F(\lambda_E, \lambda_F) = k \cdot F_\lambda(\lambda_F) I_A(\lambda_E) \tag{3.147}$$

where k is a proportionality constant depending on the experimental setup. The absorbed light intensity $I_A(\lambda_E)$ is the difference between the incident $I_0(\lambda_E)$ and the transmitted $I_T(\lambda_E)$ light intensity:

$$I_A(\lambda_E) = I_0(\lambda_E) - I_T(\lambda_E) \tag{3.148}$$

where the transmitted light intensity $I_T(\lambda_E)$ can be expressed by the Lambert–Beer law (Equation 3.122):

$$I_T(\lambda_E) = I_0(\lambda_E) e^{-2.3 \cdot \epsilon(\lambda_E) c \cdot z}. \tag{3.149}$$

By using Equations 3.148 and 3.149 Equation 3.147 can be rewritten:

$$I_F(\lambda_E, \lambda_F) = k \cdot F_\lambda(\lambda_F) I_0(\lambda_E) \left[1 - e^{-2.3 \cdot \epsilon(\lambda_E) c \cdot z}\right]. \tag{3.150}$$

Recording the steady-state fluorescence intensity I_F as a function of the emission wavelength λ_F for a fixed excitation wavelength λ_E yields the fluorescence emission spectrum, that is, it reflects the probability distribution of the different vibronic fluorescence transitions $F_\lambda(\lambda_F)$. Equation 3.150 shows a rather complicated dependence of the steady-state fluorescence intensity on the concentration c. However, for low concentrations the term in square brackets in Equation 3.150 can be approximated as

$$1 - e^{2.3 \cdot \epsilon(\lambda_E) c \cdot z} = 2.3 \cdot \epsilon(\lambda_E) c \cdot z - \frac{1}{2} [2.3 \cdot \epsilon(\lambda_E) c \cdot z]^2 + \cdots \tag{3.151}$$

For dilute solutions, the higher term can be neglected and a direct proportionality between the concentration c and the fluorescence intensity is obtained:

$$\begin{aligned} I_F(\lambda_E, \lambda_F) &= k \cdot F_\lambda(\lambda_F) I_0(\lambda_E) [2.3 \cdot \epsilon(\lambda_E) c \cdot z] \\ &= 2.3 \cdot k \cdot F_\lambda(\lambda_F) I_0(\lambda_E) \cdot A(\lambda_E) \end{aligned} \tag{3.152}$$

where $A(\lambda_E)$ is the absorbance at λ_E (see Equation 3.123). However, for a quantitative analysis of fluorescence emission spectra, one always has to keep in mind that this

linear relationship between the fluorescence intensity and concentration is only valid for dilute solutions, that is, $A \approx 0.01$.

Steady-state fluorescence experiments can be also performed in another way by recording the fluorescence intensity as a function of the excitation wavelength λ_E for a fixed detection wavelength λ_F. This yields a fluorescence excitation spectrum. Equation 3.152 shows that the fluorescence intensity recorded as a function of the excitation wavelength is characterized by the product $I_0(\lambda_E) \cdot A(\lambda_E)$. This means that if it is possible to account for the wavelength dependence of the incoming light intensity, the fluorescence excitation spectrum depends only on the absorption $A(\lambda_E)$, that is, it reflects the absorption spectrum. To be more precise, provided that only one ground-state species exists, the corrected fluorescence excitation spectrum [i.e., compensation of the wavelength dependence of the incoming light $I_0(\lambda_E)$] is identical with the absorption spectrum. Hence a comparison between fluorescence excitation and absorption spectra yields valuable information about the sample species present. Figure 3.59 shows a comparison between the absorption, fluorescence emission, and fluorescence excitation spectra of a dilute aqueous cinoxacin solution.

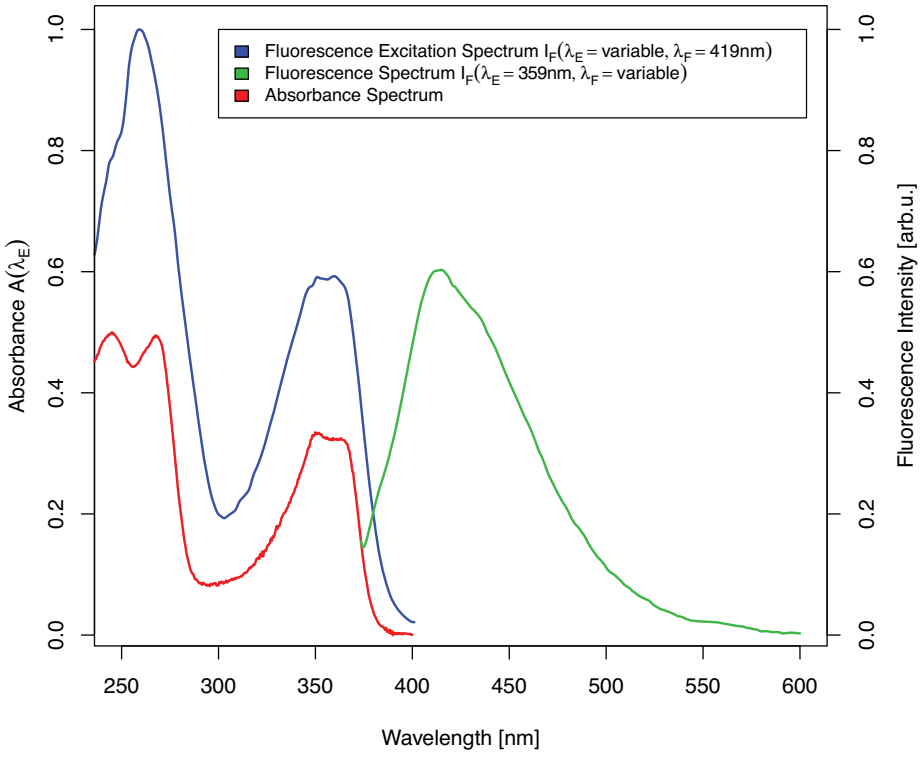

Figure 3.59 Absorption, fluorescence excitation, and fluorescence emission spectra of cinoxacin.

3.11.3
Nonradiative Energy Transfer

So far, we have only considered intramolecular S_1 deactivation channels (see Figure 3.58) when deriving the above-mentioned quantitative fluorescence intensity expressions. However, the interaction of electronically excited molecules with other molecules may compete with fluorescence emission if these intermolecular interactions take place on similar time scales as the excited state lifetime. The intermolecular deactivation of an excited molecule by another molecular system is called fluorescence quenching. Several intermolecular fluorescence quench processes exist. Most of these processes involve a fast transfer process from a donor to an acceptor such as electron, proton, or energy transfer. In the following we focus on radiationless excitation energy transfer from an electronically excited donor to an acceptor, since this is the basis of one of the most important fluorescence techniques in biophotonics to quantify such important processes, for example, protein–protein and protein–DNA interactions or conformational changes of proteins, and so on.

Nonradiative energy transfer requires a significant spectral overlap of the emission spectrum of the donor D with the absorption spectrum of the acceptor A. This means that for a nonradiative energy transfer, the existence of isoenergetic vibronic transitions of the donor and acceptor is required. In other words, these transitions are in resonance, that is, they are coupled (see Figure 3.60).

Various interaction/coupling mechanisms between donor D and acceptor A responsible for the energy transfer exist. In Section 3.9 (see footnote 14 on page 172), we have seen that the coupling between two states $|\psi_i\rangle$ and $|\psi_f\rangle$ is usually expressed by a coupling matrix element $\langle\psi_f|\hat{V}|\psi_i\rangle$ with the perturbation $\hat{V}$. Let us assume that the energy transfer process can be described by one electron of the donor D and one electron of the acceptor A. For this assumption, the initial and final wavefunctions can be expressed by

$$\begin{aligned}\psi_i &= \frac{1}{\sqrt{2}}[\psi_{D^*}(1)\psi_A(2) - \psi_{D^*}(2)\psi_A(1)] \\ \psi_f &= \frac{1}{\sqrt{2}}[\psi_D(1)\psi_{A^*}(2) - \psi_D(2)\psi_{A^*}(1)]\end{aligned} \tag{3.153}$$

where the wavefunction ψ_i represents the situation where the electron on the donor D is excited (D^*) and that on A is not and the final wavefunction ψ_f characterizes the situation after the energy transfer, that is, the electron on A is excited (A^*) and that on D is not. The numbers 1 and 2 symbolize the two electrons involved in the energy transfer process. The form of the wavefunctions (antisymmetrized product wavefunctions) takes into account that electrons are not distinguishable. Hence the coupling matrix element U between donor D and acceptor A due to a perturbation $\hat{V}$ reads as follows:

$$U = \langle\psi_{D^*}(1)\psi_A(2)|\hat{V}|\psi_D(1)\psi_{A^*}(2)\rangle - \langle\psi_{D^*}(1)\psi_A(2)|\hat{V}|\psi_D(2)\psi_{A^*}(1)\rangle. \tag{3.154}$$

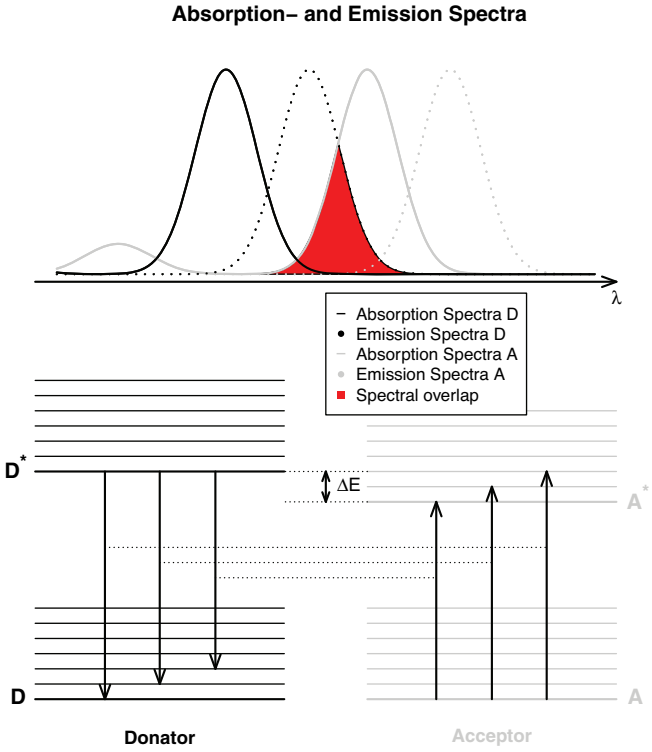

Figure 3.60 Energy level diagram representing the resonance (coupling) of donor and acceptor vibronic transitions (adapted from [19]).

The first term is called the Coulomb term and represents the situation where the initially excited electron on D returns to the ground state whereas simultaneously the electron on A is becoming excited. It is referred to as Coulomb energy transfer because it is a consequence of the electrostatic repulsions between the electron at the donor and that at the acceptor. The second term describes the exchange of two electrons between A and D and is therefore called the exchange term. These two terms are characterized by different operating distances r between the donor and acceptor. The exchange term is a short-range process because it describes an energy transfer process by an exchange of an electron due to intermolecular orbital overlap. However, the Coulomb term can be approximated by a long-range dipole–dipole interaction between the transition dipole moments of the donor $\mu_{fi}^{D} = \langle D^* | \hat{\mu} | D \rangle$ and acceptor $\mu_{fi}^{A} = \langle A^* | \hat{\mu} | A \rangle$ transitions $D \rightarrow D^*$ and $A \rightarrow A^*$, respectively (Figure 3.61). In other words, the electron relaxing from D^* to D generates a transition dipole moment μ_{fi}^{D} which can interact with the transition dipole moment μ_{fi}^{A} simultaneously created by the excitation from A to A^*.

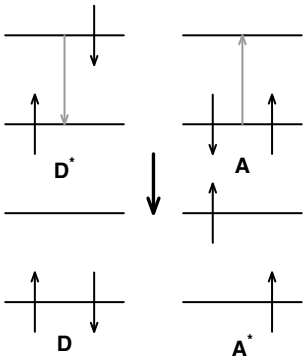

Figure 3.61 Illustration of long-range dipole–dipole Coulomb interaction.

It should be noted that in contrast to the exchange interaction, the Coulombic dipole–dipole interaction does not require contact between donor and acceptor as it is a long-range interaction. The Coulombic mechanism is equivalent to the energy being transferred across the space between the donor and acceptor. The Coulombic term of Equation 3.154 can be expressed under the approximation of a dipole–dipole interaction between the transition dipole moments μ_{fi}^{D} and μ_{fi}^{A} as follows:

$$U^{dd} \sim \frac{|\mu_{fi}^{D}| \cdot |\mu_{fi}^{A}|}{r^3}(\cos\vartheta_T - 3\cos\vartheta_D\cos\vartheta_A) \tag{3.155}$$

where r is the distance between the donor D and the acceptor A. The angles ϑ_T and ϑ_A describe the orientation between the two transition dipole moments and are defined in Figure 3.62.

Equation 3.155 shows that the long-range dipole–dipole interaction is large if the two transitions $D \rightarrow D^*$ and $A \rightarrow A^*$ are fully allowed, that is, their transition dipole moments are large. Furthermore, the dipole–dipole interaction strength depends on the mutual orientation of the transition dipole moments (see Figure 3.62).

3.11.3.1 Förster Resonance Energy Transfer (FRET)

The Coulombic dipole–dipole energy transfer is called Förster resonance energy transfer after Theodor Förster, who developed a detailed theory for such a long-range Coulombic dipole–dipole energy transfer. FRET is considered to be a very weak coupling process. This means that the absorption spectrum of the coupled donor–-acceptor system is almost identical with the sum of the absorption spectra of the individual components. This is the case if the vibrational relaxation in the excited donor D^* is much faster than the energy transfer to the acceptor. The transfer rate for a FRET process can be derived with the help of Fermi's golden rule (see footnote 14 on page 172), employing Equation 3.155 as the coupling matrix element. The density of states ρ is expressed by the spectral overlap between the donor emission spectrum and the acceptor absorption spectrum. Hence the following expression for the FRET transfer rate can be derived:

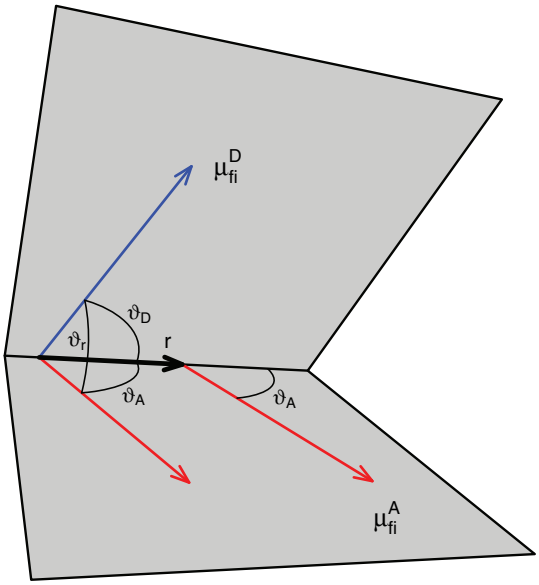

Figure 3.62 Illustration of angles ϑ_T and ϑ_A describing the orientation of the two transition dipole moments μ_{fi}^{D} and μ_{fi}^{A} (adapted from [17]).

$$k_{D\to A}^{dd} = k_D\left(\frac{R_0}{r}\right)^6 = \frac{1}{\tau_D^0}\left(\frac{R_0}{r}\right)^6 \tag{3.156}$$

where k_D is the radiative decay rate of the donor, τ_D^0 is the excited state lifetime of the donor in the absence of energy transfer, and R_0 is the Förster radius, namely the distance at which the intensity decreases caused by energy transfer and spontaneous internal decay are equal, that is, $k_{D\to A}^{dd} = k_D$. The r^6 dependence of the transfer rate on the donor–acceptor distance is a result of the square modulus of the dipole–dipole interaction $\left|U^{dd}\right|^2$ in Fermi's golden rule. The Förster radius can be determined from the spectral overlap of the fluorescence emission spectrum of the donor and the absorption spectrum of the acceptor:

$$R_0^6 = \frac{9000\cdot \ln 10\cdot \kappa^2 \Phi_D^0}{128\cdot \pi^5 N_L n^4}\int_0^\infty I_D(\lambda)\epsilon_A(\lambda)\lambda^4 d\lambda \tag{3.157}$$

where $\kappa^2 = (\cos\vartheta_T - 3\cos\vartheta_D\cos\vartheta_A)^2$ is the orientational factor (see Figure 3.62 and Equation 3.155), Φ_D^0 is the donor fluorescence quantum yield in the absence of the acceptor, n is the average refractive index of the medium for the wavelengths of the spectral overlap, $I_D(\lambda)$ is the normalized fluorescence spectrum of the donor [i.e., $\int_0^\infty I_D(\lambda)d\lambda = 1$], and $\epsilon_A(\lambda)$ is the extinction coefficient of the acceptor. Typical values for the Förster radii, that is, for distances over which energy transfer is important, lie in the range of 15–60 Å. The transfer efficiency can be expressed by

$$\Phi_{D\to A}^{dd} = \frac{k_{D\to A}^{dd}}{k_D + k_{D\to A}^{dd}} = \frac{k_{D\to A}^{dd}}{\frac{1}{\tau_D^0} + k_{D\to A}^{dd}}. \tag{3.158}$$

In combination with the distance dependence of Equation 3.156, it follows for the transfer efficiency:

$$\Phi_{D\to A}^{dd} = \frac{1}{1+\left(\frac{r}{R_0}\right)^6} = 1-\frac{\tau_D}{\tau_D^0} \tag{3.159}$$

where τ_D and τ_D^0 are the excited state lifetimes of the donor D^* (i.e., decay of the donor fluorescence subsequent to pulse excitation) in the absence and presence of the acceptor, respectively. The transfer efficiency also relates to the fluorescence quantum yield of the donor as follows:

$$\Phi_{D\to A}^{dd} = 1-\frac{\Phi_D}{\Phi_D^0} \tag{3.160}$$

where Φ_D and Φ_D^0 are the donor fluorescence quantum yields in the presence and absence of the acceptor, respectively.

As has been stated above, in addition to the distance r between the donor and acceptor, the relative orientation of the transition dipole moments of the donor μ_{fi}^D and acceptor μ_{fi}^A also plays a crucial role in the energy transfer efficiency (see Figure 3.62). The relative orientation is expressed by the orientational factor $\kappa^2 = (\cos\vartheta_T - 3\cos\vartheta_D\cos\vartheta_A)^2$ (see Equation 3.157). For systems where the orientation remains constant during the energy transfer (e.g., use of highly viscose solvents or rigid coupling of donor and acceptor to large and stiff molecules), κ^2 can reach values between 0 (transition dipole moments are orthogonal) and 4 (collinear arrangement). For parallel transition dipole moments, $\kappa^2 = 1$. If both donor and acceptor can rotate, the orientational factor must be replaced by an average: if both chromophores D and A undergo fast isotropic rotation, that is, rotation is considerably faster than the energy transfer rate, the average orientational factor is given by $\kappa^2 = 2/3$. If the donor and acceptor are freely movable but the rotation is significantly slower than the energy transfer, the orientational factor results in $\kappa^2 = 0.476$.

The importance of FRET for biophotonics results in its potential to act as an "optical nano ruler" in the range 10−100Å. The donor–acceptor distance can be determined by either time-resolved or steady state fluorescence measurements via the energy transfer rate (see Equations 3.159 and 3.160):

$$r = \left(\frac{1}{\Phi_{D\to A}^{dd}} - 1\right)^{\frac{1}{6}} R_0. \tag{3.161}$$

The distance between the donor and acceptor should be in the range $0.5R_0 < r < 1.5R_0$ because the Förster radius R_0 is a benchmark for donor–acceptor distances, which can be determined via FRET.

Advances in fluorescence labeling techniques (see The Appendix of this chapter) to introduce fluorophores selectively in biomolecules or in living biological cells (in particular the availability of genetically encoded fluorescent proteins) have allowed the visualization of cellular and single protein processes by means of FRET. This means that FRET measurements are predominantly utilized in biophotonics as a molecular ruler to determine distances between biomolecules labeled with appropriate donor and acceptor chromophores, that is, which are attached to special sites of biomolecules such as proteins. Then it is possible to monitor dynamic molecular processes such as conformational changes manifesting themselves by alterations in the donor–acceptor distances; for example, the donor–acceptor distance in the normal protein is too large for FRET to take place but, as a result of a conformational change of the protein, the donor–acceptor distance is reduced and FRET can occur. Other processes that can be monitored via FRET include (1) conformational changes (e.g., protein folding), (2) ligand receptor interactions or protein–protein aggregation, and (3) protein hydrolysis (see Figure 3.63). For all these processes, the donor–acceptor distance changes from distances where FRET cannot take place to distances where FRET can occur, or vice versa.

Hence the FRET technique adapted to modern fluorescence microscopy is unique in generating fluorescence images (FRET efficiency images) sensitive to molecular dynamics such as conformational changes (e.g., protein folding), ligand-receptor interactions (e.g., protein–protein and protein–DNA interactions), and so on. As mentioned above, FRET manifests itself either through a decrease in the fluorescence lifetime of the donor, or in a quenching of the donor fluorescence intensity and a simultaneous increase in the acceptor fluorescence. Therefore, different methods exist to record FRET efficiency images. Usually it is advantageous to plot the acceptor emission at donor excitation $I_A(\lambda_{abs}^D, \lambda_F^A)$ divided by the donor emission at donor excitation $I_D(\lambda_{abs}^D, \lambda_F^D)$. Such FRET ratio images yield better signal-to-noise ratios than

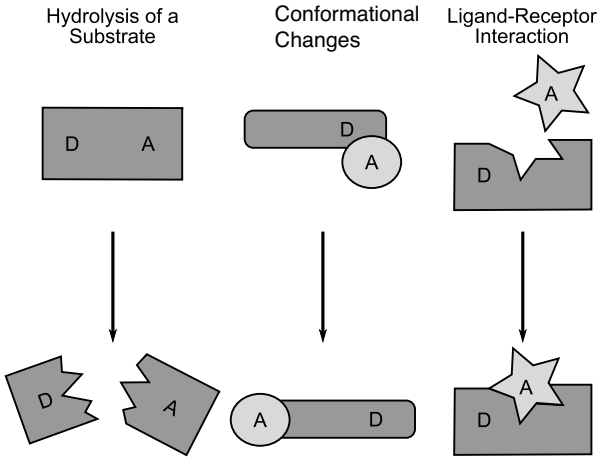

Figure 3.63 Illustration of FRET applications (adapted from [17]).

when solely recording the acceptor fluorescence at donor excitation since both donor decrease and acceptor increase contribute to the signal. Very often it is also necessary to correct for cross-talk, that is, direct excitation of the acceptor when exciting the donor if the donor and acceptor absorption spectra overlap. This can be done by control measurements with samples that are only labeled with the acceptor. Further, it is often required to correct for bleedthrough of donor fluorescence into the acceptor fluorescence detection window in the absence of FRET. This correction is accomplished by control measurements for samples that contain only the donor. An easier way of recoding FRET images which are independent of the above-mentioned spectral contaminations cross-talk and bleedthrough consists in recording the fluorescence lifetime of the donor fluorescence which is reduced if FRET occurs. The generation of fluorescence images based on differences in the exponential decay times of fluorescence is called fluorescence lifetime imaging microscopy (FLIM). In other words, FLIM yields images with the intensity of each pixel determined by the fluorescence lifetime τ and therefore allows viewing of the contrast between fluorophores with different decay times or changes in the decay time of one particular fluorophore due to intermolecular interactions such as in FRET imaging.

3.11.4 Photobleaching

One problem in fluorescence spectroscopy/microscopy with fluorescently labeled biomolecules is photobleaching, which is the permanent loss of the fluorescence emission of a fluorophore due to its exposure to the excitation light. Photobleaching is a dynamic process where the fluorophore molecules are photochemically destroyed on exposure to the excitation light. The average number of absorption fluorescence emission cycles that a fluorophore can carry out before being destroyed by photobleaching depends on the excitation light intensity, the molecular structure of the fluorophore and its chemical environment. Some fluorophores are already bleached after the emission of a few photons whereas others can run through thousands or millions of excitation and emission cycles until photobleaching occurs. The molecular mechanism of photobleaching is only poorly understood. Photobleaching is a matter of different photochemical reactions leading to light-induced damage or modification of the fluorophore. Electronically excited molecules might react with other molecules, leading to irreversible covalent changes of the fluorophore. Furthermore, a fluorophore which ends up in a long-lived triplet state has much more time to react with other molecules in its environment.

Hence the observation of fluorophores in fluorescence microscopy might be hampered because the fluorophores will be destroyed at a certain point by photobleaching due to exposure to the excitation light. However, photobleaching can also be exploited in fluorescence microscopy to characterize the motion or diffusion of molecules. This technology is called fluorescence recovery after photobleaching (FRAP), where a fluorophore is intentionally photobleached by strong laser irradiation. After photobleaching, the fluorescence intensity recovers because fluorophores might diffuse from the environment into the bleaching (i.e., measuring)

area. The recovery of the fluorescence intensity depends on the mobility of the fluorophore. Hence FRAP allows the determination of diffusion coefficients and further parameters determining the mobility of molecules. Additionally, the overall fluorescence intensity decreases due to photobleaching of a certain region can also be monitored. This decrease in fluorescence intensity is caused by the diffusion or transport of molecules into the bleaching region. This fluorescence microscopy approach is called fluorescence loss in photobleaching (FLIP).

3.11.5
Multi-Photon Excited Fluorescence

The recent progress in the development of high-intensity ultrashort laser sources revolutionized fluorescence microscopy by utilizing nonlinear optical phenomena to create a higher microscopic contrast. These ultrashort laser pulses, if focused down, generate extremely high light intensities. As we have seen in Section 3.6, such high intensities allow one to induce multi-photon absorption processes. Multi-photon absorption leads to a simultaneous absorption of $m \geq 2$ photons by a fluorophore. Such a nonlinear dependence can be utilized for applications in which a reaction should be initialized out of only a small spatial area. Thus multi-photon absorption is especially suited to microscopic applications. By the application of a femtosecond titanium:sapphire laser (see Section 3.7) providing excitation wavelengths in the range 800−960 nm, fluorophores absorbing at 400−480 nm (absorption of two photons) or 270−320 nm (absorption of three laser photons) can be excited and their red-shifted fluorescence can subsequently be detected (see Figure 3.64).

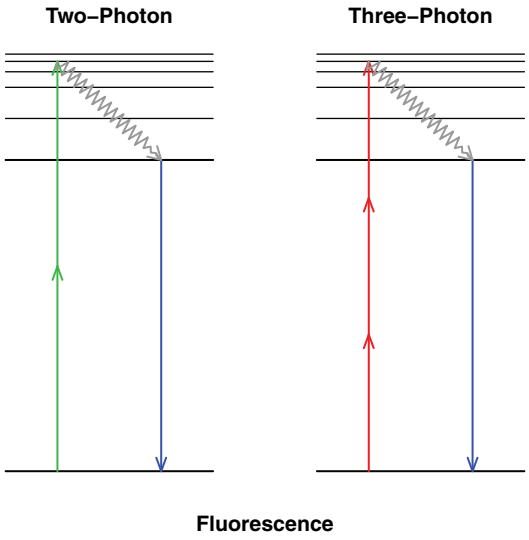

Figure 3.64 Illustration of multi-photon fluorescence emission.

The simultaneous absorption of two or three photons results in a very good localization of the fluorescence light, since such a nonlinear absorption process can only take place in an extremely small volume. Hence multi-photon absorption yields an inherent three-dimensional effect making the application of a confocal pinhole unnecessary, see page 439 (6.1.5.4). There are other advantages of multi-photon absorption fluorescence microscopy. (1) Since the fluorophores are not excited by one high-energy photon but rather through the simultaneous absorption of many low-energy photons, sensitive living biological samples can be investigated in a sparing way. Both the emission of fluorescence and possible bleaching effects, that is, photochemical or thermal degradation of the sample, are limited to a small volume. (2) The excitation wavelength and the fluorescence wavelength are spectrally far apart, resulting in low background noise since the detection of fluorescence light is not disturbed by the broadband excitation laser. Two- or multi-photon absorption fluorescence spectroscopy has emerged since its discovery in 1990 as an indispensable biophysical method providing valuable information about subcellular biochemical processes within living cells. Furthermore, multi-photon imaging by means of NIR femtosecond lasers is characterized by high penetration depths and therefore allows the description of biological tissue with high spatial resolution and good contrast.

3.11.6
Fluorescence Nanoscopy

At the end of this section, recent advances in significantly reducing the spatial area from which fluorescence light can emerge should be briefly summarized. This concept, which is called reversible saturable (or switchable) optical linear fluorescence transitions (RESOLFT) is based on having fluorescent molecules which can exist in two distinct states A and B.[19] Whereas A is a bright state (i.e., shows fluorescence emission), the molecular state B is a dark state (i.e., does not fluoresce). The transition from state A to B can be induced by light and the back reaction from B to A can be either spontaneous or effected by light, heat, and so on:

$$\mathrm{A} \underset{k_{\mathrm{BA}}}{\overset{k_{\mathrm{AB}}}{\rightleftharpoons}} \mathrm{B} \tag{3.162}$$

where k_{AB} and k_{BA} are the rate constants for the transitions $\mathrm{A} \rightarrow \mathrm{B}$ and $\mathrm{B} \rightarrow \mathrm{A}$, respectively. Hence the changes in the normalized populations N_{A} and N_{B} of the states A and B are

$$\frac{\mathrm{d}N_A}{\mathrm{d}t} = -k_{AB}N_A + k_{BA}N_B = -\frac{\mathrm{d}N_B}{\mathrm{d}t}. \tag{3.163}$$

19) It will be shown later that A and B can be two different electronic states of the same molecule or of two different molecules that can be converted into one another by, for example, reversible photoisomerization.

Solving this first-order differential equation yields an expression for the variation of the population of A with time. As $t \to \infty$, the population of state A reaches its equilibrium value, which is given by

$$N_A^{\infty} = \frac{k_{BA}}{k_{AB} + k_{BA}}. \tag{3.164}$$

The rate constant k_{AB} for the light induced depletion of state A is given by

$$k_{AB} = \sigma \cdot I \tag{3.165}$$

where σ is the molecular absorption cross-section and I the light intensity inducing the transition $A \to B$. The molecular absorption cross-section is given by the molar absorption coefficient ϵ : $\sigma = \frac{\epsilon}{N_L}$, where N_L is Avogadro's number.

Equation 3.164 together with Equation 3.165 yields

$$N_A^{\infty} = 1 - N_B^{\infty} = \frac{k_{BA}}{\sigma I + k_{BA}} = \frac{1}{1 + \left(\frac{\sigma}{k_{BA}}\right) I} = \frac{1}{1 + \frac{I}{I_{sat}}}. \tag{3.166}$$

The saturation intensity $I_{sat} = k_{BA}/\sigma$ is the intensity where 50% of the molecules are in state A and 50% in state B. Figure 3.65 shows the dependence of the normalized populations N_A and N_B as a function of the applied light intensity.

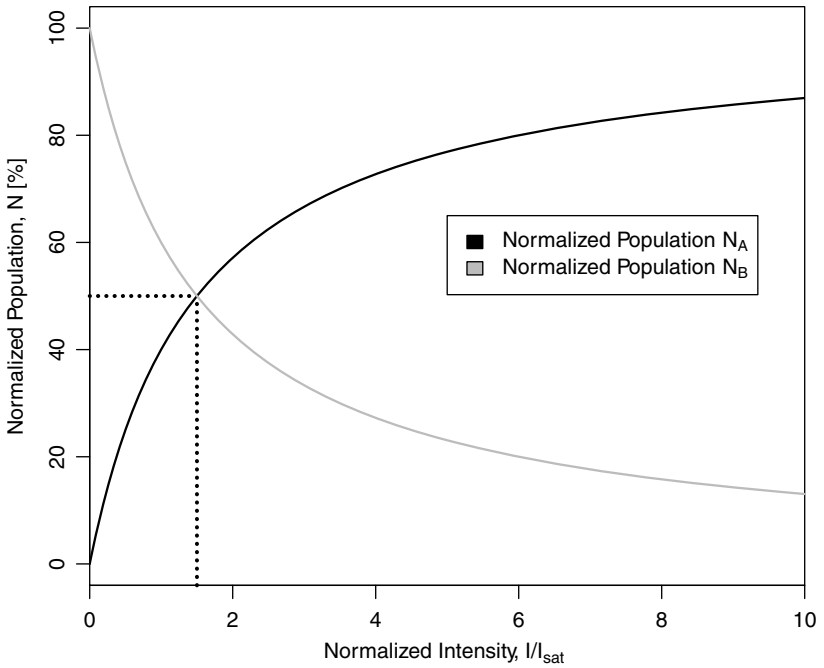

Figure 3.65 Plot of the normalized populations N_A and N_B as a function of I/I_{sat} (adapted from [25]).

It can be seen that for $I \gg I_{sat}$ all molecules end up in the nonfluorescent state B, that is, $N_A^{\infty} \to 0$. Hence it is possible to switch off the fluorescence by shifting all molecules from the bright state A into the dark state B. The principle of reducing the spatial area of fluorescence emission is now based on confining the spatial area of molecules in state A by an intensity naught and simultaneously parking the fluorophores outside the naught in the dark state B. This can be achieved by applying a spatial intensity distribution I for which the intensity at one point x_i equals $I(x_i) = 0$. For one dimension, such an intensity naught can be best realized by a standing wave:

$$I(x) = I_0 \sin^2\left(2\pi n \frac{x}{\lambda}\right) \tag{3.167}$$

where n is the refractive index and λ the wavelength of the light. If this intensity distribution is applied to a spatial distribution of molecules $C(x)$ which are initially in the bright state A for $I_0 \gg I_{sat}$, practically all molecules will be transferred to the dark state B except those which are located around the small area around x_i (see Figure 3.66).

The larger the ratio $I_0/I_{sat} \gg 1$, the smaller the spatial region in which state A is populated becomes. It can be shown that the minima of the standing wave intensity distribution create regions of molecules in the bright state A with a full width at half-maximum (FWHM) of

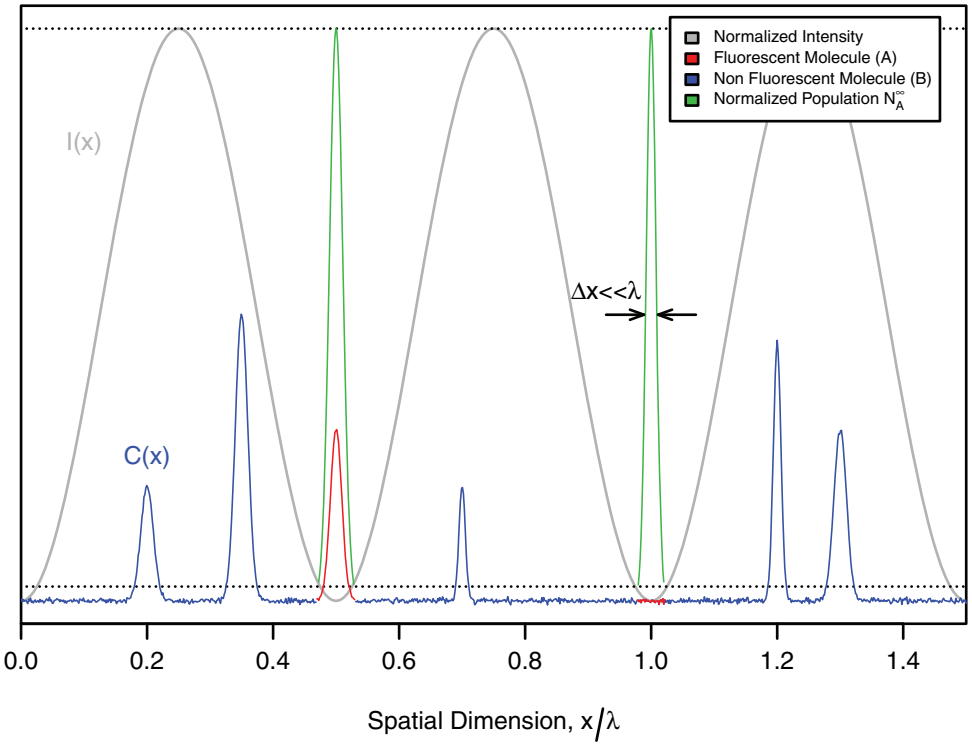

Figure 3.66 Illustration of the RESOLFT principle to create arbitrarily sharp regions of fluorescent molecules (adapted from [24]).

$$\Delta x \approx \frac{\lambda}{\pi n \sqrt{\frac{I_0}{I_{\text{sat}}}}}. \tag{3.168}$$

Thus, if already a small fraction of the overall intensity I_0 is sufficient to promote the molecules into the dark state B, the areas of finding molecules in the bright fluorescent state A are confined to the minima (nodal points) of the standing waves (see Figure 3.66). The fluorescence image is generated by scanning the intensity nodes across the sample $C(x)$. By doing so, all the molecules initially in state A will be temporally transferred to state B except those molecules situated at the nodes. The object $C(x)$ is displayed by the fluorescence observed from the molecules in the bright state A squeezed to an area much smaller than $\lambda/2$. A sequential readout of these transient ultrasharp bright areas yields a high-resolution fluorescence image. The spatial resolution of this image is then determined by the ratio I_0/I_{sat}, which determines the spatial area of the bright state A (see Equation 3.168).

The important relationship $\Delta x \approx (I_{sat}/I_0)^{\frac{1}{2}}$, which was derived for one dimension, is commonly valid for every applied spatial intensity distribution around a naught x_i. If the naught is generated by a lens with an aperture angle α and the fluorescence light is collected by the same lens, the spatial resolution can be approximated by the following relationship:

$$\Delta x \approx \frac{\lambda}{2n \cdot \sin\alpha \sqrt{1 + \frac{I_0}{I_{sat}}}} \tag{3.169}$$

which can be seen as an extension of Abbe's equation (see Section 6.2.2.5).

3.11.6.1 **Stimulated Emission Depletion Microscopy (STED)**

The first experimental realization of the RESOLFT principle is called stimulated emission depletion microscopy (STED). Here, the S_1 state of the fluorophores is the bright state A and the S_0 state is the dark state B. The light-induced transition between the bright S_1 state and the dark S_0 state is accomplished by stimulated emission (see Section 3.7). This means that the S_1 fluorescence is suppressed by stimulated emission from the S_1 (A) into the S_0 (B) state. In doing so, stimulated emission is used to quench the spontaneous emission of fluorescence light in such a manner that only fluorescence at the edge of the fluorescence spot is quenched. Figure 3.67 displays the excitation scheme applied for this stimulated fluorescence quenching called "stimulated emission depletion."

The molecules are excited into an electronically excited state by an excitation laser from where the molecules would normally relax back into the electronic ground state spontaneously by emission of fluorescent light on a nanosecond time scale. However, the application of a high-intensity STED laser pulse that is red shifted and slightly shifted in time compared with the excitation laser leads to stimulated emission of the electronically excited molecules into excited vibrational states of the electronic ground state before they have the chance to fluoresce spontaneously, since stimulated emission is much faster than spontaneous emission. These vibrationally excited

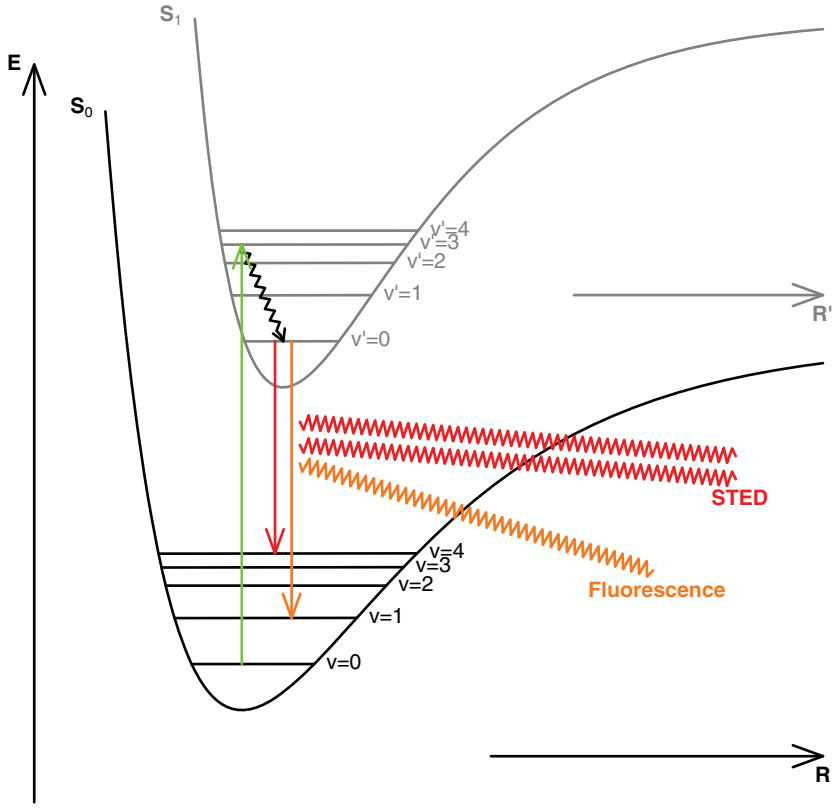

Figure 3.67 Illustration of the STED excitation scheme.

ground-state molecules cannot be excited by the excitation laser any longer. If one chooses a donut beam profile for the STED laser pulse with a central naught which is overlapped with the excitation laser, that is, the STED laser profile is almost dark within the focal point of the excitation laser but very intensively circularly symmetric to the excitation laser, an extreme reduction in the size of the focal spot occurs since only molecules inside both laser foci are not affected by the de-excitation process. Thus the fluorescence light originates from an extremely sharp spot of only a few nanometers in size. Excitation and subsequent de-excitation by the doughnut-shaped STED beam is achieved by synchronized femto- or picosecond pulses allowing the temporal separation of excitation and de-excitation by stimulated emission. The energy of the formerly excited molecule is carried as a further photon in the STED beam. STED microscopy reduces the investigation volume to 0.67 al (attoliters), which is 18 times smaller than that which can be obtained by conventional confocal fluorescence microscopy. The spatial resolution is determined by the intensity of the STED pulse: the more intense the donut beam, the more strongly the effective S_1 population is squeezed to the middle of the donut. The spatial area for which fluorescence is allowed becomes smaller with an increasing STED beam intensity

because then a large fraction of the donut intensity is lying above the saturation intensity I_{sat} and prevents population of the bright state S_1. However, regardless of how high the STED beam intensity is, fluorophores situated at the donut naught will always emit fluorescence light because at the naught no stimulated emission takes place. Hence by scanning the naught across the sample, structures much beyond the diffraction limit are obtained.

The saturation intensity given by $I_{sat} = k_{BA}/\sigma$ depends on the fluorophores or, more precisely, on the two states A and B. The saturation intensity I_{sat} can be approximated by

$$I_{sat} = \frac{1}{\sigma \cdot \tau} \tag{3.170}$$

where τ is the spontaneous emission lifetime of state A. Hence for STED, fairly large saturation intensities are required to reach high spatial resolutions due to the rather short fluorescence lifetime of the S_1 state in the nanosecond range. However, high intensities might lead to sample degradation or photobleaching. Therefore, the application of lower saturation intensities is preferable.

In general, the longer living both states A and B are, the smaller I_{sat} becomes and therefore according to Equation 3.169 the smaller the intensity I_0 becomes that is necessary to go beyond the diffraction limit and coming close to achieving molecular resolution. Therefore, other bright–dark pairs A and B besides S_1 and S_0 in fluorophores with long lifetimes are required to achieve low saturation intensities. The ultimate form of "optical saturation" (see Figure 3.65) is optical switching, that is, the employment of optically bistable molecules where only the bright state A yields fluorescence by excitation to a transient fluorescent state A * (A $\leftrightarrow$ A*) (e.g., photo-transformable *cis–trans* isomers where only one isomer yields fluorescence). These molecular photoswitches allow very low saturation intensities, if it is possible to switch between the long lived fluorescent (A $\leftrightarrow$ A*) and dark (B) states.

3.11.6.2 Photoactivated Localization Microscopy (PALM) and Stochastic Optical Reconstruction Microscopy (STORM)

At the end of this chapter, two other fluorescence microscopy methods achieving nanometer resolution, namely photoactivated localization microscopy (PALM) and stochastic optical reconstruction microscopy (STORM) should be briefly explained. Both PALM and STORM are based on the readout of single molecules from random coordinates. This is achieved by switching on molecules into a bright state A so that only fluorophores that are far apart from each other can be identified as single fluorescent molecules. This means that at the beginning all molecules are switched off, that is, are in state B. Then the molecules are switched on into the fluorescing state A with such a low intensity that the switched-on molecules are further away than half the wavelength. This means that statistically molecules in the direct neighborhood remain in the dark state B. The molecules which were switched on are fluorescence excited several times (A $\rightarrow$ A*) and N photons are detected. In other words, PALM and STORM utilize a molecular process leading to an emission of N photons from the same spot. Subsequently the molecules return spontaneously

(by photobleaching) to the dark state B′ (PALM) or they are sent systematically into the dark state B (STORM). If the movement of the molecules is negligible, each molecule leaves single, separable diffraction broadened spots on the camera whose centroid is determined by a fitting procedure. Each diffraction spot belongs to a single molecule. Fitting an image consisting of N photons can also be seen as N measurements of the fluorophore position in which every measurement has an uncertainty determined by the point spread function (PSF), which describes the response of an imaging system to a point source or point object. The precision with which a single switched-on fluorophore can be localized is given by

$$\Delta_{\mathrm{loc}} = \frac{\Delta_{\mathrm{PSF}}}{\sqrt{N}} \tag{3.171}$$

where Δ is the width of the PSF. A high-resolution image is constructed sequentially by stochastic registration of single switched-on molecules and plotting their position Δ_{loc} as a point. Figure 3.68 illustrates a typical PALM imaging cycle.

First, all fluorescent molecules (red dots) in the field of view are switched off (green dots) by a strong red laser. In a second step, only a small percentage of fluorescent molecules (green light) are switched on such that their images do not overlap. Third, the fluorescence emission of the switched-on molecules is recorded. This fluorescence emission is used to localize the fluorophore position (gray dot) with nanometer accuracy.

The molecule within these single-molecule techniques STORM and PALM has to pass through the bright–dark cycle $[\mathrm{B} \rightarrow \mathrm{A}(\leftrightarrow \mathrm{A}^*) \rightarrow \mathrm{B}(\mathrm{B}')]$ only once since the emission of the N photons takes place via multiple excitation steps in the fluorescent state A^*. In other words, the high-resolution image is assembled molecule by molecule via a single switching cycle $\mathrm{B} \rightarrow \mathrm{A} \rightarrow \mathrm{B}(\mathrm{B}')$ per single molecule. The difference between PALM and STORM is that for PALM photobleaching due to the exposure to the fluorescence excitation light is utilized to switch off A. This means that for PALM the switching cycle is $\mathrm{B} \rightarrow \mathrm{A} \rightarrow \mathrm{B}'$, that is, B′ is different to B. For STORM, B equals B′ since the molecules are actively switched from A to B.

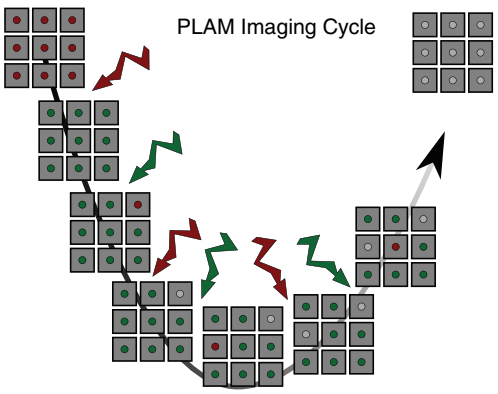

Figure 3.68 Illustration of PALM imaging cycle (adapted from [23]).

This is in contrast to RESOLFT, where constant cycling is required since ensuring state A for a chosen nodal point requires nearby molecules to be switched to the dark state B.

3.12 Elastic Light Scattering

Inhomogeneities inside a medium can also lead to scattering, which is a second effect in addition to absorption (see Section 3.4) that leads to a decrease in the intensity of transmitted light. This section deals with elastically scattered light, which refers to the fact that the wavelength of the light remains unchanged as no energy loss or gain has occurred, very much like a rubber ball which hits a wall, thereby changing only direction but not speed. Scattering is a process which depends strongly on the wavelength of light. Generally, it increases rapidly with decrease in wavelength.

This section aims a short introduction to elastic light scattering. For further reading, [3, 18] are recommended.

There are two mechanisms which are responsible for a decrease in the intensity of a light wave while propagating through a medium. As already detailed (see Section 3.4), one of these mechanisms is the absorption of radiation, during which the energy of the wave is dissipated and which leads to a decrease in the amplitude of the wave. A second mechanism, which also decreases transmission through a medium, is scattering, where light is either elastically or, with a much lower probability, inelastically scattered (see Section 3.13). The former effect is exploited, for example, in nephelometry, where laser light is passed on into a dilute suspension of small particles and the light scattered elastically under an angle of $70-75^\circ$ is collected and investigated to determine the levels of certain proteins.

In analogy with the Lambert–Beer law (Equation 3.38), the dependence of the intensity $I(z)$ with increasing travel distance along the z-direction is given by

$$I(z) = I_0 \exp(-S'z) \tag{3.172}$$

where S' is the scattering coefficient. For dilute solutions, it is possible to determine the so-called scattering cross-section σ_s with a conventional spectrometer directly from the opacity of the sample:

$$S' = N \cdot \sigma_s \tag{3.173}$$

where N represents the number of particles per unit volume. The scattering cross-section is the effective cross-section of the scattering particles within which an incident photon can be deflected.

In the following, we deal only with elastic light scattering, also known as Rayleigh scattering. Inelastic light scattering (Raman sattering) will be treated in detail in Section 3.13.

In the case of elastic light scattering, the incoming electric field induces a time-dependent dipole moment $\mu_{ind}(t)$ and forces the dipole to vibrate. The dipole in turn emits radiation as a consequence with an intensity I_s. Due to the incoming electric field $E = E_0\cos(\omega_0 t)$ at the scattering center ($z = 0$), an oscillating dipole results, which is given by

$$\mu = \alpha \cdot E = \alpha \cdot E_0 \cos(\omega_0 t). \tag{3.174}$$

If the scattering centers are much smaller than the wavelength λ, the Rayleigh equation holds, which is given by

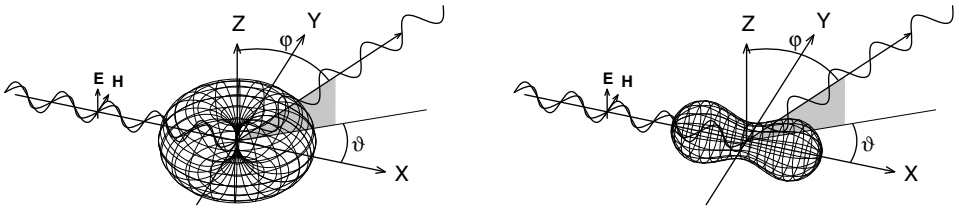
$$\frac{I_s}{I_0} = \frac{16\pi^4\alpha^2}{r^2\lambda^4}\sin^2\varphi. \tag{3.175}$$

It describes the distribution of the Rayleigh scattering, which in the case of monochromatic, perpendicularly polarized light is independent of the azimuth angle ϑ but depends strongly on the zenith angle φ. As can be seen from Equation 3.175, the intensity is indirectly proportional to the fourth power of the wavelength λ or directly proportional to ω^4. The emitted intensity possesses a maximum perpendicular to the dipole axis, as can be seen from Figure 3.69, and is zero along the dipole axis. It is proportional to the square of the dipole moment and indirectly proportional to the square of the distance r from the emitting dipole.

Fairly often, however, the incoming light is unpolarized. In this general case, a superposition of light waves with all possible polarizations results in

$$\frac{I_s}{I_0} = \frac{8\pi^4\alpha^2}{r^2\lambda^4}\left(1 + \cos^2\vartheta\right). \tag{3.176}$$

If there is more than one scatterer in a comparably small volume (multiple scattering, for example molecules in a solution), the scattered waves are nearly always in-phase and interfere constructively. If the scatterers are not small compared with the wavelength, for example in the case of macromolecules, then the scatterer itself consists of a number of scattering centers. Light that is scattered from different scattering centers is generally excited out-of-phase (the wave hits the center at different times and therefore with different phase) and therefore the emitted waves also have different phase and the interference can be both constructive and destructive.



(a) Polarized light (b) Unpolarized light

Figure 3.69 Illustration of the orientation dependence of Rayleigh scattering (adapted from [18]).

Macromolecules in a liquid are usually not perfectly dissolved by a liquid but lead to a colloid or even a suspension. Colloids or suspensions show certain degrees of opacity or turbidity, the investigation of which is carried out by nephelometry (see above).

The theoretical treatment of elastic light scattering can become rather complicated. Originally this problem was solved by Gustav Mie in 1908 for a homogeneous dielectric sphere. Mie's original problem was to understand the various colors in absorption and scattering exhibited by small colloidal particles of gold suspended in water. To obtain the solution, the incident plane wave and also the scattering field can be expanded into radiating spherical vector wavefunctions, while the internal field is expressed as regular spherical vector wavefunctions. By applying the boundary condition on the spherical surface, the expansion coefficients of the scattered field can be computed. A comparably modern way of solving such problems is the *T*-matrix approach. Within this approach, the scattering from anisotropic and anisometric particles can also be treated. Since an exhaustive treatment of this theory is well beyond the scope of this book, we just discuss some of the most important results. One of these results is that the variation of extinction (i.e., absorption + scattering) with frequency depends strongly on the size of the particles. In frequency regions with weak absorptions, the variation of extinction with frequency shows three characteristics: (1) the interference structure which dominates and tends to look like a damped harmonic oscillation; (2) the ripple structure, which is an irregular fine structure; and (3) a monotonically increasing extinction with increasing frequency for the range in which the particle diameter is smaller than the wavelength of light. The last chracteristic implies that the onset of the extinction due to scattering is strongly dependent on the particle size as a result of Mie theory, which explains the various colors of the colloidal gold particles in water (or in glass) as being due to diameter variations of the particles. Figure 3.70 displays the scattering

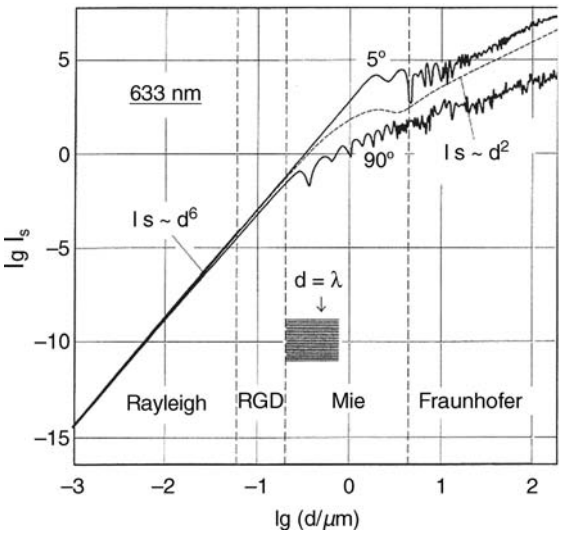


Figure 3.70 Scattering intensity I_S as a function of the particle diameter d (taken from [18]).

intensity I_s as a function of the particle diameter d. It can be seen that the scattering intensity increases by 20 orders of magnitude whereas the particle diameter increases only by five orders of magnitude. For smaller particles, the scattering intensity increases with the sixth power of the particle diameter. For larger diameters d in the range of the wavelength of light, the scattering dependence becomes more complicated and the scattering intensity varies rapidly with the particle diameter. Furthermore, it can be seen that the curve bends down in the area of the wavelength of visible light and the scattering intensity increases only about quadratically with the particle diameter.

3.13
Inelastic Light Scattering (Raman Scattering)

In Section 3.8, it was shown that the direct absorption of IR radiation can promote molecules from their vibrational ground state into the first excited molecular vibrational state. Such vibrational transitions depend directly on the atoms present in the molecule and in particular how these atoms are chemically bonded to each other. Therefore, the vibrational IR absorption pattern of a particular molecule can be seen as its molecular fingerprint and tells a lot about the molecule itself and about the surroundings in which it is embedded. Vibrational transitions can also take place via an inelastic scattering process that was first discovered 1928 by C.V. Raman. This so-called Raman effect marks an indirect approach to excite molecular vibrations. The Raman effect can be interpreted quantum mechanically as an inelastic collision between photons and molecules. Raman and IR spectroscopy are therefore complementary methods exhibiting different selection rules determining which vibration of a molecule can be excited by what method. Although Raman scattering is a fairly weak effect compared with direct IR absorption, Raman spectroscopy has proven in the last few decades its feasibility as a very flexible method in biophotonics. The application of IR absorption spectroscopy for *in vivo* studies is strongly limited by the broad and intense IR absorbance of water. However, unlike IR, water does not interfere with Raman spectroscopy since water has a very weak Raman signal. Hence Raman spectra can be easily collected from aqueous solutions, which is why Raman spectroscopy is perfectly suited for *in vivo* studies. Raman-based methods have emerged in recent years as an extremely powerful method for bioanalytical and biomedical applications, that is, to study biological samples such as cells and tissues. The principle is that Raman spectra contain information on molecular vibrations that provide a highly specific fingerprint of the molecular structure and biochemical composition of cells, tissues, and so on. Diseases and other pathological anomalies are accompanied by changes in these properties. The method provides this information without external markers such as stains or radioactive labels. Raman spectroscopy is a nondestructive technique and, in general, requires only minimal or no sample preparation. However, although the specificity of Raman spectroscopy is very high, its sensitivity, that is, the cross-section of the

Raman effect is rather poor. Since only a small proportion of the incident photons are inelastically scattered, the detection of molecules that are present in very low concentrations is limited. To overcome the disadvantage of low signal intensities from most biomolecules, special Raman signal-enhancing techniques can be applied. The two most prominent approaches are the resonance Raman effect and surface-enhanced Raman scattering (SERS). In addition to these two linear Raman signal-enhancing techniques, the nonlinear variant of Raman spectroscopy CARS also belongs to the most promising Raman techniques because it combines signal enhancement due to the coherent nature of the process with further advantages such as directional emission, narrow spectral bandwidth, and no disturbing interference with autofluorescence. In the following, an introduction to the basic theoretical concepts of linear and nonlinear Raman scattering is given.

The following section provides a rapid introduction to inelastic light scattering. Interested readers are referred to [5]. Nonlinear Raman-techniques are described in [10].

3.13.1
Theoretical Description of Inelastic Light Scattering

Earlier (see Sections 3.1,3.2 and 3.12), it was shown that light can polarize molecules. For visible wavelengths, mainly the electrons contribute to the induced polarization by becoming distorted against the atomic nuclei through the interacting electromagnetic field. Thus the interaction of light with matter induces an electric dipole moment within the molecules (see Equation 3.174). The polarizability α is a measure of how easily electrons can be distorted within a molecule.[20)] The induced dipole moment oscillating with the frequency of the electromagnetic field emits an electromagnetic wave in all directions. If the polarizability α does not change with time, the frequency of the emitted secondary wave corresponds to the frequency of the oscillating induced dipole, that is, the frequency of the external electromagnetic wave inducing the dipole. This type of elastic scattering is called Rayleigh scattering (see Section 3.12).

However, since molecules are always vibrating, the polarizability α is not constant over time, but changes according to the different vibrational frequencies of the molecular normal modes q (see Section 3.8). In other words, the nuclear motions modify the polarizability as the electron density rapidly (adiabatically) adjusts to the momentarily nuclear geometry to minimize overall the energy of the system. The dependence of the polarizability on the nuclear coordinate q can be expressed by expanding the polarizability into a Taylor series around the equilibrium nuclear geometry $q = 0$:

20) It should be noted that α represents a third-rank tensor. If not explicitly mentioned, the tensor characteristics can be neglected for most of the expressions derived in this section.

$$\alpha = \alpha(q) = \alpha(0) + \left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \cdot q + \cdots . \tag{3.177}$$

The nuclear oscillation with a characteristic frequency ω_R along each normal coordinate q can be approximated by a harmonic oscillation (see Section 3.8):

$$q = q_0 \cdot \cos(\omega_R \cdot t). \tag{3.178}$$

Inserting Equations 3.177 and 3.178 into Equation 3.174 yields for the induced dipole moment:

$$\mu = \left[\alpha_0 + \left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \cdot q_0 \cos\omega_R t\right] E_0 \cdot \cos\omega_0 t. \tag{3.179}$$

With the help of common trigonometric relations, Equation 3.179 can be rewritten as

$$\begin{aligned}\mu = \alpha_0 E_0 \cos\omega_0 t \quad &+ \frac{1}{2}\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \cdot q_0 E_0 \cos(\omega_R - \omega_0)t \\ &+ \frac{1}{2}\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \cdot q_0 E_0 \cos(\omega_R + \omega_0)t.\end{aligned} \tag{3.180}$$

Equation 3.180 shows that the time-dependent induced dipole moment, which acts as a source of the scattered radiation, oscillates on three distinct frequencies: the first term oscillating on the frequency ω_0 of the incoming electromagnetic wave represents the elastic light scattering [i.e., Rayleigh scattering (see Section 3.12)] whereas the second and third terms which oscillate with the difference or sum frequency between the incoming light ω_0 and normal mode frequency ω_R express the inelastic or Raman scattering activity. The second term oscillating on the difference frequency is the source for the so-called Stokes scattering, which is red shifted with respect to the excitation frequency ω_0. The Stokes scattered light contains information about the molecular scattering system due to its dependence on ω_R. The third term represents the source of inelastically scattered light which is blue shifted with respect to the incoming frequency ω_0 and is called anti-Stokes Raman scattering. Since the frequency of the anti-Stokes radiation also depends on the normal mode frequency, it also yields molecular information.

Consequently, the secondary radiation emitted by the molecule is a superposition of the exciting frequency and the various vibrational frequencies of the molecule. Dispersing this secondary radiation into its frequency components yields, in addition to the strong Rayleigh scattering, also weak sidebands. The distance between the Rayleigh wavelength and the wavelength of the sidebands corresponds to the vibrational frequencies of the molecule. The appearance of these sidebands due to an inelastic light scattering process was first discovered by C.V. Raman in 1928.

It is also possible to derive an expression for the intensity of the inelastically scattered light based on the classical description of light scattering, that is, the classical picture of interaction between an oscillating electromagnetic field and

a molecular system. The starting point for these considerations is the total power $\mathcal{P}$ emitted by an oscillating Hertzian dipole μ, which is given by

$$\mathcal{P} = \frac{1}{6\pi\varepsilon_0 c^3}\left|\frac{d^2\mu}{dt^2}\right|^2 \tag{3.181}$$

where $d^2\mu/dt^2$ is the second derivative of the dipole moment μ with respect to time t. Since each oscillating induced dipole serves as a Hertzian dipole, that is, as an antenna emitting secondary scattered radiation, μ in Equation 3.181 can be replaced by the induced dipole given in Equation 3.180. In the following we concentrate on the term of the induced dipole moment which leads to the Stokes radiation:

$$\mu_{\text{Stokes}}(t) \sim \frac{1}{2}\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \cdot q_0 E_0 \cos(\omega_R - \omega_0)t. \tag{3.182}$$

Inserting the second derivative of the induced Stokes dipole moment $\mu_{\text{Stokes}}(t)$ with respect to the time t yields for the average power

$$\bar{\mathcal{P}} = \frac{q_0^2}{12\pi\varepsilon_0 c^3}\left[\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0}\right]^2 \cdot (\omega_0 - \omega_R)^4 |E_0|^2. \tag{3.183}$$

Here an averaging over time has been performed (i.e., temporal average over the oscillating part). The intensity observed at 90° is given by

$$I = \frac{3 \cdot \bar{\mathcal{P}}}{8\pi}. \tag{3.184}$$

Inserting Equation 3.183 into Equation 3.184 and using the relationship $I_0 \sim |E_0|^2$ yields an expression for the scattered Stokes intensity:

$$I_{\text{Stokes}} = \text{constant} \cdot I_0 \cdot (\omega_0 - \omega_R)^4 \cdot \left[\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0}\right]^2. \tag{3.185}$$

From this classical description of the Raman scattering intensity, it can be seen that the inelastically scattered light intensity depends on the derivative of the electronic polarizability at the equilibrium geometry along the normal coordinate q: $(\partial\alpha/\partial q)|_{q=0}$. Hence for a normal mode q to be visible in a Raman spectrum the polarizability must change along the normal coordinate with a nonzero gradient at the equilibrium geometry $q = 0$. Therefore, $(\partial\alpha/\partial q)|_{q=0}$ and ω_R in Equation 3.185 depend on the molecular system under study whereas ω_0 and I_0 are experimental parameters determining the experimentally observed Raman intensity. This means that the Raman scattering intensity can be increased by increasing the Raman excitation intensity or by using higher excitation frequencies, that is, shorter Raman excitation wavelengths.

The classical description of Raman scattering provides a qualitative or intuitive understanding of inelastic light scattering. However, for a quantitative description of inelastic light scattering, a quantum mechanical approach is required. An obvious

example where the classical description falls short is its failure to account for the different intensities of Stokes versus anti-Stokes radiation. The Raman effect can be interpreted quantum mechanically as an inelastic collision between photons and vibrating molecules. Photons can be scattered from molecules. This scattering process corresponds to a transition into an extremely short-lived transition state, the so-called virtual level (see Figure 3.71). This virtual level is a state of a photon and a molecule during an infinitesimally short time period, that is, a collective quantum energy state of the entity molecule and photon. The molecule can subsequently relax back from this virtual level into the original (starting) molecular state or into an energetically excited molecular state. If the scattering process starts from the vibrational ground state and ends up in a vibrational excited state via a transition into the virtual state, it is called Stokes Raman scattering (see Figure 3.71). If the molecules are initially already in a vibrationally excited state and are transferred by the

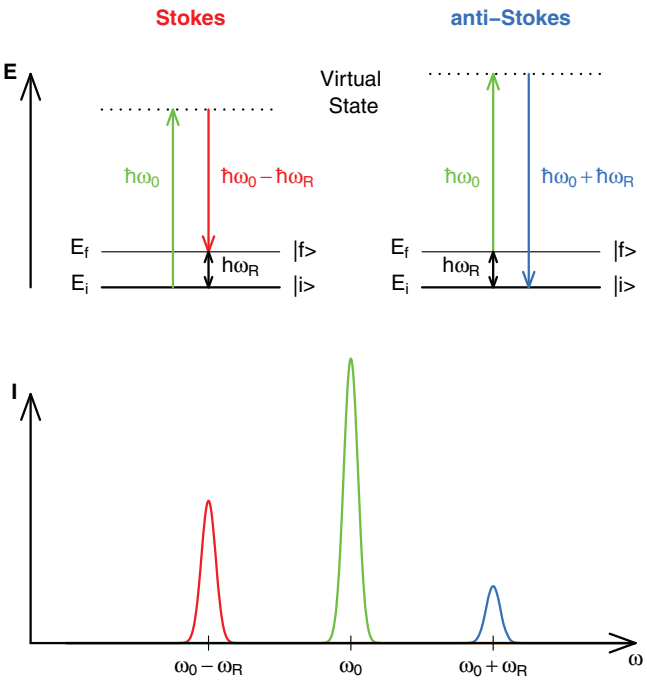

Figure 3.71 Illustration of inelastic light scattering (Raman effect) on a quantized molecular system. Note that the intensity ratio between Stokes Rayleigh and anti-Stokes scattering displayed in the lower part was chosen for the sake of clarity of presentation and is not in accordance with what is experimentally observed. Approximately only one in 10^6 photons is inelastically scattered. The Stokes to anti-Stokes intensity ratio, which would be identical according to the classical dipole model (see Equation 3.180), is determined by the population density ratio between the initial ($|i\rangle$) and final ($|f\rangle$) states determined by the Boltzmann distribution. This means that the Stokes to anti-Stokes intensity ratio depends on the energy difference between the initial ($|i\rangle$) and final ($|f\rangle$) states, that is, on the population of the excited state ($|f\rangle$).

scattering process into the vibrational ground state, it is referred to as anti-Stokes Raman scattering (see Figure 3.71). Since at room temperature the vibrational ground state is usually, according to the Boltzmann distribution (see Equation 3.114), significantly more populated than the vibrationally excited states, the Stokes Raman spectrum of a sample is more intense than the anti-Stokes Raman spectrum. For Rayleigh scattering, the states before and after the scattering process are the same (see Figure 3.71). These scattering processes are classified as two-photon processes since two photons are involved. It should be mentioned that inelastic light scattering (Raman scattering) can occur with a change in vibrational, rotational, or electronic energy of a molecule. In other words, Raman scattering is the inelastic light scattering on a quantized system, that is, energy is exchanged between the incident photons and the molecules where the exchanged energy can be equal to the rotational, vibrational, or electronic energy levels of the molecular scattering system. However, the majority of Raman studies are primarily concerned with the vibrational Raman effect.

The two vibrational spectroscopic methods Raman and IR absorption spectroscopy (see Section 3.8) are complementary methods based on two different light–matter interaction phenomena, thus exhibiting different selection rules. Selection rules determine which vibration of a molecule can be excited by what method. In the case of IR absorption, one photon directly promotes the molecule via an absorption process into a higher vibrational state whereas in the Raman scattering process two photons are involved. In order for a molecular vibration to absorb an IR photon, the dipole moment of the molecule has to change during the course of the vibration, that is, only those vibrations are IR active which give rise to an oscillating dipole. However, as shown above (see Equation 3.185), the polarizability has to change during the vibration so that a molecular vibration can be promoted via an inelastic scattering process into a higher vibrational state.

Raman spectra are usually plotted as the intensity of scattering versus the shift in the wavenumber values of the scattered light from the incident light (see Figure 3.72). Therefore, it is not the absolute wavenumber value that is plotted as in IR absorption spectra (see Figure 3.43), but rather the Raman shift (i.e., relative wavenumber values = wavenumber differences), that is, the shift of the detected wavenumber value with respect to that of the excitation laser. As has been mentioned above, Stokes lines which have a longer wavelength than the incident wavelength (Rayleigh line) due to an energy exchange to the molecules usually display a much higher intensity than anti-Stokes lines which originate from an energy gain from the scattering sample. Therefore, usually the more intense Stokes Raman spectrum (i.e., inelastically scattered light on the long-wavelength side of the excitation line) is observed/recorded.

The combination of Raman spectroscopy with a conventional microscope (micro-Raman spectroscopy) allows for the spatial investigation of samples in the sub-micrometer range. In other words, Raman microscopy allows one to record "molecular" maps of heterogeneous samples such as biological cells or tissue. Therefore, Raman imaging combines the spectral fingerprint information with the lateral information on a cellular and even subcellular level. Raman spectroscopy belongs to the molecular spectroscopic methods with one of the highest information

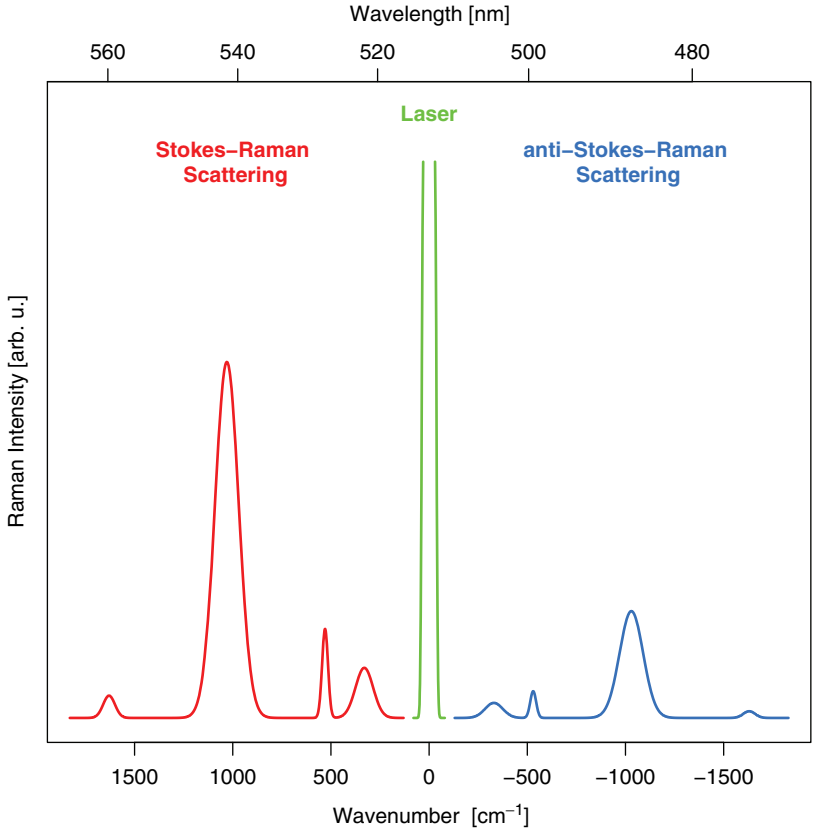

Figure 3.72 Illustration of Stokes versus anti-Stokes Raman scattering.

contents. However, although Raman spectroscopy is characterized by an unprecedented high molecular specificity, its sensitivity, that is, the conversion efficiency of the Raman effect, is rather poor. Since only a small proportion of the incident photons are inelastically scattered, the detection of molecules that are present in very low concentrations is extremely limited. Furthermore it takes a relatively long time to record a complete Raman image of a larger sample area.

Cells and tissues are mainly composed of proteins, nucleic acids, lipids, and carbohydrates. These biological macromolecules consist of defined monomeric subunits such as amino acids and nucleosides. Due to the small Raman cross-sections of these molecules, the Raman spectra of cells and tissues have low intensities. As a consequence of the small number of different subunits, the spectra of cells and tissues often share some similarities that require data with high signal-to-noise ratios to identify the specific spectral signature. To overcome the disadvantage of low signal intensities from most biomolecules, Raman signal enhancement effects were utilized, such as resonance Raman scattering (RRS) and SERS. Whereas the former technique probes vibrations of electronic chromophores, the latter depends

on short-range interactions with metal surfaces in the nanometer range. In the following, these two Raman signal-enhancing effects are discussed in more detail.

3.13.2
Resonance Raman Scattering (RRS)

We start the discussion by reviewing the concepts of RRS, where we particularly focus on theoretical aspects that are of importance for the application of resonance Raman spectroscopy in biophotonics. The classical description of Raman scattering as shown in Equation 3.185 provides a starting point for the discussion of ways in which to enhance the weak Raman scattering cross-sections. Equation 3.185 reveals that the Stokes scattering intensity depends on the polarizability α, or more precisely on $(\partial\alpha/\partial q)|_{q=0}$ and on the incident light intensity I_0. Consequently, the two commonly applied Raman signal-enhancing mechanisms RRS and SERS utilize these two quantities. However, for a quantitative description of resonance Raman spectroscopy, we have to move on to a more detailed explanation of Raman scattering based on the semi-classical picture of Raman scattering, which treats the molecule quantum mechanically (i.e., the polarizability is expressed fully quantum mechanically by means of perturbation theory) but considers the electromagnetic field classically (scattering from a Hertzian dipole). In other words, $\left|(\partial\alpha/\partial q)|_{q=0}\right|^2$ in Equation 3.185 is replaced by the square modulus $|\alpha|^2$ of the quantum mechanical expression of α (because α is a complex quantity):

$$I_{\text{Stokes}} = \text{constant} \cdot I_0(\omega_0 - \omega_R)^4 \cdot |\alpha|^2 \tag{3.186}$$

In resonance Raman spectroscopy, the dispersion relation of the polarizability α (i.e., its frequency dependence) is utilized to enhance the Raman scattering intensity. For the derivation of the polarizability tensor components, second-order perturbation theory must be applied since Raman scattering is a two-photon process. By doing so, Kramers, Heisenberg, and Dirac derived an expression for the transition polarizability tensor:

$$(\alpha_{\sigma\rho})_{\text{fi}} = \sum_{\psi_r} \left(\frac{\langle\psi_f|\hat{\mu}_\rho|\psi_r\rangle\langle\psi_r|\hat{\mu}_\sigma|\psi_i\rangle}{\hbar\omega_{ri} - \hbar\omega_0 - i\Gamma_r} + \frac{\langle\psi_f|\hat{\mu}_\sigma|\psi_r\rangle\langle\psi_r|\hat{\mu}_\rho|\psi_i\rangle}{\hbar\omega_{rf} + \hbar\omega_0 - i\Gamma_r} \right) \tag{3.187}$$

where

$\alpha_{\rho\sigma}$	component of the polarizability tensor $\alpha(\rho, \sigma)$ of the Raman transition $i \rightarrow f$ (i.e., ρ, σ refer to the molecule fixed Cartesian vectors x, y, z)
σ	polarization of the incident light
ρ	polarization of the scattered light (Raman)
$\|\psi_i\rangle$, $\|\psi_f\rangle$, $\|\psi_r\rangle$	initial, final, and intermediate states of the Raman scattering process
ω_0	angular frequency of the incident radiation
ω_{ri}	angular frequency of the transition $i \rightarrow r$

r	sum over all unperturbed intermediate states
Γ_r	damping, which correlates with the lifetime of the intermediate states ψ_r.

The transition dipole moments (see Equation 3.121) in the nominator of Equation 3.187 are illustrated in Figure 3.73.

Equation 3.187 can be interpreted such that Raman scattering is a two-photon process which involves a virtual dipole transition from the initial state $|\psi_i\rangle$ to the complete manifold of intermediate eigenstates $|\psi_r\rangle$ of the unperturbed molecule followed by another virtual dipole transition to the final state $|\psi_f\rangle$. For nonresonant Raman scattering ($\omega_{ri} >> \omega_0$ see Figure 3.73a), the weighted summation over all possible states results in no information on the eigenstates $|\psi_r\rangle$. The initial $|\psi_i\rangle$ and final $|\psi_f\rangle$ states play the determining role.

That changes when the angular frequency of the excitation light ω_0 approaches the transition angular frequency ω_{ri} of an electronic absorption band of the molecule (see Figure 3.73b). Equation 3.187 reveals that for such a case, that is, when $\omega_0 \approx \omega_{ri}$, the polarizability α will be increased dramatically because the denominator of the first

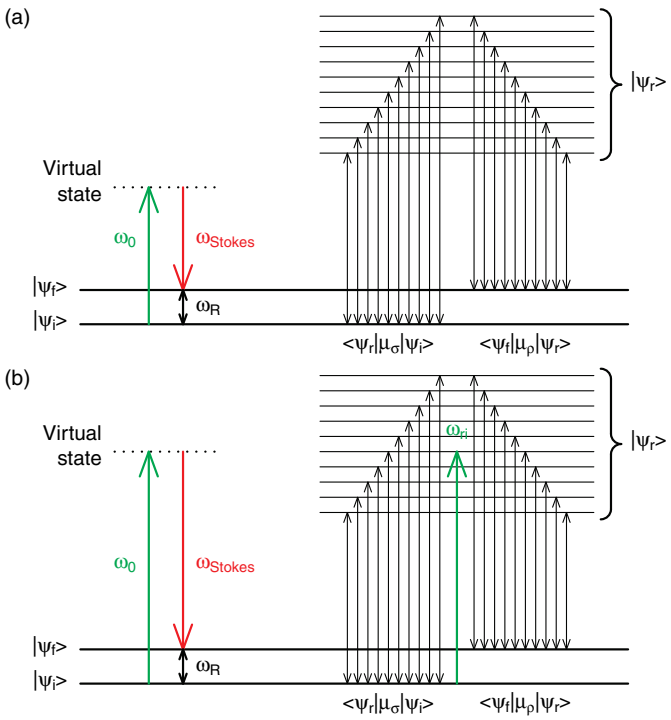

Figure 3.73 Energy level diagram illustrating the sum-over-states description of the Raman transition polarizability tensor (see Equation 3.187). (a) Nonresonant Raman scattering; (b) resonance Raman scattering where the Raman excitation frequency matches the electronic transition of the molecule, that is, $\omega_0 \approx \omega_{ri}$.

term in the sum in Equation 3.187 becomes small, causing the first term to become very large. This explains the Raman signal enhancement of up to six orders of magnitude that is observed for resonance Raman as compared with normal Raman scattering. Therefore, in resonance Raman spectroscopy, the Raman excitation wavelength is chosen to be in or near resonance with an electronic absorption of the molecular scattering system (see Figure 3.73b). For such resonance Raman conditions ($\omega_0 \approx \omega_{ri}$) the first term in Equation 3.187 dominates over the second term and the Raman polarizability in Equation 3.187 reduces to

$$(\alpha_{\sigma\rho})_{fi} = \sum_{\psi_r} \left(\frac{\langle \psi_f | \hat{\mu}_\rho | \psi_r \rangle \langle \psi_r | \hat{\mu}_\sigma | \psi_i \rangle}{\hbar\omega_{ri} - \hbar\omega_0 - i\Gamma_r} \right). \tag{3.188}$$

This expression for the transition polarizability tensor in electronic resonance can be further simplified by utilizing the same assumptions as outlined in Section 3.9, Equations 3.128 and 3.129. This means that rewriting the transition dipole moments in the nominator of Equation 3.188 by applying the Born–Oppenheimer approximation and the Condon approximation results in

$$(\alpha_{\sigma\rho})_{fi} = \sum_{\psi_{el'}} \bar{\mu}^{(0)}_{\rho,\psi_{el}\psi_{el'}} \bar{\mu}^{(0)}_{\sigma,\psi_{el'}\psi_{el}} \sum_{\chi_{v'}} \left(\frac{\langle \chi_{v_f} | \chi_{v'} \rangle \langle \chi_{v'} | \chi_{v_i} \rangle}{\hbar\omega_{ri} - \hbar\omega_0 - i\Gamma_{\psi_{el'}\chi_{v'}}} \right). \tag{3.189}$$

As discussed in Section 3.9, $\bar{\mu}^{(0)}_{\rho,\psi_{el}\psi_{el'}}$ and $\bar{\mu}^{(0)}_{\sigma,\psi_{el'}\psi_{el}}$ are the electronic transition dipole moments at the equilibrium nuclear geometry for the electronic resonant transitions $\psi_{el} \rightarrow \psi_{el'}$ and $\psi_{el'} \rightarrow \psi_{el}$, respectively. In the context of resonance Raman spectroscopy, we are mainly concerned with the vibronic part of the polarizability tensor:

$$(\alpha_{\sigma\rho})_{fi} = \sum_{\chi_{v'}} \left(\frac{\langle \chi_{v_f} | \chi_{v'} \rangle \langle \chi_{v'} | \chi_{v_i} \rangle}{\hbar\omega_{ri} - \hbar\omega_0 - i\Gamma_{\psi_{el'}\chi_{v'}}} \right) \tag{3.190}$$

which is determined by the vibrational overlap integrals (i.e., Franck–Condon factors) for the upward and downward transitions (see Figure 3.73b), that is, between the final vibrational wavefunction of the electronic ground state $|\chi_{v_f}\rangle$ and the vibrational wavefunction $|\chi_{v'}\rangle$ of the resonant electronic excited state, $\langle \chi_{v_f} | \chi_{v'} \rangle$ and between $|\chi_{v'}\rangle$ and the intial vibrational wavefunction of the ground state $|\chi_{v_i}\rangle$, $\langle \chi_{v'} | \chi_{v_i} \rangle$. From Equation 3.190, it can be seen that in resonance Raman spectroscopy only those normal modes which possess large Franck–Condon factors are resonantly enhanced. These are exactly those modes which also account for the vibrational structure in the electronic absorption spectra, that is, the Franck–Condon active modes. In Section 3.9, it was shown that Franck–Condon active modes are vibrations whose equilibrium positions are most greatly changed by the electronic transition. However, while the vibronic pattern in absorption spectra is often washed out due to solvent–solute interactions, resonance Raman spectroscopy is the method of choice to identify these Franck–Condon active modes. Moreover, a quantitative resonance Raman intensity analysis allows one to derive the displacement Δ of the equilibrium

position of the resonant excited electronic state with respect to the ground electronic state. It can be shown that for small displacements of the resonantly excited electronic state potential surface along the resonance Raman-active normal modes, the resonance Raman intensity is approximately proportional to Δ^2. Therefore, resonance Raman spectroscopy and in particular the analysis of resonance Raman excitation profiles (i.e., recording the intensity of resonantly enhanced modes versus excitation wavelength) allows one to deduce valuable information about the structure of electronically excited states by determining the atomic displacement Δ between the ground and excited electronic states and thus the change in bond lengths and bond angles while going from the ground to the excited state. However, resonance Raman spectroscopy in biophotonics is mainly applied not because of its potential to interrogate the Franck–Condon point/region[21)] of an excited electronic state, but rather because of its high, dramatically increased sensitivity as compared with nonresonant Raman scattering.

The selection of a Raman excitation wavelength in resonance with an electronic absorption band increases the Raman cross-section of those modes which are coupled to the resonant electronic transition (i.e., the Franck–Condon active modes) of a factor of up to 10^6 as compared with nonresonant Raman scattering. This enhancement of the Raman scattering intensity significantly improves the signal-to-noise ratio and allows the detection of low-concentration substances in solution. Since resonance Raman spectra are dominated by modes characteristic of the geometric changes of the molecules during the electronic transition, resonance Raman spectra are less complex than their nonresonant counterparts since fewer vibrations contribute to the spectrum. Therefore, special emphasis can be placed selectively on these enhanced vibrations. Furthermore, the selective excitation of vibrational modes of certain electronic chromophores (e.g., of chromophores pivotal for the biological activity of the molecule) becomes possible by choosing the appropriate excitation wavelength in resonance with the electronic chromophore. Therefore, such a site specificity due to the choice of different resonance Raman excitation wavelengths is a great advantage when investigating biological samples with more than a single electronic chromophore, since it allows the selective investigation of smaller subunits in large assemblies, for example, probing the active center in proteins, which is pivotal for the function of the respective molecules, or the selective excitation of macromolecules such as proteins or DNA in the presence of other molecules, for example, in whole cells. The high sensitivity and selectivity have led to various important applications of resonance Raman spectroscopy in biological, biochemical, and medical research in recent years.

However, despite all these advantages, there are also some drawbacks when using resonance Raman spectroscopy. First, the absorption of the resonance Raman excitation light often causes photo degradation of the sample, which is why it is

21) The Franck–Condon point is geometrically identical with the minimum in the ground state, but located in the excited electronic state. However, Franck–Condon region would be more precise since a vertical transition starting from the nuclear equilibrium geometry of the ground state just represents the most probable transition. Hence the region of the excited state potential which is accessed by the vertical transitions (see Figure 3.50) is called the Franck–Condon region.

necessary to rotate the sample quickly to avoid heating (i.e., excitation light always hits a fresh sample spot). Hence the combination of the resonance Raman technique with microscopy to study biological samples is very difficult. Furthermore, reabsorption of the scattered light makes quantitative evaluation of the Raman intensity difficult and internal standards have to be used.

In Section 3.11, it was shown that an electronic absorption into the first excited singlet state S_1 is often followed by the emission of fluorescence light. Hence the greatest drawback in resonance Raman spectroscopy might be the simultaneous excitation of intense fluorescence with which resonance Raman spectroscopy has to compete if resonance Raman spectroscopy occurs also via the S_1 excited electronic state from which the fluorescence emission originates. Since the cross-section for fluorescence can be much larger than the resonance Raman cross-section, the observation of Stokes-scattered resonance Raman light is often obscured by the presence of fluorescence. This is especially the case when the Stokes shift, that is, the energy difference between the absorption maximum and the fluorescence maximum, is small. Therefore, the simultaneous observation of fluorescence and RRS becomes possible for large fluorescence Stokes shifts so that the fluorescence emission and the Stokes scattered resonance Raman light are spectrally separated (see Figure 3.74).

The masking of resonance Raman signals by fluorescence can be also avoided by the application of excitation wavelengths in the deep UV region (< 250 nm), which excite higher electronic excited states (S_n with $n > 1$). While RRS occurs directly from the Franck–Condon point of the highly excited electronic state and within about 5−10 fs after electronic absorption, fluorescence originates in most cases according to Kasha's rule (see Section 3.11) from the vibrational ground state of the first excited electronic state S_1, resonance Raman and fluorescence are energetically far away from each other, that is, spectrally well separated.

Another approach to separate RRS from fluorescence consists in utilizing the different time scales on which the two processes take place. RRS occurs immediately after electronic excitation that is within a time window of about 5−10 fs after photon absorption, the fluorescence emission decays on a nanosecod time scale. Thus, the application of ultrafast Kerr shutters allows the observation of the resonance Raman signal without emission contributions by temporally separating RRS from fluorescence emission.

3.13.3
Surface-enhanced Raman Spectroscopy (SERS)

Another way to overcome the drawback of low scattering intensity of normal Raman spectroscopy is to use SERS. The SERS effect corresponds to the enhancement (by a factor of up to 10^{11-14}) of the Raman scattering of a molecule situated in the vicinity of nanosized metallic structures (e.g., Ag or Au). The exact mechanism of the enhancement effect of SERS is still a matter of debate in the literature. There are two primary enhancement mechanisms, namely electromagnetic and chemical enhancement.

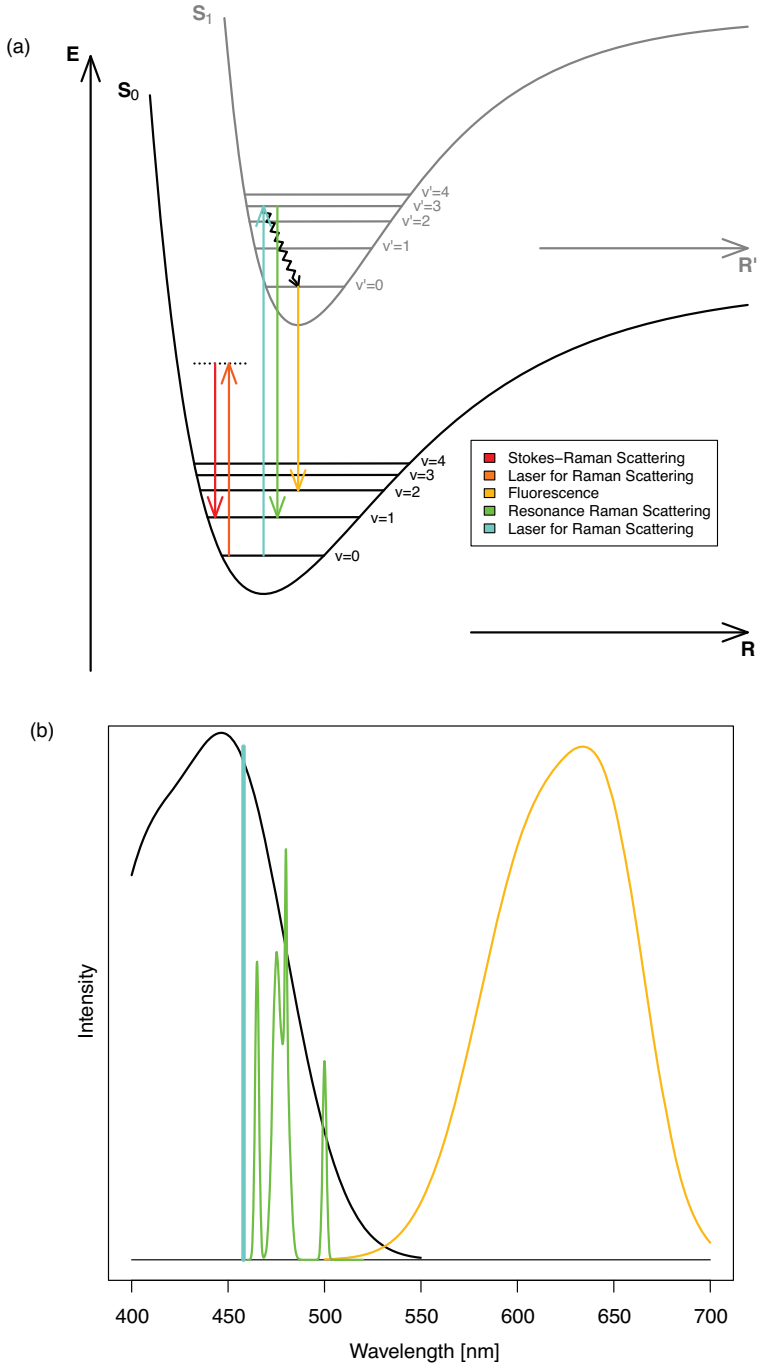

Figure 3.74 Comparison of resonance Raman spectroscopy and fluorescence emission (a). For large Stokes shifts, resonance Raman and fluorescence do not interfere (b).

The classical description of Raman scattering discussed above revealed that the Raman intensity corresponds to the total power emitted by a Hertzian dipole and is proportional to the square of the second time derivative of the induced dipole moment μ (see Equation 3.181). According to $\mu = \alpha \cdot E$, there are two ways to increase the Raman scattering intensity: first by increasing the electromagnetic field E and second by enhancing the transition polarizability tensor α. The first is named the electromagnetic field enhancement mechanism and the second the charge transfer or chemical enhancement mechanism. Although these mechanisms are substantially different from each other, distinguishing them experimentally has not been straightforward. Discussions about the relative contributions of the two mechanisms to the total enhancement are still ongoing.

The electromagnetic enhancement mechanism is based on a local increase in the electromagnetic field at metal surfaces due to the excitation of surface plasmon resonances. Plasmons can be described in the classical picture as collective oscillations of the free electron gas (conduction electrons against the fixed positive ion cores of the metal). One differentiates between bulk plasmons, which denote electron oscillations inside the bulk, and surface plasmons, which are collective charge density fluctuations at the metal/vacuum or metal/dielectric interface. In other words, surface plasmons are surface electromagnetic waves (evanescent waves) that propagate in a direction parallel to the metal/dielectric (or metal/vacuum) interface. If the metal surface is roughened the plasmons are no longer confined and the electric field can radiate in both parallel and perpendicular directions to the surface. The excitation of the plasmons in metal nanoparticles results in a polarization and an electric field exceeding that of the exciting light. Locally these fields might be much higher than the incident field, often referred to as field enhancement. For metals such as Ag, Au, and Cu, the plasmon resonances are in the visible region of the electromagnetic spectrum. Particle size and shape (morphology) were found to have a strong influence on the resonance frequency. The metallic nanoparticles should be smaller than or roughly equal in size to the wavelength of the excitation light, that is, typically sizes of up to 100 nm are used. The field enhancement should be most intense at edges where the curvature of the particle is high, and therefore the density of the electric flux is highest (lightning rod effect). If a sample is brought into close contact with a rough metal surface and the surface plasmons of the metal are excited with a laser, the enhanced evanescent electromagnetic field causes an enhanced Raman signal with a scattering cross-section 3–15 orders of magnitude larger than those for normal Raman scattering.

The simplest model to describe the electromagnetic enhancement consists in a quasi-static treatment of a single isolated metal sphere. This single metal sphere has a dielectric constant ε_i in a medium which is small compared with the wavelength, or in vacuum with the electric permittivity of free space ε_0. As shown in Section 3.1, the dielectric constant ε_i is a complex value. Furthermore, it is assumed that ε_i of the metal sphere is independent of its size. Figure 3.75 illustrates the electromagnetic enhancement mechanism. A metal sphere embedded in a medium is in the close vicinity of a molecule.

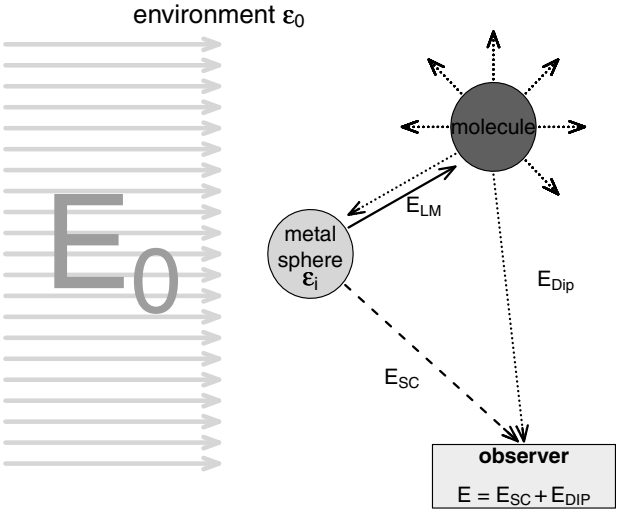

Figure 3.75 Illustration of electromagnetic enhancement.

The incident electromagnetic wave E_0 excites surface plasmons within the metal nanoparticle which induces the electromagnetic field E_{LM} which is largest directly at the surface of the particle and decreases on going into the space. The SERS signal intensity I_{SERS} is proportional to the square of the induced electromagnetic field E_{LM}:

$$E_{\mathrm{LM}}^2 = E_0^2 \cdot |g|^2 \left(1 + 3\cos^2 \vartheta\right) \tag{3.191}$$

where ϑ denotes the angle relative to the applied field direction and g is given by

$$g = \frac{\varepsilon_{\mathrm{i}} - \varepsilon_0}{\varepsilon_{\mathrm{i}} + 2\varepsilon_0}. \tag{3.192}$$

Equation 3.191 reveals that the largest field strengths are reached for $\vartheta = 0^\circ$ and 180°. The field intensity can be also increased by maximizing g, that is, the strongest field enhancements for a certain geometry are achieved for $\mathrm{Re}(\varepsilon_{\mathrm{i}}) \approx -2\varepsilon_0$ and $\mathrm{Im}(\varepsilon_{\mathrm{i}}) \ll 1$, which means that the plasmon resonance relation is met. Hence the plasmon resonance is characterized by ε_{i}. As shown in Figure 3.75, the exciting field acting on the molecule is the sum of E_{LM} and E_0, which induces a dipole in the molecule which is the source of emission of a dipole field E_{Dip} according to the radiation characteristic of a Hertzian dipole (dotted line). This emitted light can again be enhanced through the vicinity to the metal surface. This enhanced field is called E_{SC} (dashed line). The signal detected by the observer is then the sum of E_{Dip} and E_{SC}.

In summary, the metal particles act as dipoles, similarly to the molecules in the Raman scattering process as discussed above, and are the source of localized strong fields. The excited metal surface plasmons enhance both the local laser field experienced by a molecule, E_0, and the Stokes-shifted light scattered by the molecule. Hence the metal nanoparticle acts as an antenna, efficiently amplifying the Raman signal. The electromagnetic enhancement depends on, in addition to the other

parameters mentioned earlier (e.g., size and form of metal nanoparticle, plasmon resonance) the distance between the analyte and metal sphere. The range of the electromagnetic field of the excited surface plasmons quickly decreases with distance d from the surface of a spherical metal particle with radius r. A single molecule close to the metal surface experiences the following distance dependence of the electromagnetic enhancement EM_{enhance}:

$$EM_{\text{enhance}} \sim \left(\frac{r}{r+d}\right)^{12}. \tag{3.193}$$

This equation shows that larger metal particles produce an electromagnetic enhancement with further spatial range. Overall SERS uses the optical (plasmonic) properties of nanostructures to enhance the intrinsically weak Raman signal.

The second SERS enhancement mechanism, called charge transfer enhancement, can be interpreted as a surface-induced resonance Raman effect resulting from the direct chemisorption of the adsorbate on the metal surface, forming a surface complex. This interaction with the conduction and/or valence bands of the metal surface (ligand-to-metal and/or metal-to-ligand charge-transfer interactions) causes changes in the electronic structure of the analyte. If the exciting laser light is in resonance with the charge-transfer absorption of the surface–analyte complex, RRS occurs (see Section 3.13.2). As the mechanism depends on a metal–adsorbate bond, it effectively operates only on the first layer of adsorbates (absolute first-layer enhancement). Compared with normal Raman spectra, surface enhanced Raman spectra might exhibit shifted vibrational bands and a changed intensity pattern due to the selective enhancement of the vibrational modes coupling to the excited electronic transitions of the analyte–metal complex.

It should be mentioned that separation of the two SERS enhancement mechanisms is very difficult and it is almost impossible to differentiate between them in a SERS spectrum.

SERS is a very sensitive technique capable of obtaining rich chemical information on the substances in close contact with the metal. Due to the surface enhancement, the sensitivity is increased compared with normal Raman spectroscopy by 3–15 orders of magnitude. This lowers the detection limit and analytes at very low concentrations down to 10^{-11} M can be detected. It was even possible to record surface-enhanced Raman spectra from single molecules. For the interpretation of the spectra, surface selection rules have to be applied and also Raman-inactive bands may become observable. In their simplest form, those Raman bands that originate from vibrations with an induced polarization of the adsorbate electron cloud perpendicular to the metal surface are predicted to show the highest intensity.

The application of SERS in biophotonics puts some important constraints on the type of appropriate SERS substrates: (1) they must be non-toxic for the biological system under investigation, (2) they should be stable, and (3) most importantly, they should allow reproducible and quantitative SERS measurements.

Commonly metal colloids are applied as SERS substrates since they are simple to produce and easy to use. However, they exhibit a poor reproducibility since the

enhancement depends strongly on the state of aggregation because of enhanced electromagnetic field intensities between nanoparticles in the direct neighborhood. Hence the main drawback from which SERS suffers is its poor quantitative reproducibility, since the SERS signal is extremely sensitive to the nature and shape of the metal surface roughness, and to a number of factors involving the adsorption. Great research effort is therefore being put into the development of reproducible SERS substrates with well-defined shapes and hence exactly controlled plasmonic properties. The very high sensitivity of SERS allows single-molecule detection. However, it can also be possible that an impurity within a sample or a species formed by surface photochemistry is preferentially enhanced. The exclusion of such unwanted signals can sometimes be difficult, since the specific selection rules of SERS might make it complicated to relate the SERS spectra to the Raman scattering from the parent species before adsorption. Furthermore, since the analyte requires being in close proximity to a suitable roughened surface, one has to be aware of contamination of the sample with the SERS substrate metal colloid.

3.13.4
Hyper-Raman Effect

In Section 3.6, it was shown that the employment of intense light sources leads to the induction of a nonlinear polarization, that is, the induced dipole moment of a molecule is no longer proportional to the applied electric field. This nonlinearity between the induced dipole moment and the electric field strength is expressed by a power series:

$$\begin{aligned} \mu &= \alpha \cdot E + \frac{1}{2}\beta E \cdot E + \frac{1}{6}\gamma E \cdot E \cdot E + \cdots \\ \mu &= \mu^{(1)} + \mu^{(2)} + \mu^{(3)} + \cdots \end{aligned} \tag{3.194}$$

where β is the first hyperpolarizabilty ($\beta \ll \alpha$) and γ is the second hyperpolarizability ($\gamma \ll \beta$). Thus the induced dipole moment can be expressed by a linear term $\mu^{(1)}$ and nonlinear contributions $\mu^{(2)}$, $\mu^{(3)}$, and so on. Further, it has been shown in Section 3.13.1 that the polarizability α need not be constant and can be modified by the nuclear motions q. The dependence of α on q has been expressed by expanding the polarizability into a Taylor series around the equilibrium nuclear geometry $q = 0$. The first, second, and higher hyperpolarizabilty also depend, of course, on the nuclear motion q and this dependence can be also expressed by an expansion of β or γ around $q = 0$. For the first hyperpolarizability β, this expansion results in

$$\beta = \beta(q) = \beta_0 + \left(\frac{\partial \beta}{\partial q}\right)\Big|_{q=0} \cdot q + \cdots . \tag{3.195}$$

Inserting Equation 3.195 together with $E = E_0 \cos(\omega_0 t)$ and $q = q_0 \cos(\omega_R t)$ into Equation 3.194 yields for the second-order nonlinear induced dipole moment:

$$\mu^{(2)} = \frac{1}{2}\beta E^2 = \frac{1}{2}\left[\beta_0 + \left(\frac{\partial\beta}{\partial q}\right)\Big|_{q=0} \cdot q_0 \cos\omega_R t\right] E_0^2 \cos^2\omega_0 t. \tag{3.196}$$

With the help of common trigonometric relations, Equation 3.196 can be rewritten as

$$\begin{aligned}\mu^{(2)} = {} & \frac{1}{4}\beta_0 E_0^2 + \frac{1}{4}\beta_0 E_0^2 \cos 2\omega_0 t + \frac{1}{4}\left(\frac{\partial\beta}{\partial q}\right)\Big|_{q=0} \cdot q_0 E_0^2 \cos\omega_R t \\ & + \frac{1}{8}\left(\frac{\partial\beta}{\partial q}\right)\Big|_{q=0} \cdot q_0\, E_0^2 \cos(2\omega_0 + \omega_R)t \\ & + \frac{1}{8}\left(\frac{\partial\beta}{\partial q}\right)\Big|_{q=0} \cdot q_0\, E_0^2 \cos(2\omega_0 - \omega_R)t.\end{aligned} \tag{3.197}$$

Equation 3.197 shows that the second-order nonlinear induced dipole moment, which acts also as a source of scattered radiation, can oscillate at four different frequencies. The second term leads to the so called hyper-Rayleigh scattering at the frequency $2\omega_0$. The fourth and fifth terms, which vibrate with the sum and difference frequency between $2\omega_0$ and the vibrational frequency ω_R, are the source of the so-called anti-Stokes hyper-Raman ($2\omega_0 + \omega_R$) and Stokes hyper-Raman ($2\omega_0 - \omega_R$) scattering. Additionally, a term oscillating in the IR region at ω_R and a constant term which results in no radiation exist. All these classically derived frequency components can be seen in the scattered light when using an intense light source such as ultrashort laser pulses. Of particular relevance for biophotonics is hyper-Raman scattering, which is illustrated in Figure 3.76 in the form of an energy level diagram.

The hyper-Raman effect corresponds to a two-photon transition into a virtual state (see above) from where the molecule can relax back into the starting molecular state, which results in hyper-Rayleigh scattering or in an energetically excited state leading to Stokes hyper-Raman radiation. If the two-photon transition into the virtual state originates from a vibrationally excited molecule, the scattering can also end up in the vibrational ground state, resulting in anti-Stokes hyper-Raman scattering, which is usually much less intense than Stokes hyper-Raman radiation since normally for room temperature the vibrational ground state is more populated than the vibrational excited state. Since hyper-Raman scattering is overall a three-photon process, it exhibits different selection rules to linear Raman scattering (which is a two-photon process) and IR absorption (i.e., dipole transition of an IR photon). The derivation of the selection rules would go beyond the scope of this book. However, there are special normal modes which are neither Raman nor IR allowed that can be excited by hyper-Raman scattering.

3.13.5
Coherent Raman Spectroscopy

So far, all of the inelastic scattering processes discussed are considered to be spontaneous. Spontaneous means that the vibrations of the individual molecules

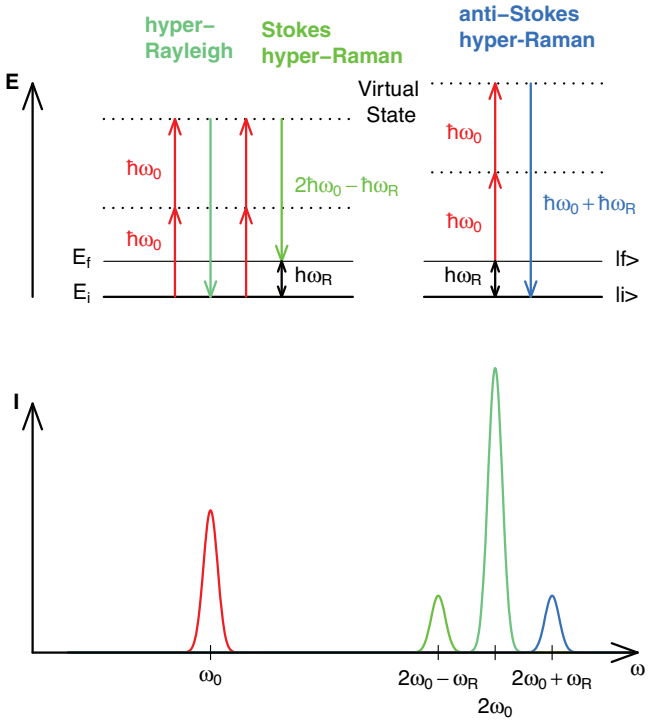

Figure 3.76 Illustration of hyper-Raman scattering on a quantized molecular system.

are all excited independently by a single exciting frequency ω_0, that is, the excited vibrations exhibit a random mode-to-mode phase relationship. The observed spontaneous Raman spectrum is just the result of a simple superposition of the excited vibrations of all molecules. In the following we introduce coherent Raman scattering processes where the irradiation of at least two laser beams of different frequencies ω_L and ω_S (L = laser, S = Stokes) generates coherently driven molecular vibrations (i.e., where the phases of the excited vibrations are locked). The establishment of a fixed phase relationship between the excited normal modes can be achieved by tuning the frequency difference between the laser frequency ω_L and the Stokes frequency ω_S to match the molecular vibrational frequency ω_R, that is, $\omega_R = \omega_L - \omega_S$. By doing so, all molecules within the common focus of the two lasers ω_L and ω_S experience ("see") the beat frequency $\omega_L - \omega_S = \omega_R$, that is, their own vibrational frequency, which results in the excitation of coherent molecular vibrations (see Figure 3.77).

3.13.5.1 Coherent Anti-Stokes Raman Spectroscopy (CARS)

In the following, we aim to give a classical description of the excitation of coherent molecular vibrations. Let us start with the assumption of having a Raman scattering medium with N harmonic oscillators per volume element that experience a displacement q under the influence of the two laser waves with frequencies ω_L and ω_S and the total field strength:

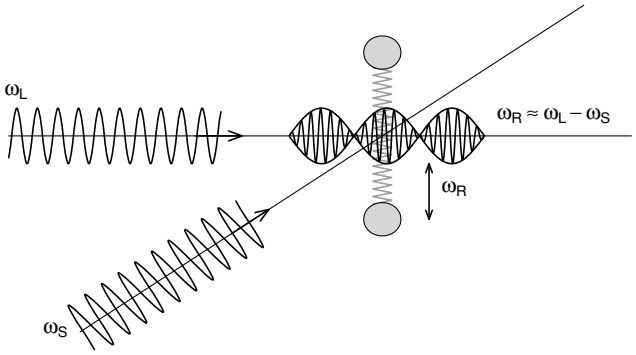

Figure 3.77 Illustration of excitation of coherent molecular vibrations within the common focus of two laser beams whose difference frequency $\omega_L - \omega_S \approx \omega_R$ matches a molecular vibrational frequency.

$$E = E_L + E_S = E_L^0 e^{i(\omega_L t - k_L z)} + E_S^0 e^{i(\omega_S t - k_S z).} \tag{3.198}$$

This displacement q leads to an electrostatic energy (potential energy) W that is stored within the molecules:

$$W = -\mu \cdot E. \tag{3.199}$$

Equation 3.199 together with the following relations derived above,

$$\mu = \alpha(q)E \tag{3.200a}$$

with

$$\alpha(q) = \alpha_0 + \left(\frac{\partial \alpha}{\partial q}\right)\Big|_{q=0} \cdot q + \cdots \tag{3.200b}$$

yields an expression for the driving force F acting on a molecule:

$$F = -\frac{\partial W}{\partial q} = \left(\frac{\partial \alpha}{\partial q}\right)\Big|_{q=0} \cdot E^2. \tag{3.201}$$

The vibration enforced by F can be described by a damped harmonic oscillator (see Equation 3.16) with a reduced mass m, eigenfrequency $\omega_R = \sqrt{k/m}$, and damping constant Γ, which is related to the linewidth of the Raman band. The classical equation of motion for this enforced vibration is obtained by considering all acting forces, that is, applying the force equilibrium condition:

$$m\frac{\partial^2 q}{\partial t^2} + \Gamma\frac{\partial q}{\partial t} + \omega_R^2 \cdot m \cdot q = F = \left(\frac{\partial \alpha}{\partial q}\right)\Big|_{q=0} E^2 \tag{3.202}$$

where the first term on the left-hand side represents the inertia force (Newton's second law), the second term considers the damping force, and the third term corresponds to the restoring force. The right-hand side of Equation 3.202

corresponds to the driving force F expressed in Equation 3.201. Inserting the solution approach $q = q_0 e^{i\omega t}$ into Equation 3.202 and also applying Equation 3.198 results in

$$\left(\omega_R^2 - \omega^2 + i\gamma\omega\right) q_0 e^{i\omega t} = \frac{1}{2m}\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \cdot E_L^0 E_S^0 e^{i[(\omega_L-\omega_S)t-(k_L-k_S)z]} \tag{3.203}$$

with $\Gamma = \gamma/m$. Since Equation 3.203 must be valid for all times, a comparison of the exponents on the left- and right-hand sides yields the frequency condition: $\omega = \omega_L - \omega_S$. This means that molecules are excited by the simultaneous interaction with the two light fields E_S and E_L to enforced vibrations on the difference frequency $\omega_L - \omega_S$. Equation 3.203 yields the following equation for the amplitude q of these enforced vibrations which propagates together with the two waves in the medium:

$$q = \frac{1}{2m}\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \frac{E_L^0 E_S^0}{\omega_R^2 - (\omega_L-\omega_S)^2 + i\gamma(\omega_L-\omega_S)} e^{i[(\omega_L-\omega_S)t-(k_L-k_S)z]}. \tag{3.204}$$

Equation 3.204 reveals that a non-vanishing amplitude q is only obtained if $(\partial\alpha/\partial q)|_{q=0} \neq 0$. This means that only Raman-active vibrations can be coherently driven. Furthermore, the resonance denominator in Equation 3.204 shows that large amplitudes q are obtained if $\omega_R^2 - (\omega_L-\omega_S)^2$, that is, for $\omega_R = (\omega_L-\omega_S)$. Therefore, if the difference frequency between the two lasers is tuned to be in resonance with the molecular vibrational frequency, the molecules are most efficiently excited to perform coherent molecular vibrations. These coherent molecular vibrations (excited by ω_L and ω_S) are able to modulate a third light wave E and thus induce a total polarization P given by

$$P = \varepsilon_0\chi E = \varepsilon_0 N\alpha(q)E = \varepsilon_0 N\left[\alpha_0 + \left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \cdot q + \ldots\right] \cdot E. \tag{3.205}$$

The term with α_0 can be neglected since it leads to Rayleigh scattering. For the third wave, one does not necessarily have to apply a wave with a different frequency, it is sufficient if, for example, $E = E_L$. Hence the nonlinear term of the polarization P can be expressed by

$$P_{NL} = \varepsilon_0 N\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \cdot q \cdot E_L. \tag{3.206}$$

Equation 3.206 expresses the nonlinear polarization P_{NL} generated by the coherent molecular vibrations q which modulate the third wave E_L. With $E_L = E_L^0 e^{i(\omega_L t - k_L z)}$ and Equation 3.204, it follows that

$$P_{NL} = \varepsilon_0 \frac{N}{2m}\left[\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0}\right]^2 \cdot \frac{1}{\omega_R^2 - (\omega_L-\omega_S)^2 + i\gamma(\omega_L-\omega_S)} \times \left(E_L^0\right)^2 E_S^0 \cdot e^{i[(2\omega_L-\omega_S)t-(2k_L-k_S)z]}. \tag{3.207}$$

Comparing this equation with the expression for the nonlinear polarization introduced in Section 3.6 (see, e.g., Equation 3.79), P_{NL} can be identified as a third-order nonlinear polarization:

$$P_{NL} = \varepsilon_0 \chi^{(3)} E_L^2 \cdot E_S^* \tag{3.208}$$

with

$$\chi^{(3)} = \varepsilon_0 \frac{N}{2m} \left[\left(\frac{\partial \alpha}{\partial q} \right) \Big|_{q=0} \right]^2 \cdot \frac{1}{\omega_R^2 - (\omega_L - \omega_S)^2 + i\gamma(\omega_L - \omega_S)}. \tag{3.209}$$

The polarization P_{NL} is the source term for the irradiation of a new electromagnetic wave:

$$E_{aS} = E_{aS}^0 e^{i(\omega_{aS} t - k_{aS} z)} \tag{3.210}$$

with $E_{aS}^0 = (E_L^0)^2 E_S^0$ and

$$\begin{aligned} \omega_{aS} &= 2\omega_L - \omega_S = \omega_L + \omega_L - \omega_S = \omega_L + \omega_R \\ \omega_L + \omega_L &= \omega_S + \omega_{aS}. \end{aligned} \tag{3.211}$$

Hence the coherent molecular vibrations excited by the two laser fields with frequencies ω_L and ω_S modulate a third wave with frequency ω_L and generate a coherent light beam at the anti-Stokes frequency $\omega_{aS} = 2\omega_L - \omega_S$. This nonlinear version of Raman spectroscopy is called coherent anti-Stokes Raman scattering (CARS) (see Figure 3.78).

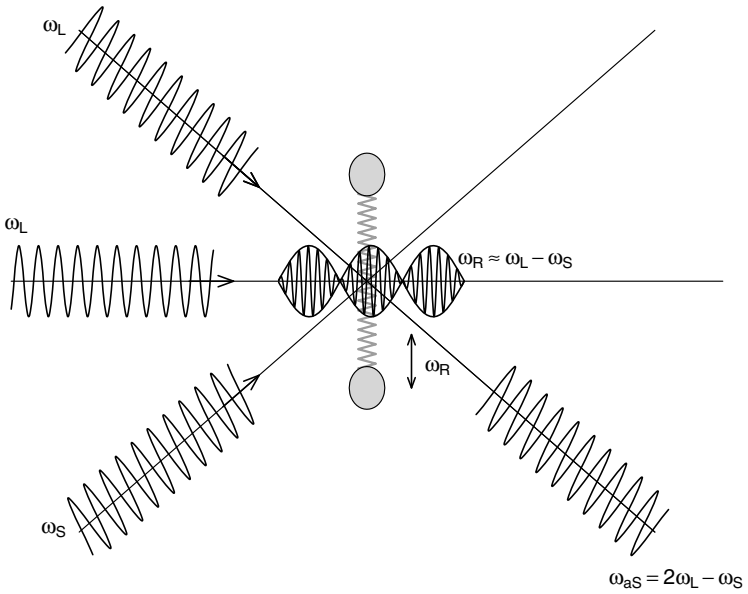

Figure 3.78 Illustration of of coherent anti-Stokes Raman scattering (CARS).

Thus, in a CARS process three laser pulses interact with the sample and generate a coherent spatially directed CARS signal (i.e., fourth pulse). CARS spectroscopy is based on the fact that two laser pulses with frequencies ω_L and ω_S drive the molecules to vibrate coherently, that is, in-phase if the energy difference between the two lasers corresponds to a Raman transition (i.e., $\omega_L - \omega_S = \omega_R$). Another photon of frequency ω_L can be subsequently scattered inelastically off this ensemble of coherently excited vibrational modes by emitting a blue-shifted, compared with the excitation lasers, anti-Stokes signal of frequency ω_{aS}. The frequency of the anti-Stokes signal arises from energy conservation, which can be derived from Equation 3.211 as follows:

$$\hbar\omega_L + \hbar\omega_L = \hbar\omega_S + \hbar\omega_{aS}. \tag{3.212}$$

The energy conservation corresponds to the generation (i.e., Stokes process) and annihilation (anti-Stokes process) of a vibrational quantum:

$$(1) \qquad \hbar\omega_L - \hbar\omega_S = \hbar\omega_R \rightarrow \text{Stokes process (generation)}$$

$$(2) \qquad \hbar\omega_L + \hbar\omega_R = \hbar\omega_{aS} \rightarrow \text{anti-Stokes process (annihilation)}$$

$$(1)+(2) \quad 2\hbar\omega_L + \hbar\omega_S = \hbar\omega_{aS} \rightarrow \text{CARS signal.} \tag{3.213}$$

This photon energy conservation can be also expressed in an energy level diagram (see Figure 3.79), which reveals that in total CARS can be seen as a four-photon process (or often referred to as four-wave mixing process).

The direction of the CARS signal is determined by the photon momentum (wavevector) conservation, which is known as the phase-matching condition (see Section 3.6). That means the sum of the wavevectors of the four participating photons must equal zero for the CARS signal to become maximum (see also further below):

$$\vec{k}_{aS} = 2\vec{k}_L - \vec{k}_S. \tag{3.214}$$

The momentum conservation for a CARS process can be also seen as the generation and annihilation of a photon momentum:

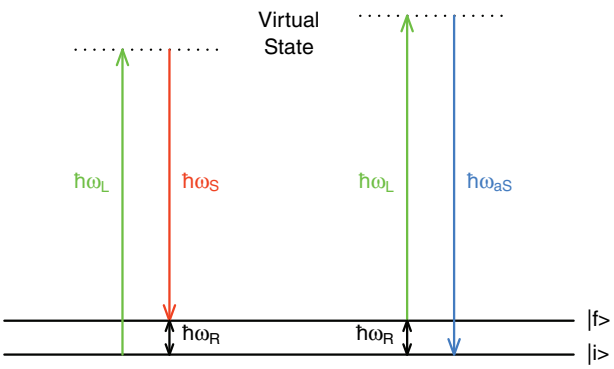

Figure 3.79 Energy level diagram representing the CARS process.

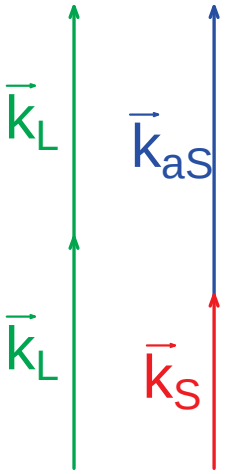
$$(1) \qquad \vec{k}_L - \vec{k}_S = \vec{k}_R \rightarrow \text{generation of photon momentum}$$

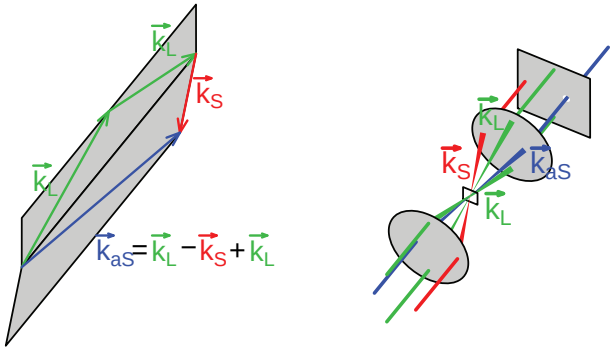
$$(2) \qquad \vec{k}_L + \vec{k}_R = \vec{k}_{aS} \rightarrow \text{annihilation of photon momentum}$$

$$(1)+(2) \quad \vec{k}_L + \vec{k}_L = \vec{k}_S + \vec{k}_{aS} \rightarrow \text{momentum conservation.} \qquad (3.215)$$

The CARS phase-matching condition is realized experimentally by special laser beam arrangements. This means that the incident laser beams have to be aligned in a precise manner such that the CARS process is properly phase matched. For gases where the linear refractive index is almost constant (i.e., $n = 1$) for a large frequency range a collinear beam arrangement can be chosen (see Figure 3.80a). However,



(a) Collinear CARS



(b) Folded BOXCARS

Figure 3.80 (a) Momentum conservation for a collinear CARS beam arrangement in dispersionless media. (b) Folded BOXCARS beam arrangement to satisfy phase matching in dense media.

in condensed phases the dispersion of the refractive index, that is, $n_i = n(\omega)$ ($i = \mathrm{L,S,aS}$) must be considered. Because $\left|\vec{k}_i\right| = \omega_i n_i / c$, it is obvious that a collinear arrangement between the four waves is not possible. Therefore, special beam geometries (CARS excitation schemes) satisfying the CARS phase-matching condition in dispersive media are required. The so-called folded BOXCARS phase-matching geometry shown in Figure 3.80b is a commonly applied non-collinear beam arrangement which is used to achieve CARS phase matching in dense media.

The starting point for the derivation of an expression for the CARS intensity is the nonlinear CARS polarization (Equation 3.207). Employing this nonlinear CARS polarization (Equation 3.207) as the source term within the Maxwell equations results in a nonlinear wave equation for the anti-Stokes amplitude E_{aS} (see also Section 3.6.1), which can be used to express the CARS signal intensity I_{aS}:

$$I_{\mathrm{aS}} \sim |E_{\mathrm{aS}}|^2 = \frac{\pi}{2n_{\mathrm{aS}} \cdot c} \omega_{\mathrm{aS}}^2 L^2 \left|\chi^{(3)}\right|^2 I_{\mathrm{L}}^2 I_{\mathrm{S}} \cdot \mathrm{sinc}^2 \left(\frac{\left|\Delta\vec{k}\right| L}{2} \right) \tag{3.216}$$

where $\Delta\vec{k} = \vec{k}_{\mathrm{aS}} - (2\vec{k}_{\mathrm{L}} - \vec{k}_{\mathrm{S}})$ and L is the interaction length over which the beams interact within the sample. $\Delta\vec{k}$ is a direct consequence of the phase-matching condition discussed above. Equation 3.216 reveals that for phase-matched conditions (i.e., $\left|\Delta\vec{k}\right| = \Delta k = 0$) the CARS signal intensity increases with L^2. For non-phase-matched conditions, however (i.e., $\left|\Delta\vec{k}\right| = \Delta k \neq 0$), the CARS signal only builds up over the coherence length $l_{\mathrm{Ph}} \approx \pi / \Delta k$ while after this a spatial–time-periodic intensity modulation due to constructive and destructive interference of the four beams that are mixed within a CARS process occurs (see Figure 3.81). This

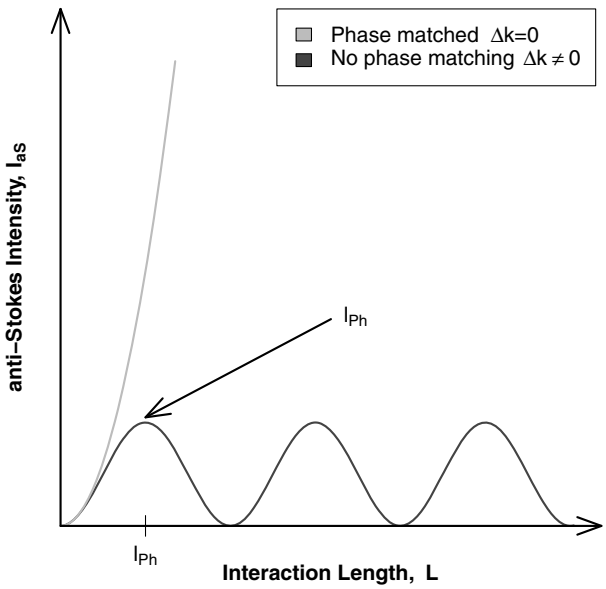


Figure 3.81 CARS signal intensity for phase-matched ($\Delta k = 0$) and non-phase-matched ($\Delta k \neq 0$) conditions.

means that for non-phase-matched beam geometries the CARS signal oscillates as a function of L with a periodicity of $\lambda_{aS}/(2\Delta n)$ and the buildup of a macroscopic CARS signal is prevented. However, $|\Delta\vec{k}|^{-1}$ is the critical interaction length for which phase matching can be neglected. Further below when discussing CARS microscopy, it will be shown that for tight focusing conditions by the use of a microscope objective with large numerical aperture it is possible to go below this critical interaction length.

In the following, linear spontaneous Raman scattering is briefly compared with its nonlinear variant CARS. It has been shown that Raman scattering is a non-directional and incoherent process with small scattering cross-sections. In contrast, CARS leads to a directed and coherent signal, which is why the weak Raman scattering intensity is enhanced significantly. The Stokes Raman signal appears at longer wavelengths compared with the excitation laser, which is why it is often masked by the simultaneous excitation of disturbing fluorescence. The CARS signal, however, emerges at shorter wavelengths than the excitation lasers and therefore experiences no disturbing interference with autofluorescence. Whereas the Raman scattering intensity is direct proportional to the volume density of scattering molecules N, the CARS signal intensity scales with N^2. The latter is a consequence of the dependence of I_{aS} (Equation 3.216) on the square modulus of the CARS susceptibility, $|\chi^{(3)}|$ (Equation 3.209), which scales linearly with N. Linear Raman scattering, that is, Stokes and anti-Stokes radiation, can be interpreted as an energy exchange between the scattered photon and the molecule or vice versa. The nonlinear CARS process can be seen as a sequence of a Stokes and anti-Stokes processes where the molecule finally ends up in the same state as that from which the CARS process started (see Figure 3.82).

As can be seen in Figure 3.82, a CARS spectrum is recorded by keeping the laser wavelength λ_L fixed and tuning the wavelength of the Stokes laser λ_S. Whenever the difference frequency between the two laser pulses hits a Raman transition ω_R (i.e., $\omega_L - \omega_S = \omega_R$), a CARS signal is generated.

However, whereas linear Raman spectroscopy leads to Raman lineshapes that are easy to interpret, CARS spectra are often characterized by complex line profiles. In the following, the CARS line profiles are discussed in more detail. The starting point is Equation 3.209, the CARS susceptibility, which can be rewritten in the close vicinity of a Raman resonance (i.e., for $\omega_L - \omega_S = \omega_R$) to yield

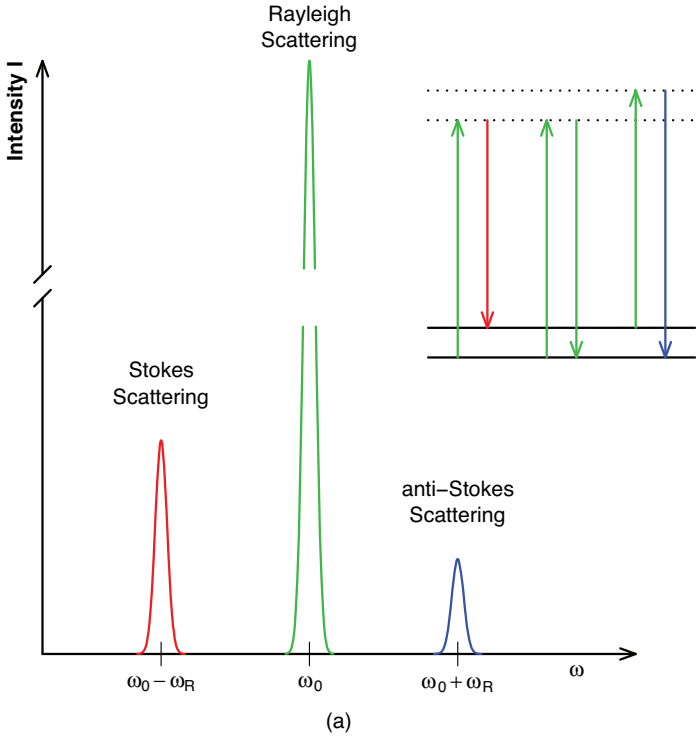
$$\chi^{(3)} = \frac{\chi_R}{2\delta + i\gamma} \tag{3.217}$$

where χ_R defines the Raman cross_section:

$$\chi_R = \frac{N}{2m\omega_R}\left[\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0}\right]^2 \tag{3.218}$$

and $\delta = \omega_R - (\omega_L - \omega_S)$ is called Raman detuning. Equation 3.217 shows that the CARS susceptibility is a complex value:

$$\chi^{(3)}_{CARS} = \chi' + i\chi'' \tag{3.219}$$



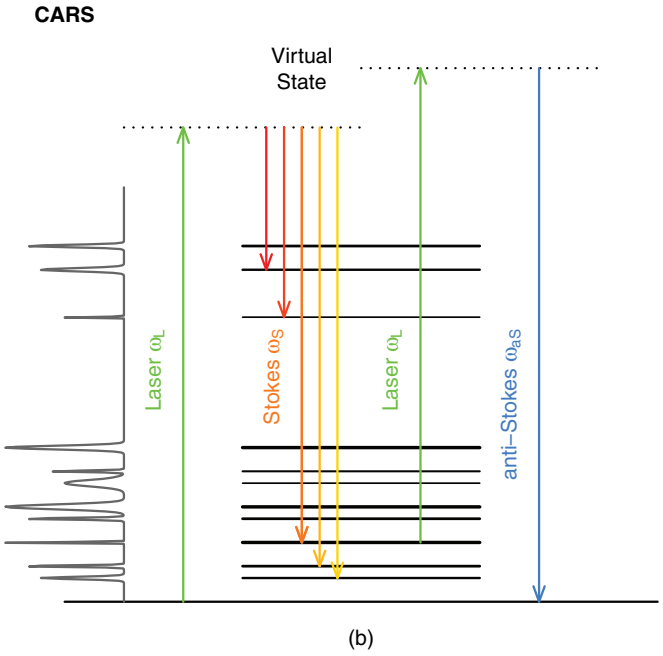


Figure 3.82 Comparison of (a) linear Raman scattering and (b) CARS.

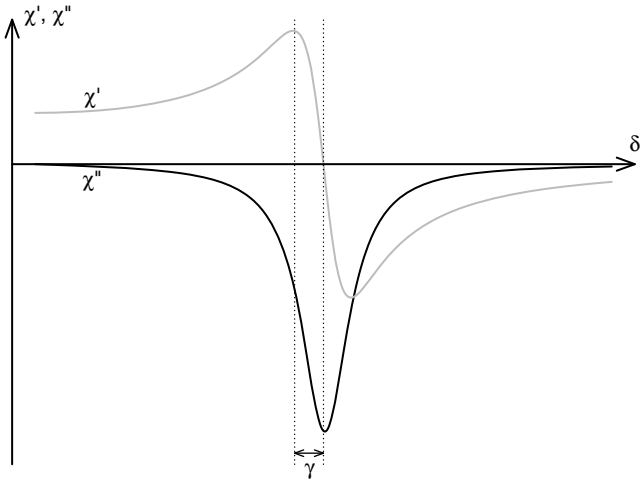

Figure 3.83 Dependence of the real χ' and imaginary part χ'' of the CARS susceptibility.

with a real part

$$\chi' = \frac{2\chi_R \cdot \delta}{4\delta^2 + \gamma^2} \tag{3.220}$$

and an imaginary part

$$\chi'' = \frac{\chi_R \cdot \gamma}{4\delta^2 + \gamma^2}. \tag{3.221}$$

The resulting functions are displayed in Figure 3.83 (see also Figure 3.8). For Raman resonance conditions (i.e., where $\delta = 0$), the real part χ' of the CARS susceptibility becomes zero and the CARS susceptibility is solely determined by its imaginary part χ''. Therefore, the CARS signal intensity in resonance with a single Raman transition is directly proportional to $\chi^{(3)}_{CARS} = \chi''$. Figure 3.83 shows that the imaginary part of the CARS susceptibility χ'' is characterized by a Lorentz profile, which is why the CARS signal for a single isolated Raman transition (see also further below) exhibits a Lorentzian lineshape. However, in addition to these resonant CARS susceptibilities due to molecular vibrations, a nonresonant contribution χ_{NR} mostly originating due to the electronic structure of the medium must also be considered. Figure 3.84 illustrates the Raman resonant CARS susceptibility and the nonresonant susceptibility due to the electronic enhancement of the medium in the form of energy level diagrams[22)].

The nonresonant contribution χ_{NR} is considered to be a real value, which is true if the two-photon transitions shown in Figure 3.84 are away from a two-photon

22) It should be noted that further energy level diagrams exist which also contribute to the nonresonant susceptibility.

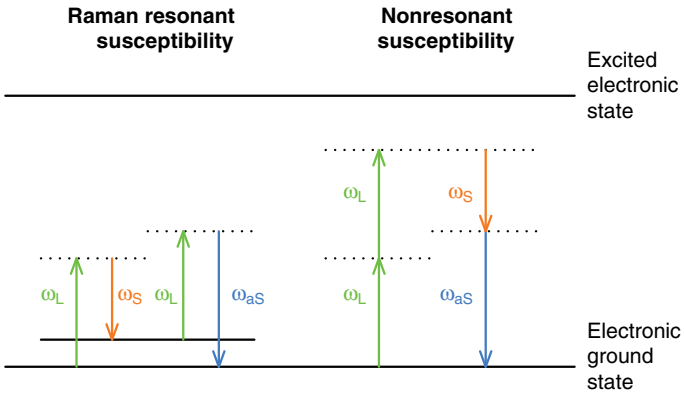

Figure 3.84 Comparison of resonant versus nonresonant CARS susceptibility.

electronic absorption (see Figure 3.83: in the case of resonant conditions the imaginary part of the susceptibility is the dominant contribution whereas for nonresonant conditions the susceptibility is mainly dominated by its real part). Furthermore, χ_{NR} does not display a strong frequency dependence, which means that χ_{NR} can be considered constant in the vicinity of a Raman transition. Hence the square modulus of the CARS susceptibility including nonresonant contributions reads as follows:

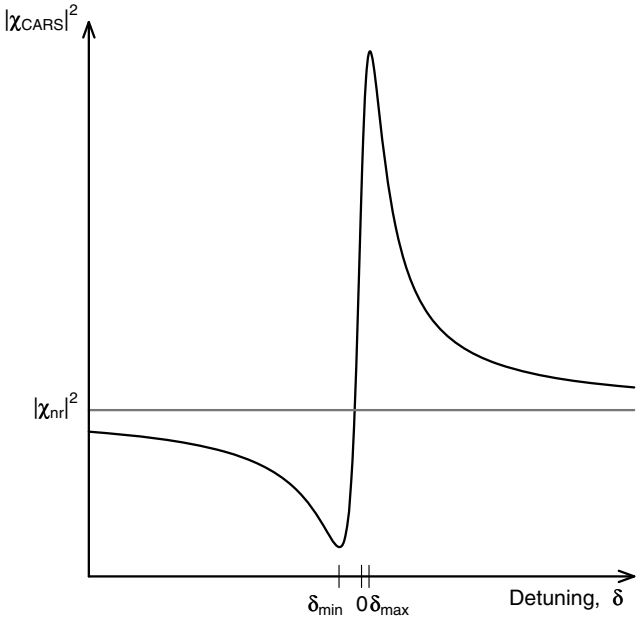

Figure 3.85 Typical dispersive CARS line profile.

$$\left|\chi^{(3)}_{\mathrm{CARS}}\right| = \left|\chi' + i\chi''\right|^2 = \chi'^2 + \chi''^2 = \left(\chi_{\mathrm{NR}} + \frac{2\chi_{\mathrm{R}}\cdot\delta}{4\delta^2+\gamma^2}\right)^2 + \left(-\frac{\chi_{\mathrm{R}}\cdot\gamma}{4\delta^2+\gamma^2}\right)^2. \tag{3.222}$$

The lineshapes observed in CARS spectra are determined by Equation 3.222. Figure 3.85 displays the square modulus of the CARS susceptibility as a function of the detuning $\delta = \omega_{\mathrm{R}} - (\omega_{\mathrm{L}} - \omega_{\mathrm{S}})$. It can be seen that the nonresonant susceptibility χ_{NR} leads to asymmetric CARS lineshapes. Depending on the magnitude of χ_{NR}, the observed CARS lines can become complex and difficult to interpret.

The situation becomes even more complicated if several Raman transitions are lying close together or spectrally overlap. Here, highly asymmetric and complicated lineshapes are observed due to interference effects among the complex resonant CARS susceptibilities of adjacent Raman transitions and/or interference with the nonresonant background, that is, χ_{NR}. Therefore, even background-free CARS spectra (if nonresonant contributions can be neglected, that is, $\chi_{\mathrm{NR}} = 0$) only lead to line profiles comparable to those observed in spontaneous nonlinear Raman scattering (i.e., Lorentzian shape) if the Raman resonant transitions are spectrally well separated from each other. If this is not the case and the Raman transitions are spectrally overlapping, interference effects between the respective Raman resonant CARS susceptibility contributions have to be considered and determine the CARS line profile. Depending on the ratio between real and imaginary parts of the various Raman resonant contributions, the observed CARS line profiles can vary drastically. Hence a quantitative CARS lineshape analysis is a complicated process.

CARS Microscopy The nonlinear variant of Raman spectroscopy CARS belongs to the most promising biophotonic techniques because it combines signal enhancement due to the coherent nature of the CARS process with further advantages such as directional emission, narrow spectral bandwidth, and no disturbing interference with autofluorescence. Particularly the introduction of CARS as a microscopic contrast mechanism allows the recording of vibrational (molecular) images (more precisely, the spatial CARS intensity distribution of one particular molecular vibration) in real time, that is, with video repetition rate. However, the combination of CARS with a conventional light microscope raises the question of how to satisfy the phase-matching condition, since it has been shown above that a collinear beam arrangement cannot be applied to dense media. However, collinear CARS microscopy is possible since for tight focusing conditions with a high numerical aperture microscope objective the phase-matching condition becomes uncritical because (1) the large angle of aperture of the microscope objective provides in the focus for every wavevector component of the laser beam ($\vec{k}_{\mathrm{L}}$) the corresponding component of the Stokes beam ($\vec{k}_{\mathrm{S}}$) required to fulfill the CARS phase-matching condition (see Figure 3.86); and (2) the CARS signal is only generated over an extremely short interaction length L. This means that tight focusing by means of a microscope objective goes below the CARS coherence length l_{Ph} (see Figure 3.81) and the interaction length is too short for a large phase mismatch to occur.

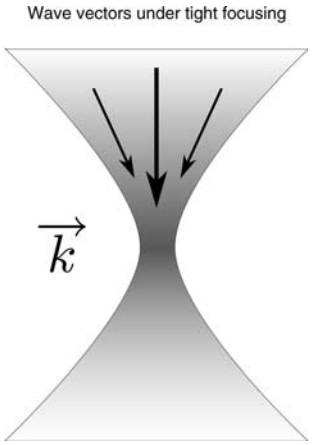

Figure 3.86 Illustration of phase matching under tight focusing conditions.

The CARS signal can be detected in either the forward (F-CARS) or backward (EPI-CARS/E-CARS) direction (see Figure 3.87). Since the wavevector mismatch for F-CARS microscopy is almost zero (i.e., $|\Delta\vec{k}| = \Delta k \approx 0$) because of the large k vector distribution generated by a high numerical aperture microscope (see Figure 3.86), all

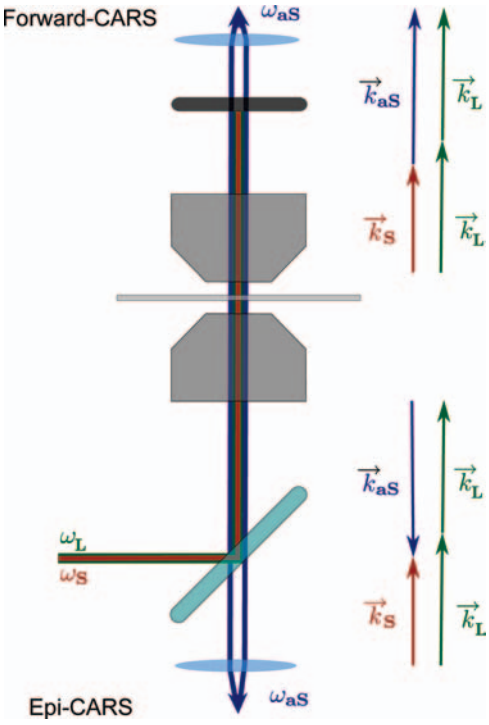

Figure 3.87 Schematic diagram of a F- and EPI-CARS microscopy.

scattering objects lead to large F-CARS signals. This is in contrast to EPI-CARS where the phase mismatch of $|\vec{\Delta}k| = \Delta k \approx -2|\vec{k}_{aS}| = 4\pi n/\lambda_{aS}$ is significant. Hence an EPI-CARS signal is only generated for scattering objects smaller than half of the anti-Stokes wavelength. Here, the magnitude of the phase mismatch acts as a filter for scattering objects of a certain size where the interaction length is below the CARS coherence length (see above).

By selectively scanning the samples, 2D- and 3D-CARS images of special molecular vibrations can be obtained. These CARS images yield detailed chemical structure information about the investigated sample. However, it has been shown above that the CARS process is not background free due to the presence of nonresonant contributions χ_{NR} to the CARS susceptibility. Hence CARS microscopy is also not background free and the Raman resonant CARS contrast is reduced due to nonresonant background signals, for example because of the electronic structure of the medium. Furthermore, water present in almost all biological samples leads, due to its spectrally broad Raman bands, to rather strong resonant background signals. These background signals are often troublesome for F-CARS microscopy since they reduce the molecular contrast due to Raman resonant signals. Here, the Raman resonant CARS signal of a small scattering object is superimposed by the much stronger, due to the larger interaction length, CARS signal of the medium (e.g., water). This large background leads to a reduced contrast for the CARS image of the object. In contrast to F-CARS, E-CARS detection allows imaging with a much better contrast because the E-CARS signal of the medium disappears due to destructive interference. However, this is not true for the E-CARS signal of the scattering object if its size is comparable to the anti-Stokes wavelength where exclusively the object contributes to the image contrast. Background reduction in CARS microscopy is a subject of current research in CARS microscopy and several approaches have been developed to reduce the background. However, a detailed discussion of these approaches would go beyond the scope of this general introduction to CARS microscopy.

Another important issue in CARS microscopy is the appropriate choice of excitation lasers. Due to the nonlinearity of the CARS process, high field strengths are required to generate a CARS signal. However, the spectral pulse widths should be as small as possible in order to excite predominantly Raman resonances and therefore generate only a small amount of the almost frequency-independent and contrast-reducing nonresonant CARS signals. In other words, the applied pulse lengths should be as short as possible for efficient CARS signal generation but on the other hand not too short that the spectral width of the pulses becomes larger than that of the Raman resonances. Therefore, picosecond pulses are usually applied in CARS microscopy.

3.13.5.2 Stimulated Stokes- and Anti-Stokes Raman Scattering

When the two laser beams with frequencies ω_L and ω_S travel through a Raman-active medium, the longer wavelength beam ω_S can experience optical amplification at the expense of the shorter wavelength beam ω_L. This effect, which is represented schematically in Figure 3.88, is called stimulated Raman scattering.

Figure 3.88 shows that the incident beam (L) loses an energy quantum $\hbar\omega_L$ whereas an energy quantum $\hbar\omega_S$ is added to the Stokes beam (S). Hence the

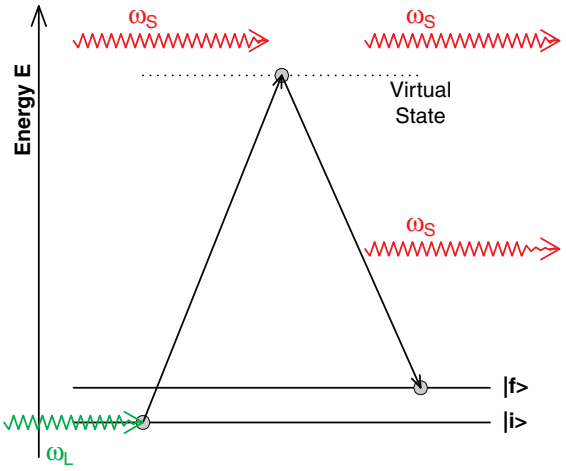

Figure 3.88 Schematic illustration of stimulated Raman scattering.

stimulated Raman effect leads to an amplification of the Stokes beam since from one excitation ω_L and one Stokes photon ω_S two Stokes photons are generated.

Stimulated Raman scattering can also occur by irradiating the Raman-active medium with just one intense input laser field with frequency ω_L because for high laser intensities the number of inelastically scattered Stokes photons can be possibly so high that stimulated Stokes scattering takes place. This means that for high laser intensities the spontaneous Stokes Raman scattering can be so strong that its influence on the molecules cannot be neglected any longer. The molecules interact simultaneously with two light waves, namely the laser wave ω_L and the Stokes wave $\omega_S = \omega_L - \omega_R$, that is, both waves are coupled by the molecules vibrating at the frequency ω_R. This parametric interaction allows an energy exchange between the laser wave as pump wave and the Stokes wave and can lead to the generation of an intensive directed radiation at the Stokes frequency $\omega_S = \omega_L - \omega_R$ (see also Figure 3.89).

In Section 3.13.5.1 an expression for the amplitude q of the enforced vibrations at the difference frequency $\omega_R = \omega_L - \omega_S$ induced by the interaction with both the light fields E_L and E_S was derived (see Equation 3.204). The induced vibrating dipoles lead to a polarization where the contribution P_S oscillating at the Stokes frequency ω_S and responsible for the Stokes Raman scattering is given by (see Equation 3.182)

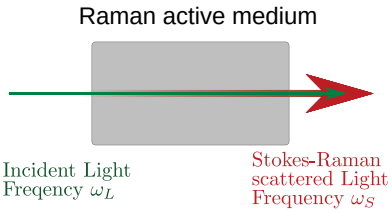

Figure 3.89 Illustration of stimulated Raman scattering, that is, the interaction of an intense laser beam leads to the generation of a forward-directed Stokes beam.

$$P_S = N \cdot \frac{1}{2}\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \cdot q \cdot E. \tag{3.223}$$

Together with q given by Equation 3.204 and $E = E_L + E_S = E_L^0 e^{i(\omega_L t - k_L z)} + E_S^0 e^{i(\omega_S t - k_S z)}$, Equation 3.223 can be rewritten to yield a nonlinear polarization:

$$P_S^{NL} = N \cdot \frac{\left[\left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0}\right]^2 (E_L^0)^2 E_S^0}{4m[\omega_R^2 - (\omega_L - \omega_S)^2 + i\gamma(\omega_L - \omega_S)]} e^{-i(\omega_S t - k_S z)}. \tag{3.224}$$

Hence a polarization wave is propagating through the medium whose contribution oscillating at the Stokes frequency k_S has the same wavevector k_S as the Stokes wave, which is why it can enhance the Stokes wave. The enhancement factor g can be calculated as follows:

$$g \sim \left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \frac{\gamma}{(\omega_L - \omega_S - \omega_R)^2 + \gamma^2}. \tag{3.225}$$

Equation 3.225 shows that for $\omega_R = \omega_L - \omega_S$, the enhancement factor becomes largest:

$$g \sim \left(\frac{\partial\alpha}{\partial q}\right)\Big|_{q=0} \cdot \frac{1}{\gamma}. \tag{3.226}$$

This means that a coherent Stokes wave (see Figure 3.89) is generated for such Raman modes which exhibit the best ratio between their Raman cross-section $(\partial\alpha/\partial q)|_{q=0}$ and linewidth γ. Very often the generated coherent Stokes wave is still so intense that a further second coherent overtone wave with the frequency $\omega_L - 2\omega_R$ can be excited, which itself excites a third coherent overtone Stokes wave, and so on (see Figure 3.90).

Whereas for spontaneous Raman scattering the anti-Stokes intensity is rather low because of the small thermal population of excited vibrational levels, the detection of anti-Stokes radiation with stimulated Raman scattering becomes possible. A considerable amount of molecules is pumped into excited vibrational levels by the intense incoming laser or pump wave and thus a strong anti-Stokes radiation at the frequency $\omega_{aS} = \omega_L + \omega_R$ can be observed (see Figure 3.91).

From Figure 3.91, it is obvious that stimulated anti-Stokes Raman scattering can be seen as a four-wave mixing process (see also Figure 3.91). Earlier it was shown that four-wave mixing processes require correct phase matching. This means that a macroscopic stimulated anti-Stokes beam can only build up if the phase-matching condition $2\vec{k}_L = \vec{k}_S + \vec{k}_{aS}$ is fulfilled. Figure 3.92 depicts the phase-matching geometry for induced anti-Stokes radiation as a four-wave interaction. Here, the Stokes (S) and anti-Stokes (aS) waves are confined to conical beams coaxial with the pump or laser beam (L). The cones can be created by rotating the plane of Figure 3.92 around k_L. Hence the radiation of a Raman-active medium with a single intense laser beam (L) generates higher order coherent Stokes beams (see Figures 3.89 and 3.90) and anti-Stokes radiation (see Figure 3.93), which is emitted in a cone whose axis is determined by the direction of the incoming laser beam L (see Figure 3.93). The

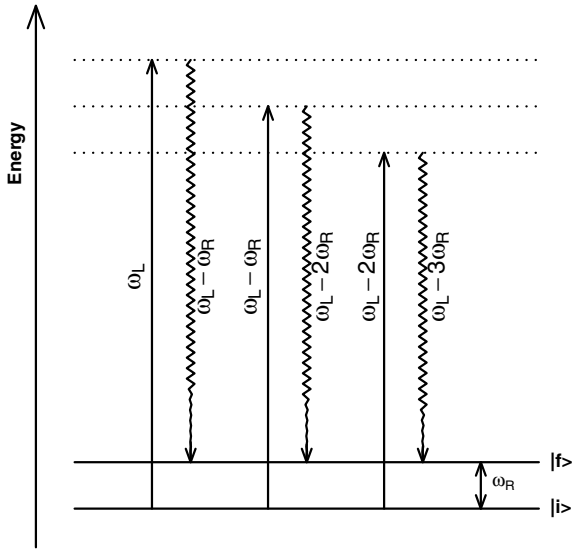

Figure 3.90 Illustration of the generation of coherent Stokes radiation and coherent overtone Stokes waves.

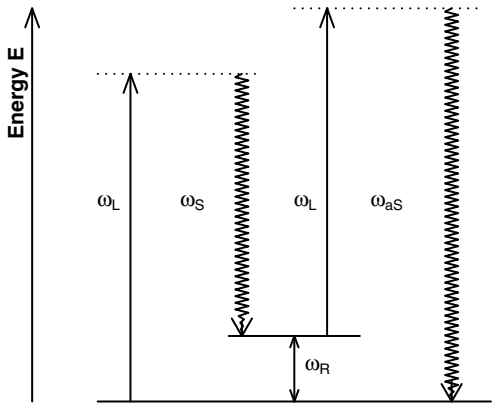

Figure 3.91 Illustration of stimulated anti-Stokes Raman scattering as a four-wave mixing process.

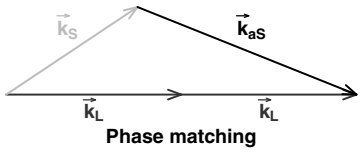

Figure 3.92 Illustration of phase-matching geometry for stimulated anti-Stokes Raman scattering.

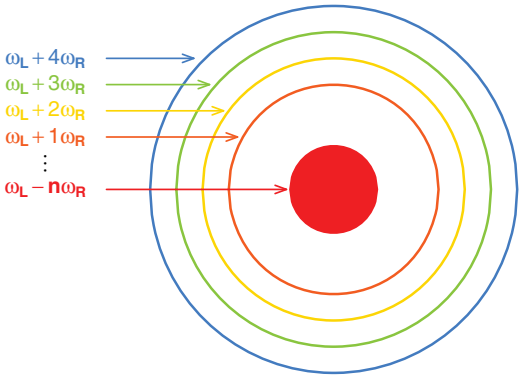

Figure 3.93 Schematic diagram of fundamental and higher order stimulated Stokes and anti-Stokes Raman radiation.

generation of stimulated Stokes and anti-Stokes Raman radiation which is depicted schematically in Figure 3.93 is often used for frequency shifting of pulsed lasers.

Stimulated Raman Scattering Microscopy Very recently stimulated Raman scattering microscopy has demonstrated its potential in biophotonics for quantitative, background-free, real-time vibrational imaging. Earlier it was shown that irradiating a Raman-active medium by two laser beams with frequencies ω_L and ω_S leads to an amplification of the Stokes beam (S) and an attenuation of the laser beam (L) due to stimulated Raman scattering (see Figure 3.88). Measuring the gain in power of the Stokes beam (S) is called stimulated Raman gain spectroscopy (SRGS) and the detection of loss of power in the laser beam (L) is called stimulated Raman loss spectroscopy (SRLS) (see Figure 3.94).

Recording the gain (SRGS) or loss (SRLS) of power of the two laser beams due to stimulated Raman scattering offers some advantages over CARS, as can be seen from the expressions describing the intensities of SRGS and SRLS:

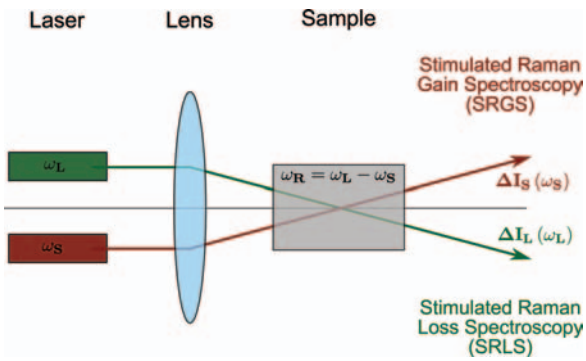

Figure 3.94 Illustration of stimulated Raman gain and Raman loss spectroscopy.

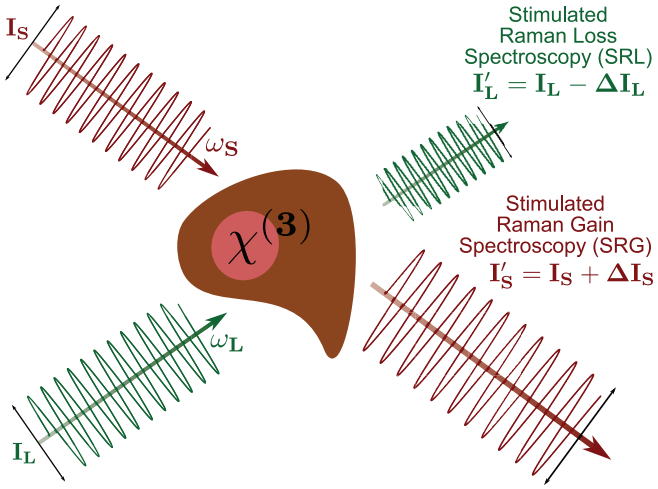

Figure 3.95 Schematic illustration of stimulated Raman microscopy.

$$\Delta I_S \sim N \cdot \left(\frac{\partial \alpha}{\partial q}\right)\Big|_{q=0} \cdot I_S \cdot I_L$$
$$\Delta I_L \sim -N \cdot \left(\frac{\partial \alpha}{\partial q}\right)\Big|_{q=0} \cdot I_S \cdot I_L. \tag{3.227}$$

The intensities scale linearly with the concentration. Furthermore, stimulated Raman scattering is background free since SRGS or SRLS signals are only generated if $\omega_L - \omega_S$ matches a Raman resonance. Hence quantitative measurements are possible. However, the loss or gain in intensity is rather small, that is, small quantities need to be detected on a large background, which is why sophisticated detection methods (heterodyne detection by means of lock-in amplifiers) are required. Figure 3.95 depicts schematically the principle of stimulated Raman scattering microscopy.

Appendix 3.A
Fluorescence Labeling Strategies for Proteins

Ingo Kleppe and Klaus Weisshart

3.A.1
Introduction

There is an increasing demand in modern biology to understand cellular processes with high temporal and spatial resolution. Recording of the underlying kinetic processes necessitates the quantification of molecule numbers, diffusion, and interaction networks within the cellular context [A1]. Specific labeling techniques in combination with sophisticated optical instruments and paired with computational power have boosted our ability to study dynamic processes and structures within a cell [A2]. In particular, fluorescence microscopy has revolutionized research in the life sciences. Combined with functionalized fluorophores, they provide an extremely powerful experimental toolbox [A3]. Modern fluorescence microscopes

offer the possibility of imaging with molecular specificity and the necessary sensitivity to view molecules in their natural environment down to the single molecule level [A4].

Labeling in principle has two major obstacles to overcome: the potential interference of the label with the function of the labeled structure and the difficulty of bringing the label to the desired target. The development of labeling techniques over the last 15 years has made these issues negligible for a very large class of molecules: the proteins [A5]. Since the decoding of entire genomes, proteins have become the biomacromolecules attracting the greatest attention as they not only shape cells through the cytoskeleton, but are also indispensable for the catalysis of biochemical reactions. As macromolecular assemblies they are involved in diverse processes such as immune responses, cell signaling, cell adhesion, and the cell cycle, to name just a few of their functions.

In recent times, new techniques have been developed to mark proteins with small organic fluorophores and semiconductor nanocrystals, but the most rapid advances have been seen in the employment of fluorescent proteins [A6]. The landmark here was the discovery of the green fluorescent protein (GFP) from the jellyfish *Aequorea victoria* in 1962 that led to a complete new labeling strategy, using the cell itself for generating the label and targeting the molecules of interest by means of molecular biology. At the top of these developments there is the enormous variety of transgenic animal strains today expressing various fluorescent proteins in different parts of their body without loss of physiological function.

The choice of a specific labeling technique depends very much on the scientific questions asked (Table 3.A.1). However, there are some general criteria to consider for the best choice of dye and labeling technique. By far the largest differentiation is the nature of the sample, that is, a solution, a fixed specimen, or a living cell [A7]. Other parameters to be taken into account are the photostability of the dye, its phototoxicity, and its photophysical properties [A8]. The size of the dye can also have a major impact, as the molecule of interest to which the tag is attached might be inactivated by steric interference.

3.A.2
General Labeling Strategies for Organelles and Biomacromolecules

Many of the dyes used as fluorescent labels are derived from molecules found in Nature. An example of a natural fluorophore is phycobilin, which is employed by cyanobacteria and red algae to collect light for photosynthesis. Although natural labels have been successfully applied for cytology and immunochemistry applications, their properties cannot be controlled sufficiently to assign broader usage to them. In addition, naturally fluorescent dyes are fairly large in size, and can interfere with molecule function.

Since the aromatic or conjugated nature of bonds in fluorophores is well understood, chemical synthesis has allowed tailoring of the properties of organic dyes with respect to photostability, spectral emission, and size [A9]. Organic dye molecules can consist of

Table 3.A.1 Strategies used for protein labeling and their applications.

	Small organic dye and Qdots	Antibody (Ab) and ligands	Fluorescent proteins (FPs)	Tags with small dyes
Labeling	Chemically linked to a protein of interest	Ab and ligand is directly coupled to organic dye or Qdot; Ab can also be detected by secondary labeling	Genetically linked to a protein of interest	Genetically linked to a protein of interest
Delivery	Administered to solution or cell medium	Administered to solution or cell medium	*In situ* expression	*In situ* expression of peptide, delivery of cell-permeable dye in medium
Application	Solution and chip assays to probe conformational changes and interactions	Detection of proteins in fixed and permeabilized cells to probe localization; detection of receptors on cell membrane	Dynamic and interactions studies in live cells	Dynamic and interaction studies in live cells
Advantages	High brightness; photostability; small size	High specificity; amplification; multicolor	High specificity; low background; live cell; multicolor	Small size; live cells; multicolor
Shortcomings	Exogenous labeling; low specificity	Fixed cells only or restricted to cell surface; huge size; intensive washing needed to reduce background	Environmental sensitivity; ectopic expression; oligomerization; low brightness	Environmental sensitivity; toxic; intensive washing needed to reduce background

just a few atoms, rendering them the ideal tools to intercalate into larger biomacromolecules without causing too much steric hindrance. Their hydrophobicity or affinity to certain chemical groups will decide on their affinity to biological structures.

A group of dyes called cell function probes are able to integrate into or penetrate the membrane and act as sensors [A10]. For example, the high hydrophobicity of DiI and derivatives enables these dyes to intercalate into membranes. Since they are specific for certain lipids, they act as markers of the membrane composition [A11]. Some membrane-permeable dyes stain specific structures or organelles, such as MitoTracker, a mitochondrial selective fluorescent label. Others are indicators of a metabolic state. For example, the fluorescence of Indo-1 and Fluo-3 is sensitive to the calcium concentration within the cell. Yet other dyes are voltage sensitive or are used to probe the pH of the microenvironment [A12]. Hoechst 33342, DAPI, TOTO, and EtBr are examples of nucleic acid staining dyes and they can have selectivity for DNA, RNA, AT pairs or GC pairs, but otherwise they are unspecific, staining the molecule throughout its length [A13]. In contrast to lipids and nucleic acids, intercalating dyes for proteins are sparse as they do not form as readily stacked structures into which a dye can intercalate. Most common are those protein dyes that bind to hydrophobic pockets in the protein or attach to certain side chains. No intercalating dye, however, will stain all proteins to the same extent and, due to their unspecific binding, intercalating protein dyes are most commonly used to stain proteins in gels, such as the SYPRO dyes [A14].

3.A.3
Protein Labeling Strategies

Labeling with a fluorescent probe has become the most commonly used protein modification in scientific research. Labeling with reactive organic dye molecules and quantum dots and the use of labeled antibodies or ligands having affinities to specific peptide sequences have been and are still heavily used for *in vitro* investigations in solution or the fixed cells. On the other hand, expression of autofluorescent proteins and selective chemical modifications by genetic engineering are the techniques of choice when it comes to live cell imaging (Figure 3.A.1) [A15].

3.A.4
Direct Labeling Strategies for Fixed Cells and Solution

To label a protein stably, an organic fluorescent dye must be functionalized with a reactive group that in turn will react with specific functional groups within amino acids, the building blocks of proteins. Functionalized dyes can react with amino groups via active ester, carboxylate, isothiocyanate, or hydrazine, with carboxyl groups via carbodiimide, and with thiol groups via maleimide or acetyl bromide. The result is a covalent linkage between the protein and the fluorophore (Figure 3.A.2). Common dye families include xanthene derivatives (fluorescein, rhodamine, eosin, etc.), cyanine derivatives (cyanines, carbocyanines, etc.), and coumarin derivatives [A11].

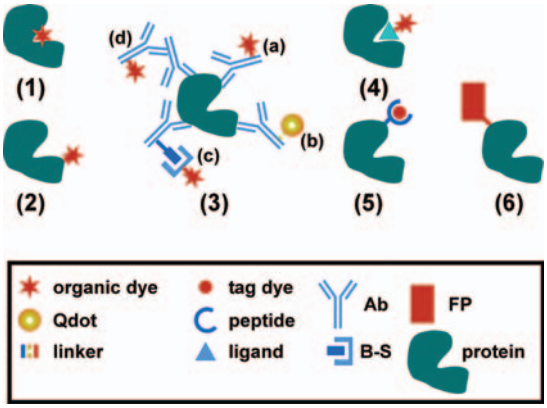

Figure 3.A.1 Labeling strategies for proteins. Fluorescent organic dyes with affinities for hydrophobic pockets or specific amino acid side chains can be used to mark proteins noncovalently and nonspecifically (1). Organic dyes can be functionalized to react with certain chemical groups of amino acids to form a covalent linkage (2). As these chemical groups exist in virtually all proteins, labeling is rather unspecific. Specific labeling is achieved by the employment of antibodies (Ab) raised against the protein (3). The antibodies recognize either sequence stretches or conformational epitopes. The primary antibody can be labeled itself with an organic dye (a) or a quantum dot (b). In sandwich techniques, the primary antibody will not be directly coupled to a fluorescent dye molecule. Instead, it is either tagged with biotin to which streptavidin conjugated to a fluorophore can bind (biotin–streptavidin system, B-S) (c), or is detected by a secondary antibody that bears the label (d). The protein can also be indirectly labeled if it can bind a ligand to which the label has been attached, as is the case, for example, for many cell membrane receptors (4). Since antibodies, quantum dots, and many ligands and organic dyes are non-cell permeable, labeling has to occur in solution and their use is restricted to *in vitro* studies or the surface of living cells. *In vivo* labeling techniques, on the other hand, include the fusion of either a self-labeling peptide sequence, to which a dye specific for such a tag will bind (5), or a fluorescence protein (FP) (6) to the protein of interest. Care must be taken not to disturb the function of the protein by these fluorescent tags.

Companies often supply these under special group names such as BODIPY, Alexa Fluor (both from Invitrogen), Atto (from Sigma Aldrich), DyLight Fluor (from Thermo Scientific), and FluoProbes (from Interchim). As these reagents represent newer generation fluorophores, they in general perform better in terms of photostability, brightness, and environmental insensitivity compared with classical dyes such as fluorescein. There is a variety of synthetic dyes available nowadays that cover the whole visible spectrum (Figure 3.A.3).

Specificity in labeling will only be obtained if the protein is in its pure form when being modified, because contaminant proteins present in the reaction mixture and harboring the functional groups of interest will also be labeled to the same extent. However, one can tailor the site of labeling by the introduction of specific amino acids at certain positions, taking care that the structure and function of the protein is not disturbed. Due to the chemical nature of the label, the reaction can only be controlled

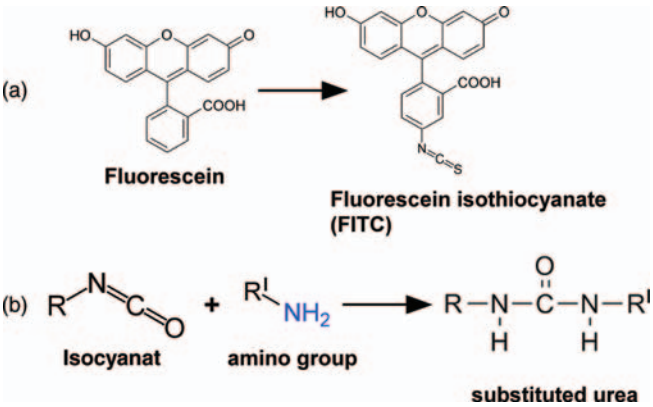

Figure 3.A.2 Functionalization and reaction of organic dye molecules. Dye molecules must be functionalized with a reactive group in order to be able to link them covalently to amino acid side chains of a protein. The example shows FITC, a derivative of fluorescein to which an isothiocyanate group has been added (a). The isothiocyanate group can react with amino groups of amino acids to attach the dye covalently to the protein (b).

to a certain extent. For example, all amino groups in the protein are potential targets for an amine reactive dye. Hence it cannot always be predicted which position will be labeled and if one or more dye molecules will be covalently linked to the protein. Fortunately, there are kits available from a variety of companies, which make the labeling procedure straightforward and allow for even tiny amounts of protein to be labeled efficiently with a defined stoichiometry.

In addition to organic dye molecules, quantum dots have also been a favorite tool for labeling proteins [A16]. Their advantage lies in their broad excitation spectra, so many wavelengths can be used to excite them, and they all show narrow emission bands. Quantum dots come in a size range between 2 and 10 nm and the larger they

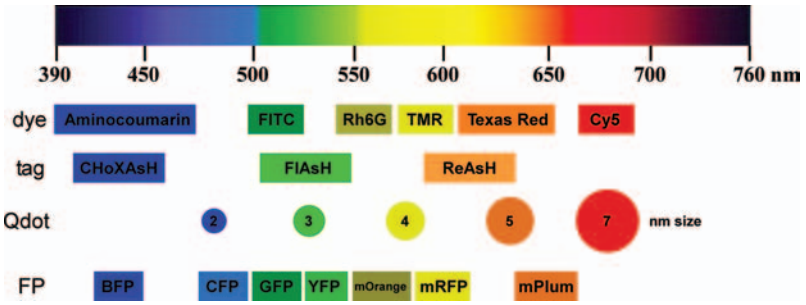

Figure 3.A.3 Spectral range of fluorophores. Common organic dyes (dye), quantum dots (Qdot), dyes binding to self-labeling peptides (tag), and fluorescent proteins (FP) are placed at the position of the spectrum according to their emission wavelength to demonstrate that each class covers a broad range of the visible spectrum. An extended list of fluorophores can be found at http://home.earthlink.net/pubspectra/ [A6].

are the more red shifted their emission wavelength is (Figure 3.A.3). Quantum dots are semiconductors and, since their core and shell are made up of heavy metal ions, they can be toxic to cells. To reduce their deleterious effects, they can be coated with biomaterial on their exterior.

3.A.5
Indirect Labeling Strategies for Fixed Cells and Solution

To provide for high specificity in labeling proteins, the employment of so-called secondary labels is of great advantage. Rather than labeling the protein directly with the organic dye molecule (or quantum dot), the fluorophore is attached to an antibody or, if appropriate, a ligand, which in turn will specifically bind to the protein of interest (Figure 3.A.1) [A7]. Antibodies are the proteins that are elicited as a defense against foreign antigens and they have the property of binding to specific epitopes or peptide stretches within a protein. They therefore represent an ideal tool to detect, for example, one sort of a molecule within a million. They can be produced against virtually every peptide sequence in different animals, allowing multiple staining of various proteins in a cell if each class of antibody is labeled with a specific dye. Polyclonal antibodies isolated from serum after triggering an immune response against an administered protein are specific for multiple parts of the antigen, whereas monoclonal antibodies recognize just one specific epitope of the target molecule, increasing the specificity of the reaction. Other strategies in antibody labeling aim at boosting the signal by sandwich technologies. In this case, it is not the primary antibody specific for the protein that is labeled with the dye, but rather a secondary one, that is specific for the primary antibody. For example, if the primary antibody was produced in mice, the secondary antibody will be an anti-mouse antibody, maybe derived in a sheep.

Another popular method is provided by the biotin–streptavidin system (Figure 3.A.1). Biotin is a vitamin that is bound by streptavidin, a bacterial protein produced in the species *Streptomyces* and consisting of four identical subunits. The biotin–streptavidin interaction is one of the strongest known biological noncovalent linkages. The primary or secondary antibody is biotinylated and then stained with streptavidin that is coupled to an appropriate dye. The advantage of such a system is that with the same primary antibody different stains are possible, depending on the dye attached to the streptavidin. Antibodies are, however, large proteins with a size of around 20 nm, so, like other labeled proteins, quantum dots, or labeled ligands, they are normally not cell permeable and are therefore restricted to cell surfaces with regard to live cell imaging (Figure 3.A.4). The constant F_c part of antibodies can also be bound by specific receptors on some immunologically relevant cells. In such cases, it is mandatory to use only the flexible F_{ab} fragments, which are made up solely by the specific binding sites to avoid unspecific staining. Antibody and ligand staining procedures are most commonly used on fixed and permeabilized cells in immunofluorescence and imunohistochemistry applications (Figure 3.A.5).

The only way to deliver labeled proteins into the cell would be by microinjection or electroporation procedures, which are stressful to some cell types (Figure 3.A.6).

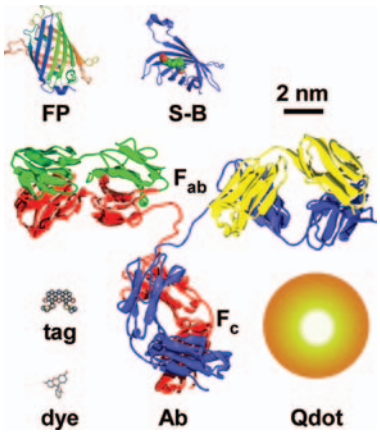

Figure 3.A.4 Sizes of protein labels. Depicted to scale are the dimensions of fluorescein (dye), ReAsH (tag), a medium-sized quantum dot (Qdot), a typical IgG (Ab) with its F_c and F_{ab} fragments indicated, the biotin–streptavidin (monomeric) complex (B-S), and GFP (FP). Typical protein sizes are above the size of GFP, but below the size of IgG.

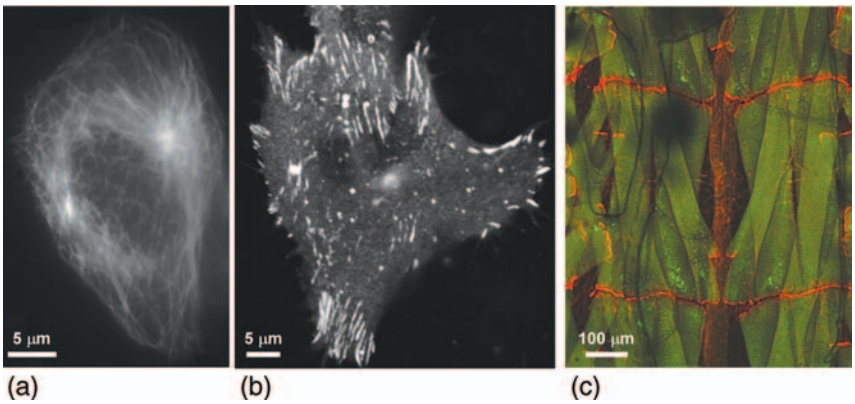

Figure 3.A.5 Use of protein labels. (a) Fixed and permeabilized HepG2 cell stained with a microtubule-specific antibody coupled to Alexa 647. Microtubules provide one component of the cell's cytoskeleton. (b) Live HepG2 cell transiently expressing paxillin fused to tdEOS. Paxillin is involved in the formation of focal adhesions, which are the attachment points of a cell to the substrate. (c) Section of a third instar larva of *Drosophila melanogaster* expressing mCD8 fused to GFP (green channel) and stained with an integrin-specific antibody coupled to Cy3 (red channel). Individual channels are false colored and merged. mCD8 is an ectopically expressed mouse protein, which is membrane linked and highlights the muscle cells. Integrins are receptors that mediate the contact of a cell with the tissue surrounding it, which can be either other cells or the extracellular matrix.

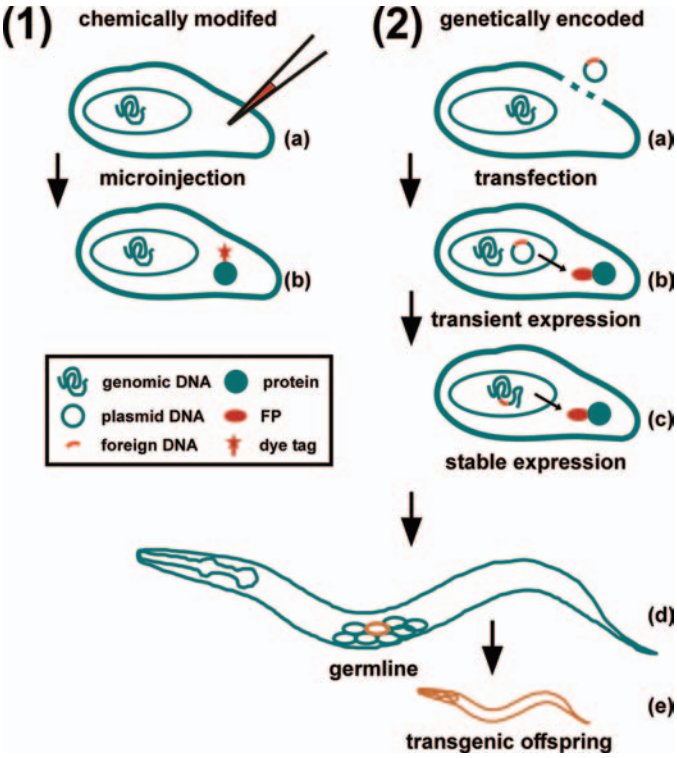

Figure 3.A.6 Methods of delivery of fluorophores into cells. Proteins chemically linked to a fluorophore (or exogenously expressed and purified fluorescence fusion proteins) can be administered into the cell by microinjection (1). The amount delivered can be controlled by adjusting the microinjected volume (a). Experiments are usually carried out immediately after injection, as proteins will be degraded over time and would be diluted out during cell division (b). To express a peptide sequence or a fluorescence protein (FP) fused to a protein of interest in a cell, their coding DNA sequences are cloned into a plasmid (2). The plasmid is delivered into the cell by transfection (a). Depending on the promoter, different levels of the fusion will be expressed. Experiments are normally done within days, since the protein is only transiently expressed as the cell tends to degrade the plasmid with the foreign DNA (b). By introducing a resistance marker along with the plasmid, cells expressing the resistance gene can be selected for. With time the foreign DNA will be integrated into the genome to result in a stably transfected cell line (c). If the cell is from the germline, it can be re-transplanted into the ovary or developing embryo, resulting in a transgenic organism that depending on the promoter used expresses the fusion protein tissue and developmental specific (d). Alternatively, in invertebrate model organisms such as the nematode *Caenorhabditis elegans* (d), the fruit fly *Drosophila melanogaster* and the zebra fish *Danio rerio*, the DNA can be injected directly into the egg with the offspring expressing the protein fusion (e).

Although the protein concentrations administered can be controlled to a certain extent using these techniques, the disadvantages are that it is a laborious technology, requires experimental skills, and proteins will dilute out during cell division. Moreover, degraded proteins cannot be replenished, in contrast to strategies involving endogenous expression. This is where autofluorescent proteins have their great advantage.

3.A.6
Direct Labeling Strategies for *In Vivo* Studies with Autofluorescent Proteins

Since the discovery of the GFP from the jellyfish *Aequorea victoria*, there has been an explosion in the isolation and creation of new fluorescent proteins (FPs) from various organisms covering a wide range of the visible spectrum (Figure 3.A.3) [A6]. Two strategies have been employed to expand the variety of available FPs even further: first, by saturated mutagenesis of known sequences and screening for desired properties of the mutants; and second, by rational design, where crucial amino acids responsible either for building the chromophore or contributing to its direct environment are deliberately altered. The latter approach has yielded, for example, numerous GFP-derived FPs that cover a broad spectral emission range. Since they have been termed according to the matching color of fruits such as banana, cherry, and plum, they are known as the fruit basket of FPs [A8].

The beauty of FPs is that they can be easily cloned from organisms and genetically linked to any protein of interest with modern molecular biological approaches. It can be decisive for the preservation of function as to which end, N- or C-terminal, the FP is attached to its target, and this can often only be established by trial-and-error experiments. Nevertheless, DNA recombinant technologies are nowadays well established, so that creating a fusion between an FP and the protein of interest is straightforward and commonplace in many biological laboratories.

Several options exist to express an FP-tagged protein in a cell. The most commonly used approach is transient expression of the fusion protein (Figure 3.A.6). To this end, an expression vector harboring the construct is transfected into cells with a suitable protocol and the cells are cultivated for the time required to express the fusion. Expression levels can partly be tailored by using differently powerful promoters, which represent the control sequences for expression in a cell. There will always be, however, a distribution of expressed quantities in the expressing cell population. On the other hand, this can be used as an advantage, since cells with desired or physiological expression levels can be screened and selected for. It should be noted that all FP proteins have a maturation time and can change their fluorescence properties until their mature state, so the time point at which the experiment is scheduled could well influence the outcome [A18]. The downside of transient expressions is their variability in efficiencies and only a certain percentage of cells will have the construct expressed.

If a selection marker, such as an antibiotic-resistance gene, is cloned along with the fusion protein, a selective pressure can be used to establish stably transfected cell lines that integrate the foreign piece of DNA over time into the cellular genome. This

procedure can last for months, but once in hand, a stably transfected cell line has the huge advantage that all the cells will express the fusion at approximately the same level. How strongly the protein is expressed depends on both the promoter used and the integration site within the genome. Hence it is possible to select for cell lines having just the right expression levels.

If an embryonic stem cell or a germ cell was the target for expression, it can be re-implanted into the developing embryos and all descendant cells of that particular stem cell will express the FP-tagged protein, if it is under a constitutive promoter (Figure 3.A.6). By choosing specific promoters, expression can be even limited to certain developmental stages or tissues. One should keep in mind that not only the recombinant stem cell will contribute to the cell mass of the developed organism and in this case will often be mosaic. If the gene was introduced directly into the germline, all cells of the offspring can potentially express the construct (Figure 3.A.6).

The greatest uncertainty when working with FP-tagged proteins is the precise concentration of the endogenous protein. Even if the concentration is known, it is unclear what the active fraction of it really is. Hence it is difficult to judge whether the expression levels of the fusion can be regarded as representative of the native pool. In a best case scenario, the tagged protein would completely replace the endogenous one in quantities and function.

There are several possibilities to interfere with or prevent the expression of the endogenous protein. One technique is the so-called knock-out technology, in which both copies of the gene are specifically removed from the diploid genome by DNA recombination. Even lethal knock-outs can be cultivated, when the missing protein is compensated for by its transient ectopic expression. Finally, to create an only fusion construct, a knock-in of the respective sequences can be performed, leading to the replacement of the endogenous by the tagged product. A second approach is RNA interference (RNAi). Messenger RNAs coding for a protein can be targeted for destruction by small complementary RNAs. If they are specific for the endogenous protein, it is only this type that will be destroyed, leaving the fusion untouched.

The properties of the dyes will in the end decide if they will be appropriate for the experiment in mind. The FP fused to a protein of interest should have the ability to be expressed in a cell in sufficient quantities. It also should show a high enough brightness and photostability in order to provide for sensitivity and longevity of the experiment in mind and should not be toxic to the cell. Next, the FP should not oligomerize to prevent ambiguities in interpretation, especially when interactions are the object of study. Also, the fluorescence of the FP should be insensitive to local environmental influences that might confound quantitative data interpretation.

There are many applications of fluorescent proteins (Figure 3.A.7) [A15]. The classical use is to study the localization of a labeled protein (Figure 3.A.5). However, more advanced methods have been developed over time that involve two or more different labeled species and that allow the dynamics and turnover of proteins to be studied. If the emission spectra of two FPs are well separated, they can be used for co-localization studies with a minimum of cross-talk. If the emission spectrum of one FP overlaps the excitation spectrum of the other, the pair of them can be used in interaction studies using FRET, a non-radiative process where the energy of the donor

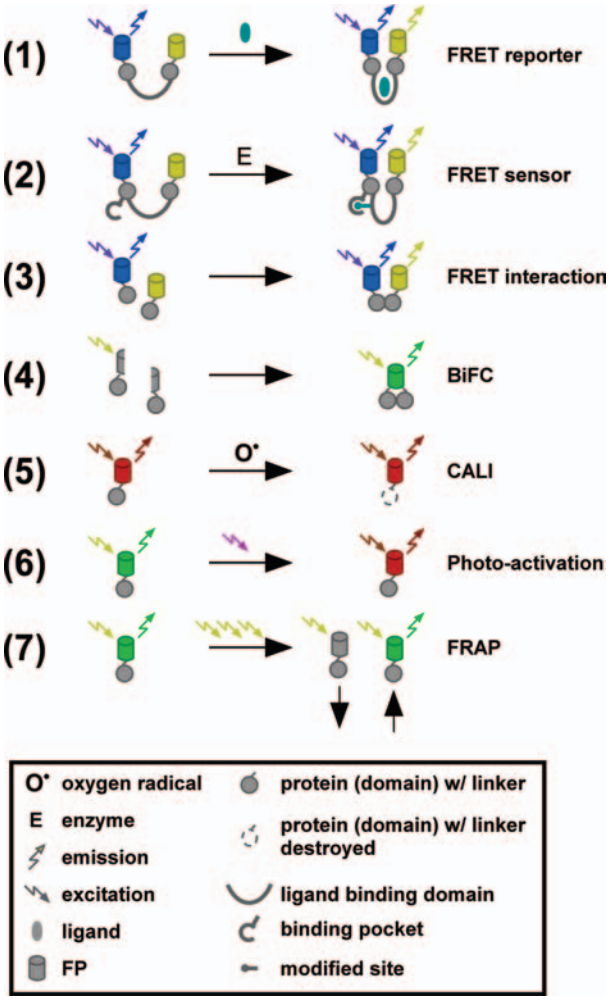

Figure 3.A.7 Advanced applications of fluorescent proteins. Conformational changes induced by binding of a ligand (1) or a modification such as phosphorylation by an enzyme (E) (2) brings the acceptor in close proximity to the donor, both of which are bound at different sites to the same protein. The acceptor fluorescence by FRET acts as a reporter or sensor on the conformation. Likewise, FRET can indicate interaction of two proteins as their conjugated donor and acceptor FP come in close proximity upon binding (3). Interaction can also be measured by bimolecular fluorescence complementation (BiFC), where two split parts of the FP attached to the two interacting partners can fold and form the chromophore when in close proximity (4). High-intensity illumination of certain FPs such as KillerRed leads to the production of oxygen radicals that can destroy the attached protein or a structure to which it binds via a process called chromophore-activated light inactivation (CALI) (5). Some FPs called optical highlighters can change their spectrum when illuminated with wavelength in the violet spectral range (6). This allows tracking of the movement of the activated versus the unchanged proteins. In FRAP, high-intensity illumination is used to bleach fluorophores at a defined site. The speed of redistribution of non-bleached fluorophores from the vicinity into the bleached area is a measure of the diffusion of these molecules.

can be transmitted on to the acceptor if both molecules are in very close proximity. If the donor is excited with its specific wavelength, an emission from the acceptor would be indicative of a very close proximity of the proteins with the two FPs attached [A19]. FRET can also be used for sensing. For example, calmodulin fused to the FRET pair CFP–YFP can be used for Ca^{2+} detection. Upon binding of calcium, calmodulin changes its conformation to allow energy transfer between CFP (donor) to YFP (acceptor) [A20]. Another way to study interactions is to provide the protein binding partners of interest with only parts of the same FP, for example, one obtains the N-terminal and the other the C-terminal end of it. On their own, both fusions are nonfluorescent as they cannot form the conjugated system necessary for fluorescence. If their attached proteins come into close proximity, however, both ends can complement each other and properly fold to restore the chromophore. If the FP can be switched, activated, or converted from one fluorescence state to the other by light induction, for example, from a dark to a bright state or between different spectral states, they can be used for turnover studies as the fate of only the switched FPs can be studied against the background of the non-switched molecules. Another use of these so-called optical highlighter proteins is in super-resolution microscopy. Here molecules are so sparsely activated that only a few at a time are visible and non-overlapping, making it possible to determine their localization precisely [A21]. FPs susceptible to rapid photobleaching can be used in a technique called fluorescence recovery after photobleaching (FRAP). A small area of the cell is bleached and the kinetics of recovery of the FP into the bleached area can be used to estimate its diffusion coefficient [A22]. Even phototoxicity can be of use for some settings. For example, KillerRed readily produces reactive oxygen species upon excitation, which in turn can wreak havoc in the vicinity of where they are produced. This opens up the possibility of locally destroying certain cellular structures or organelles if KillerRed is targeted to them [A23].

3.A.7
Indirect Labeling Strategies for *In Vivo* Studies Using Self-Labeling Protein Tags

Genetic engineering has made it possible to introduce sequences within a protein that can bind to low molecular weight compounds [A24]. Care should be taken that this so-called self-labeling tag is introduced at a site that does not interfere with protein function. Since the compound is labeled externally, it must be cell permeable and excess unbound label has to be removed for high-contrast images. Using self-labeling tags, protein expression and labeling are uncoupled and hence cannot interfere with each other.

Three types of peptide or protein tags for fluorescence labeling have been established for broader usage. The tetracysteine tag (TC-tag or Lumio tag) consists of the hexapeptide sequence Cys–Cys–X–X–Cys–Cys. It is bound specifically by biarsenic fluorophores CHoXAsH, FlAsH (fluorescent arsenical helix binder) and ReAsH (resorufin arsenical helix binder) that emit in different spectral windows (Figure 3.A.3) [A20]. In the reaction, the labeling reagents increase dramatically in their fluorescence. However,

the reagents can bind as well to analogous sequences with two closely spaced Cys residues, making background levels higher compared with the use of FPs. Also, arsenic compounds can be toxic to cells exposed to them for long periods and antidotes have to be delivered simultaneously. In addition, the labeling reagent binds the cysteines only in their reduced state and hence the labeling efficiency is affected by the pH.

Other tags are derived from enzymes and hence are relative large in size [A25]. The HaloTag, for example, a derivative of a dehalogenase enzyme, has a molecular weight of 33 kDa. A variety of HaloTag labeling reagents are available, including two fluorescent labels based on fluorescein and tetramethylrhodamine, and also a biotin-derivative. The SNAP-tag, on the other hand, is a derivative of human protein alkylguanine-DNA-alkyltransferase (AGT) 20 kDa in size, which reacts with a variety of substrates that can deliver a dye.

3.A.8 Prospects

FPs have made a major impact on the analysis of molecular dynamics, localization, and behavior *in situ*. There certainly are needs for brighter, more photostable and redder shifted variants and efforts will be made to close that gap. Tailoring the properties of FPs will doubtless expand their usage in new and evolving technologies such as super-resolution and photosensitizing [A23]. If an adverse effect on the proper function is introduced by the relatively huge FP tags, resorting to small-sized tags such as the TC-tag or even organic dyes might be beneficial [A8]. One exciting avenue is the incorporation of optical switches and triggers into proteins to render them amenable to photomanipulation [A26]. Optogenetics is another emerging field where light is used to modulate specific responses [A27]. As fluorescence techniques ensure high spatial and temporal resolution and demonstrate their compatibility with live cells and organisms by being nondestructive, they will continue to be an important tool in the analysis of protein dynamics and networks in the future.

4
Light Sources

Rainer Riesenberg and Andreas Wutting

4.1
Introduction

Radiation emitted by light sources can be characterized by its spectral properties, spatial power density, power per unit area, solid angle (radiance), spatial homogeneity, polarization properties, coherence properties, and the reproducibility of all this, to name only a few. These properties depend on the process in which the light is generated and also any subsequent influence by light propagation, light–matter interaction, and so on.

To cope with this situation, the first part of this chapter reviews some of the most important properties of light, and the second part addresses fundamental principles of light generation and the corresponding light sources and devices. We only consider artificial light sources and many source types and aspects can be treated only briefly, otherwise this chapter would require a whole book volume. The main attention is directed to the application relevance in chemistry, biology, and medicine. For more detailed information, we recommend specialized technical literature and for specific construction forms and designs of light sources we recommend consulting manufacturers' catalogues and Internet sites.

4.2
Brief Review of Light Properties

4.2.1
Spectrum

Light as an electromagnetic phenomenon propagates through space as a transversal, polarized wave. In addition to the polarization properties described later in this chapter, light is particularly characterized by its wavelength or, in the case of non-monochromatic light, by the composition of components with different wavelengths.

At not too high irradiance levels, most materials respond linearly to incident light, allowing the light–material interaction to be considered separately for each

Handbook of Biophotonics. Vol.1: Basics and Techniques, First Edition.
Edited by Jürgen Popp, Valery V. Tuchin, Arthur Chiou, and Stefan H. Heinemann.

wavelength. As a consequence, it is possible to define material properties such as refractive index, absorption, birefringence, and so on as a function of the wavelength and it becomes useful to characterize non-monochromatic light by its spectrum, that is, the above-mentioned composition of monochromatic light components with different wavelengths.

Light–matter interactions will then influence the shape of the spectrum, allowing information to be deduced about the material. If this happens through a linear physical process (i.e., one that responds linearly to the field amplitude of the light), the light source must deliver sufficient intensity throughout the spectral range of interest and its spectrum must be known well and should be stable. Examples of measurement approaches using such linear processes are absorption spectrometry and spectrally resolved reflectometry. In nonlinear processes due to the amplitude, such as Raman scattering or fluorescence, energy is transferred between different wavelengths and it is often advantageous or even necessary to irradiate a sample only with monochromatic light of a known single wavelength or a specific combination of several monochromatic contributions.

The range of all wavelengths is coarsely subdivided into several main ranges, as shown in Figure 4.1. The visible (VIS) spectral range of light lies between a minimum wavelength of about 400 nm and a maximum wavelength of about 750–800 nm (depending on the conditions), corresponding to oscillation frequencies between 7.5×10^{14} and 3.7×10^{14} Hz. To longer wavelengths and lower oscillation frequencies, the spectrum extends into the infrared (IR), terahertz, microwave, and radio-frequency ranges, whereas to shorter wavelengths it extends into the ultraviolet (UV), extreme ultraviolet (EUV, XUV), X-ray and gamma-ray ranges. For biological applications usually only the UV, VIS, and near-infrared (NIR) to mid-infrared (MIR) regions will be of interest.

It should be noted that exactly monochromatic waves are a purely theoretical construct, since they would require an infinite duration of the wave train. Every temporal restriction, that is, pulsing, of such an exactly monochromatic wave corresponds to a mixture of several infinite waves with slightly different wavelengths and thus to an effective spectral broadening. For pulse durations in the range of

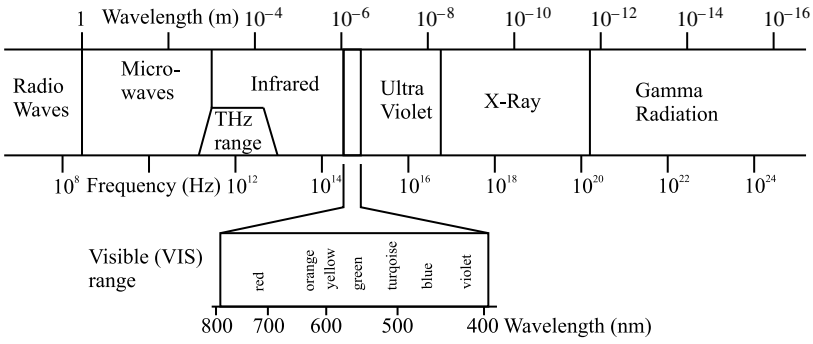

Figure 4.1 The wavelength ranges of electromagnetic radiation.

nanoseconds or longer, this spectral broadening can usually be ignored, but for shorter pulse durations it increases significantly and for pulse durations in the femtosecond range it comes into the order of the wavelength itself.

4.2.2
Radiometric Properties and Beam Parameter Product

The basic radiometric property to which all other properties can be traced back is the so-called optical flux ϕ, which effectively is a power and can be measured in watts. The flux describes, for instance, the optical power emitted by a light source or entering an aperture or optical system. In a next step, the total flux can be related to an area, a wavelength range, a solid angle, or any combination of them, leading to seven more radiometric properties, which are listed in Table 4.1.

In addition to the flux, as the second basic radiometric property, sometimes the optical energy Q is of interest, which simply describes the integral of the flux over a certain time interval and can therefore be used to describe light pulses or results of an integration process in a measurement. According to the flux itself, seven more radiometric properties can be defined by relating Q to an area, wavelength range, or solid angle. Not considered here are the so-called photometric properties, which are very similar to the radiometric properties, but related to the spectral sensitivity of the human eye.

Light originating from different light sources can be focused on a sample with different efficiencies, depending on the light generation process and the actual physical conditions in this process. Depending on the light source, either the radiance or the flux [1] or their respective spectral counterparts are best suited to characterize the "intensity" (in its loose meaning) of the light source.

Table 4.1 Overview of radiometric properties of optical radiation.

Name/symbol	Description	Typical unit
(Radiant) flux ϕ	Total optical power	W
Non-spectral properties		
(Radiant) intensity I	Flux per unit solid angle in a given direction	W sr^{-1}
Irradiance E	Flux per unit area at a given surface element;	W cm^{-2}
(also radiant exitance)	For sources the term "radiant exitance" is used	
Radiance L	Flux per unit solid angle in a given direction and projected unit area	W sr^{-1} cm^{-2}
Spectral properties		
Spectral flux ϕ_λ	Flux per unit wavelength at a given wavelength	W nm^{-1}
Spectral intensity I_λ	Intensity per unit wavelength	W sr^{-1} nm^{-1}
Spectral irradiance E_λ	Irradiance (exitance) per unit wavelength	W nm^{-2} nm^{-1}
(also spectral exitance)		
Spectral radiance L_λ	Radiance per unit wavelength	W nm^{-2} nm^{-1} sr^{-1}

4.2.2.1 Diffuse Sources

When considering the irradiance at a detector or sample to be maximized, the radiance or spectral radiance is the essential parameter of a diffuse source, because there exists no passive, linear optical system that could increase the irradiance above the value observed at the surface of a completely diffuse radiator, often referred to as Lambertian radiator. For such radiators the radiance and irradiance (radiant exitance) directly at the surface become identical up to a factor of π, that is,

$$E_{\text{Source}}(\lambda) = \pi L_{\text{Source}}(\lambda). \tag{4.1}$$

The radiance itself is constant in optical systems without diffusers or absorbers and otherwise can only decrease. A passive optical system violating this observation would also violate the second law of thermodynamics.

The change of the irradiance in an optical system is furthermore closely related to the spatial coherence properties of the light, which are discussed below. At the surface of a completely diffuse radiator, the spatial coherence of the radiation has a minimal value. Increasing the spatial coherence (and thus making the light focusable) always requires a corresponding reduction of the irradiance (by reducing the solid angle at constant radiance), and vice versa, focusing of diffuse radiation increases the solid angle and reduces the spatial coherence. At a constant irradiance, the spatial coherence in an optical system can only be decreased, for instance by a diffuser which diffuses the light in a non-recoverable way, or for constant spatial coherence the radiance and irradiance can only be decreased, for instance by an absorber. Summarizing, if a sample is to be examined using a diffuse light source, the maximally achievable irradiance at a target surface, for example, the sample or the detector, is given by

$$E_{\text{Target}}(\lambda) \leq \frac{\pi L_{\text{Source}}(\lambda)}{1 + \cot^2\alpha} \tag{4.2}$$

where α is the half-angle under which the target is illuminated (Figure 4.2).

In a similar manner, the irradiance at a (perfectly) diffusely scattering sample or optical element limits the maximal irradiance in all subsequent parts of the optical

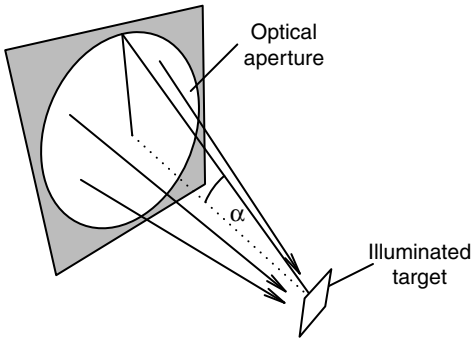

Figure 4.2 The maximal irradiance that can be achieved at an illuminated target surface depends on the radiance and the angle under which the target is illuminated by the optical system.

system, even if the sample is illuminated with a nondiffuse light source. In such cases, the scattering surface has to be considered as a new light source whose irradiance determines the radiance in the subsequent parts of the optical system. Thus, if low irradiance at the final detector is a problem, one should aim for the best possible focusing at the sample.

4.2.2.2 Nondiffuse Sources

If a nondiffusely radiating light source such as a laser is used in a measurement system, often the (spectral) flux is better suited to describe the intensity of the light, since in principle it can be focused down to the diffraction limit. This is exactly possible if the source emits a single, fixed, and known spatial radiation mode and the subsequent optics are matched to that mode. The term "mode" here denotes only a radiation distribution with a fixed amplitude and phase relation between all its points and with a single, fixed wavelength. If there is a small number of additional modes, the properties of the light can be described appropriately by the flux and an additional parameter M^2 describing the mode quality, in terms of the focusability of the light. A value of $M^2 = 1$ is perfect; single-mode lasers typically have values better than 1.3 and multimode lasers can have values in the range of hundreds to thousands. For higher numbers of spatial modes, the source must again be considered as a diffuse radiator with a certain radiance.

With the M^2 parameter, it is possible to define the so-called beam parameter product (BPP), which relates the radius w_0 of a focused spot to the half opening angle φ of the convergent beam:

$$\mathrm{BPP} = \varphi w_0 = M^2(\lambda/\pi). \tag{4.3}$$

M^2 thus describes the broadening of the spot compared with a (Gaussian or Airy) single-mode spot. For a nearly diffraction-limited spot with a small M^2 parameter and the definitions made in Figure 4.2, the effective peak irradiance in the center of the Airy diffraction disk is given by

$$E_{\mathrm{Peak}} = \phi \cdot \frac{\tan^2\alpha}{2\lambda^2 M^4}. \tag{4.4}$$

4.2.3 Coherence

Coherence is the ability of a light field to show interference effects between different spatial points at the same time (spatial coherence), between different time points at the same spatial position (temporal coherence), or a mixture of both (spatio-temporal coherence). Interference effects in turn are effects where the time-averaged flux or radiance of the sum of two or more light fields differs from the sum of their individual fluxes or radiances, that is, there occurs mutual enhancement or suppression of the intensities.

For the most general case of spatio-temporal coherence, the coherence can be described by a four-dimensional function with a large number of degrees of freedom.

So, for instance, the coherence function at the entrance pupil of a camera contains the whole (colored) image information of the scene which is imaged by that camera. This is in spite of the fact that the camera pupil itself is practically homogeneously illuminated by the scene, when only the intensity of the light is considered. The camera optics here undertake the task of a computer, which reconstructs the information contained in the coherence function into an image by bringing different points of the entrance pupil to interference in the detector plane with a certain relative temporal delay.

From this example, it should be clear that also the coherence properties of a single light source cannot always be described analytically and that it will often be necessary to resort to simplifying models. On the other hand, manipulation of the coherence function of a light source can also be used to achieve particular effects. In the following, some basic aspects of temporal and spatial coherence are discussed.

4.2.3.1 Temporal Coherence

The temporal (self-) coherence function of a light source, that is, the autocorrelation of the field strength over time, is equal to the normalized Fourier transform of the spectrum of the light source. The narrower the spectrum of the light source, the larger is its coherence length. This dependence is known as the Wiener–Khinchin theorem. For a nearly Gaussian spectral intensity distribution with an FWHM (full width at half-maximum) of $\Delta\lambda$ around a center wavelength λ, the coherence length is given by

$$L_C = \frac{2\ln(2)}{\pi} \cdot \frac{\lambda^2}{\Delta\lambda}. \tag{4.5}$$

Examples of coherence functions are given in Figure 4.3. Typical coherence lengths [2, 3] range from 600 nm for sunlight or the continuum light of a short arc mercury lamp, over 300 μm to 300 mm for single lines of spectral lamps, a few meters for standard lasers, to more than 30 000 km for specially stabilized He–Ne lasers.

A large temporal coherence can turn out to be disadvantageous if the light passes multiple interfaces or surfaces of optical elements, because the parasitic reflections created at these surfaces can come to interference and create disturbing structures, which moreover are extremely sensitive to temperature changes, mechanical vibrations, or changes of the optical system, and therefore cannot be calibrated out of the measurement result. Figure 4.4 shows the difference between holographic microscopy images obtained with a strongly coherent laser light source and a short arc lamp, where a prominent line was filtered out, giving a temporal coherence length of about 15 μm (and a spatial coherence diameter of about 60 μm) [4]. For the long coherence laser, parasitic reflections at optical interfaces such as lenses or sample holder slides lead to disturbing interferences. These vanish if the coherence length is less than the distances between the optical surfaces. It can, however, still be large enough to enable coherent techniques, such as the computer-based reconstruction of the recorded holograms, to be used.

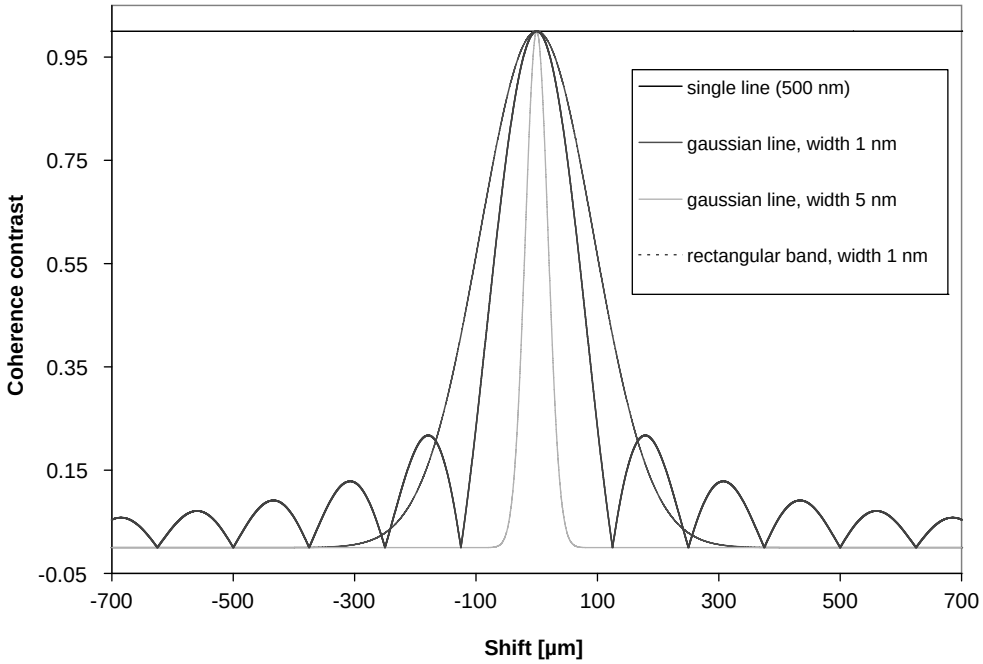

Figure 4.3 Coherence functions for different spectra. A single, monochromatic line has a constant unit coherence function. Gaussian lines (here 1 and 5 nm FWHM around a center wavelength of 500 nm) also have a Gaussian coherence function and a rectangular band spectrum leads to an abs(sinc)-shaped coherence function with a central peak and side lobes.

4.2.3.2 **Spatial Coherence**

Many light sources generate light inside a surface or volume through statistically unrelated elementary processes, for instance, thermal light sources, plasma light sources, or fluorescent dyes. As a consequence, the light emitted from different points of such sources is uncorrelated and thus mutually incoherent. This does not mean, however, that at later stages in an optical system the incoherence is preserved. Instead one of the fundamental theorems of optics, the van Cittert–Zernike theorem states that the spatial coherence of light increases as it moves away from the source. For the degree of coherence between two points of a light field, it is essential how far these points are separated and under which angle (along the direction, which links the two points) the light source appears to each of them. Roughly, the mutual coherence increases with a lower apparent angle of the source and with a shorter distance between the points. Particularly for a circular light source, the distance d_c between two points at which the first minimum of the mutual coherence occurs is given by

$$d_c \approx 1.22 \cdot \frac{\lambda}{\sin \alpha} \tag{4.6}$$

where α is the half-angle under which the source appears to the two points. One may note that the coherence diameter d_c is exactly the diameter of the diffraction Airy disk, and indeed the partial spatial coherence can be considered a result of diffraction-

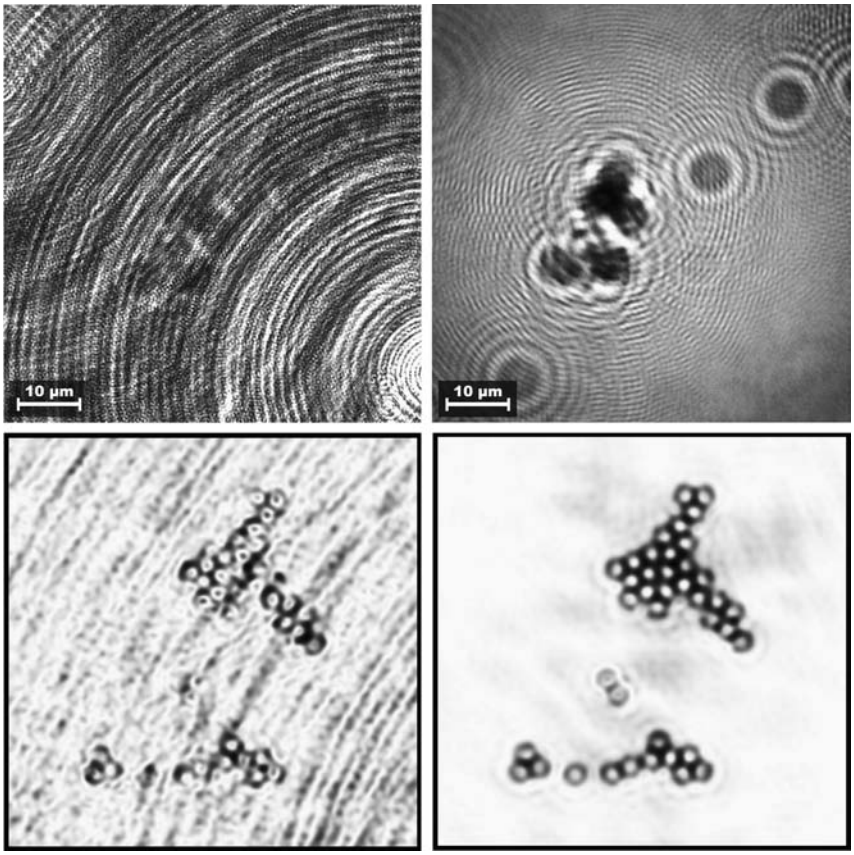

Figure 4.4 Difference between holographic microscopy recordings for high coherence and application-adapted coherence length of the light source. The top images show the holograms and the bottom images the computationally reconstructed object intensity distributions of a cluster of 1 µm polymer beads. In the left column a long coherency laser has been used, leading to parasitic interferences from optical surfaces and an accordingly low quality of the reconstruction. In the right column a light source with a coherence length of approximately 15 µm has been used. Parasitic interferences are efficiently suppressed, but the numerical reconstruction still works well, although the method requires coherent light.

caused broadening of incoherently illuminated points in the plane of the measurement, that is, the light field can be viewed as a superposition of extended, but mutually incoherent diffraction figures, such as the Airy disk in the case of a round source. Accordingly, it is even possible to set up an equation for the propagation of the coherence function that closely resembles the propagation equation for a fully coherent light field. This would, however, go far beyond the scope of this book. The only important thing here is the fact that the minimal spatial coherence diameter in any plane of an incoherently illuminated optical system – even after passing simple optical elements such as lenses – is determined by the angular shape under which the source appears to the considered point. The coherence diameter can be increased further or the coherence function can be modeled into complicated shapes by

interference optical elements or nonregular optical elements such as lens arrays, screens with multiple apertures, diffusers, and so on.

4.2.4 Polarization

Light is a transversal electromagnetic wave, that is, in isotropic media electric and magnetic components of the field are orthogonal to the propagation direction and the direction of energy transport. For plane, monochromatic electromagnetic waves, this allows two base polarization directions for the electrical field component inside the plane of the wave to be introduced (Figure 4.5). Monochromatic here means that the wave contains only a single wavelength or oscillation frequency and that the field strength of any field component varies over time proportional to a phase-shifted sine. The two base polarization directions can then be assigned individual amplitudes and a relative phase shift, to model any possible electrical polarization state of the wave. Depending on phase shift and amplitudes, linear polarization with any direction inside the wave plane, circular polarization, or general elliptical polarization results. Linear polarization in this case means that the electrical field vector oscillates only in a single direction, whereas for elliptical polarization the field vector follows the shape of an ellipse one time per oscillation period.

Matter – for instance in optical devices, examined chemicals, and so on – can respond sensitively to the polarization of the light or change it, if it has anisotropic, chiral, or inhomogeneous properties. This is the case, for instance, for several types of crystals (birefringence), materials under mechanical stress (stress birefringence), certain materials in a magnetic field (Faraday effect), chiral organic molecules, colloidal structures, and many more. Also, light scattering processes or non-perpendicular passing of optical surfaces usually influence polarization properties. In sensitive or quantitative measurements, this can lead to measurement errors, which are often hard to avoid. The strong polarization sensitivity of some scattering

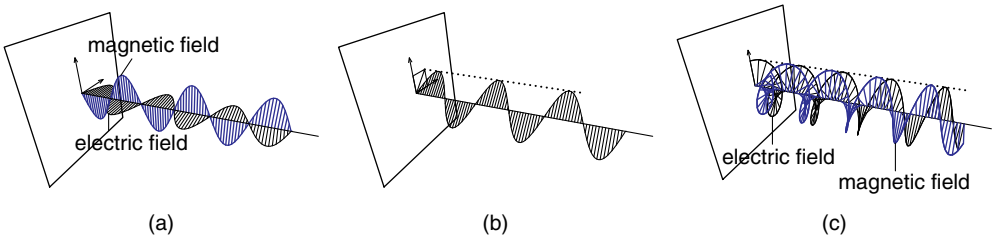

Figure 4.5 Polarization of light. (a) Monochromatic, linearly polarized light shows a sinusoidal electrical field strength which varies along one direction when the time or propagation position coordinate is changed. The magnetic field vector varies proportionally to the electric field vector, but is perpendicular to it. (b) A linear wave with an electric field vector varying along a direction between the coordinate axes can be described as a linear superposition of two waves varying along the coordinate axes and having a zero phase difference between each other. (c) If the phase difference in the latter example becomes non-zero, an elliptical or circular wave will result.

processes furthermore leads to severely nonrotationally symmetric angle distributions of the scattered light, if the illumination is done with linearly polarized light. This can reduce or increase the efficiency of light collection when the detector is oriented at an angle to the illumination, and therefore has to be carefully considered in system designs, which use such setups for the optical examination of samples. An example could be a Raman spectrometry setup where the sample is illuminated from the side by a laser and a centrally placed microscope lens collects the scattered light. The dependence between polarization of incident light and Raman scattered light is given by the so-called Raman scattering tensor, which depends on the incident and scattered wavelengths, the scattering material, and its orientation in case of an anisotropic material. Also, the Rayleigh scattering, that is, elastic scattering of the incident radiation without a wavelength shift, leads to a spatially varying distribution of the scattered light, which can be used, for instance, to suppress this normally unwanted contribution of the signal.

When spectral properties, directional distribution, and polarization properties including relative phase information are put together, a classical light field can be described completely by a three-dimensional vector function (polarization amplitudes + relative phase) of three parameters (wavelength + two angles for the propagation direction or alternatively a three-dimensional wavenumber vector). Between the vacuum wavenumber vector $\vec{k}$ (Figure 4.6), the vacuum wavelength λ, the oscillation frequency ν, and the tilt angles with respect to the x- and y-axes, α and β, the following relations exist:

$$\lambda = 2\pi/\|\vec{k}\| \tag{4.7}$$

$$2\pi\nu = c \cdot \|\vec{k}\| \tag{4.8}$$

$$kx = \|\vec{k}\| \sin\alpha \tag{4.9}$$

$$k_y = \|\vec{k}\| \sin\beta. \tag{4.10}$$

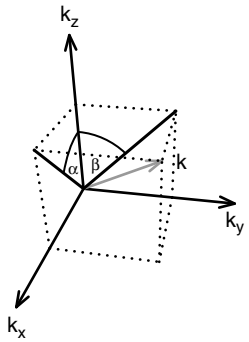

Figure 4.6 The wavenumber vector and the propagation angles.

4.3
Light Generation and Light Sources

4.3.1
Processes of Light Generation

4.3.1.1 General Emission Processes

In most cases light is generated when an electrically charged particle or particle system changes from a state of higher energy to one of lower energy. The energy difference then will be equal to the energy of the emitted radiation plus eventually generated mechanical energy (heat). Exceptions to this fundamental type of light generation are direct particle reactions such as the radiant annihilation of an electron–positron pair or nonlinear processes such as the decay of one photon into a multitude of photons with the same total energy inside a nonlinear optical material.

The usual light sources for practical applications are nearly always based on the transition of an electron system from a state of higher energy to one of lower energy. Inside this class of light sources, one often finds a strict subdivision into thermal and nonthermal light sources. However, the main difference between these two groups is simply the fact that the population of states of higher energy in a thermal light source is driven only by temperature effects near a thermal equilibrium state, whereas nonthermal light sources usually use more direct mechanisms for populating the higher states.

The thermal activation in a thermal light source has the consequence that at any wavelength the spectral radiance of the light source cannot be larger than the value given by Planck's blackbody radiation equation, that is,

$$L_{\text{Source}}(\lambda, T) = u(\lambda, T) \cdot \frac{2\pi hc^2}{\lambda^5 \left[\exp\left(\frac{hc}{\lambda k_B T}\right) - 1\right]} \tag{4.11}$$

where k_B is the Boltzmann constant, h is Planck's constant, c is the speed of light, and $u(\lambda, T)$ is a wavelength-, temperature-, and material-dependent emission coefficient. Typical blackbody radiation curves for the temperatures of the Sun, incandescent lamps, and halogen lamps are given in Figure 4.7 for $u = 1$. In the case of the lamps, u is, however, only about 0.5.

For pure blackbody radiation ($u = 1$), the spectral source radiance has a peak at a wavelength

$$\lambda_{\text{Peak}}(T) = b/T \tag{4.12}$$

where $b = 2.8977685 \times 10^{-3}$ m K is called Wien's displacement constant. The relation is known as Wien's displacement law. The total radiance produced by a blackbody is given by the Stefan–Boltzmann law, which states that the surface radiant exitance is given by

$$E_{\text{Source}}(T) = \sigma T^4 \tag{4.13}$$

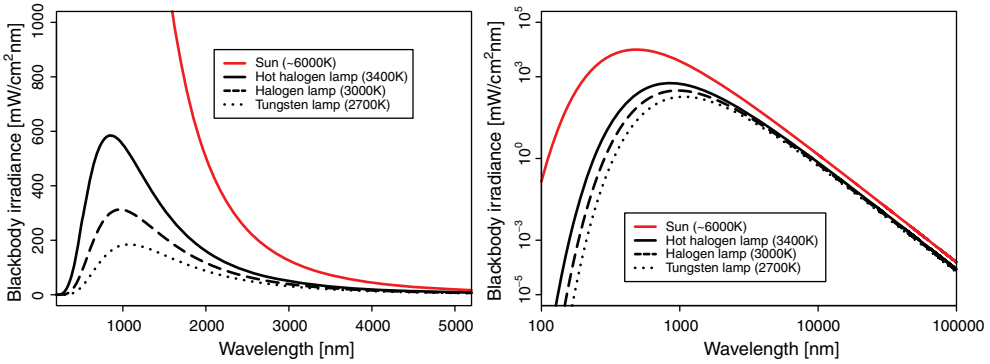

Figure 4.7 Spectral surface irradiance (exitance) distributions for thermally radiating blackbodies at different temperatures; Particularly for the tungsten and halogen lamps, the really observable surface spectral exitances will be about 50% of these values, since they are bad blackbodies with a low emission coefficient. Furthermore, the most energy is emitted in the NIR region, leading to low efficiency for illumination purposes.

with the Stefan–Boltzmann constant $\sigma = 5.670400 \times 10^{-8}\ \mathrm{W\,m^{-2}\,K^{-4}}$. Due to the freedom of the emission coefficient, the spectrum is, however, in no way limited to resembling the shape of the pure blackbody radiation with $u = 1$. This is particularly true for low-pressure, single-atom, light-emitting gases, whose thermal emission spectra practically consist only of very narrow, gas-specific emission lines. In the opposite direction, the radiating subsystem of a nonthermal light source can practically always be assigned a thermodynamic temperature, which then differs strongly, however, from the temperature of the remainder of the light source, leading to a situation where one is far away from thermal equilibrium of the total system.

Aside from thermal activation, there exist a large number of technically used excitation processes. Some of them are listed in Table 4.2.

Table 4.2 Some excitation processes and according light sources.

Excitation process	Example light sources
Thermal	Incandescent light bulb, high-pressure gas emission lamp (secondary excitation process)
Collision (mostly due to a flowing current or in a plasma)	Gas laser, gas discharge lamp
Optical excitation	Fluorescent dyes, solid-state lasers
Charge carrier injection in diodes	Light-emitting diode (LED), diode laser
Chemical reaction	Chemoluminescent substances, chemical laser
Direct acceleration of charge carriers	Synchrotron light source, X-ray tube
Other nonlinear optical processes/ inelastic scattering	Raman laser, optical parametric oscillator

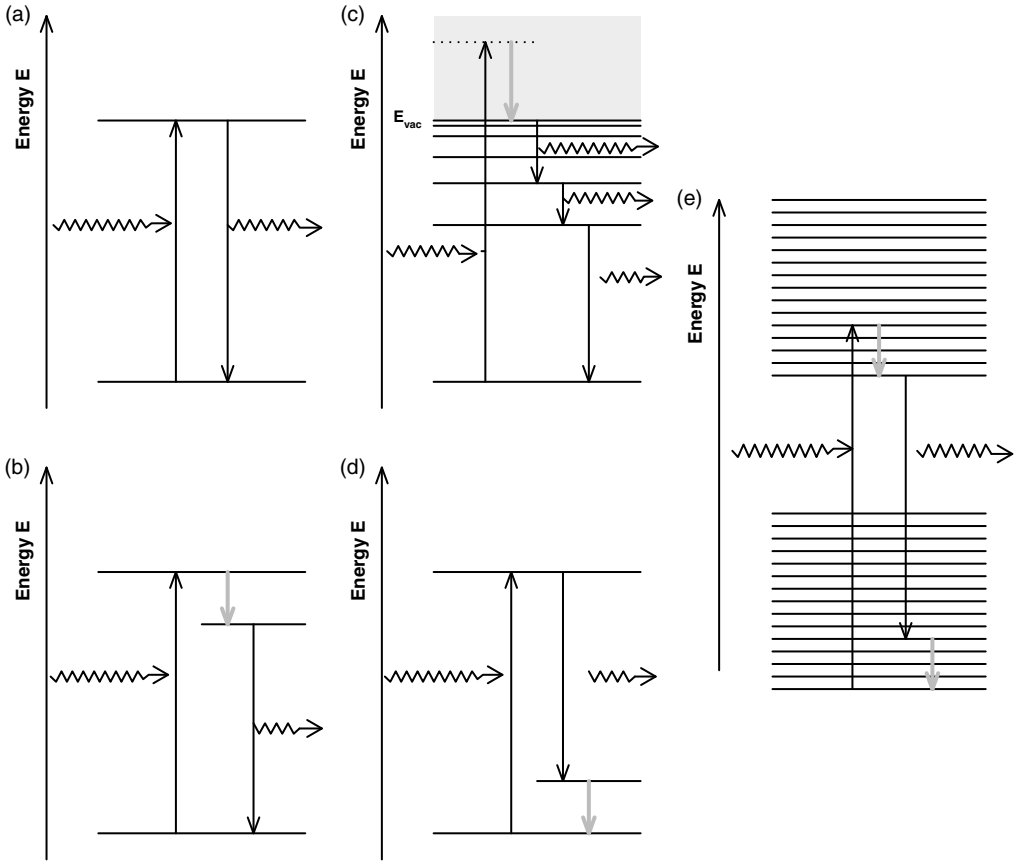

Figure 4.8 Some basic schemes of excitation and light emission. (a) Simple model of a two-level system; (b) plasma excitation and emission of a gas; (c) simple three-level system; (d) Raman Stokes scattering in a three-level system; (e) excitation and emission in a fluorescent dye molecule.

Figure 4.8 shows some examples of excitation and light emission processes that can occur in light sources. In detail, the following processes are shown:

- Simple model of a two-level system: the excitation energy and energy of the emitted photon are identical; if the system is already excited, it will be de-excited by the excitation source with the same probability as a nonexcited state will be excited.
- Plasma excitation and emission of a gas: an outer electron is excited from its bound ground level to a virtual level above vacuum energy E_{Vac}, leading to ionization. Excitation here can occur, for instance, by collision with a fast, free electron (collision ionization) or with another gas molecule. The free energy ground state is then repopulated from a vacuum state. This can occur directly or via intermediate higher energy levels, leading to the emission at different, gas-specific emission levels.

- Simple three-level system: an electron is excited to a higher energy level and then decays rapidly to a somewhat lower third level by a nonradiative decay. Such a level will eventually not be de-excited by the excitation source and can be relatively stable, leading to a low spontaneous emission and allowing laser action through stimulated emission.
- Raman Stokes scattering in a three-level system: an incident photon excites the system from the ground state and then first returns to a state above the ground state, emitting a red-shifted photon. The system later returns to the ground state in another process such as nonradiative relaxation.
- Excitation and emission in a fluorescent dye molecule: the dye molecule will normally be in or near the ground state and can be excited into one of the states of a higher band by a short-wavelength photon. Then it usually relaxes by nonradiative processes to the lower edge of the upper band, from where it can recombine to one of the levels of the lower band, emitting a photon at a longer wavelength than the exciting photon. The cycle closes with a nonradiative decay to the ground state.

4.3.1.2 **Laser Emission**

One of the most important types of light source in analytical applications is the laser, since it can produce extremely coherent, monochromatic, often strong and non-diffuse radiation, which can be focused down to or near the diffraction limit. There is a huge variety of laser types and principles and the underlying theory is considerably more complex than the theory of other light sources, since lasers are strongly nonlinear devices. We will not attempt to go into all these details but rather describe some fundamental properties of lasers. For those interested in a deeper understanding we recommend reading the textbook by Svelto [5]. This section on laser principles is given before the sections on individual types of light sources, since many of these light source types can be modified to operate as lasers. Instead of discussing these sources twice, we will include the laser aspects in their general discussion. For instance, lasers are available based on light-emitting diodes (LEDs), low-pressure gas discharge, hollow-cathode emission, fluorescent dyes, fluorescence in solids, Raman processes, optical down-conversion in nonlinear materials, and chemoluminescence, to name just a few. The important difference between the non-laser and the laser light sources is that in the latter the stimulated emission is made the dominant light generation mechanism by appropriate arrangements. The term "laser" accordingly means "light amplification by stimulated emission of radiation." The characteristic features of a laser are a medium that can emit light through a stimulated emission process (an optical amplifier) and a means for feedback of part of the generated light (Figure 4.9). There are also a few devices that do not need the feedback unit, since their amplification is large enough to permit laser-like action without it. Such devices are called superlasers or superluminescent sources.

Stimulated emission can occur when a photon hits a quantum mechanical system in an excited state, there is a lower, free state which can be reached in a radiating transition, and the energy difference between this state and the current state of the system corresponds to the wavelength of the photon. The quantum mechanical

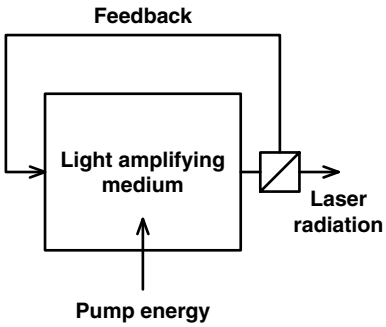

Figure 4.9 Basic principle of a laser. A medium capable of amplifying light by a stimulated emission process is pumped, that is, excited into a higher energy state with inversion. From there, it can return to the ground state by spontaneous or stimulated emission. A feedback unit directs a part of the emitted light back into the medium. The combination of an amplifier and a feedback unit makes the arrangement strongly nonlinear and works as an optical oscillator. If the spontaneous decay rate is low enough and the fraction of the fed back light is large enough, stimulated emission will become dominant, creating a strong, coherent emission.

system can be, for instance, an excited atom or molecule or a more complex system. In the following we will simply speak of an atom, keeping in mind the other possibilities. If the above-mentioned conditions are met, then there is a certain probability P_1 that the incident photon de-excites the atom and generates a second photon, which then will have exactly the same phase, polarization, and wavelength as the incident photon. To achieve a high ratio between stimulated and spontaneous emission, the initial higher energy state should be metastable, that is, have a low spontaneous decay rate, no matter whether the decay corresponds to the laser transition or another transition. Furthermore, if the atom is in the lower state, the incident photon will excite it with the same probability P_1 into the higher state. Hence, to achieve a net amplification, more atoms have to be in the higher state than in the lower state, which is called an inversion.

To achieve this inversion, the higher state of the laser transitions has to be populated to a high fraction of the atoms. Populating a higher state is possible by collision effects or semiconductor charge injection, but also by direct optical pumping from the ground state. However, then the pumping photons would also lead to stimulated emission from the higher state to the ground state, limiting the population of the upper state to below 50% and avoiding inversion. In a more advantageous scheme, the pumping will thus not be done directly from the ground state to the upper laser state, but to a higher, intermediate state, which quickly decays to the upper laser state, so that the pumping radiation will not stimulate a transition to the ground state. This scheme corresponds to the three-level system shown in Figure 4.8c. The drawback of this simple system is that the laser radiation, which can cause stimulated emission from the upper to the lower laser level, can also be absorbed by the laser transition, if many atoms are in the lower state of the laser transition. Since this lower level is the ground state, the population density will be

high, particularly when the stimulating field is strong, leading to reduced amplification efficiency due to re-absorption.

Another, but exotic, possibility to achieve inversion is to have a lower state of the laser transition, which is sparsely populated, and to populate the upper state to a higher degree. Here, the lower state of the laser transition has to be somewhat higher than the ground state and should rapidly decay to it. As a result, the population density of that state will be low. Hence again this results in a three-level system, but this time the excitation and emission form a Raman-like process, as shown in Figure 4.8d. One drawback here is that atoms which have already been pumped to the higher laser state can be de-excited by the pump radiation, which again limits the efficiency of the process. Moreover, the pump transition will normally lead to a rapid decay from the upper state, circumventing the laser transition and mainly yielding Rayleigh scattering in the amplifier material. The most advantageous laser schemes thus have at least four levels, as shown in Figure 4.10.

Such a system combines the two advantageous aspects of the previously discussed three-level systems and avoids their drawbacks. In contrast, as described above, an optically pumped pure two-level system will combine the drawbacks of the two types of three-level system in such a way that it becomes impossible to achieve inversion. If the pumping is done through another mechanism, some types of two-level systems can also achieve inversion.

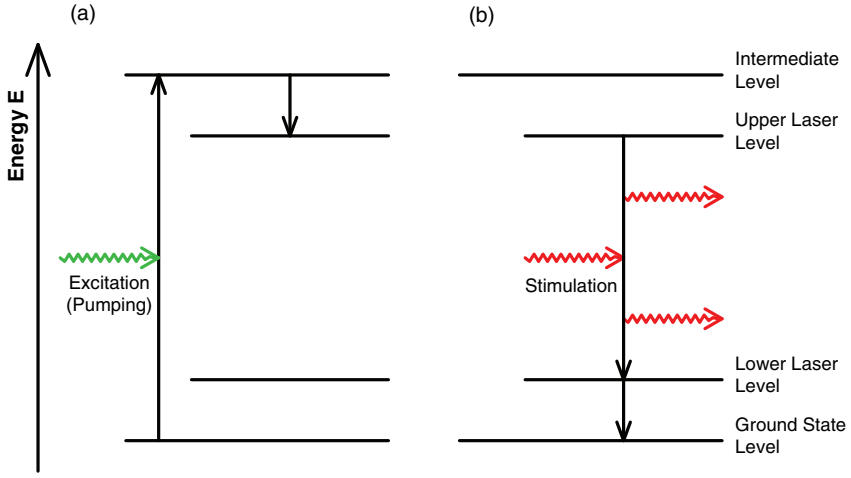

Figure 4.10 Stimulated emission with the example of a four-level system as one of a number of possible stimulated emission schemes for lasers. In a first step, an upper laser level is populated by a pumping process, usually via an intermediate level. An incident photon with an energy corresponding to the laser transition can stimulate the transition, leading to the emission of a second photon. The latter will have the same properties as the stimulating photon, that is, exactly share its wavelength, polarization, and propagation direction. Instead of an upper intermediate level, there is often a broader so-called pump band, which allows optical pumping with a broader spectral bandwidth of the pump radiation.

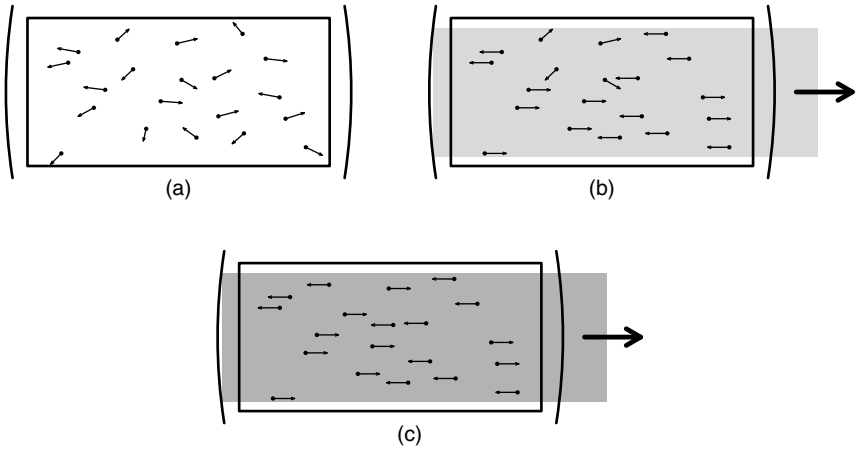

Figure 4.11 Build-up of a laser process; In the example a laser medium between two mirrors, one fully reflecting and one partially transparent, is shown. The mirrors form the feedback unit and act as a Fabry–Pérot resonator. (a) Directly after pumping, the medium starts to emit radiation randomly by spontaneous emission. Only photons reflected by one of the mirrors will re-enter the laser medium. (b) Photons, which re-entered the laser medium after reflection can stimulate further excited atoms or molecules in the laser medium, transferring their own wavelength and phase to the newly emitted photons. Due to the Huygens principle, a field starts to build up with a directional distribution and wavelength spectrum dictated by the mirrors. (c) After several rounds between the mirrors, the field becomes so strong, that practically all still excited atoms or molecules will emit their energy by stimulated emission. Since different wavelength and spatial modes of propagation are partially competing with each other, one or a few modes will win over others.

If inversion is achieved and feedback is established, laser emission can build up. Figure 4.11 shows the build-up of a laser process for a laser medium in a Fabry–Pérot cavity, consisting of two mirrors. Initially starting with spontaneous emission, the cavity will select certain propagation modes and wavelengths which can build a stable field. Since the stimulated emission amplifies a present field, the medium will emit an increasing fraction of its stored energy into this field. The cavity acts as a resonator, which is dedamped by the laser medium, turning the arrangement into an optical oscillator which can have a high Q factor and an accordingly small bandwidth. An oscillation, that is, a laser activity will take place if the losses after one round trip through the laser cavity (including the losses of the light exiting the cavity) are smaller than the inverse amplification factor, which is caused by the active medium during one round trip. As a second condition, the light field has to be stable, that is, reproduce its shape and phase after one round trip, otherwise the fields resulting after different round trips would interfere destructively. Due to the latter condition, the field in the cavity and in any optical oscillator can be decomposed into several discrete modes of different spatial distribution and/or wavelength.

Depending on the amplification properties of the laser medium, these modes may be amplified by the same excited atoms or by different subgroups of them. In the first case, the mode which best fits to the cavity and the amplification properties will

stimulate most of the excited atoms, thereby suppressing the other modes. This is called a mode competition. After a short time, only the dominant mode will survive. The best fitting mode will usually be the mode which has the largest cross-section with the laser medium and has a wavelength next to the peak amplification wavelength of the medium.

In the second case, multiple modes which are in not too strong competition with each other can survive. Such a situation can arise if the modes have a low spatial cross-section (for instance, a centered mode and a ring or "donut" mode) or if they have such different wavelengths that they will be amplified by different sub-species of the atoms. This is typical of, for instance, laser diodes. If several similarly well-fitting modes are in competition with each other, in either of the two cases a jumping between different modes – so-called mode hopping – can occur for different reasons. To achieve stable, single-mode laser emission, additional stabilization precautions will be necessary.

4.3.2
Thermal Sources

One of the best-known groups of thermal radiators for technical illumination purposes is the group of tungsten filament lamps and halogen lamps. In addition to these types of lamps, ceramic radiators and thin-layer radiators also belong to the thermal light sources. Other light sources also emit thermal radiation, such as high-pressure gas discharge lamps; however, the thermal emission there is not the main or only mechanism and these light sources will not be discussed in this section.

4.3.2.1 Tungsten Filament Lamps

Tungsten filament lamps, such as the well-known incandescent light bulb, are based on a tungsten filament as the light-emitting element. The filament is either a spiral or double-spiral wound tungsten coil or a flat ribbon, the latter giving a better defined geometry. The filament is heated by an electric current to a temperature of 2700 K to maximally 3400 K, so that it accordingly emits an approximate continuous blackbody radiation spectrum with an intensity maximum between 1080 and 730 nm. Compared with a pure Planck-type blackbody radiator, the spectral flux is reduced by the spectral emission coefficient of tungsten. For a wavelength of 200 nm and for usual working temperatures, this coefficient is about 0.5 and drops to less than 0.2 for a wavelength of 3 μm. Directly at the filament surface, the peak spectral radiance is in the order of 100–300 mW sr^{-1} cm^{-2} nm^{-1}, but particularly for the coil-type filament the distribution of radiance is inhomogeneous and the average radiance is below the value at the surface. To protect the tungsten filaments from oxygen – which would immediately react with the tungsten at high temperatures – the filament is placed inside a glass tube or bulb. In former times the latter was evacuated, but nowadays it is filled with a protective gas for different reasons. Energy losses due to convection and thermal conduction by the gas can be minimized best by using a protective gas with a high molecular weight and a low number of rotational degrees of freedom. Consequently, the noble gases xenon and krypton are used for high-quality lamps, whereas in cheaper lamps often a nitrogen–argon mixture is used.

For emission in the VIS region between 400 and 800 nm, the highest efficiencies would result for a working temperature of about 7000 K, but even tungsten, which has one of the highest melting points, melts at 3695 K. For a working temperature of 3400 K, the lifetime of the lamp shortens to a few hours, compared with about 1000 h for a temperature of 2700 K.

4.3.2.2 Halogen Lamps

Halogen lamps are a special type of tungsten lamp. Through the operation of a normal tungsten lamp, part of the tungsten filament sublimes and evaporates the wall of the glass bulb, creating a black, absorbing layer. To limit the sublimation rate, the working temperature and therefore the efficiency of the lamp have to be limited, and furthermore the glass bulb must be made sufficiently large to avoid too high absorption by the deposited tungsten layer which develops during the lamp lifetime.

In halogen lamps, the net sublimation rate and the tungsten deposition are limited by using a halogen additive in the filling gas. The sublimed tungsten reacts with the halogen and is stopped from settling down at the glass bulb. Near the filament, the tungsten halide decomposes because of the high temperature, so that the tungsten can settle back on the filament, which in this way can at least partly be regenerated. These mechanisms allow comparatively small glass bulbs to be used and the working temperature to be increased to about 3000 K to achieve a higher lamp efficiency. At the same time, the average lamp lifetime can be increased from 1000 h for a conventional tungsten lamp to about 3000 h. It is possible to operate halogen lamps up to about 3400 K, but only at the price of a drastically reduced lifetime.

4.3.3 Low-Pressure Gas Discharge Lamps

Low-pressure gas discharge lamps include a large number of construction types, filling gases, spectral properties and excitation types. All these sources have in common light generation by a radiative electron recombination or a radiative transition between different molecular excitation states in a plasma, that is, a partly ionized gas. The excitation of the gas can be accomplished by different physical processes, the most usual ones being direct excitation by a flowing current (arc lamps), capacitive excitation by a high-frequency electric alternating field, or inductive excitation by a magnetic alternating field, which generates a closed electrical current inside the plasma. The gas from which the plasma is generated is often a noble gas such as argon, neon or xenon, a metal vapor, or a mixture of both. In such a case there are no molecules in the gas and the emitted spectrum mainly consists of narrow, atomic transitions. If the lamp is filled with a molecular gas, the emitted spectra will be broader or continuous. Depending on the conditions, there are three different types of electrical discharge in a gas, of which two are used for light generation purposes, the glow discharge and the arc discharge. Figure 4.12 shows the basic dependence between the electrical voltage across and the electrical current through a gas in a strongly simplified diagram. The three types of discharge are distinguished by different currents and are separated by unstable ignition breakdown

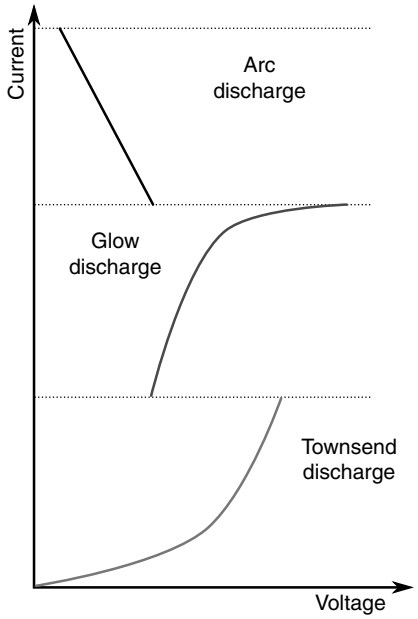

Figure 4.12 Basic discharge types in a gas. Glow discharge and arc discharge produce a plasma and can be used for lighting applications.

processes. The arc discharge furthermore has a negative differential resistance, requiring arc discharge light sources to be operated with a resistor.

4.3.3.1 Cold Cathode Fluorescent Lamps and Spectral Lamps

Cold cathode fluorescent lamps (CCFLs), sometimes also called neon lamps, consist of a glass or silica (quartz) tube with two electrodes and are filled with a (atomic) noble gas and eventually a metal vapor. A voltage applied to the electrodes leads to a glow discharge current, which excites the atoms by collision processes. Depending on the lamp type, the light emission takes place only near the cathode or at higher voltages additionally in the so-called positive column. Whereas lamps emitting only in the negative column are useful only for small indicator lamps, lamps emitting in the positive column usually give more light and can emit it nearly over the full length of the tube. Particularly for atomic gases, the emitted spectra consist of a number of lines which are very narrow and can be used for absolute wavelength calibration and also the determination of the spectral smear of spectrometers. Spectral lamps containing argon and mercury are particularly useful in the UV range, where they have a very strong emission line at 253.6 nm and further, weaker emission lines at some more wavelengths below 400 nm, which mainly originate from the mercury component. More lines occur in the VIS and NIR regions, where the latter are mainly caused by the argon component. Other lamp types and their predominant colors include pure helium (white–pink), neon (red–orange), argon (blue), krypton (white),

or xenon (violet) lamps and are – in addition to versions with mercury addition – frequently used for artistic illumination purposes and luminous advertising.

4.3.3.2 Energy-Saving Lamps

Energy-saving lamps are based on mercury arc-based lamps which are coated with a fluorescent dye or a mixture of multiple fluorescent dyes. In contrast, they usually have a heated cathode to allow electron emission at lower voltages. The dyes are optimized for efficient absorption of the dominant 253.6 nm peak of the mercury spectrum and are tailored to produce a certain color or color temperature, for instance to achieve an enjoyable room illumination or to achieve suitability for photographic purposes. However, the dye mixtures usually do not exhibit a continuous spectrum, but a spectrum with 3–6 more or less isolated emission ranges, rendering them less usable for spectroscopic purposes.

4.3.3.3 Hollow-Cathode Lamps

Similarly to spectral lamps, hollow-cathode lamps deliver spectra with a multitude of well-defined, narrow spectral emission lines. A larger variety than in the case of arc discharge lamps is possible due to a larger possible variety of emitting materials. Practically every metal and even a number of nonmetals and material combinations can be used as a characteristic material. The materials are placed in a hollow cathode inside a glass tube which is filled with an inert gas (Figure 4.13).

By applying a large voltage across the electrodes, a plasma discharge builds up in the buffer gas and the cathode material is gradually evaporated due to a sputtering process. The evaporated material is subsequently excited and ionized by collision with charge carriers and other particles in the plasma and starts to emit its own, characteristic radiation. The main application of hollow-cathode lamps is in atomic absorption spectrometry (AAS), since the light source spectra can be matched to the absorption spectra of the substances to be detected, leading to significant sensitivity increases of up to several orders of magnitude in comparison with nonspecific light sources.

The lifetime of the hollow cathode is limited by the cathode material which is available for sputtering. Since the sputtering speed is approximately proportional to the current, the lifetime is given in milliampere hours. Typical lifetimes of

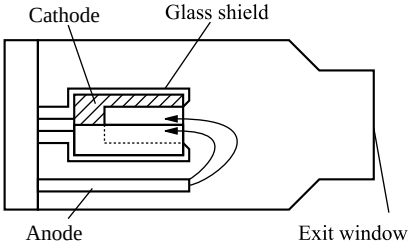

Figure 4.13 Basic layout of a hollow-cathode lamp.

commercial hollow cathode lamps are around 5000 mAh. A comprehensive overview of hollow-cathode lamps and their spectral lines is given in, for instance, [6].

4.3.3.4 Hydrogen and Deuterium Lamps

If broadband emission is required in the UV region, hydrogen and deuterium arc discharge lamps are a good choice. Of the two, the deuterium lamp provides a somewhat higher intensity. Both types can produce stable, well-characterized outputs and are therefore employed as irradiance standard sources. Although these lamps are operated at low to medium pressures, they do not deliver line spectra, but really continuous spectra. The reason for this is that the excitation and emission process is not a plain electronic one, but involves transitions between different molecular states and even dissociation of the gas molecules. The lifetime of these lamps is typically about 2000 h, but can range between 1000 and 5000 h.

4.3.4 High-Pressure Gas Discharge Lamps

High-pressure gas discharge lamps are filled with a plasma-generating gas, which at room temperature is already at or above normal pressure and will have increased pressure during operation. The gas is excited either by an incident radiofrequency radiation or alternating magnetic field (as for sulfur lamps), or by an arc discharge. Due to the high pressure there is a high probability that an excited atom will collide with another atom before it radiatively returns to the ground state. On the one hand, this causes the normally narrow spectral emission peaks of atomic gases to broaden significantly. On the other, it leads to a conversion of a large fraction of the electrically induced energy into heat of the plasma. The plasma therefore can gain higher temperatures than any solid and particularly in lamps with a very high pressure it can emit a corresponding thermal broadband radiation. Due to the high temperature, the pressure increases significantly when the lamp is in use.

4.3.4.1 Short Arc Lamps/High-Intensity Discharge (HID) Lamps

The predominant type of high-pressure gas discharge lamps are arc lamps with a short electrical arc, so-called short arc lamps. These lamps typically have a very high pressure of about 10–40 MPa (when in use) and can produce broadband radiation with extremely high radiances. The arc length typically is only a few millimeters and the most intense radiation is produced near the cathode (Figure 4.14). Depending on the lamp type, a second intense radiance maximum can exist near the anode.

Example emission spectra from one xenon and one xenon–mercury lamp with a 2 mm short arc are shown in Figure 4.15. At a distance of 50 cm from the lamps, the spectral irradiance of the xenon lamp is about one-tenth the value of the solar irradiance at sea level, except for the spectral absorption features of the atmosphere and some more narrow extra emission bands of xenon. The average spectral irradiance between 250 and 2000 nm is about 1 $\mu W\ cm^{-2}\ nm^{-1}$ and more than 50% of this irradiance originates from a region significantly smaller than 1 mm^2. Precise measurements of the spectral radiance distribution inside a xenon short arc

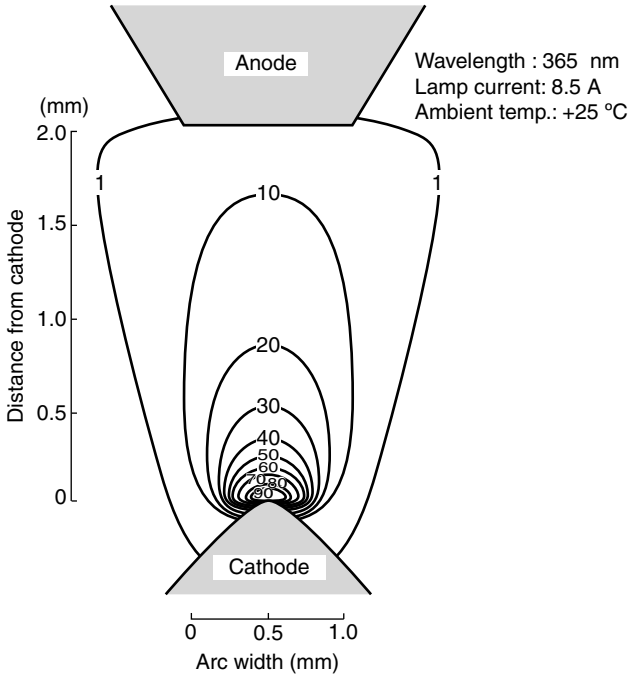

Figure 4.14 Typical cross-sectional view of the intensity distribution in the flare of a high-pressure xenon short arc lamp, here with the example of a Hamamatsu L2273. The radiance increases dramatically towards the cathode (image: Hamamatsu datasheet.)

lamp (Figure 4.16) have been performed by, for instance, Nakar *et al.* [7]. Results for measured spectral radiances in a 2 mm gap, 150 W short arc xenon lamp were presented, which show that in the brightest spot near the cathode the spectral radiance peaks at about 2 W sr^{-1} cm^{-2} nm^{-1}; for shorter wavelengths the measured values decrease because of the measurement method and would otherwise increase slightly further. Compared with peak radiances of about 90 mW sr^{-1} cm^{-2} nm^{-1} at $\lambda = 1073$ nm for a tungsten lamp operating at 2700 K or about 160 mW sr^{-1} cm^{-2} nm^{-1} at $\lambda = 966$ nm for a halogen lamp operating at 3000 K, this is a 12–22 times larger peak spectral radiance, which furthermore occurs at much shorter wavelengths.

Short arc lamps are therefore particularly well suited for creating high-intensity illumination of samples, for non-laser-based beam scanning confocal microscopy, for fluorescence excitation, for projecting brilliant images, or for illuminating objects at larger distances.

4.3.4.2 Other High-Pressure Gas Discharge Lamps

Further prominent gas discharge lamps which are not short arc lamps are the sulfur lamp and the high-pressure sodium (HPS) lamp. Both lamps are used because of their high efficiency for lighting applications and can produce high luminous fluxes

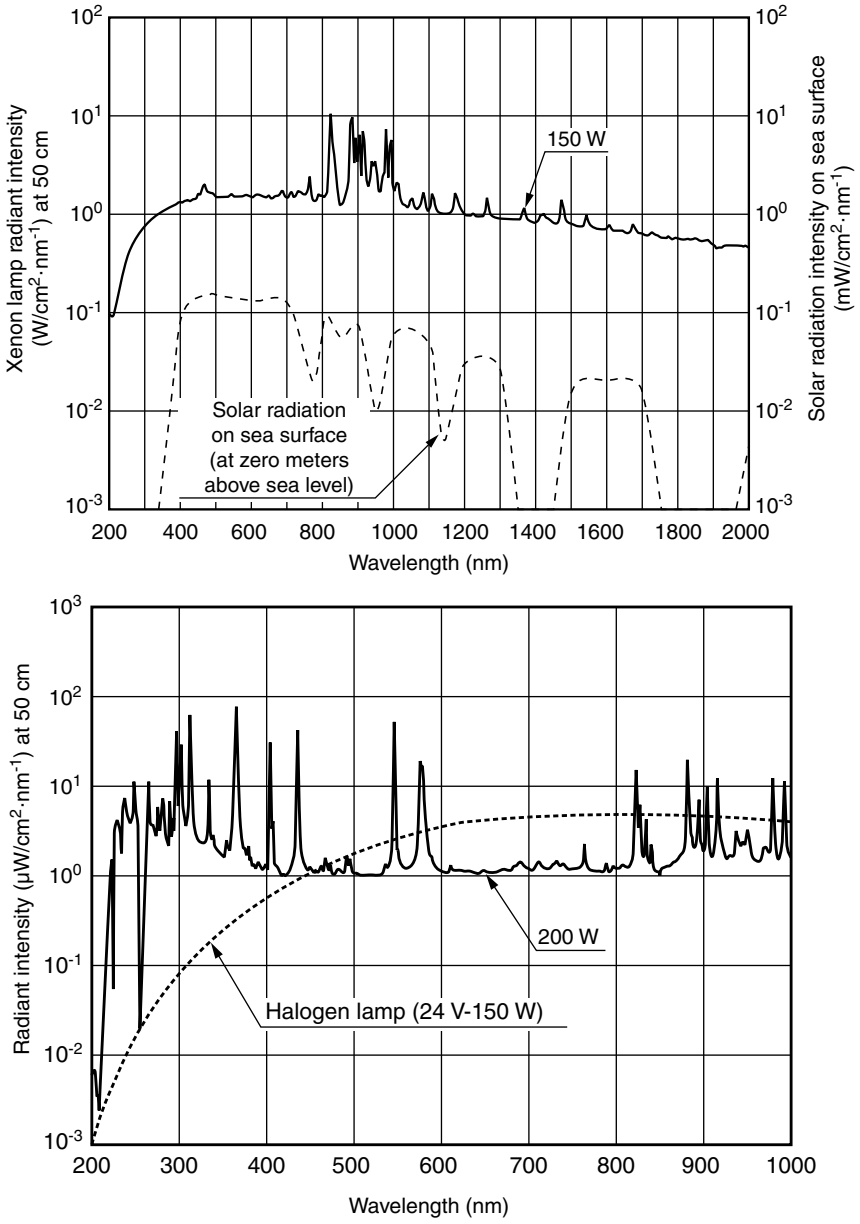

Figure 4.15 Spectral irradiances of a 150 W xenon arc lamp (Hamamatsu L2273) and a closely related 200 W mercury–xenon arc lamp (Hamamatsu L2423) at a distance of 50 cm. The addition of mercury particularly increases the UV emission, but also adds additional spectral peaks and absorption features. Note the different scales of the two charts (charts taken from Hamamatsu datasheet.)

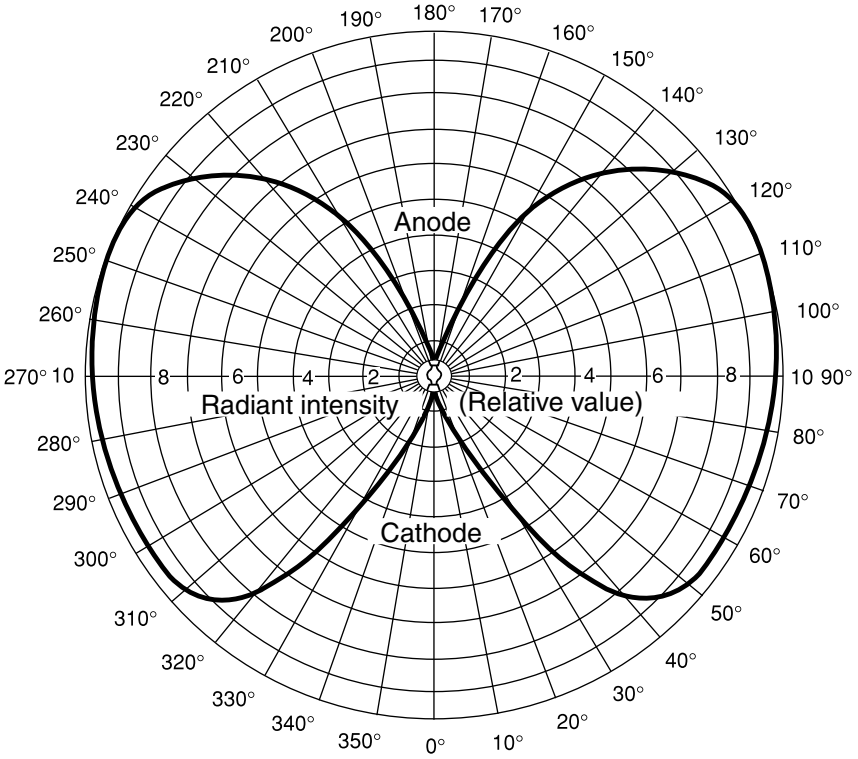

Figure 4.16 Typical angular radiance distribution of a short arc lamp with the example of a Hamamatsu L2273 150 W xenon lamp (chart taken from Hamamatsu datasheet).

but not high radiances, since the light generation occurs in relatively large volumes. The HPS lamp is an arc lamp with a long arc, whereas the sulfur lamp is electrodeless and uses a magnetron to excite the sulfur vapor with 2.45 GHz microwave radiation. Whereas the HPS lamp produces mainly yellow light, the sulfur lamp emits through nearly the whole visible spectral range, but only very little in the IR and UV ranges.

4.3.4.3 Gas Lasers

The principle of the low-pressure gas discharge emission lamp can be extended to build lasers. The first gas laser ever build was a helium–neon (HeNe) laser which was directly pumped by an electrical current. In contrast to normal gas discharge arc lamps, the energy scheme here is more complicated, to achieve good laser conditions. Helium and neon are mixed with relative partial pressures of approximately 10:1 at a total pressure of about 100 Pa. The electrical current first excites the helium atoms into the 2^1s or the 2^3s state, which then transfer their energy to the neon atoms, exciting them into the $3s$ or $2s$ state in a collision process. These states are metastable and can go to the $3p$ and $2p$ states by stimulated emission. The corresponding wavelengths are 632.816, 1152.3, and 3391.2 nm and have a very narrow spectral width. From the $3p$ and $2p$ states the neon atoms can return to the ground state by

spontaneous emission. Because of the very narrow amplification profiles, HeNe lasers can be made very stable with a highly precise emission wavelength and coherence lengths of several thousand kilometers. Even for nonstabilized HeNe lasers the coherence length is already in the range of the resonator length. A second important gas laser is the argon ion laser, which can produce up to 10 different laser wavelengths and high radiant fluxes of up to several watts. The most important of the large number of emission lines of the argon ion laser are at wavelengths 514.5, 496.5, 488.0, 467.5, 457.9, and 351 nm, with the first one giving the highest output power.

Further gas lasers in use are krypton ion lasers, argon–krypton lasers, helium–cadmium lasers, copper vapor lasers, and certain lasers based on hollow cathodes.

4.3.5
Light–Emitting Diodes (LEDs)

Light-emitting diodes (LEDs) are semiconductor devices in which the excitation of electrons is a direct effect of an electrical current flowing across a p–n junction. The current, which flows in the forward direction of the diode, injects conduction electrons from the n region and conduction holes from the p region of the device into the depletion zone, where they recombine with each other. The basic principle is shown in Figure 4.17.

In semiconductor materials with a direct bandgap, the recombination has a large probability of being radiative, that is, of producing photons. A direct bandgap is one

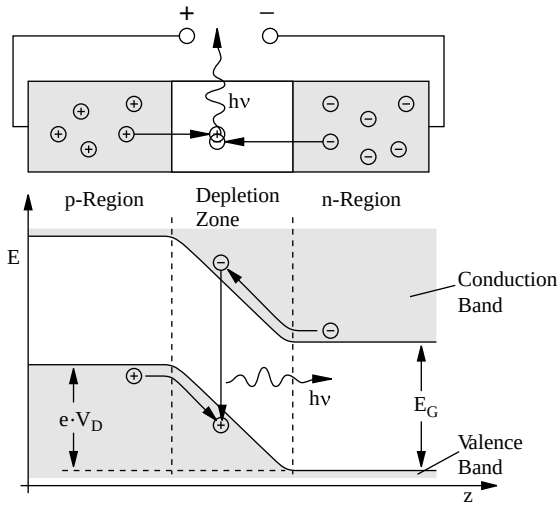

Figure 4.17 Principle of the LED. A semiconductor diode is operated in the forward direction, leading to injection of holes from the p region and of electrons from the n region of the diode into the depletion zone. There they will recombine, eventually emitting a photon with a frequency equal to or slightly larger than the bandgap energy E_G, divided by Planck's constant.

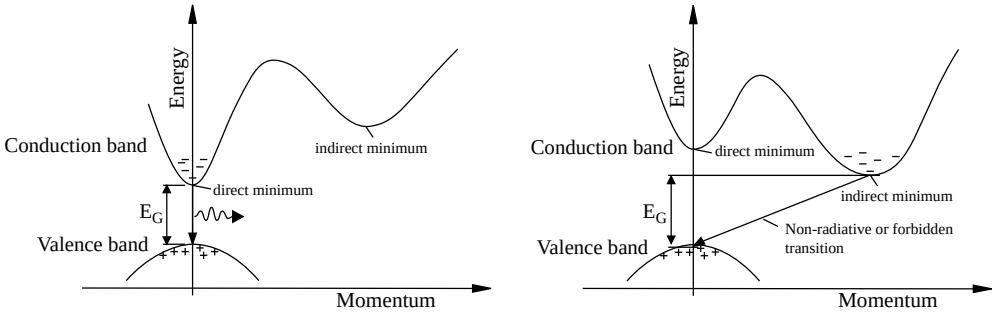

Figure 4.18 Direct and indirect semiconductors in the momentum–energy diagram. In direct semiconductors the transition of an electron from the conduction to the valence band is possible with a small or no change of the momentum, so that photons can be emitted. In indirect semiconductors, the lowest energy states of the conduction band differ significantly from the lowest energy hole states of the valence band in their electron momentum. If only such states are populated, the transition between the conduction and valence band is connected to a large momentum change, which cannot be accomplished by a photon. The material will not show optical activity.

where the mechanical momentum of the electron or hole does not change between conduction band and valence band, so that the energy can be transferred to a photon which has a negligible mechanical momentum. The process of light generation is called electroluminescence. In contrast, for indirect bandgaps, the recombination happens non-radiatively and mostly produces heat if no further modifications are made to the material. The large momentum change during recombination in an indirect semiconductor can only be accomplished by coupling to phonon modes of the semiconductor grid, preventing the emission of photons. Typical materials with a direct bandgap are GaAs, GaN, InP, certain GaAsP alloys, and AlGaAs, whereas SiC, GaP, silicon or germanium belong to the indirect bandgap materials. The difference between direct and indirect bandgap materials is sketched in Figure 4.18.

By introducing localized impurities (or "traps") in indirect bandgap materials, additional energy levels are created. Because of the localization, these traps can interact with a wide range of electron and hole momentum values, thereby connecting the minimum of the conduction band with the maximum of the valence band. Holes from the valence band and electrons from the conduction band can convert to the trap energy levels with emission of a photon. An electron and a hole at a trap create a so-called exciton, which can recombine. These possibilities of incorporating indirect bandgap materials in LEDs are shown in Figure 4.19.

Early LEDs were mainly based on the materials $GaAs_{1-x}P_x$, $Al_xGa_{1-x}As$, and GaP, partly with additional dopings, and emitted at wavelengths between 555 nm (yellowish green) and 940 nm, and beyond this range multiple quantum well systems of InGaAs and InP have been used for the range between 940 and about 1600 nm. LEDs for shorter wavelengths became possible more recently due to new material and technology developments based on GaN, InGaN, InAlGaN, AlGaN, ZnO, ZnSe, AlN, InN, and diamond and also SiC as a substrate material. Currently, LEDs with wavelengths down to 247 nm are commercially available [8], shorter wavelength

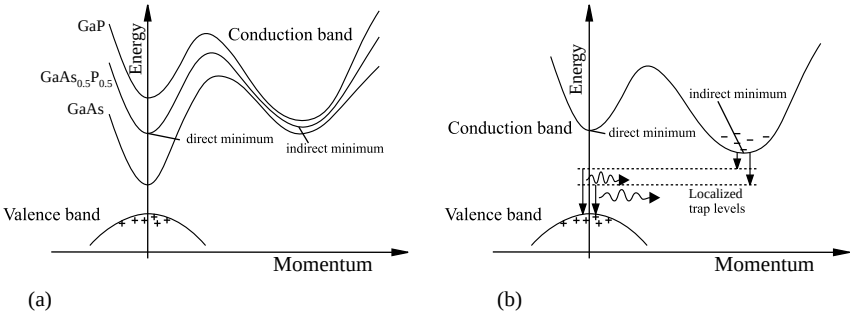

Figure 4.19 Possibilities for emitting photons from an indirect semiconductor material. (a) By creating alloys (here $GaAs_{1-x}P_x$) between an indirect semiconductor (GaP) and a direct semiconductor (GaAs), the relation between indirect and direct minima can be shifted, so that from a certain point a direct semiconductor alloy results. This method also allows one to tune the bandgap and the emitted color in a certain range. (b) By introducing local impurities (trap atoms or molecules), the momentum change between conduction and valence band states can be bridged and photon emission becomes possible. The energy of the photons depends on the trap energy levels and thus on the type of impurity. More specifically, so-called excitons, that is, electron–hole pairs, form at the traps, which have a high probability of recombination.

devices down to 230 nm are under development [9], and devices down to about 200 nm can be imagined based on the mentioned materials. A main direction of the developments is an increase in the radiant flux of LEDs, to make them suitable for lighting applications. These developments have already led to LED devices which, in addition to a high flux, can produce a relatively high radiance and spectral radiance and can therefore be very interesting for measurement applications, where gas discharge lamps are too large, energy consuming, expensive, or otherwise not well suited. Table 4.3 list some recent (mid-2010) high-power LEDs and their properties.

As can be seen from the table, source radiant exitances of up to $90\,W\,cm^{-2}$ and spectral source exitances of up to $4\,W\,cm^{-2}\,nm^{-1}$ can be delivered by the devices, particularly in the blue and violet spectral region, where halogen lamps deliver significantly less than $100\,mW\,cm^{-2}\,nm^{-1}$.

A further advantageous property of LEDs is their direct electrical modulation capability, which in addition to information transfer permits lock-in measurements without a mechanical chopper or stroboscopic measurements. The maximally possible modulation frequency depends on the recombination time of the electron–hole pairs in the depletion zone and can vary widely between different LED types. Typical recombination times are between about 1 μs for older homojunction GaAs LEDs and less than 10 ns for newer LEDs, leading to modulation frequencies from below 1 MHz to more than 100 MHz. For higher frequencies, operation as a laser diode (see the next section) is advantageous.

4.3.5.1 **Laser Diodes**

A wide range of LEDs can be operated as lasers. In contrast to other laser types using optical pumping or excitation through collision processes, an LED can produce an

a) The radiant and spectral exitance values are estimated based on the chip areas and the radiant flux values of the output power (datasheet). For LEDs, where only lumen (lm) values are given, the radiant flux was additionally estimated based on the wavelength. Further chips with a potentially high radiance are those produced by Nichia Corp., but here no reliable data on chip areas were available.

b) Values in parentheses are additionally available.

inversion directly through the injection process [10]. As a result, only two energy levels are necessary for the laser process and the only remaining critical parameters are the relation between the probabilities for stimulated and spontaneous emission and the amplification per unit length. In many LED materials, these parameters are well suited to create a laser even with very short lengths of the active medium. This is particularly true at longer wavelengths.

In the simplest case, a laser diode consists of an edge-emitting LED with a waveguide structure, concentrating the radiation along a line and with facets at the end of this structure, which act as mirrors and create a Fabry–Pérot cavity. Often, no additional reflection layers are necessary for the mirrors, because the high refractive index of the semiconductor leads to a sufficiently large reflection coefficient. Another simple diode laser type is vertically emitting laser diodes, so-called vertical cavity surface-emitting lasers (VCSELs), which consist of a very thin – that is, short – laser cavity between mirror layers. The thickness of the laser cavity can be as small as three wavelengths.

As for all lasers, the radiance limitations of the underlying light source, that is, the LED, are overcome. Also, due to the stimulated emission, which de-excites the higher laser levels faster than a spontaneous emission would do, diode lasers allow even higher modulation frequencies than their LED counterparts. However, to avoid frequency-limiting oscillations connected to the switching between lasing and non-lasing states, the laser diode needs to be held in a lasing state all the time and modulation would be done between two different intensities. Direct modulation frequencies of up to 66 GHz have been reported for special VCSELs [11].

Because of the spectrally very broad amplification profiles and the high amplification, usually several laser modes will oscillate in a diode laser. This leads to a spectral width of the laser that is broader than for other lasers and results in a short coherence length in the range of the cavity length, but with periodic revivals. In applications where a small emission bandwidth is needed, more advanced implementations such as distributed feedback (DFB) lasers or external cavity diode lasers (ECDLs) with additional tuning elements can be used. In the DFB diode laser, the active region itself or a part of it is structured and forms a Bragg grating, which only permits efficient amplification of a single laser mode. Simple designs provide a fixed wavelength, whereas more advanced designs permit wavelength tuning by temperature control or electro-optic effects. The external cavity diode laser uses a dispersive element such as a reflection grating outside the diode as one of the two mirrors. Figure 4.20 shows the basic layout of an ECDL in a Littrow arrangement. Again, only one wavelength is reflected back in such a way that laser amplification can occur and this wavelength can be tuned through the amplification bandwidth of the laser medium by aligning the dispersive element.

Currently, diode lasers with wavelengths down to 375 nm are commercially available and shorter wavelength devices (partially with indirect, optical pumping) are under development. Diode lasers can therefore potentially serve in applications for which currently often large, expensive, and energy-consuming lasers with frequency conversion or excimer lasers with toxic gases are needed.

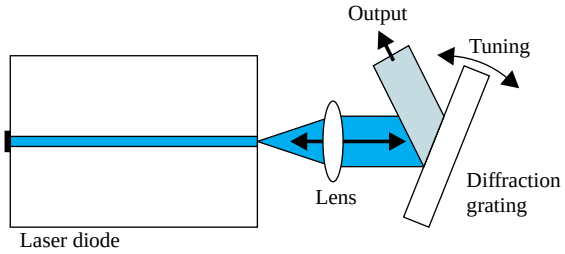

Figure 4.20 External cavity diode laser with a grating in Littrow configuration.

4.3.5.2 Optically Pumped Semiconductor Lasers

In addition to laser diodes which are pumped directly through the injection current, there also exist semiconductor lasers which are pumped optically by an LED. With such lasers, already significantly shorter emission wavelengths than for directly pumped diode lasers have been reported. Particularly lasing at a wavelength as low as 231.8 nm for a cooled AlGaN multiple quantum well laser and 241.5 nm for an uncooled one have already been demonstrated in the laboratory [12].

4.3.5.3 Other Sources

There exists a wide range of other light sources that have not been discussed here. One important type is the diode-pumped solid-state (DPSS) laser. Here, a laser medium such as a neodymium-doped yttrium–aluminum–garnet (Nd:YAG) crystal is pumped optically by one or a number (called a stack) of high-power IR laser diodes. The Nd:YAG laser, as one of the currently most important types of DPSS laser, can emit strong laser radiation at a wavelength of 1064 nm and less strong laser radiation at 946, 1320, and 1444 nm. Output powers can reach at high as 10 kW and it is possible to operate in a continuous wave or pulsed mode. Due to the high power of the primary laser radiation, it is possible to create shorter wave laser sources by frequency conversion, for instance the green 532 nm line, which is achieved by frequency doubling. The latter is often done inside the laser cavity. It is also possible to create the third and fourth harmonic waves, leading to emission wavelengths of 355 and 266 nm.

Fiber lasers are a special version of DPSS lasers. Here, a fiber with a doped core is pumped from one end. The pumping radiation is coupled into a wider core, which surrounds the doped core. Due to the large length of the fiber, the pumping radiation can be efficiently absorbed by the doped core and be converted into laser radiation with a low (i.e., good) M^2 parameter. In this way, even the very faint Raman process can be used to produce a laser. Before laser diodes were available for pumping, gas discharge lamps were used to pump solid-state lasers, such as the first laser ever, the ruby laser.

Supercontinuum light sources – sometimes called white light lasers – are light sources which use optically nonlinear effects to broaden spectrally the initially monochromatic or low bandwidth radiation of a laser. For short and very intense pulses from femtosecond lasers, crossing of a medium such as a fluid or even air is

often sufficient to achieve this effect; for longer pulse durations or continuous laser radiation, the transmission through a long optical fiber with nonlinear effects is necessary. The great advantage of a supercontinuum source is the production of nondiffuse, that is, diffraction-limited, very intense broadband radiation or white light, which cannot be produced by other light sources. Such radiation is useful, for instance, for white light confocal microscopy, spectroscopy, or optical coherence tomography (OCT), sometimes also referred to as white light interferometry.

Dye lasers are optically pumped lasers, similar to solid-state lasers. Instead of a spectrally relatively narrow laser transition in a solid body, these lasers use dyes (often in a liquid), which can have a very broad amplification bandwidth. It is therefore possible to tune the wavelength of the laser emission of a dye laser in a very wide range of typically 30–60 nm bandwidth by changing the laser resonator. Dye lasers are available from the near-UV to the MIR region.

Tunable monochromatic laser-like radiation can also be produced by a so-called optical parametric oscillator (OPO). This device mainly consists of an optically nonlinear crystal in an optical resonator. It converts an incident monochromatic laser beam into two beams whose oscillation frequencies add up to the oscillation frequency of the incident radiation, that is, the energy of each incident photon is distributed to two new photons. The underlying physical process is called parametric three-wave mixing. Tuning is achieved by appropriately aligning the optical resonator and the crystal; however, the alignment of an OPO is complicated and small instabilities or misalignments – for instance due to temperature changes – can lead to an interruption of the conversion process. OPOs are therefore primarily used in scientific laboratories and less often in industrial applications.

5
Optical Detectors

Rainer Riesenberg and Andreas Wuttig

5.1
Introduction

The main focus of this chapter will be CMOS (complementary metal–oxide–semiconductor) and CCD (charge-coupled device) technologies and the photodiode/photoconductor technology on which they are based, since they are most relevant for biophotonics applications. Other light detection technologies are only briefly mentioned to give a coarse overview.

5.2
Devices for Light Detection

5.2.1
Sensitivity and Detectivity of Light Detectors

5.2.1.1 Responsivity

The term responsivity denotes the strength of a light detector's output current in relation to the power of the incident light [1], measured in amperes per watt ($\mathrm{A\,W^{-1}}$). Such a figure is typically only valid for a single wavelength, since in semiconducting detectors, for instance, the generated photocurrent is more related to the incidence rate of photons. Furthermore, the efficiency of light-to-current conversion is itself dependent on the wavelength via the quantum efficiency $\eta(\lambda)$. For example, for a photodiode without internal gain it can be calculated as

$$R = \eta(\lambda)\frac{e\lambda}{hc} \tag{5.1}$$

where $\eta(\lambda)$ is the quantum efficiency of the electron–hole generation process, h is Planck's constant, e is the charge of the electron and c is the speed of light. In addition to material-related properties, the quantum efficiency may also subsume the transmissivity of the detector surface, that is, the efficiency at which light enters the detector. In this case, it is also referred to as external quantum efficiency, otherwise as

Handbook of Biophotonics. Vol.1: Basics and Techniques, First Edition.
Edited by Jürgen Popp, Valery V. Tuchin, Arthur Chiou, and Stefan H. Heinemann.

internal quantum efficiency. For other semiconducting detectors, the responsivity–wavelength behavior may differ from the above equation by a gain factor, describing the internal multiplication of an initially generated photoelectron or electron–hole pair. For thermal detectors, which are based on the measurement of incident energy rather than incident photon flux, the responsivity looks completely different and may even be constant over certain wavelength ranges. For other detectors, responsivity may not be a useful figure at all, since their output may not be described properly by a current.

5.2.1.2 Noise, Sensitivity, and Detectivity

In contrast to responsivity, the figure of sensitivity loosely speaking describes the lowest detectable amount of light of a given wavelength, and as such is always a useful performance figure for a detector. The sensitivity of a detector is closely related to its dark noise, that is, the nonsystematic uncertainty involved in a measurement, and more precisely describes the amount of light for which a specific minimal signal-to-noise ratio SNR_{req} of the output of the detector is achieved. For low light levels, the noise of a detector can often be considered independent of the signal. For this case, the sensitivity can be characterized by the noise equivalent power (*NEP*), which is connected to the noise level σ and the responsivity R of the detector by

$$NEP = \frac{\sigma}{R}. \tag{5.2}$$

The noise elongation r of a single measurement of the detector output will be centered to zero, that is, the expectation value $\langle r \rangle$ is zero, since a nonzero expectation value can be subsumed under the systematic measurement errors. The square of the noise level, called the noise variance, is then given by the expectation value of r^2, that is, $\sigma^2 = \langle r^2 \rangle$. The value σ itself is often referred to as the root mean square (rms) of the noise. If the noise generation processes yield a white or pink noise, that is, noise with constant spectral power density at least up to a certain frequency limit, the relevant noise variance itself depends on the bandwidth of the system consisting of detector and measurement electronics and will be proportional to it. Furthermore, the ultimate limit of noise generation of a detector is very often given by statistical noise processes, which take place independently at different points inside the sensitive area or volume of a detector. If the thickness of the sensitive area is chosen to be an optimal value, the surface remains the only important parameter for these processes and the noise variance becomes proportional to the detector area. Taking these influences together, a new property of a detector, its so-called detectivity or specific detectivity, D^*, can be defined:

$$D^* = \frac{\sqrt{A \cdot \Delta f}}{NEP} \tag{5.3}$$

where A is the sensor area, Δf is the bandwidth, and *NEP* is the noise equivalent power, that is, the radiant flux, which generates a signal with $SNR = 1$. D^* describes the quality of a detector or the performance of a detector technology.

5.2.2
Light Detection Through Thermal Effects/Thermal Detectors

If light is absorbed by a material, its energy will cause a transition from a lower to a higher energy state. These transitions can be electronic transitions, changes of molecular energy levels, or lattice vibrations of a solid-state body. If from this higher level a radiative transition to a lower level is improbable or impossible, the energy can gradually be converted into vibrational energy, that is, heat. This heat can then be detected in a temperature measurement, giving an indirect measure of the incident light intensity. Thermal detectors make use of exactly this measurement scheme, combining a good absorber with a low specific heat capacity and a sensitive temperature sensor. Since absorbers can be made efficient over wide wavelength ranges, thermal sensors are cost-efficient detectors for wavelength ranges, where otherwise only very expensive or even no detectors would be available. The most frequently used thermal detectors are uncooled bolometers, thermopiles, and pyropiles, which have typical detectivities in the range 10^8 to $10^9\,\mathrm{cm{\cdot}Hz^{0.5}{\cdot}W^{-1}}$. This is relatively low compared with most other detector technologies. In contrast, the most sensitive thermal detectors are superconducting edge transition bolometers, which achieve detectivities higher than $10^{10}\,\mathrm{cm{\cdot}Hz^{0.5}{\cdot}W^{-1}}$.

5.2.3
Light Detection Using the Photoelectric Effect

The photoelectric effect is the emission of electrons (so-called photoelectrons) from a material when it is illuminated with photons. The latter are absorbed by the material in such a way that the energy is transferred to an electron. If the energy of the photon is higher than the binding energy of the electron, it can leave the material. The effect thus works particularly well for short wavelengths and is used in a number of photodetectors.

5.2.3.1 **Phototube**
The simplest photodetector based on the photoelectric effect is the phototube. It consists of a gas-filled or vacuum tube with a photocathode and an anode. Photons absorbed by the cathode lead to emission of electrons from the cathode, which then move to the anode and generate a current pulse. Simple phototubes without amplification capabilities are outdated, since detector technologies now exist that are cheaper and better.

5.2.3.2 **Photomultiplier**
The photomultiplier or photomultiplier tube (PMT) is a phototube that is capable of multiplying single photoelectrons several million times, each time generating a large current pulse. In the more recent types of PMTs, the amplification is achieved by a number of so-called dynodes, which are electrodes at voltage levels between those of the anode and cathode. The voltages between all the electrodes in the PMT are tailored in such a way that the photoelectron emitted from the cathode is first accelerated

towards the first dynode. Upon its impact on the dynode, it already has such a high kinetic energy that several secondary electrons will be emitted from the dynode as a result of the impact. The electron packet created is then accelerated towards the next dynode, where every electron again creates several secondary electrons. This process is repeated until the anode is hit by a large packet of electrons coming from the last dynode.

PMTs are still in use because they permit relatively sensitive detection of light. However, their sensitivity compared with other detector types is often overestimated. Taking the poor IR sensitivity and the high effort for the electronics on the one hand and the semiconductor-based alternatives on the other (see below) into account, however, this is not one of the best reasons for using them as photodetectors. The more important properties of a photodetector are their very high temporal resolution, the large sensitive area, which can be achieved at low noise levels, and the fact that the gain factor can be varied by several orders of magnitude by simply changing the voltages of the dynodes.

5.2.4
Light Detection Using Internal Photoelectric Effects

The term "internal photoelectric effects" here will subsume all effects where absorbed light generates free charge carriers inside a medium, leading to changed electrical properties of a device containing such a medium. Normally, the medium will be a semiconductor and the free charge carriers will be generated as electron–hole pairs, when the absorbed photons elevate electrons from the valence band to the conduction band of the semiconductor. This can lead to the effect of photoconductivity and to the photovoltaic effect, depending on the device.

5.2.4.1 **Photoconductor**

The photoconductor is the simplest semiconducting optical detector. It has a resistance that is indirectly proportional to the incident intensity. Photoconductors are usually made of an amorphous film of the semiconducting material, coated on an insulating substrate and connected by metal contacts. The latter often have a so-called interdigital shape to increase the overall conductivity and the gain of the device (Figure 5.1). Typical semiconductor materials for optical detectors and their most important physical properties are given in Table 5.1.

Once a photon has been absorbed by the photoconductor material, an electron–hole pair is created, that is, an electron is elevated into the conduction band and a hole is created in the valence band. Such an absorption can occur when the energy of the incident photon is higher than the bandgap energy of the semiconductor, that is,

$$E_{\mathrm{Phot}} = \frac{hc}{\lambda} \geq E_{\mathrm{G}}. \tag{5.4}$$

According to this, there exists a cutoff wavelength above which the material will not be sensitive to incoming radiation. After generation, photoelectron and hole diffuse through the photoconductor until they recombine with other holes and electrons.

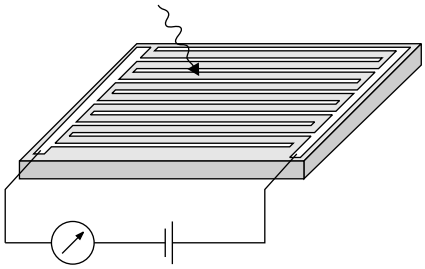

Figure 5.1 Photoconductor interdigital electrodes. Incident photons create free charge carriers, which cause a current, if an external voltage is applied.

The mean time until recombination is given by the inverse of the so-called recombination rate. If a voltage is applied at the metal contacts, an electrical field is generated inside the photoconductor. As a result, the diffusion motion of the charge carriers will change into a directed drift motion and a global current, the photocurrent, can be observed. For usual detector geometries and applied voltages, the time it takes an electron to travel through the detector is much shorter than the recombination time. If an electron reaches the positive metal electrode and is extracted from the semiconductor, another conduction band electron will be injected for it at the negative electrode to retain electrical neutrality. A photoelectron thus effectively can travel several times through the detector and the observed global current will be increased by an according factor, the gain factor G. The highest values

Table 5.1 Bandgaps and corresponding cut-off wavelengths for different semiconductors at temperatures of 300 and 4 K, compiled from Wagemann and Schmidt [2], Jones [3], Nahory *et al.* [4], and Hansen and Schmit [5].

Material	300 K		4 K	
	E_G (eV)	λ_{cut} (μm)	E_G (eV)	λ_{cut} (μm)
Si	1.11	1.12	1.20	1.03
Ge	0.67	1.85	0.74	1.68
PbS	0.41	3.02	0.29	4.28

a) Bandgaps depending on material composition; InGaAs given in [4], MCT given in [5].

that have been achieved for G are in the region of 10^5. Since the recombination rate of electrons increases with increase in the number of available holes and the recombination rate of holes increases with increase in the number of available electrons, the responsivity will become nonlinear. The average recombination time of the detector itself determines the time constant of the detector, that is, the speed at which it responds to changes in the incident intensity. For a given detector geometry and operation voltage, larger gain factors can therefore only be achieved at the expense of slower detection.

5.2.4.2 **Photodiode**

Photodiodes of the basic type (Figure 5.2) are formed by a p–n junction in a semiconductor, that is, by a contact between a p-doped region, in which charge transport only takes place in the form of hole conduction, and an n-doped region, where electrons are responsible for charge transport. Between these two regions an insulating zone without free charge carriers builds up due to diffusion processes of electrons and holes, because free electrons will recombine and be captured in the p zone (loading it negatively) and free holes will do the same in the n zone. Inside the insulating zone, called the depletion zone, an electrical field is generated due to the capture of the two types of charge carriers on the two different sides of the p–n junction. Finally, the system of n zone, p zone, and depletion zone effectively forms a charged capacitor. Similarly to the case of the photoconductor, incident light with a photon energy higher than the bandgap energy E_G generates electron–hole pairs, which without an electrical field would diffuse through the device but with an electrical field will generate a photocurrent.

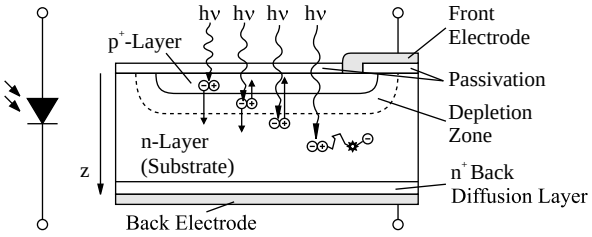

Figure 5.2 Basic layout of a photodiode. Below a transparent and probably anti-reflective passivation layer (in silicon photodiodes typically SiO_2 or Si_3N_4) a thin, n- or p-type layer is processed on to a substrate of opposite weak doping by thermal diffusion. The back side of the substrate is heavily doped with the same type of doping as the substrate itself as a transition to the back-side metal electrode. The top layer (here the p region) is connected to a further front-side metal electrode. At the interface between p- and n-type layers a depletion zone with an internal electrical field builds up, expanding mainly into the weakly doped substrate. If photons are absorbed inside or near the depletion zone, electron–hole pairs generated by the absorption will be separated due to the field of the depletion zone, leading to a measurable voltage or current at the electrodes. Photons absorbed at a larger distance from the depletion zone will in contrast be very unlikely to lead to a signal, since the generated charge carriers will only diffuse randomly through the material until they recombine with other charge carriers or are eventually captured by the depletion zone with a very low probability.

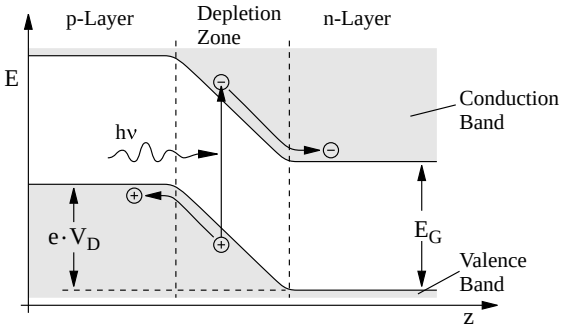

Figure 5.3 Energy diagram for the photodiode shown in Figure 5.2. An electron–hole pair is generated when the energy of an incident photon is absorbed by elevating an electron from the valence band to the conduction band. For this, the photon energy $h\nu$ needs to be larger than the bandgap energy E_G. If the absorption process takes place in or near to the depletion zone, the two charge carriers will be separated due to the spatial variation of the band energies.

As a first fundamental difference from the photoconductor, the electrical field will only be observed in the depletion zone between the n- and the p-conducting parts. Additional fields applied from the outside will only lead to a change in the width of the depletion zone and the voltage drop V_D (see Figure 5.3) about it. If the photon is absorbed inside the depletion zone, the electrical field will drag the electron into the n region and the hole into the p region, thereby creating a photocurrent which can either be extracted from the photodiode through contacts at the n and p regions or which otherwise leads to a charge and voltage change of the diode capacitance. According to this, photodiodes can be operated in the photoconduction mode or in the photovoltaic mode, depending on their bias voltage (Figure 5.4):

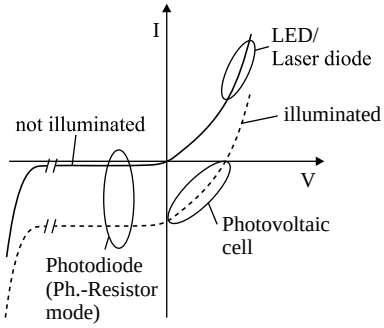

Figure 5.4 Depending on its operational conditions, a photodiode acts as a photoconductor, a photovoltaic cell, or a light-emitting device, each located in a certain quadrant of the voltage–current (V–I) diagram. Different diode designs and materials are, however, differently well suited for each of the modes. Particularly for light emission, a number of additional conditions, such as having a direct semiconductor or exciton levels, have to be met, otherwise the diode will only heat up instead of emitting light.

- **Operation as a photovoltaic cell**: A photodiode illuminated by light in its sensitive region will generate a photovoltage and drive a photocurrent, if it is properly connected in an electric circuit. This mode is employed in, for example, solar cells, which are just photodiodes with a large collecting area. If the photodiode runs free or is operated at a large load impedance, the photoinduced voltage will approach the open-circuit voltage, which has a disadvantageous dependence on the illuminated power. Such an operation regime would therefore not be useful for light intensity measurements, as long as the voltage is not being reset between readouts. At low impedance values of the external load or in short-circuit operation, the current will become proportional to the incident intensity. For most sensitive measurements without an amplifier, the external impedance should be set to the effective impedance of the photodiode. In this mode of operation, the photodiode will, however, be relatively slow and the dependence between illumination power and output power of the photodiode is nonlinear, so a good calibration is required. Faster operation with a higher measurement precision due to a linear response is possible if the photodiode is operated in the short-circuit mode and the resulting current is measured using a current-to-voltage converter.
- **Operation with reverse bias voltage**: If a voltage in the reverse direction is applied to the photodiode, incident light will still lead to a photocurrent. Since this current is also directed in the reverse direction, the photodiode effectively acts like a photoconductor, but without the gain mechanism observed in real photoconductors, since no replacement electrons can be injected into the hole-conducting p region of the photodiode. Because of the applied voltage, the depletion zone will broaden, leading to a lower capacity and a faster response, so detection of faster signals will become possible. The bias voltage will, however, also lead to a temperature-dependent dark current, which in turn leads to an associated shot noise and a degraded linearity between incident power and total output current. If the bias voltage is raised above a certain device-dependent level, the photodiode will act as an avalanche photodiode. Due to an avalanche effect, every absorbed photon will lead to an avalanche breakdown, resulting in an internal gain of the photoinduced charges. This increases the effective responsivity of the device, which makes it easier to read out the signals of single photons. This is described in more detail in a separate section.

At low photon energies, that is, energies inducing only one electron–hole pair per absorbed photon, the theoretical responsivity limit for a monochromatic wavelength is given by Equation 5.1. This limit can only be achieved if the wavelength corresponds to the energy of the bandgap. Shorter wavelengths will yield at best the same current per number of photons, which means a lower current per incident power. Figure 5.5 shows a comparison between the sensitivities achieved by real detectors and the maximal responsivity for the case of a quantum efficiency of 100%. Typical features of detectors are illustrated in Figures 5.6–5.10 and Table 5.2.

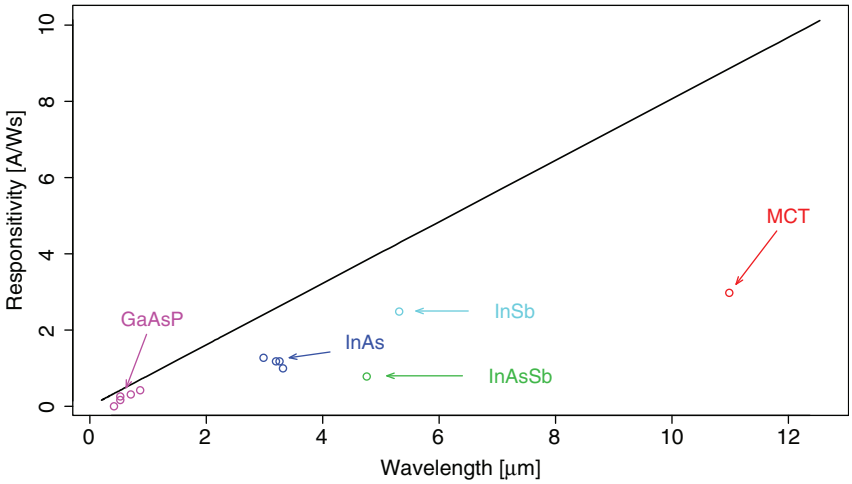

Figure 5.5 Maximal theoretically possible responsivity of photodiodes and responsivities achieved by real photodiodes and a photoconductor (MCT) [6].

5.2.4.3 PIN Photodiode

The PIN (positive–intrinsic–negative) photodiode is a special type of a photodiode, which has an intrinsic (i.e., weakly doped or undoped) region between the positively and negatively doped regions (Figure 5.11). The insertion of an intrinsic region has two advantageous effects:

- Most photons are absorbed in the intrinsic region. Due to the electric field present, the photoinduced charge carriers will be directed quickly to the p- and n-doped regions instead of eventually getting there by a drift process. At the same time, due to the greater thickness of the depletion zone, the capacity of the device is comparatively low. Together, this leads to a very quick response of the PIN photodiode to changing light intensities. The operating frequencies of the fastest PIN photodiodes are in the range of tens of gigahertz, making them ideal for optical communication applications.

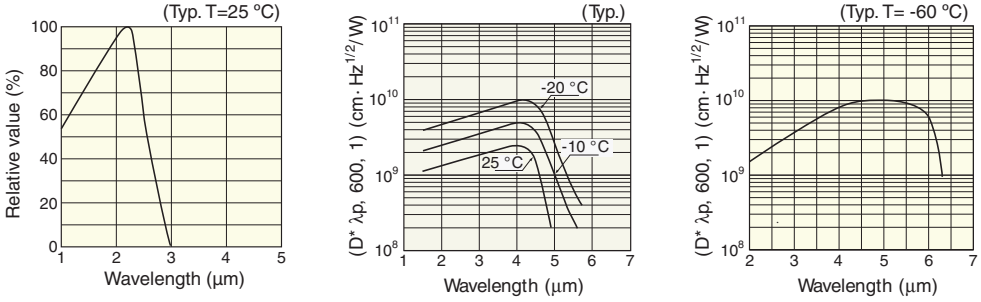

Figure 5.6 Typical spectral detectivities of PbS, PbSe, and InSb detectors manufactured by Hamamatsu.

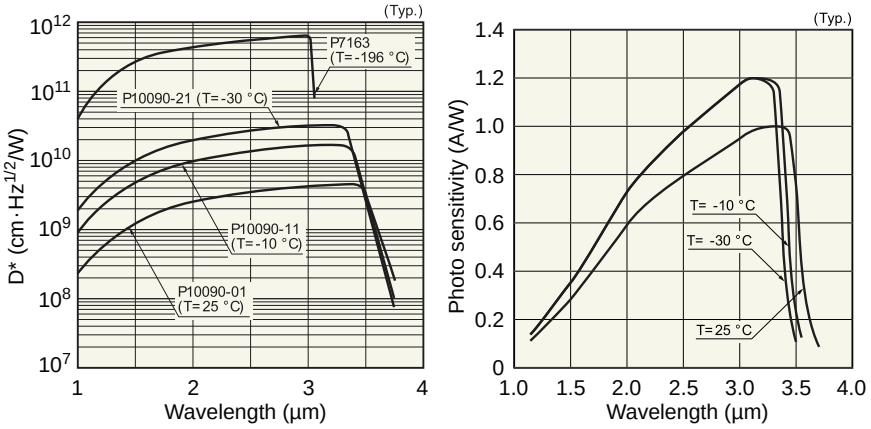

Figure 5.7 Typical detectivities and responsivities (referred to as "photosensitivities") of InAs detectors manufactured by Hamamatsu (diagrams taken from Hamamatsu datasheet).

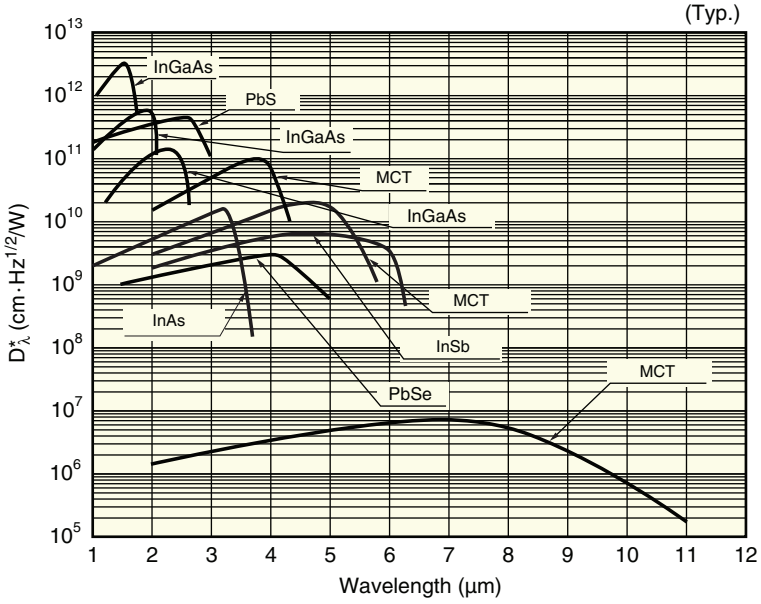

Figure 5.8 Spectral detectivity chart of different cooled photodetector devices manufactured by Hamamatsu (diagram taken from Hamamatsu datasheet). The sensitivities depend not only on the material, but also on the material modification, the operating conditions, and the device layout. A larger long-wavelength cutoff normally implies a lower sensitivity. Beyond 10 µm this relation is partly reversed, but lower detector temperatures have to be used.

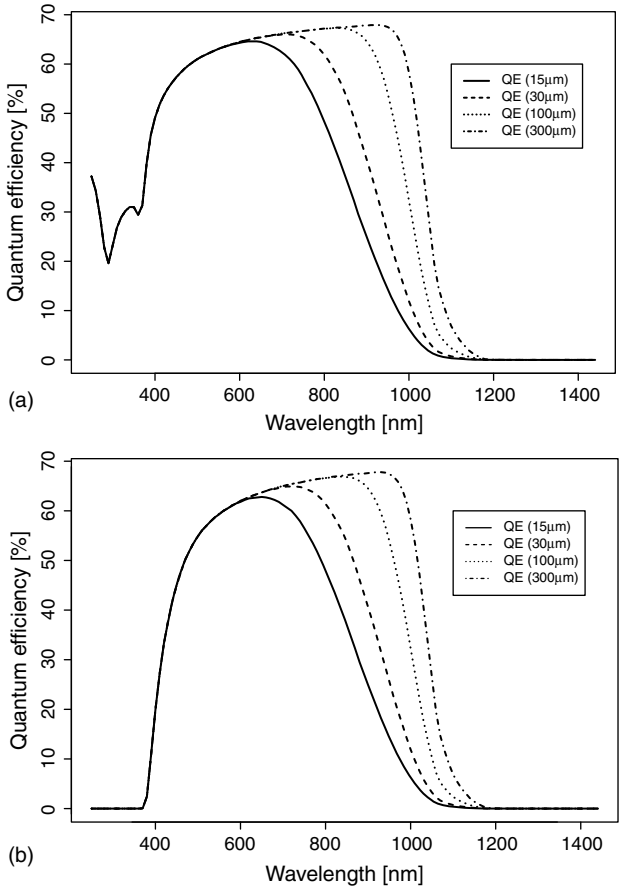

Figure 5.9 Theoretical maximum quantum efficiencies of silicon photodiodes with thicknesses of the depletion zone between 15 μm (solid lines) and 300 μm (dashed-dotted lines), thicknesses of the non-sensitive part of the top layer of 5 nm (a) and 100 nm (b) , and no antireflective coating. The quantum efficiencies are calculated only from the wavelength-dependent refractive indices and absorption coefficients.

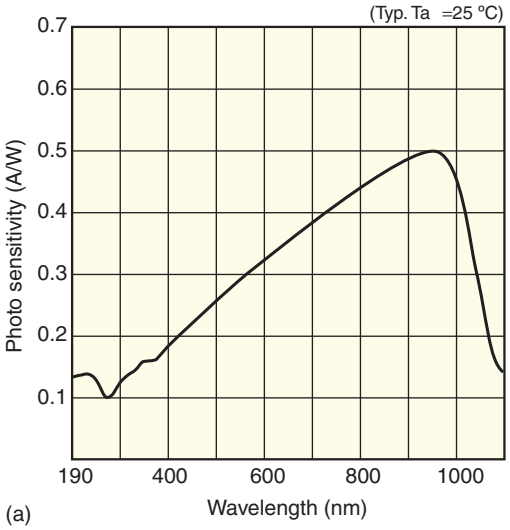
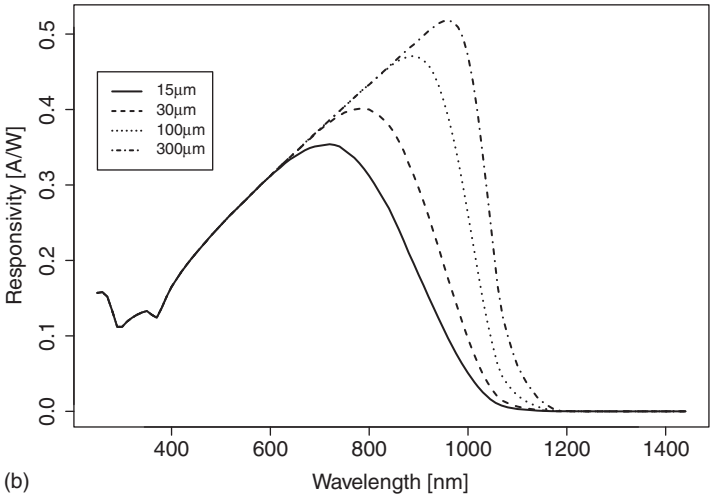
- The larger sensitive volume compared with a normal (p–n) photodiode leads to a more efficient collection of light, particularly at the long-wavelength end of the sensitivity region, where photons start to pass through the diode material without being absorbed.

5.2.4.4 **Pinned Photodiode**

The "pinned" photodiode is mentioned here because it must not be confused with the PIN photodiode. Pinning is a method to reduce the dark current of a photodiode working in the accumulation regime by three or more orders of magnitude. Pinning



(a)



(b)

Figure 5.10 (a) Responsivity ("photosensitivity") of a silicon photodiode manufactured by Hamamatsu (diagram taken from Hamamatsu datasheet) and (b) theoretical responsivity for silicon photodiodes with thicknesses of the depletion zone varying between 15 and 300 μm, with a non-sensitive top layer of 1 nm thickness, and without anti reflective coating. The shape of the responsivity curve of the real detector indicates a thickness of the sensitive region of at least 300 μm.

is practically only employed in image sensors of the CCD or CMOS type, particularly for cooled, high-performance devices, where it raises the usual silicon photodiode peak detectivities from values in the range $10^{12}-5\times10^{14}$ to $>10^{17}$ cm·Hz$^{0.5}$·W^{-1}. Pinning will be discussed in more detail in Section 5.3.2.7.

Table 5.2 Photosensitive semiconductor materials and properties of some corresponding detectors available from Hamamatsu. Particular properties depend on the material modification, for instance the quantitative composition of HgCdTe.

Material	Peak wavelength (μm)	Responsivity at peak wavelength (A W^{-1})	Max. wavelength (μm)
PbSe	4.0–4.3	—	4.8–5.2
PbS	2.2	—	2.9
InSb	4.5–5.3	Typically 2.5	5.5–6.7
InAs	3.0–3.35	1.0–1.3	
HgCdTe (MCT)	3.6–17	Typically 3	4.3–22
Si	0.7–0.96	0.25–0.72	1.1
GaP/GaAsP	0.37–0.71	0.06–0.4	0.4–0.76

5.2.4.5 **Avalanche Photodiode**

If the voltage across a depletion zone of a photodiode is made sufficiently large, charge carriers generated by photon absorption will be accelerated so much that they gain enough energy to generate secondary electron–hole pairs which again are accelerated, and so on. By this so-called avalanche effect, every absorbed photon will induce a large number of charge carriers and an accordingly large current pulse. This internal gain mechanism is used in avalanche photodiodes (APDs), which can be operated in two main modes, the linear mode and the Geiger mode. In the linear mode, the APD is operated below the breakdown voltage. As described above, an initially generated electron–hole pair will be multiplied by a certain factor, leading to an increased total responsivity. Typical gain factors are 10–50 for germanium and InGaAs APDs and 100–1000 for silicon APDs. After the single initial electron–hole pair has been multiplied and contributed a certain current pulse to the total

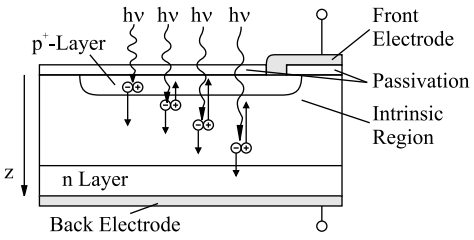


Figure 5.11 The PIN photodiode is similar to the standard photodiode, but it has a large intrinsic (undoped) region between the p and n layers. Since the intrinsic region has no free charge carriers, there is an electrical field, which can separate photocharge pairs, making the intrinsic region photosensitive. Particularly long-wavelength radiation, which is not well absorbed by silicon, can be detected better because of the greater thickness of the sensitive volume.

photocurrent, it will not lead to further generation of secondary charge carriers. The multiplication process itself is subject to two main noise contributions. The first contribution is a result of the statistical nature of the charge amplification and increases as the square of the shot noise level by a factor of 2. The second contribution is excess noise, which is related to the statistics of ionization by different charge carrier types. The square of this factor typically ranges between 3 and 10, depending of the APD type. The main advantage of an APD operated in the linear mode is that very low light levels can be detected at a high speed using relatively simple preamplifiers. Due to the shot noise amplification they are, however, not adequate for high-precision measurements of extremely low light levels.

The problem of shot noise amplification is partly overcome in the second operation mode, the Geiger mode. This mode is also frequently referred to as the "photon counting mode," since here single photon absorption events are detected and counted. In the Geiger mode, the APD is operated at a reverse voltage beyond the breakdown voltage, leading to a very high gain of 10^5–10^8. Normally, an APD operated above the breakdown voltage would be permanently conducting a large current even without incidence of light or generation of dark charge carriers. An additional external current limiter will, however, induce a statistical fluctuation of the current, which also includes a fluctuation to a zero current with a high probability. Once the current becomes zero, it requires a photoinduced or dark charge carrier to trigger a revival of the current. The average time until the current drops to zero is called the recovery time of the APD and if the photon rates and dark charge generation rates are significantly below the inverse of this time, the APD can be used to count photons directly, avoiding excess noise due to the amplification process. The new limiting factors are the dark charge generation rate (which, however, already contributed in the linear mode), the recovery time, an excess noise related to the probability of the incidence of two or more photons within the recovery time, and the phenomenon of afterpulsing, that is, the generation of further current pulses after the pulse due to an absorbed photon. Afterpulsing is mainly caused by temporary trapping and later release of individual charge carriers. For typical detectors, the recovery time varies between about 100 ns and 1 ms, essentially limiting the operating frequency to values between 1 kHz and about 10 MHz [7] and the acceptable photon rates to a fraction of these values, depending on the application. Faster recovery times down to less than 2 ns have been reported, however, for InGaAs APDs [8].

Summarizing, APDs can be used for measurements at high precision, high temporal resolution, or high speed, but they will not be as sensitive as a photodiode with a good preamplifier. Particularly when measurement speed or temporal resolution is not critical, cooled integrating photodiodes such as pinned photodiodes will yield a higher precision and at the same time allow for a relatively large photon flux.

5.2.4.6 **Metal–Semiconductor–Metal (MSM) Photodetectors**

Consisting of a semiconductor between two metal electrodes, the metal–semiconductor–metal (MSM) type of detector looks much like a photoconductor; however, there is a fundamental difference, namely a Schottky contact instead of an

ohmic contact between the metal electrodes and the semiconductor. The Schottky contacts of the MSM act like diodes and avoid injection of charge carriers from the metal into the semiconductor. The response time of the MSM is thus determined by the short average time that a charge carrier needs to reach an electrode and not by the much longer charge carrier recombination time, making the MSM detector very fast. The MSM detector is even faster than a PIN photodiode and reaches operating frequencies of hundreds of gigahertz [9, 10], but dark current values of current MSM detectors are 10–100 times larger than those of very sensitive PIN photodiodes [11, 12] and the quantum efficiency is limited due to the necessity for dense interdigital metal electrodes on the front side of the detector. MSM detectors are therefore mainly of interest for high-speed optical communication. As a further consequence of the diode nature of the metal–semiconductor contacts, there is no internal gain in an MSM detector.

5.2.4.7 **Phototransistor**

A phototransistor effectively is a normal transistor which is housed in a transparent material. The base–collector junction here acts as a photodiode but, due to the amplification of the transistor, the overall device has an internal gain. Phototransistors are a convenient means of achieving a high responsivity with a minimum of external electronics, which is advantageous for low-cost optical data transmission or devices such as light barriers. For measurement applications, however, the poor linearity of phototransistors is a disadvantageous feature.

5.2.4.8 **Remarks on the Sensitivity of Semiconducting Light Detectors With and Without Internal Gain Mechanisms**

Photoconductors, avalanche photodiodes, and phototransistors have significantly larger responsivities than photodiodes without internal gain mechanisms, that is, the current observed at their output is larger for the same incident intensity. This does not mean, however, that they are more sensitive to light. Whether or not a sensitivity gain or loss is achieved depends mainly on the quality of the readout electronics under comparison, the readout mode, and the working temperature of the photosensitive device. In general, the noise of an intensity measurement cannot be lower than the noise of the light. For classical light, this is at best the shot noise of the photons, which for practically all relevant light sources is given by a Poisson distribution with a variance equal to the number of detected photons. The best-case noise level of a measurement will therefore become equal to the square root of the number of detected photons:

$$\sigma_{\text{phot}} = \sqrt{N_{\text{phot}}}. \tag{5.5}$$

This fundamental noise level is raised further due to internal noise of the detector, readout noise, or noise induced by the gain mechanism. In more complex devices such as CCDs (discussed below), other noise contributions such as clock-induced noise or reset noise may arise.

5.2.5 Noise of Semiconducting Photodetectors

5.2.5.1 Dark Current Noise

Dark current noise, also referred to as dark current shot noise, is an intrinsic, signal-independent noise caused by the detector. Due to thermal activation, doping, material defects, or material interfaces, free charge carriers are present in a semiconducting light detector even if no light is irradiated on it. Since the generation of different electron–hole pairs is statistically independent, the probability of the generation of a certain number of dark charge pairs within a fixed period of time is given by a Poisson distribution with an average of μ and a variance, which is also μ. Whereas the average charge per unit time, the so-called "dark current," can be determined by careful calibration of the detector and then subtracted from the measured signals, the variance implies a noise, which cannot be removed from the measured signals. It is therefore important to minimize the dark current for sensitive measurements. Several optimizations contribute to this:

- **Cooling of the detector**: The dark current grows exponentially with the temperature. For silicon photodiodes, the dark current will increase by a factor of approximately 10 for every 20 K temperature increase (see Figure 5.12).
- **Minimizing the detector area to an optimal value**: The dark current of a detector with a given technology is directly proportional to its sensitive area. Small light spots should therefore preferably be measured by small detectors and large light spots by large detectors. Whether in the optimal case the detector should cover the whole spot or cut it at some point depends on the shape of the spot and the relative strength of other noise sources.

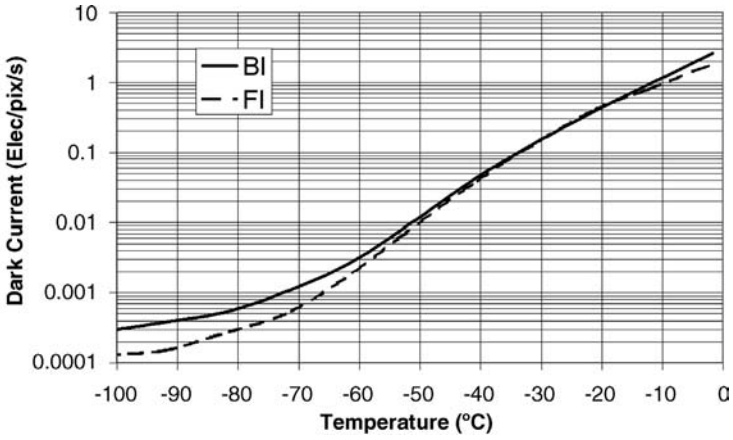

Figure 5.12 Temperature dependence of the dark current of a scientific CCD (Camera: Andor Newton DU940N using an e2v CCD42-10 detector chip with multi pinned phase operation; figure taken from datasheet; pixel size in each direction is 13.5 μm).

- **Using a detector technology with a low dark current**: Using photodiodes instead of photoconductors or thermal detectors, using devices with pinned photodiodes instead of standard photodiodes, and so on.

5.2.5.2 Nyquist–Johnson Noise

If the photodetector has certain electrical properties of a resistor – no matter whether it is a photoconductor, photodiode, or something else – it will show a fundamental thermal noise, the Nyquist–Johnson noise. If the parallel connection to the detector and the input impedance of the amplifier have a resistance R, it will produce a voltage noise with an expectation value of its variance of

$$\langle V^2 \rangle = 4k_B T \cdot R \cdot \Delta f. \tag{5.6}$$

In photodiodes, the resistance R corresponds to the sum of the series resistance and the so-called shunt resistance, the meaning of which is depicted in Figure 5.13.

Depending on the input impedance of the amplifier, this will translate into an according current noise of

$$\langle I^2 \rangle = \frac{4k_B T \cdot \Delta f}{R} \tag{5.7}$$

which adds to the measured signal. To minimize the Nyquist–Johnson current noise, the shunt resistance and amplifier input impedance should be high and the photodiode should be cooled.

5.2.5.3 Flicker Noise and 1/f Noise

$1/f$ noise, as its name implies, is a noise whose intensity is indirectly proportional to the frequency. $1/f$ noise does not originate from a particular single source, but is created in all places where physical processes reduce their intensity at higher "speeds" or show a certain kind of recurrence. In fact, however, it is not yet fully understood.

Flicker noise looks much like $1/f$ noise, but it can have a steeper frequency slope and may even have a peak at a low nonzero frequency. Flicker noise is connected to a current flow and originates, for instance, from generation and recombination of charge carriers, impurities in a conductor, or electrical contacts.

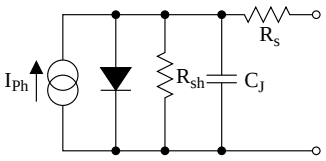

Figure 5.13 Equivalent circuit diagram of a real photodiode, consisting of an ideal current source, which produces a load-independent photocurrent I_{Ph}, an ideal diode, a shunt resistance R_{sh}, a junction capacitance C_J, and a series resistance R_S.

5.2.5.4 Excess Noise

The term "excess noise" covers several noise mechanisms in the detector, which increase the noise to be expected due to photon and dark current statistics. Flicker noise is one type of excess noise. Other excess noise is generated in most internal signal amplification mechanisms, which thus sometimes decrease the sensitivity.

5.2.5.5 Read Noise

The term "read noise" subsumes all noise contributions which are contributed by the readout process of the detector, particularly in amplification, charge-to-voltage conversion, or digitization. There are signal-independent and signal-dependent contributions and individual contributions may be specific for a particular readout technology. Therefore, only the most prominent read noise contributions will be briefly listed here.

- **Quantization noise**: If the signal is digitized, there will be an uncertainty of $\pm^1/_2$ least significant bit (LSB) of the A/D converter. Additionally, the quantization levels of the A/D converter are never exactly equally spaced, for lower quality A/D converters there may even be missing codes (i.e., some quantization levels will never be seen), or the dependence between input signal and code output may be non-monotonic. Quantization noise can be eliminated when the system is operated in a photoelectron counting mode, where every photocharge leads to a change of the A/D output by more than one LSB. This is only useful, however, in low light situations.
- **Amplifier shot noise**: Similarly to amplification mechanisms inside the detector, amplification of a signal in an amplifier is a statistical process and will create an excess noise which depends on the particular design of the amplifier electronics. Optimally, a photocharge signal will thus not be amplified itself, but instead amplification will be applied to a current or voltage signal, which is derived from the charge that is held statically in a capacitance. The relative amplifier shot noise will thus decrease with the inverse square root of the readout time and in this way can in principle be reduced to values below a single photocharge, if the readout time is made large enough.
- **Amplifier thermal noise**: As the readout amplifier is an electronic device, it will contribute some noise due to leak currents, which are equivalent to the dark current in the photodetectors. Furthermore, a Nyquist–Johnson noise will be created by the input impedance of the amplifier, particularly if this impedance is neither very high nor very low. Cooling the first amplifier stage or increasing the readout time helps to reduce these contributions.
- **Output capacitor reset noise**: Some advantageous detector designs require a charge-to-voltage conversion, which uses a small capacitance (i.e., one with a high conversion factor) as the converter. At the beginning of the readout process, the voltage of the output capacitor has to be reset to a reference level, which never succeeds exactly, so there is a so-called reset noise. This noise can be reduced by several approaches, which are discussed later in the sections on image detectors.

5.3
Image Detectors

5.3.1
Pixel-Based Image Detectors

Pixel-based image detectors consist of a plurality of light-sensitive detector elements such as those described above. Part of the existing image detectors, among them the most common types of image detectors, CCD and CMOS or active pixel sensor (APS) detectors, additionally contain some electronics to address the individual pixels and direct their signal to one or more electrical outputs. In this way, the signals can be serialized for further processing by a computer or other electronics. Other imaging devices with a low total number of pixels may not contain pixel selection electronics; instead, the signals of the pixels are directed individually to separate outputs and an external multiplexer will be needed to serialize them if needed. Besides their differences, all those devices can be characterized by some common properties, which will be discussed in the following.

5.3.1.1 Pixel Number, Pixel Pitch and Nyquist Frequency

The pixel number gives the number of individually addressable light-sensitive detector elements of an image detector. The most common pixel arrangement is the rectangular arrangement. In the most common case, detector elements are arranged in a Cartesian grid with a certain number N_y of identical and equidistantly spaced pixel rows, each containing N_x equidistantly spaced, identical detector elements or pixels. Thus a rectangular array with $N_x \times N_y$ pixels will be formed. For the special case of $N_y = 1$, the image detector is called a linear array, otherwise a two-dimensional array. Array sizes vary from 2×1 to thousands by thousands. For example, the high-resolution photographic-purpose CCD chip CCD595 from Fairchild Imaging has a pixel number of 9216×9216, giving a total of about 85 megapixels.

The pixel pitches along the x- and y-directions are often equal and normally driven by considerations of sensitivity, application constraints, technology constraints, or cost optimization. For UV–VIS image detectors, current pixel pitches range from 1.5 μm for low-cost CMOS image detectors to about 26 μm for very sensitive scientific CCDs. IR image detectors can have even larger pixel pitches of up to several hundred micrometers, depending on their application area, but typically they are also in the range up to 25 μm for semiconducting 2D IR detectors.

In addition to the rectangular arrangement, there are a number of special arrangements, for instance with different types of detector elements, pixel rows which are tilted by 45° with respect to the image rectangle (Fuji Super CCD), or pixels which are arranged in a hexagonal grid instead of a Cartesian grid. Special care has to be taken when the performance of such devices is compared with those of the usual rectangular pixel arrangements.

An array with a pixel pitch Δx along a certain direction can resolve a sine-shaped periodic spatial intensity variation which has maximally one local maximum and one

local minimum over a distance of $2\Delta x$, that is, a period which is less than $2\Delta x$ or a spatial frequency which is lower than $1/(2\Delta x)$. Any signal with a shorter period will lead to aliasing and look like a periodic signal of another, lower frequency inside the allowable range. Non-sinusoidal signals can be decomposed into a series of sinusoidal signals (Fourier transform). To reproduce such signals correctly, the maximal non-vanishing spatial frequency must be lower than the so-called Nyquist frequency $1/(2\Delta x)$. This is known as the Nyquist–Shannon sampling theorem or, in brief, sampling theorem. A signal which complies with the given condition is called Nyquist sampled or Nyquist–Shannon sampled by a detector with pitch Δx.

5.3.1.2 Pixel Geometry and Spatial Pixel Response

In every regular pixel arrangement, a pixel can be assigned a unit cell, which in the rectangular arrangement can be chosen as a rectangle with side lengths equal to the pixel pitches in the x- and y-directions. Ideally for most applications, the pixel would be 100% sensitive to light which is absorbed inside the unit cell and would not respond to light absorbed outside. This ideal situation cannot be accomplished in reality, however. On the one hand, large parts of the unit cell may not be light sensitive due to shading from conduction structures or since they contain some per-pixel electronics; on the other hand, light absorbed in the unit cell of one pixel may also contribute to the signal of the neighboring pixels, making it impossible to predict safely which pixel will collect a photoelectron generated at a certain position of the image detector. The latter is typically a result of the finite absorption depth and of photocharge drift effects in the detector material.

Both effects can be jointly described either in the form of a spatial pixel response or of a so-called modulation transfer function (MTF). For a more precise treatment, the angular distribution of the incident light and the wavelength would also have to be considered.

The MTF is the Fourier transform of the spatial pixel response. It directly describes how the modulation depth of a fully modulated sine-shaped intensity distribution with a certain period is reduced due to the spatial pixel response. An MTF value of $+1$ means that after the detection the modulation depth still is maximal, and a value of zero means that only the average intensity of the incident sine wave is seen by the detector and that the details on the modulation are completely lost. At negative values of the MTF, the sine wave is registered inversely, that is, dark parts are seen as bright parts and vice versa. Figure 5.14 shows real pixel responses of an IR detector and Figure 5.15 gives some typical idealized spatial pixel responses and their corresponding MTFs.

As discussed above, the Nyquist frequency of the image detector lies at a spatial frequency of a half inverse pixel pitch. MTF values below this frequency should be large to achieve a high sensitivity and resolution. Whether MTF values for higher frequencies should be large or small depends strongly on the systems in which the image detector is used, since larger spatial frequencies of the incident light will be folded into the Nyquist range due to the Moiré effect. This Moiré effect is used in subpixel detection systems such as double-array spectrometer [14] or scanning multichannel spectroscopy arrangements [15]. In normal imaging systems, where each

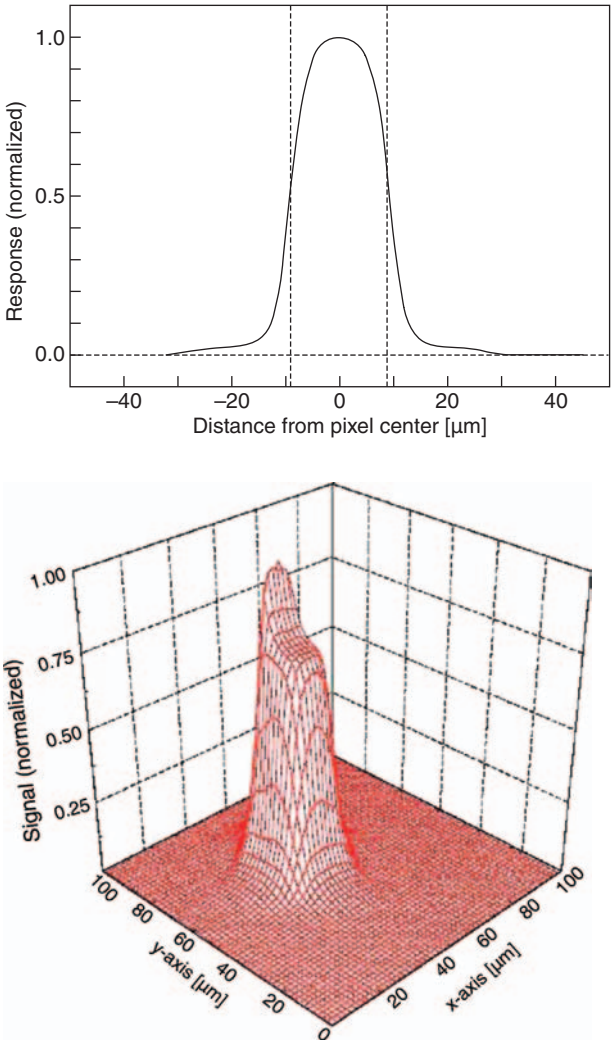

Figure 5.14 One- and two-dimensional pixel response of an MCT image sensor (Teledyne H2RG #40) at a wavelength of 1300 nm as determined experimentally by Barron *et al.* [13].

image is treated individually, Moiré effects will be very annoying. Good imaging systems therefore either contain a spatial low-pass filter in front of the detector or they are dimensioned such that the Abbé cutoff frequency of the optics lies near or below the Nyquist frequency of the detector.

5.3.1.3 Image Acquisition Timing

The acquisition of an image by an image detector consists of two main parts, image exposure and image readout. Image exposure is the exposure of the image detector to

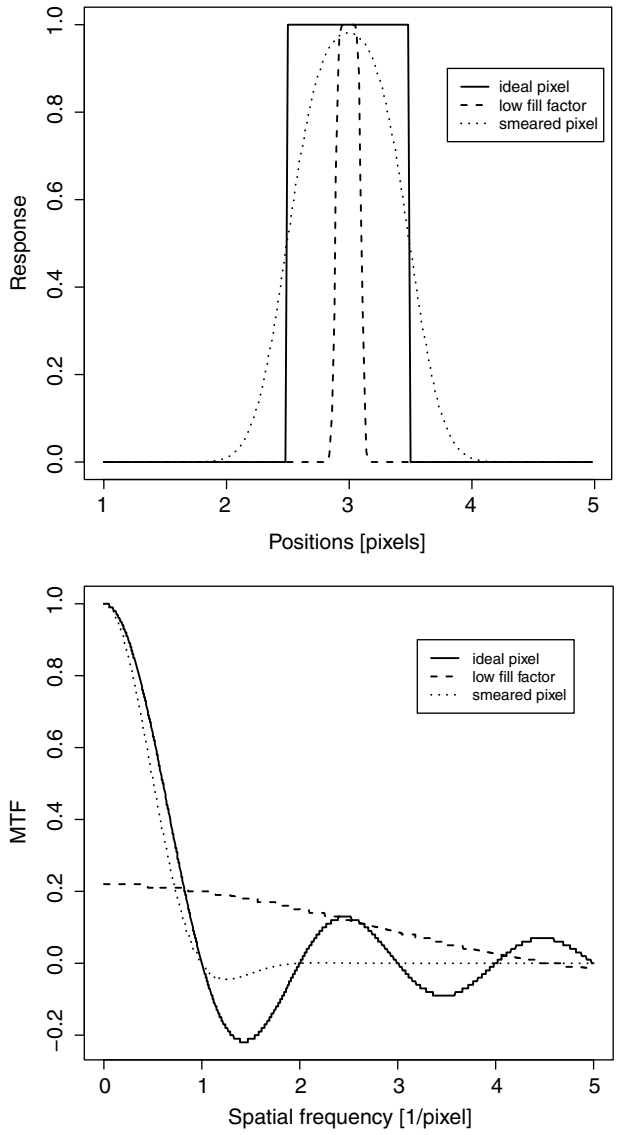

Figure 5.15 Different spatial pixel responses and their corresponding modulation transfer functions; Shown are an ideal pixel with rectangular response and a fill factor of one, a slightly smeared pixel with a low fill factor, such as could be found in a CMOS APS detector, and a smeared pixel with 100% fill factor, as can be observed at back-illuminated CCDs. The Nyquist frequency of the MTF lies at 0.5 per pixel. All given spatial pixel responses lead to MTFs which are non-zero beyond this point, meaning that aliasing could occur.

light, allowing the detector elements to change their state depending on the incident radiation. Two fundamental types of behavior of the detector elements can be distinguished.

The first is characterized by the change in a physical parameter towards an equilibrium value which depends on the incident radiation. The most important example of such a system is an array of thermal detectors, which change their temperature as a reaction to the incident radiation. If the radiation intensity changes from one value to another, the temperature follows with a certain time constant. Consider an image acquisition consisting of an exposure followed by a single temperature readout for each pixel. Exposing the detector to the radiation much longer than the time constant of the detector elements will not yield any significant signal-to-noise gain compared with an exposure which is about 2–3 times the time constant. Not taking into account any errors made in the readout process, the precision of the intensity measurement will depend on the time constant rather than the exposure time. For exposures much shorter than the detector time constant, this will change to the opposite. This type of behavior is not limited to thermal detectors, however, but would also apply to semiconductor detectors, which average incident radiation only by means of a low pass and are read out at a discrete point in time for each measurement. This type of detector will here be referred to as an averaging detector.

The second type of behavior, the accumulating behavior, can be observed in semiconductor detectors with a per-pixel integration capacitance. Here every photon which is absorbed and converted into a photocharge pair will immediately lead to a change of the stored photocharge of the capacitor by one electron. Unless no saturation of the capacitor occurs, the capacitor voltage thus changes practically instantaneously and proportionally to the absorbed energy. In contrast, for the above-described detector behavior, it would have changed proportionally to the incident intensity, showing a delay due to the time constant. For a detector of the accumulating type, the observed signal will on average be directly proportional to the integration time.

Therefore, provided that no saturation occurs, a higher precision of the measured intensity value can be achieved by increasing the exposure time. Figure 5.16 shows an example series of photon incidences and corresponding changes of the temperature signal of an averaging thermal detector and of the accumulated charge of an accumulating detector. Both detectors are modeled as ideal detectors; nonetheless, the thermal detector shows a much worse output signal than the accumulating detector. To circumvent the problems of an averaging detector, its time constant can be made small and a signal accumulation circuit can be connected to its output, so that the overall system behaves approximately like an accumulating detector.

Before the exposure in an accumulating detector starts, the accumulation capacitor of the detector element or a separate accumulation circuit have to be reset. Depending on the technology, the pixels can have some reset gate, which generates a short cut of the capacitors, loads it to a reference voltage, or extracts the charges. Particularly for CCD pixels, the photocharges have to be shifted out of the pixels. In case of a reset, the remaining photocharge in the capacitors will not be exactly zero or at a reference value, but some additional, random charge will remain, which is known as reset

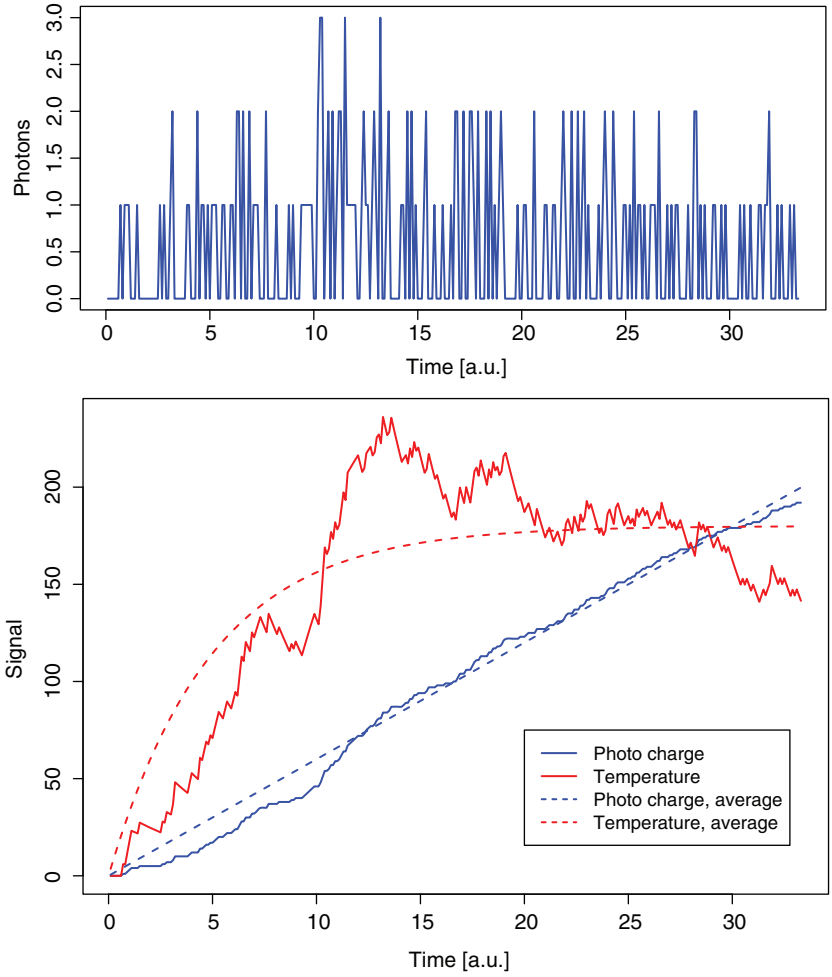

Figure 5.16 Example of statistical incidence of photons and corresponding observed temperature and photocharge of a thermal and a semiconducting (accumulation-type) detector. It can easily be seen that the statistical nature of the light leads to large uncertainties of the measured temperature value and the derived average intensity value, while the accumulated photocharge increases relatively linearly with time and gives a good measure of the average intensity.

noise. For detectors with a possibility of a nondestructive pixel charge readout, such as many CMOS active pixel sensor detectors, the residual charge could be measured right after the reset and before starting the exposure, so it could be subtracted after finishing the measurement. This timing regime is known as double sampling or correlated double sampling and is the simplest timing where the charge readout is not only done after finishing the exposure. More advanced timing regimes for high-sensitivity applications are Fowler sampling, where multiple charge measurements

are performed in the first and in the last third of the exposure time, and sampling-up-the-ramp, where charge measurements are performed continuously during the exposure. After such a measurement, the incident intensity can be determined by fitting a linear function to the series of obtained charge values. Figure 5.17 gives an overview of these readout schemes.

In contrast to image detectors with a nondestructive readout capability, CCD detectors will only be read out after exposure. Since in a CCD detector photocharges are shifted laterally through the chip for readout, there are still several timing parameters that influence the sensitivity and noise of the image acquisition. Also, the summation of pixel charges, the so-called binning, is accomplished by special timing schemes. These timing schemes will be discussed in more detail in the section on CCD operation modes.

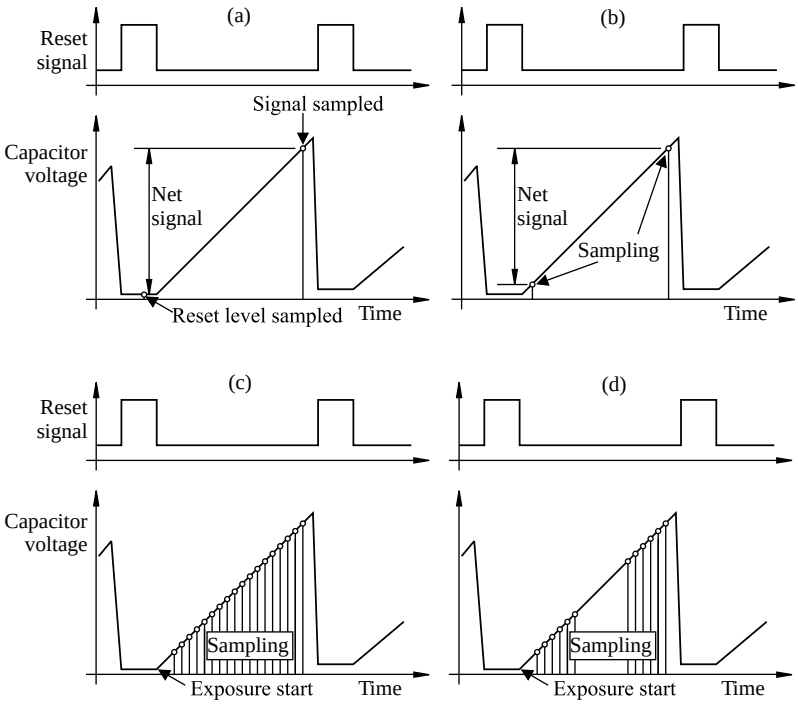

Figure 5.17 Fundamental sampling regimes during exposure of a CMOS detector pixel with non-destructive readout capability. (a) Double sampling or correlated double sampling, recording the reset voltage level and the signal level after integration; in a device with correlated double sampling, the differencing between the two levels is done in the analog hardware path. (b) A double sampling scheme could also be sampling two extreme points during integration, which are separated by a specified time. However, this is not commonly done. (c) Sampling-up-the-ramp, determining the slope of the capacitor voltage by continuous sampling during the integration period. (d) Fowler sampling, determining the voltage slope by sampling during the first and the last third of the integration time.

After all, the user of an image detector will usually be confronted with two main timing parameters, the exposure time and the readout time. The latter can be measured in seconds per pixel and is the time that the output amplifier and A/D converter are given to acquire the signal of a single pixel.

5.3.2 Charge-Coupled Devices (CCDs)

The invention of the CCD image detector was a by-product of the development of an analog shift register for data storage applications. This shift register was initially intended to replace the magnetic memory which was used at that time.

CCDs are almost always silicon-based image detectors. In the UV–VIS spectral region they belong to the most sensitive available detectors and can even be applied for single photon detection. However, the potential of a high sensitivity is not tapped in all CCD types and implementations. Instead, available CCD chips differ significantly in their properties not only between cheap consumer CCDs and high-performance scientific CCDs, but also within these groups. There is no such thing as the best CCD, which is superior in all applications. To select the appropriate CCD for a given application thus requires a basic knowledge about different CCD types and their characteristics and limits. It is the aim of this section to give a coarse overview of the most relevant topics without going too much into the details.

5.3.2.1 General Principle of CCD Operation

CCD image sensors are arrays of photodiodes with an internal capacitance for accumulating photocharges and a capability to shift these charges through the array. Figure 5.18 shows the schematic layout of a simple CCD pixel of a so-called three-phase CCD along with its potential diagram. On a heavily doped substrate an epitaxial layer with a relatively low doping, that is, a high resistivity is grown. The top of this layer is oxidized to create an insulator. Gate electrodes on top of the oxide layer can create a potential well in the epitaxial layer (the substrate is drawn to ground), where charges can accumulate. In the figure, such a potential well is formed below the electrode set to positive voltage, whereas below the electrodes under negative voltage no potential well is created. Accumulated charge carriers will therefore collect below the positive electrode and cannot escape laterally. By repeating the arrangement of positively and negatively loaded electrodes, a lateral pixel structure can be created. The system consisting of top electrode, oxide, and silicon here forms a so-called metal–oxide–semiconductor (MOS) capacitor and the system of differently doped silicon layers acts like a photodiode, including a depletion zone. The electrodes are made of an optically transparent material, so light can enter the silicon and create electron–hole pairs. If this happens inside the depletion region, the charge pairs are separated, so that one species of charge carriers is always drained into the substrate and the other accumulates below the oxide. This simple type of CCD is called a surface channel CCD.

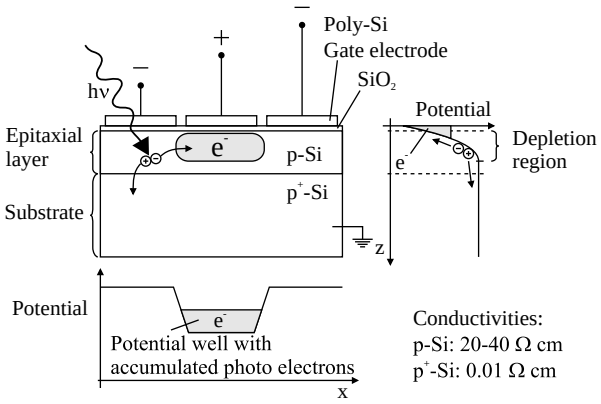

Figure 5.18 General layout of a single pixel of a three-phase CCD (surface channel, i.e., no buried channel) and situation during exposure. Photons absorbed in the approximately 5–10 μm thick depletion region of the CCD will be captured with nearly 100% efficiency in the potential well generated due to the applied voltage, while photoelectrons generated in the bulk of the substrate will undergo a random walk and either recombine with holes or eventually move into the depletion region where they will be captured.

So far, we have only considered a linear structure. Figure 5.19 shows the corresponding two-dimensional arrangement. Whereas in one direction (here tagged the "transfer direction") the described electrode structure leads to a pixelation, in the orthogonal direction different rows of pixels have to be separated by a so-called channel stop. This is a lateral interruption of the lightly doped regions of the epitaxial layer by heavily doped stripes. These stripes have a doping similar to the substrate and are therefore at the same voltage potential, which leads to a fixed lateral confinement of the potential wells along the direction perpendicular to the transfer direction. To

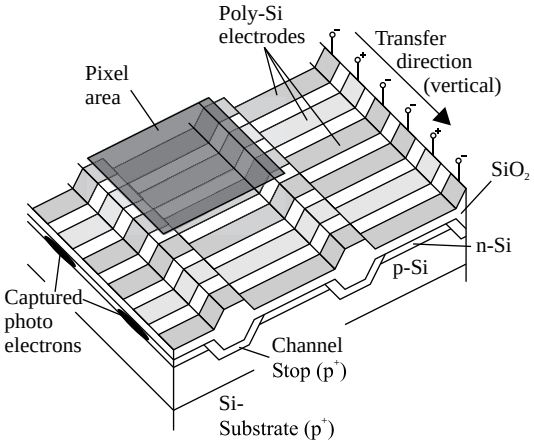

Figure 5.19 Simplified layout of a three-phase front-illuminated p-type buried-channel CCD.

avoid a high electrical capacity between the electrodes and the substrate, the thickness of the gate oxide is increased in the channel stop regions. A pixel of the CCD area now extends over the range between two channel stops and one group of electrodes, that is, three electrodes in the case of a three-phase CCD.

5.3.2.2 Full Well Capacity and Blooming

As described before, the photocharges are collected by a potential well. The depth of the potential well, however, is itself dependent on the number of collected charges. At some point, the well will vanish and additional photocharges can no longer be captured by the well and will spill out laterally. The limit of the number of charges is called the full well capacity and the lateral spill is called blooming. For a given layer structure of a CCD, the full well capacity of a pixel is proportional to its area, that is, larger pixels will commonly provide a larger full well capacity. Typical values are between 15 000 electrons for small pixel consumer CCDs and around 500 000 electrons for scientific CCDs with 26 μm pixel pitch.

The full well capacity limits the dynamic range of a CCD, which effectively is given by the ratio between the full well capacity and the noise level. Cooled scientific CCDs with a pixel size of 26 μm and readout noise of three electrons achieve typical dynamic ranges of larger than 150 000:1 or ∼100 db, while consumer CCDs have typical dynamic ranges of 3000:1 to 5000:1.

Excess charges leaking from a filled potential well will migrate to neighboring pixels, where they will be captured, until these pixels also achieve their full well charge. One intensively illuminated pixel or even a so-called hot pixel, that is, a pixel with a significantly increased dark current, can thus flood a whole number of pixels in its vicinity, mostly along the transfer direction. There exist certain improved types of CCDs which remove excess charges through a so-called anti-blooming (AB) gate. The principle of the AB gate is shown in Figure 5.20. An additional gate electrode, which is placed next to the pixels and parallel to the channel stop, lowers the potential below it so much that excess charges will not flow to other pixels, but through the gate. Behind the gate the charges are extracted through a drain electrode. One drawback of the

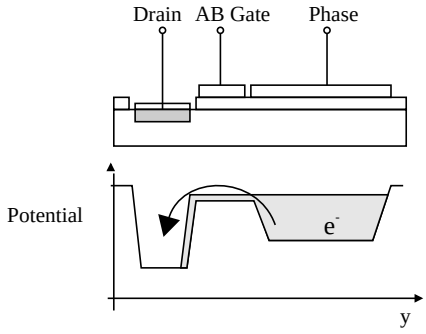

Figure 5.20 Principle of the AB gate. A gate electrode which is located next to a pixel slightly reduces the potential height, so that excess charges will flow through it. After passing the AB gate, the electrons arrive at a drain electrode, through which they can be removed from the chip.

anti-blooming gate is a reduction of the fill factor of the CCD, so for low-light applications it is often better to omit it, whereas for applications with high intensities it may be essential to achieve acceptable results. Additionally, the use of an AB gate considerably reduces the full well capacity of the pixels. Since a lower full well capacity means a lower dynamic range of the CCD, and a high dynamic range is particularly important for high-intensity applications, the latter will suffer from anti-blooming when the pixel size becomes too small.

5.3.2.3 Charge Transfer and Electronic Shutter Capabilities

In a CCD, the photocharges accumulated through the exposure time are not read out directly in the place where the exposure occurred. Instead, they are shifted out of the detector area to one or more sites where they are measured. The basic readout process for the example of a three-phase CCD is shown in Figure 5.21. By setting the gate electrodes of the CCD to different voltage levels, the lateral position and width of the potential well can be altered. The photocharges will always follow the well and can thus be shifted through the detector towards a detector edge.

In addition to the three-phase operation, there are also other operation schemes, using from one to four phases and partly involving a laterally varying doping to create the potential well and define a shifting direction for the photocharges. The laterally varying doping is at least necessary for all CCD types with less than three phases; however, these schemes will not be discussed here. To read out a two-dimensional image, in the simplest case the whole image is first shifted along the transfer direction of the light-sensitive area – which is often referred to as the vertical direction – by one pixel, so that the lowest pixel row is shifted out of the light-sensitive area and transferred into a one-dimensional CCD structure, whose transfer direction is

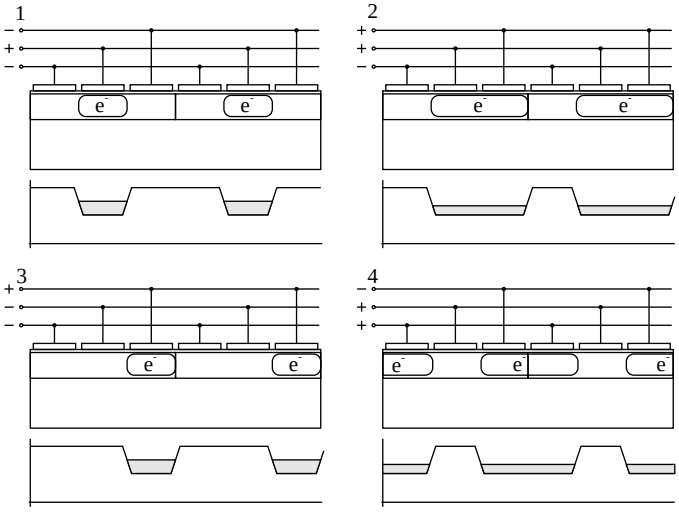

Figure 5.21 Principle of charge transfer at readout time for a three-phase CCD. Shown are the first four of the six steps necessary to shift the charges by the distance of one pixel pitch.

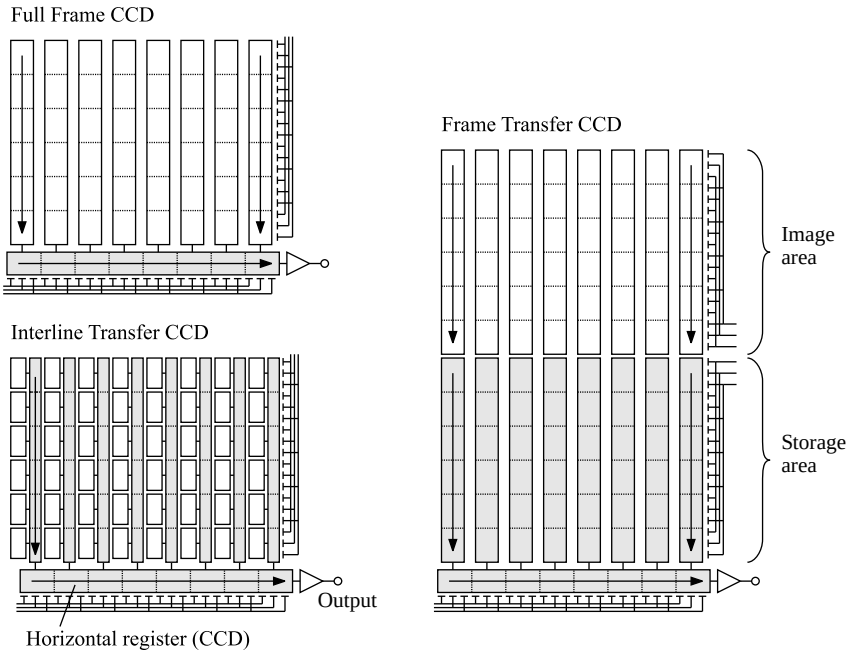

Figure 5.22 Basic CCD image transfer modes.

perpendicular to that of the light-sensitive area and which is shielded from light. This CCD structure is called the readout register or the horizontal shift register. Once an image row has been transferred into this register, the charges can be shifted towards an output node at the end of the shift register, where they can be measured and subsequently discarded. When the shift register is emptied, the next image row can be transferred into it by a vertical shift of the image. The CCD type implementing this fundamental readout scheme is called the "full frame CCD" (see Figure 5.22).

One problem with the full frame CCD is that the light-sensitive area of the image remains light sensitive also during readout. If light continues to fall on to the CCD, accumulation will continue, but since the image is progressively shifted through the CCD, the light will contribute to pixels at the wrong vertical coordinate, leading to a vertical smear effect. One possibility to avoid this is the use of a mechanical shutter or a pulsed light source, but often both possibilities are problematic for reasons that will not be discussed here. Hence certain CCD schemes have been developed to achieve an electronic shuttering capability. For high-quality applications the so-called frame transfer CCD is frequently used. In a frame transfer CCD, the light sensitive "image area" is complemented by an equally large shielded "storage area." After an exposure has finished, the whole image can be shifted rapidly from the image area into the storage area. Then the readout is started from the storage area, as was done from the light-sensitive area of a full frame CCD. By separating the vertical shift electrodes of storage and image areas, the next exposure can be started immediately after the image has been shifted into the storage area and continue during readout. The fast transfer

of the image from the image to the storage area still leads to a certain smear, which is very small, however, compared with the image intensity and can usually be ignored, particularly for long integration times. Otherwise it is at least very well correctable by computational methods because of its low amplitude.

A third scheme, which is in widespread use in consumer devices, is interline transfer. Here, the light-sensitive pixels are not directly connected to the vertical transfer electrodes but are linked to a shielded vertical CCD readout structure by a transfer gate (also a MOS capacitor). For every column of pixels, there exists an adjacent vertical readout register, so that the fill factor of the light-sensitive area is significantly below 100%. After an exposure, the transfer gates are opened, so that the photocharges are transferred into the shielded vertical readout registers. From there they can be read out similarly to the full frame CCD or the frame transfer CCD. Also, the next exposure can start immediately after the transfer, which takes only one or a few clock periods. In addition to the lower fill factor, another drawback of the interline transfer CCD is a limited electronic separation between light-sensitive pixels and the vertical registers, so that through exposure photocharges can be captured directly in the vertical registers, leading to a vertical smear effect.

For frame transfer CCDs and interline transfer CCDs, additional variants exist that permit interlaced readout, that is, for first reading all odd and then all even rows of an image. Interlaced readout modes were introduced for older television standards and are not of interest for scientific applications and of only secondary interest for the recently introduced high-definition video formats, so they will not be discussed here.

For high data or frame rate applications, the number of readout nodes of a CCD can be increased, for instance by subdividing the light-sensitive area into an upper and a lower part, which are shifted to the upper and lower edge, respectively, for readout. Additionally, the readout register can be separated into two parts, one leading to an output node at the left and the other leading to an output node at the right side. If all this is not enough, the shift register can be separated into shorter pieces, each with its own output node, and in extreme cases, such as CCDs for adaptive optics control, every pixel column can have its own output node [16].

5.3.2.4 **Charge Readout**

To read out the charge from the CCD, a so-called floating diffusion (FD) site is used. This is a direct electrical contact (i.e., the oxide is removed) which acts like a capacitor and thus generates a charge-proportional voltage, which can be measured by an external high-impedance amplifier. The term floating diffusion was coined, since this voltage "floats" depending on the charge. Figure 5.23 shows the basic arrangement of the overall output node.

The FD capacitance is placed directly at the end of the horizontal shift register. Charges from this register can therefore be shifted directly into the FD. Immediately after the FD, a single MOS transistor, the reset gate (RG), follows. This gate links the FD to a second direct electrical contact, the reset drain (RD), which is held at a low potential and will thus drain any charge which flows in through the RG. The capacitance of the floating diffusion capacitor is made small to achieve a large conversion coefficient, that is, voltage per unit charge. This small capacitance,

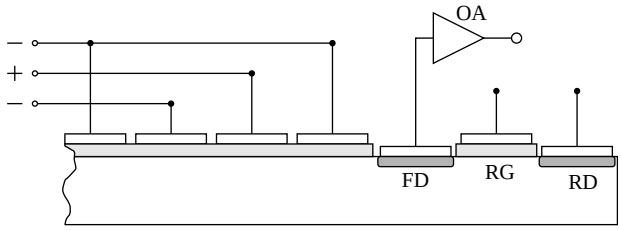

Figure 5.23 Typical output node at the end of a horizontal shift register; Charges are shifted by the shift register into the floating diffusion (FD) output capacitance, which acts as a charge-to-voltage converter, so the charge can be measured by an output amplifier (OA). To remove the charges from the FD, a reset gate (RG) can be opened, transferring the charges to the reset drain (RD), from where they can be extracted from the chip.

however, causes certain noise in the reset process, that is, the draining of the charges through the RG and RD. To remove this noise from the final measurement result, the already mentioned correlated double sampling is used, that is, the charge inside the FD is measured a first time immediately after the reset and a second time after the pixel charge has been shifted into the FD. Subsequently, the difference value is taken, preferably by a hardware-based analog differencing unit. After draining the charge to the RD, the next measurement cycle can be started. As described in the next section, it is also possible to shift the charges of multiple pixels into the FD, holding the reset gate closed.

5.3.2.5 **Binning and Windowing**

By employing the charge shifting capabilities of a CCD in the right way and using some additional structure for erasing charges, so-called dump gates, CCDs can easily be timed in such a way that sub-frames of the full image can be detected and that the charges of adjacent pixels can be combined into a sum charge, which is only read out once and thus is disturbed only once by the readout noise of the readout circuit. Reading out sub-frames is called windowing. Along the vertical direction, a subset of the image rows can be selected for readout by discarding unwanted rows, once they have arrived in the horizontal readout register instead of shifting them to the output node and measuring the charges. The skipping is achieved by opening a reset gate (a MOS transistor) below the shift register, which connects to a dump gate, that is, a direct electrical connection (the oxide layer here is removed), from where charges can be drained out of the chip. Immediately after the content of the register has been discarded, the next image row can be shifted into it. In the horizontal direction the selection of certain image columns is achieved by skipping over unwanted pixels. Similarly to the vertical skipping, they are simply quickly transferred to a reset drain or dump gate by means of a reset gate. The vertical reset gate can be omitted, however, then unwanted image lines would have to be discarded by shifting them to the horizontal reset drain, which would take significantly more time.

Binning, that is, the co-addition of charges inside the CCD, uses the same mechanisms of skipping over certain lines and pixels during readout, but does not

use the vertical reset gate and applies a different timing on the horizontal reset gate. Consider that again an image line which arrived in the readout register is not transferred to the output node, but instead the next image line is shifted into the horizontal register. In contrast to the previously discussed dumping of the charges from the previous line by means of the vertical reset gate, this time the charges of the previous line will still be present in the horizontal register. Then the charges of the second line are added to those charges already present, effectively leading to an addition of the two adjacent image rows. This process can be carried on until the full well capacity of the horizontal register is achieved. Similarly, pixels lying in the horizontal shift register can be co-added along the horizontal direction by skipping over individual pixels without dumping their charge to the reset drain through the reset gate. The charges will be accumulated in the floating diffusion gate and can be measured together after the accumulation. With a CCD it is therefore possible to bin (i.e., co-add) an arbitrary number of adjacent horizontal image lines in a free, arbitrary pattern and discard other lines. This is supported by most scientific CCD controllers. Within each image line or group of binned lines, adjacent pixels could be binned along the horizontal direction and others could be discarded in an arbitrary pattern, which could differ between different line groups. Although easily implementable, such operations are only supported by a few scientific controllers. The whole set of controllers only allows a fixed, regular binning and windowing of only one sub-window along the horizontal direction but several identical windows along the vertical direction.

5.3.2.6 **Charge-Transfer Efficiency (CTE) and Buried Channel CCD**

When an image is read out from the CCD, it has to be shifted through a large number of MOS capacitors; for a pixel located diametrical to the output node, a total of $N_x \pm N_y$ individual shift steps has to be performed. It is very undesirable to lose a significant fraction of photocharges through the whole shifting procedure or to smear the charges over multiple pixels. This makes it essential to have a very high charge-transfer efficiency (CTE) between subsequent MOS capacitors. Consider, for instance, a 1000×1000 pixel CCD. If the CTE in one shift step is as high as 99.99%, that is, one electron per 10 000 would be lost, the overall transfer efficiency for a charge packet undergoing 2000 transfers would still only be a poor value of 81.9%. To achieve an overall efficiency of, say 99%, the CTE here would have to be at least 99.9995%. For larger CCDs the situation is even more demanding; thus for the largest current CCD with 9216×9216 pixels, the same figure of 99% total efficiency would require a CTE of 99.99995%. Unfortunately, at the semiconductor–oxide interface, there is a large number of charge traps, which extract or temporarily capture charges during readout. It is therefore not possible to achieve a sufficiently high CTE for moderately sized to large CCDs with certain quality requirements using a surface-channel CCD.

The issue of surface traps is overcome by adding an additional layer to the CCD, generating a buried channel. This layer is doped inversely to the doping of the substrate and deforms the potential well in such a way that the charge collection will occur at some distance from the surface, as shown in Figure 5.24.

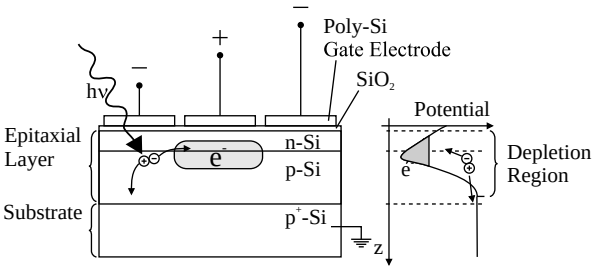

Figure 5.24 To reduce the influence of surface charge traps, increase the charge transfer efficiency, and suppress surface dark current, an additional n-doped layer (p-doped layer for n-type substrates) is employed. This layer deforms the charge collection potential and separates the photocharges from the surface, provided that the gate voltages are in a proper range. This type of CCD is called a "buried channel CCD."

5.3.2.7 **Multi-Pinned Phase (MPP)**

Multi-pinned phase (MPP) operation of a buried channel CCD is an essential step in suppressing the surface dark current, which is usually the largest noise source inside the detector array. In the MPP mode, all gate electrodes are held or clocked in the so-called "inverted state" during integration, that is, the applied gate voltage is driven so much into the negative range (for a CCD based on a p-type substrate) that holes from the channel stop region migrate to the Si–SiO_2 interface and thus populate the n channel. In the inverted state the accumulated holes shield the potential from the gate voltage; thus lowering the gate voltages below the level, where inversion occurs, will no longer alter the potential. This behavior is called pinning and the potential is said to be in a pinned state. In the pinned state the dark current is reduced by approximately three orders of magnitude (Figure 5.26).

If a normal CCD would be set into the fully inverted state, there would be no lateral potential wells and confining potential barriers along the translation direction of the CCD, which could define a pixel. To allow charge accumulation in the fully inverted state, an additional doping below part of the electrodes is introduced into the manufacturing process. This doping leads to a different potential than in neighboring undoped regions, as shown in Figure 5.25. Here a p-type doping is added below

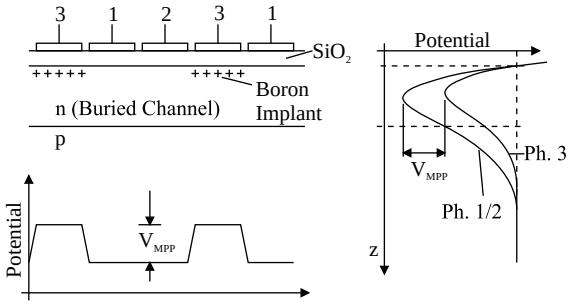

Figure 5.25 Layout and potential diagrams of a three-phase MPP CCD.

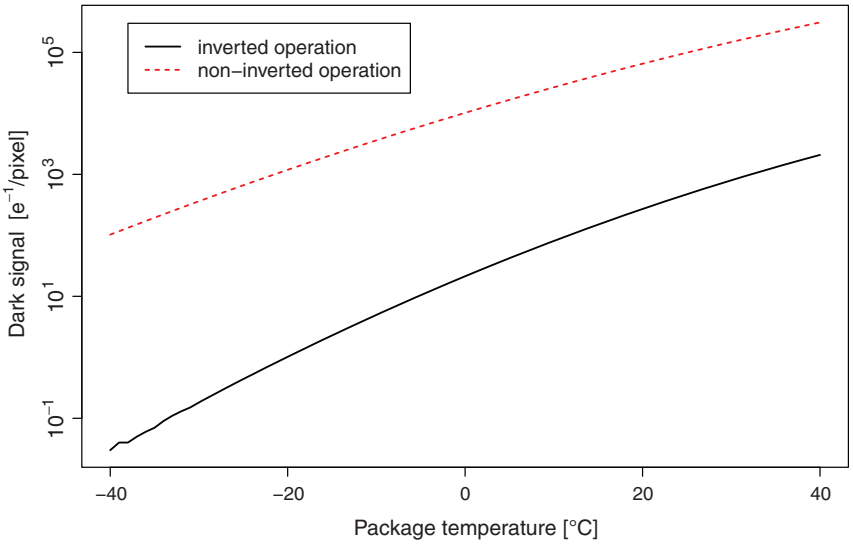

Figure 5.26 Comparison of temperature-dependent dark current for two versions of the same CCD detector. The lower, solid line shows the dark current for the front-illuminated e2v sensor chip CCD30-11 with "advanced inversion mode," a type of MPP; the higher, dashed line shows a front-illuminated CCD30-11 with deep depletion and noninverted operation. The dark current of the latter is roughly 1000 times larger, which is mainly attributed to the noninverted operation.

the electrodes of phase 3, leading to a relative potential barrier of height V_{MPP} below these electrodes in the fully inverted state. Photocharges will therefore accumulate below the electrodes of phases 1 and 2.

The fully inverted state is only left for vertically shifting the image, that is, for the short periods of time between the readout of two adjacent horizontal image lines through the horizontal CCD register. The horizontal register itself is not operated in MPP mode and has no corresponding doping structures, since this would not make any sense and instead lead to spurious charge generation, which is an unwanted noise contribution.

5.3.2.8 Back Side Thinning and Back Illumination

Although the gate electrodes of the CCD are made of a transparent material such as polysilicon, they reduce the quantum efficiency of the CCD by blocking part of the light. Below a wavelength of about 400 nm they even block all the incident radiation. A fundamental solution to this problem is provided by a back-thinned, back-illuminated CCD. In such a CCD, the material, at least in the image area, is etched down from the back side to thicknesses of 10–15 μm, approximately to the interface between the epitaxial layer and p^+-doped substrate. The interface here is used as an etch-stop for a selective etching agent. In early back-thinned CCDs, etching was carried out in such a way that a free-standing silicon membrane inside a thick silicon frame resulted. The mechanical properties and the homogeneity of such a system are

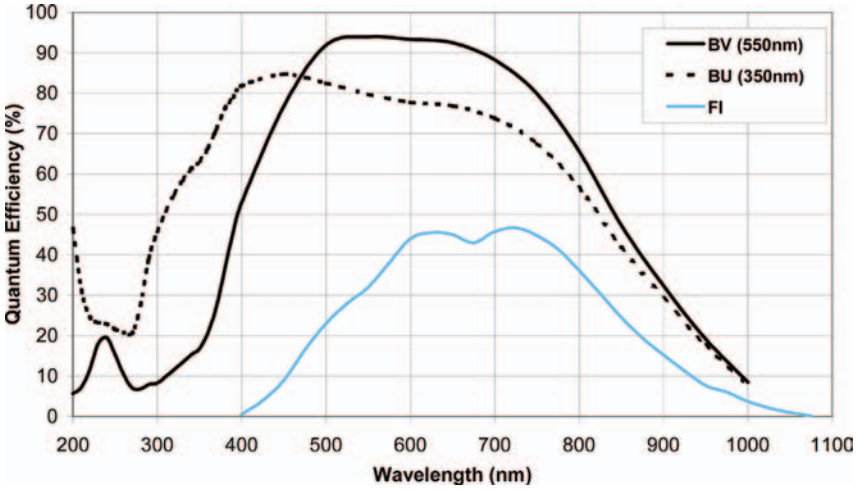

Figure 5.27 Comparison of quantum efficiencies of front- (FI) and back-illuminated (BU/BV) CCDs with the example of an e2v CCD42-10 for two different VIS anti-reflective coatings of the back-illuminated types and at a temperature of −90 °C (diagram from Andor DU-440 datasheet).

not very desirable, however. In newer back-thinned CCDs, the front side of the chip is bonded to a second silicon substrate before thinning and effectively, after the thinning, a thick and stable CCD chip with buried electrode structures results. The entry of light into the sensitive region is now only impaired by the Fresnel reflections at the surface and a usually extremely thin layer with reduced efficiency. The latter results from charge traps at the back side and a finite probability that photoelectrons will thermally diffuse to these traps against the global electrical field direction. The Fresnel reflections can be reduced further by an anti-reflective coating. Figure 5.27 shows a comparison of two typical quantum efficiency curves achieved by a front-illuminated and a back-illuminated high-performance scientific CCD. The back-side operation not only permits detection in the UV range, but also increases the quantum efficiency in the VIS and NIR range. For high-sensitivity applications, back-illuminated CCDs have therefore become a standard.

In addition to many critical issues involved in the manufacturing of good back-illuminated CCDs, however, there are some properties of these devices that limit their applicability in some cases. One of these properties is a reduced short-wavelength MTF performance. Short-wavelength photons are absorbed near to the back side. The generated photocharges have to move almost through the whole thickness of the thinned chip, until they can be captured by the potential well at the front-side buried channel, which also constrains their lateral position. Before this capture occurs, the photocharges have to cross a region with lower electrical field strength. In improperly designed, processed, or operated CCDs there may even remain a region which is not depleted and thus shows no electrical field. Since the charge carriers show a temperature-induced diffusion motion additionally to their directed motion in the electrical field, they will not move to their capture sites along a

straight line, but also show a stochastic lateral movement. In the regions with a weak field, the relation between lateral motion and motion towards the front side will become particularly large and this allows some charge carriers to drift to neighboring pixels before they are captured. This causes an electronic blur, that is, the MTF of the CCD is degraded particularly in the UV spectral range. In scientific back-illuminated CCDs with standard operation conditions a blur in the region of 15 μm [full width at half-maximum (FWHM)] can be observed. With the usual pixel sizes of scientific CCDs this will not be a problem, provided that no sub-pixel information is involved in a measurement approach. At wavelengths longer than 600 nm, the MTF performance will be approximately the same as for front-illuminated CCDs, but here another problem, so-called etaloning, arises due to multiple reflections between the front and back sides of the chip.

Alternative methods for achieving UV sensitivity without back-side thinning are the use of a fluorescent coating on top of the electrode structure or of so-called open electrodes, which do not cover the entire pixel area and thus allow part of the UV radiation to enter the photosensitive layer directly. These techniques will not achieve the same high quantum efficiencies as back-thinned CCDs, but are less expensive and furthermore may have better MTF characteristics, particularly at shorter wavelengths and for the open electrode type.

5.3.2.9 **Etaloning at Long Wavelengths and Deep Depletion CCDs**

In the NIR range beyond about 600 nm, silicon becomes increasingly transmissive and an ever larger fraction of the incident radiation can pass through the whole CCD thickness without being absorbed. This not only limits the NIR sensitivity of the CCD, but also leads to an additional annoying effect, so-called etaloning. Since the CCD chip is transmissive but has a large surface reflection coefficient because of its high refractive index of about 3.5–4 in the NIR region, it starts to act as a Fabry–Pérot etalon, where light is reflected forwards and backwards several times, causing interference fringes. Etaloning leads to a preference of certain wavelengths over others with a very strong dependence on the thickness. Since thickness – particularly in back-thinned CCDs – varies spatially, a monochromatic image will be disturbed by a fringe structure, and precise quantitative measurements will become very difficult. The effects are most severe for back-thinned CCDs and can lead to intensity modulations of more than 50% of the total intensity.

One way to reduce etaloning and achieve a higher quantum efficiency in the NIR region is to use a CCD with deep depletion. The thickness of the sensitive (depleted) layer here is increased to about 40 μm using a high-resistivity silicon. Back-illumination and back-thinning can still be used, and the latter accounts for the increased thickness of the depleted layer, that is, the thickness of a back-thinned deep depletion CCD will be much larger than that of a standard back-thinned CCD. The drawback of deep depletion CCDs is that they cannot be operated in fully inverted (i.e., MPP) mode, so the dark current at a given temperature is about 1000 times larger than that of a CCD using MPP operation at the same temperature and deeper cooling is necessary to achieve the same dark current values. For applications with

short integration times, however, an increased dark current may be acceptable as a price for the increased IR quantum efficiency.

For radiation with a coherence length (see Chapter 4) below the doubled optical thickness of the CCD, the etaloning will vanish. For example, at a wavelength of 1000 nm (the refractive index here is 3.57) and a thickness of 40 μm, this coherence length is about 285 μm. Care still has to be taken if the investigated radiation is known to have highly monochromatic peaks, for instance from a laser line which is mixed into another spectral distribution, or if the CCD is used in a spectrometer with such a high resolution that the coherence length of a single channel becomes larger than the critical value. Particularly the limit of the spectral with (FWHM) is given by

$$\Delta\lambda \geq \frac{\ln 2}{\pi} \frac{\lambda^2}{d_{\mathrm{CCD}} \cdot n_{\mathrm{Si}}(\lambda)} \tag{5.8}$$

where d_{CCD} is the thickness of the CCD and n_{Si} is the refractive index. For the above example, a spectral resolution of better than 1.5 nm (corresponding to a wavenumber resolution of 15 cm^{-1}) could lead to etaloning despite the deep depletion CCD. For methods such as Raman spectroscopy this is not a particularly high resolution, so etaloning is likely to occur if no further precautions are taken. In addition to anti-reflective coatings, which can substantially suppress etaloning, these precautions can include roughening of the back side (with respect to the incident radiation). In fact, a certain "roughening" already occurs due to the electrode structure and the channel stops. Roughening will suppress etaloning if the spatial coherence diameter of the incident radiation is significantly smaller than the spatial spread which is caused by the roughening. Otherwise, it will lead to speckle noise. In well-designed spectroscopic devices, however, the spatial coherence diameter should be smaller than a pixel pitch, at least along the direction of the dispersion, so the etaloning/speckle noise will be reduced significantly. In a spectroscopic system with an anti-reflective coated, back-side roughened, deep depleted CCD, the spectra will look visually smooth and free of etaloning. However, if precise quantitative measurements have to be performed, one should be aware that none of the anti-etaloning precautions can really eliminate etaloning completely.

5.3.3
Photodiode Arrays (PDAs), Active Pixel Sensors (APSs/CMOS), and IR Focal Plane Arrays (FPAs)

As in the previous section on CCDs, it is the aim of this section to give some fundamental properties of photodiode array (PDA), active pixel sensor (APS), and focal plane array (FPA) detectors and here particularly on CMOS APS sensors, since these are most relevant for many applications. This knowledge should enable one to choose among different available sensors for a certain application. Since APS technology is much more variable and heterogeneous than CCD technology, currently developments in this sector are extremely fast, and future developments can only be foreseen to a small extent, it is particularly important to understand some basic principles and their implications for device performance. In contrast, it would

be useless simply to list different APS types and their performance parameters. For a complete understanding of this section and for complementary information, it is recommended also to read Section 5.3.2 on CCDs.

5.3.3.1 Plain Photodiode Arrays and Focal Plane Arrays

In addition to CCDs, monolithically integrated arrangements of photodiodes without a charge shifting capability can be used to record one- or two-dimensional intensity distributions. In the simplest case, these PDAs do not contain any readout electronics or pixel addressing capability and partly also have no relevant photocharge integration capability. Such pure PDAs are usually only used if either the technology of the PDA does not easily allow the integration of readout electronics, if different pixels have to be read out truly parallel at a high speed, or if a very small total number of pixels makes the integration of readout electronics useless or inefficient. Examples of technologies that do not easily allow for the integration of readout electronics are in principle all non-silicon-based types of photodiodes, which are particularly interesting in the IR region, and technologies with processes that are incompatible with standard electronic processes. Further, they also include types of photodiodes with incompatible voltage levels of signals or bias voltages, such as avalanche photodiodes.

For PDAs without readout electronics, which are linear, or have a small number of pixels, connections for each pixel are usually drawn out to the lateral boundaries of the array, where they can be connected individually to some follow-up electronics. If the latter can be used to address the photodiodes individually to reset their accumulated charges or connect them to one or a few outputs, it is called a multiplexer and is often based on CMOS technology. Sometimes a CCD-like device may also be used, but this is less common.

For PDAs with larger pixel numbers it will not be possible to connect every pixel individually from the lateral border. This situation is typical of IR image detectors, often referred to as FPAs. Here a hybrid solution is used, where a PDA chip of some IR-sensitive semiconductor material is placed on top of a silicon-based so-called readout integrated circuit (ROIC) chip, that is, a two-dimensional multiplexer. The two chips are connected by indium solder bumps (Figure 5.28).

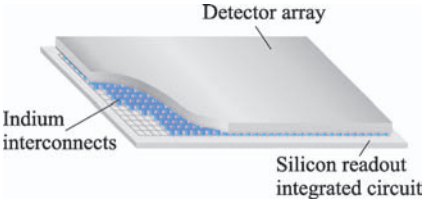

Figure 5.28 Basic scheme of a hybrid IR FPA. The FPA consists of an array of IR-sensitive photodiodes, photoconductors, or sometimes other detector types without any readout electronics. The readout is accomplished by a separate silicon ROIC, which is bonded to the detector array using indium bumps. The ROIC is a complete CMOS imager, but without integrated photodiodes. These are replaced by the contacts below the indium bumps.

The term FPA is also used for image detectors which use light-sensitive elements other than photodiodes, such as thermal detectors and photoconductors. Except for the photodiodes or other light-sensitive elements, which are replaced by contact structures, ROICs are very similar to the CMOS active pixel sensors discussed in the next section, and work as multiplexers with or without integrating capacitors. For some imagers the ROIC may also be based on a CCD instead of a CMOS design. Furthermore, sometimes even silicon-based PDAs are connected to a separate ROIC in a hybrid arrangement. One reason, as before, can be incompatible production processes for readout and PDA; a second reason is, however, the wish to achieve a high fill factor. Particularly, if there is a lot of functionality in each pixel, the achievable fill factors of a monolithic sensor are very limited.

The hybrid technology of FPAs is very complex for several reasons, such as the connections between light-sensitive chip and ROIC, thermal expansion mismatch between the different materials, or the processing steps which are necessary to make the light-sensitive elements electrically connectable from the back side. In addition to the already high costs of good IR photodiode or photoconductor arrays, this complexity is the second main cost factor of FPAs, which are still relatively expensive.

Once a photodetector array has been connected to a multiplexer or ROIC, it practically becomes an APS with all of its possibilities and limitations. The details of the operation of such a device will therefore be discussed only in the section on APS image detectors, without explicitly mentioning the applicability to PDAs and FPAs.

5.3.3.2 CMOS Image Detectors/Active Pixel Sensors

The APS [17] is characterized by the fact that every pixel contains its own readout amplifier, addressing and reset electronics, and probably further elements. In addition to different possible technologies for the intra-pixel electronics, APSs also cover a wide range of light detector technologies and can be monolithically integrated as well as hybrid devices. Usually they will be based on a photodiode or pinned photodiode as the detector element, but may also use a thermal or photoconducting detector or borrow from CCD technology in the form of the photogate.

The APS is often simply referred to as a CMOS image sensor. However, on the one hand it is not limited to a CMOS technology and on the other it would also be possible to manufacture a passive pixel sensor on a CMOS technology base. Except for pixel electronics designs which share transistors between pixels, the simplest pixel design has three transistors and is therefore called a 3T pixel. Here one transistor is needed to reset the accumulated pixel charge, one is needed to address the pixel, and one realizes the amplifier functionality. The principle of an APS with 3T pixels is shown in Figure 5.29, the realization with three MOS transistors is shown in Figure 5.30, and a typical signal diagram of the capacitor voltage is show in Figure 5.31.

The number of transistors per pixel is not limited to any maximum value, and every pixel can in principle have very complex signal-processing capabilities. Typically, the number of transistors varies from three to seven, allowing for more or less complex timing, exposure, and shutter modes and for different handling of over-exposure situations. For more special demands, there are, however, pixels with

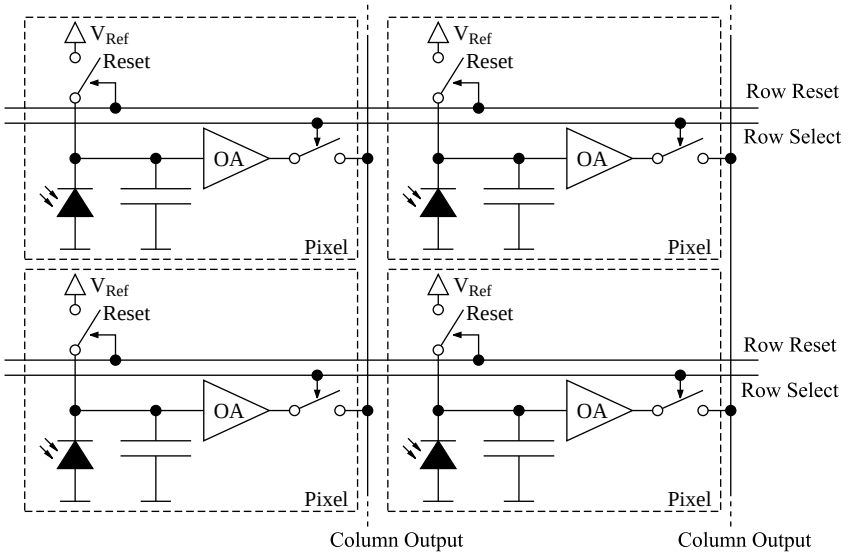

Figure 5.29 Coarse principle of a simple 3T pixel architecture: Before an integration starts, an integration capacitor in each pixel is reset to a reference voltage V_{DD}. When illuminated, the photodiode in each pixel discharges the capacitor, whose voltage is amplified by a per-pixel output amplifier (OA). By setting one row select signal active, all pixels of this row are enabled to forward their OA signal to their according column output line. At the end of each line for instance an individual analog-to-digital converter exists, or a further switch per column allows one of the columns to be forwarded to a common chip output or ADC.

a much larger number of transistors, such as a 37 transistor pixel design with per-pixel analog-to-digital conversion for a high-speed image sensor reported by Kleinfelder *et al.* [18].

The main problem with too many transistors per pixel is a low resulting fill factor, but this can be overcome, at least partly, by using a hybrid approach or

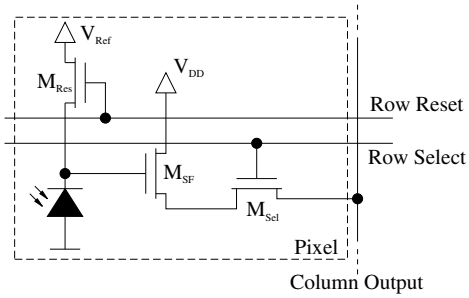

Figure 5.30 Realization of a 3T pixel with three MOSFET transistors. Transistor M_{Sf} is a so-called source follower and acts as the output amplifier. By activating the row select line, its output is transferred to the column output line via the transistor M_{Sel}. Transistor M_{Res} is used for charge reset, the charge is stored inside the photodiode capacitance.

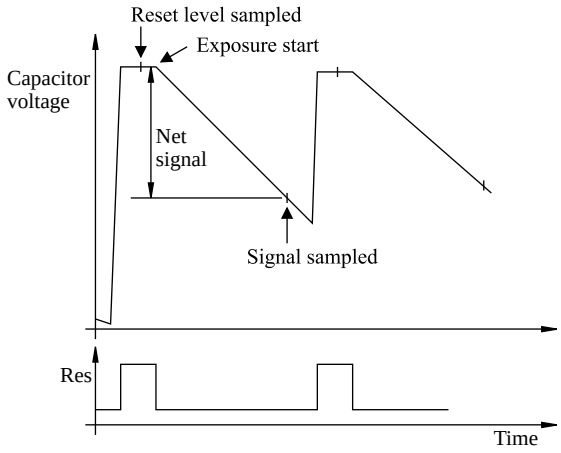

Figure 5.31 Typical exposure timing of a 3T APS pixel. The integration capacitance is first reset to a reference voltage level, which is then immediately sampled before the start of the integration to suppress reset noise. After an exposure time, the now reduced capacitor voltage is sampled a second time to determine the signal (i.e., the accumulated intensity).

back-illumination. Also, lens arrays on top of the APS are used to increase the fill factor. However, they also cause some problems for scientific applications, which will not be discussed here.

5.3.3.3 Double Sampling and Correlated Double Sampling (CDS) in APS Imagers

One common feature of most APS imagers is that at some stage a per-pixel capacitance will be used either to integrate a photocurrent or to convert a stored charge into a voltage using a capacitance. Before the integration or the charge transfer, the capacitance needs to be reset to a reference voltage. Similarly to the reset noise at the floating diffusion site of a CCD output node, this does not work perfectly. Instead, a reset noise occurs when the capacitance is reset to the reference voltage. Moreover, the average reset level varies from pixel to pixel, which is called fixed pattern noise (FPN).

These noise contributions can be eliminated by double sampling (DS) (not to be confused with the statistical method) or correlated double sampling (CDS). In APS detectors, the CDS scheme is based on a hardware feature which generates the difference signal between the two sampled values of one pixel integration in the analog domain. For this purpose, at the end of each column output line, there exists one dedicated CDS circuit, which can store the two values in two separate sample-and-hold units and derives the difference voltage. The principle of such a unit is shown in Figure 5.32. Since the CDS unit needs the two sampled voltages of one pixel directly after each other, it is clear that the pixel itself needs to have a possibility to store the reset voltage throughout the integration period and transfer it to the column output line on demand. This is not possible with a 3T pixel design and requires at least a 4T pixel. For pixel architectures where the reset noise is generated in

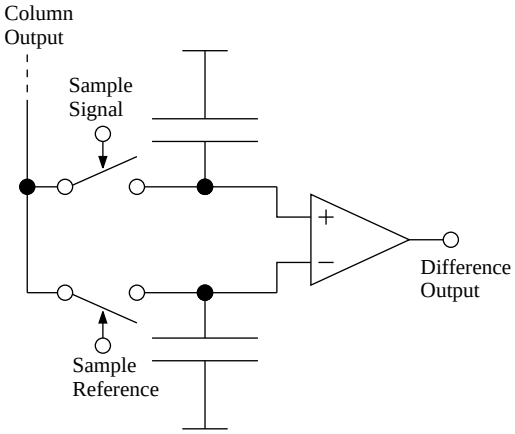

Figure 5.32 Schematic principle of a correlated double sampling circuit at the end of each column output line of a CDS capable APS imager; Two parallel sample-and-hold circuits, each mainly consisting of a switch and a storage capacitor, are used to sample the reference and the signal level of a pixel sequentially. A differential amplifier produces a new signal, which is corrected for the reference level.

a charge readout after the exposure, an extra charge storage capability is not necessary.

The two DS schemes can be used to solve the problems of reset noise and FPN; however, they produce their own, weaker noise and errors. In the case of DS, an additional noise contribution is added due to the second necessary voltage measurement, and in the case of CDS, the CDS circuitry causes a column fixed pattern noise, which has to be removed by further means. The DS approaches furthermore only work well if the output amplifiers respond linearly to the photocharge. It should be mentioned that in contrast to the term "correlated double sampling," the term "double sampling" is not in widespread use in the context of measuring electrical properties.

5.3.3.4 **Exposure Integration Schemes**

One criterion to categorize APS pixels is the way in which the integration of the incident light is done. This issue is closely related to the type of light-sensitive element.

Many APS detectors are based on photocurrent-producing light-sensitive elements such as standard photodiodes or photoconductors. The operation of a pixel here starts with preloading the accumulation capacitance with a certain charge (i.e., to a certain voltage), which is then drained by the photocurrent of the light-sensitive element. One drawback of this approach is a reduced sensitivity for low intensities, since it is much harder to detect a small number of missing charges on a large charge background than to detect the charges themselves as an absolute signal. This is complicated by reset noise and FPN, which have to be corrected particularly well in order to achieve a good low light sensitivity.

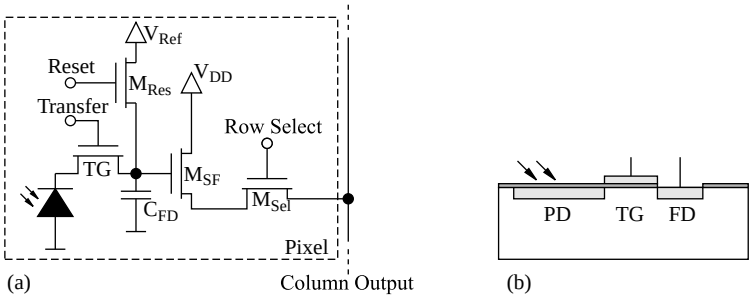

Figure 5.33 Design of a simple 4T pixel with pinned photodiode (PD), transfer gate (TG) and floating diffusion (FD) as a storage/measurement capacitance. (a) General pixel design; (b) the three elements in a cross-sectional view; The arrangement resembles the combination of transfer gate and floating diffusion as known from the readout node of a CCD. Instead of a pixel of the CCD readout register, the pinned diode is directly connected to the transfer gate.

More sensitive pixel designs are based on a photogate or pinned photodiode, which in a similar manner to CCDs accumulate photocharges in a local potential well (Figure 5.33). These elements are not available in all technologies, however. In the pinned photodiode, the potential well is created by the structure of the doping, usually a buried n channel, and in the photogate it results from a voltage which is applied to a transparent electrode above the sensitive area. Although the photogate effectively is a MOS transistor, we will not count it here in the number of transistors of the pixel. Before the exposure, the potential wells are flushed to a zero charge. Photocharges are then collected during integration. After the integration, the charge is transferred to a small capacitance, where it is converted into a voltage that can be read out in the usual way. The charge transfer is accomplished by a transfer gate, that is, an additional MOS transistor between the light sensitive element and the measurement capacitance. The latter is usually laid out as a floating diffusion capacitor. This arrangement closely resembles the readout node of a CCD (see Section 5.3.2.4) and the charge transfer between light-sensitive element and floating diffusion capacitance is accomplished by a deeper potential well of the floating diffusion capacitor than of the light-sensitive element.

Reset noise and FPN here mainly apply to the capacitance and not to the light-sensitive element. The DS or CDS operation here therefore compares the voltage of the measurement capacitance before and after the charge is transferred to it. Both values can be determined after the integration, so CDS can be implemented already in the simple types of photogate- or pinned photodiode-based pixels. In contrast to pixels based on plain photodiodes or photoconductors, the charge of the photogate or pinned photodiode cannot be read out nondestructively during the exposure. For the pinned photodiode, however, it would be possible to transfer photocharges repeatedly to the floating diffusion capacitor during the exposure time without resetting the latter during this time. This would permit an indirect kind of Fowler or up-the-ramp sampling (Figure 5.17) by a simple change of the timing.

5.3.3.5 Electronic Shutter Modes

As opposed to the CCD, pixels of an APS sensor can be read out and reset more or less randomly and their charge will not be shifted through the light-sensitive area. Hence in principle no shutter capability is needed to avoid spatial blur in the readout process. However, as a minimum requirement for the acquisition of usable images without an external shutter or a pulsed illumination, it should additionally be possible to achieve equal exposure times for all pixels. The starting point of an exposure is always determined by the resetting (photodiode/photoconductor) or flushing (pinned photodiode/photogate) of the integration capacitance and can be done individually for every pixel row or globally for all pixels, even for the simplest pixel types. The true problem, particularly for simple pixel types, is to set the end point of the exposure integration. In the 3T pixel the exposure is effectively stopped when the pixel charge is read out and cannot be stopped in another way. Since only one row can be read at a time and different rows must be read sequentially, the only possibility for maintaining a constant exposure time for all pixels of the array is also to start the exposure of different pixel rows sequentially. This cheapest of all shutter approaches is called a "rolling shutter." The array exposure starts with resetting the first row, waiting for one row readout time, resetting the second row, and so on. One exposure time after resetting the first row, the accumulated charges of the first row are read out, then the second row follows, and so on. The readout of the lower row may already start when the resetting of the higher rows is still in progress. In an extreme case, the exposure time can even be shorter than the row readout time; however, this has to be supported by the on-chip control logic.

The rolling shutter approach works well for capturing fixed or slowly changing intensity distributions, but for fast processes or dynamic scenes it produces artifacts. Here a snapshot operation – also called global shutter operation – of the image sensor is desirable. To achieve a real snapshot capability, that is, start and stop the exposure interval for all pixels simultaneously, a second charge storage capability in addition to the integrating capacitance is required, such as is present in the 4T pixel of APS with a pinned photodiode or photogate. A usual 3T pixel can be extended in a similar manner to a 4T pixel with a standard photodiode or photoconductor by adding one transistor and one storage capacitor. In both types of 4T pixels, however, the snapshot operation is in conflict with the CDS capability. The reason is simple: the exposure is in both cases stopped by transferring the accumulated charge to the floating diffusion node or the newly introduced storage capacitor. To achieve snapshot operation, this would have to be done simultaneously for all pixels. However, as pointed out above, for CDS operation the charge transfer has to be done row by row with a sampling by the CDS circuits before and after each transfer. The same 4T pixel can thus be used for snapshot operation and for CDS operation, but not for both at the same time. Again, the choice is determined by the readout timing of the on-chip control logic. To achieve CDS and snapshot operation simultaneously, at least a 5T pixel design is necessary. Further transistors may be added to achieve anti-blooming (i.e., prevent spill-out of excess charges in an over-exposure situation), improve performance parameters of the pixel, or add preprocessing capabilities to the pixels (intelligent sensors).

5.3.3.6 Back-Side Thinning of CMOS Image Detectors

Starting from the first decade of the twenty first century – and even earlier in astronomy research – back-illumination has also been introduced in CMOS APS technology. This development was driven by sensitivity problems with consumer cameras with large numbers of small pixels, but also by the fact that it has major advantages for scientific applications. With the introduction of back-illumination, APS devices start to offer the same potential for scientific applications as CCDs, particularly high sensitivity and detection down to the deep-UV region. At the same time, they retain their specific advantages over CCDs, particularly a much simpler external electronic circuitry, significantly lower power consumption, and the potential for much smaller pixels. Consequently, the development of scientific back-illuminated APS devices is particularly interesting for the space sector [19].

Instruments in Biotechnology and Medicine

Andreas Voss, Karl-Heinz Feller, and Dieter Beckmann

Biophotonics is a fusion of photonics and biology and represents interactions between light and biological material; it combines optical technologies, microelectronics, and imaging for applications in medicine and biotechnology. The increasingly aging world population increases tremendously the financial pressure on our health care systems. Efforts are under way to develop technologies that increase the efficiency of the patient care process. One such technology is biophotonics.

The application of biophotonics in diagnostics and therapy has already and will continue to have an increasing major impact on health care and the health care industry. This chapter is intended as an introduction to applications of biophotonics in medicine and biotechnology, not as an in-depth, exhaustive, and complete treatise on this field. The objective is to provide a basic knowledge of a range of topics to stimulate the reader to learn and think further about the challenges of biophotonics and to initiate and intensify studies in this field.

6.1
Photonic Instruments in Medicine

6.1.1
Introduction

6.1.1.1 Optical Window of Cells and Tissues

Concerning the irradiation of human tissue with light, different aspects of light–matter interactions have to be discussed. In general, the effects of light on human tissue depend on the wavelength of the irradiated light and, of course, on the intensity of the light. Furthermore, the duration of application (skin effect) is of great importance. In this respect light–(human) matter interactions are of very complex nature. Concerning the wavelength dependence of light penetration into cells and tissues, as shown in Figure 6.1 [1, 2], absorption and multiple scattering affect the penetration of the light. At short wavelengths [in the deep ultraviolet (UV) region], the penetration is short due to high absorption coefficients (ε in $mM^{-1}\,cm^{-1}$) and strong Rayleigh scattering. In the visible region, the absorption decreases (no water

Handbook of Biophotonics. Vol.1: Basics and Techniques, First Edition.
Edited by Jürgen Popp, Valery V. Tuchin, Arthur Chiou, and Stefan H. Heinemann.

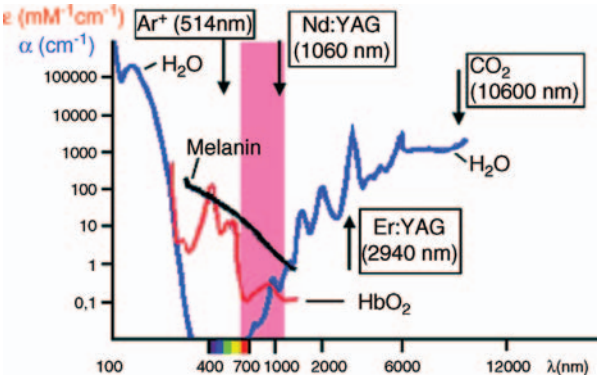

Figure 6.1 Optical window of cells and tissue with water, melanin, and oxyhemoglobin absorption coefficients [3].

absorption) and the Rayleigh scattering vanishes with λ^4. In the near-infrared region, the water absorption increases again and multiple scattering in heterogeneous media becomes more and more dominant. In connection with this behavior, different actions can be taken in different wavelength regions.

In Figure 6.1, the different penetration depths of light as a function of the wavelength are shown and the absorption spectra of the important components water, melanin, and oxyhemoglobin are depicted. It becomes clear that between 400 and 700 nm a so-called "optical window" of the tissue appears where neither water absorption nor scattering diminishes the penetration depth significantly. In this manner, the "optical window" is defined as the range of wavelengths where the light has its maximum depth of penetration into the tissue. Further in Figure 6.1 some examples of lasers are indicated (with their wavelengths) preferentially used in laser therapy for different indications.

6.1.1.2 Laser Light–Matter Interaction as a Function of Intensity

Light–matter interaction in biophotonics is based on the intensity of light (power flow density) treating the matter and the application time (which is often directly correlated with the peak intensity due to the effect of producing higher peak intensities by pulse shortening).

The dependence on the energy density or better reflected by the power flow density as shown in Figure 6.2. Different processes in cells and tissues occur in the human body [1, 2, 4], which will be discussed in more detail in the following chapter. As already mentioned, the other parameter is the application time: at long application times reflecting the accumulation of energy (or simply photons) in the body, at short times more reflecting the dependence of the peak intensities obtained with powerful lasers from the extremely shortened pulse length.

6.1.1.3 Photochemical Treatment of Tissues

At the lowest photon densities, processes occur which are well known in photophysics and photochemistry, such as the photoinduced isomerization process. An

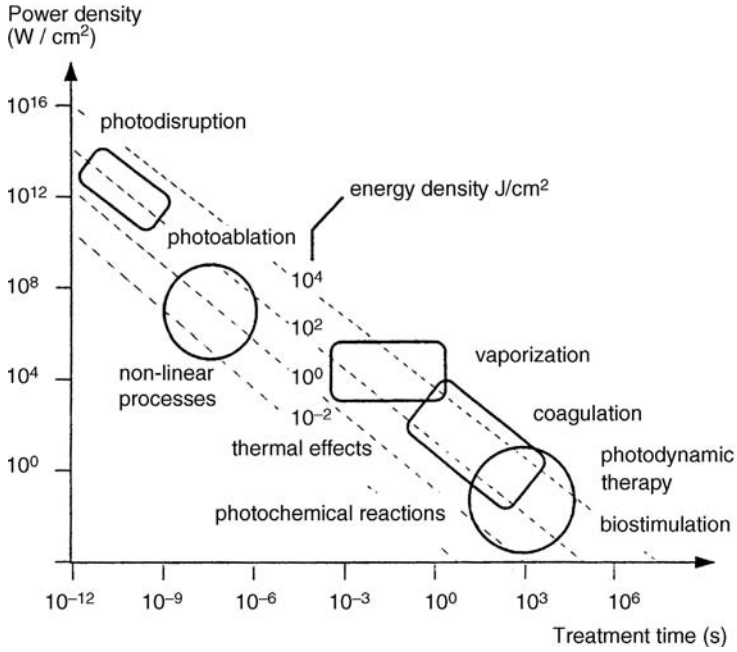

Figure 6.2 Laser light–matter interaction effects as a function of power density ($W\,cm^{-2}$) and treatment time (s). Dotted straight lines indicate the energy density region ($J\,cm^{-2}$). (with permission from Ringelhan [5]).

important example of such processes is the *cis–trans* isomerization of rhodopsin as the basis of the vision process in the human eye. A medical application is the treatment of hyperbilirubinemia, the cause of icterus (jaundice) in newborn babies, the basis of which is increased levels of bilirubin. Another example is photodynamic therapy where the patient is treated with HPD (hematoporphyrin derivative) (see Figure 6.3 for structure), which is selectively bound to cancer cells. After irradiation of the tissue, the excited HPD transfers the energy to the oxygen (in the surrounding) via a dynamic quenching process to create singlet oxygen. This further creates hydroxyl radicals, which destroy the cancer cells [6].

Other examples of processes that occur in this intensity region are photoinduced synthesis in plants and UV-induced melanin production in skin. The basis of life on Earth is the photoinduced charge separation in the reaction center as the primary process of photosynthesis.

It should be added that biostimulation also belongs to this intensity region. Biostimulation is defined as a process of laser treatment at extreme low intensities (below the threshold of reversible tissue damage, Section 6.1.3). So far, no results have been published which prove that biostimulation of human cells and tissues makes any impact.

All these processes have in common that compared with usual photon densities in laser applications, they proceed at very low intensities. In principal they need no laser irradiation and could be performed with classical light sources. The advantage of

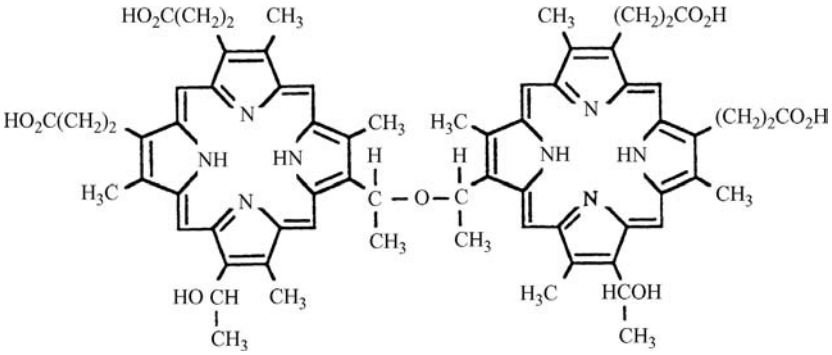

Figure 6.3 HPD – hematoporphyrin derivative.

lasers in this intensity region is often connected with proper guidance of the light to the tissue.

6.1.1.4 Thermal Processes in Light–Matter Interaction

At higher intensities, thermal effects play a crucial role in the understanding of light–matter interactions. Thermal effects depend strongly on the wavelength. On the one hand, the absorption in water is the main cause of thermal changes in cells and tissues, and on the other, the shorter the wavelength the higher is the amount of energy deposited in the tissue or cell. In general, thermal treatment of tissue is connected with different damage regions. When the tissue is vaporized under peak power irradiation, this sharp cut is surrounded by an irreversibly damaged zone covered by a carbonized interface (or called the necrosis zone). As can be seen in the Figure 6.4, at lower excitation intensities, lower heating of the tissue leads to reversible effects (for more details, see [1, 2, 4, 7]).

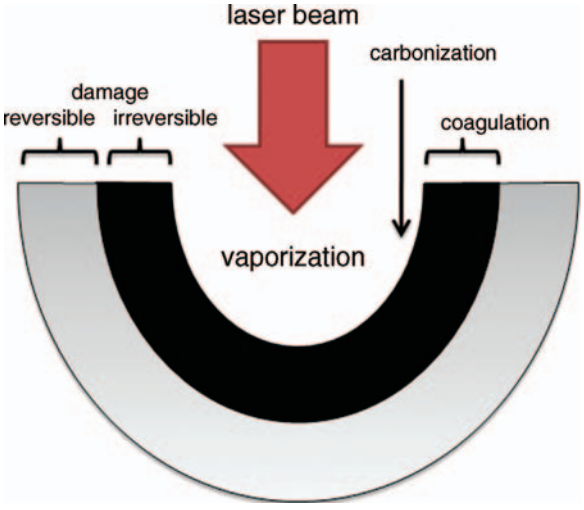

Figure 6.4 Zones of thermal treatment of skin at high laser intensities.

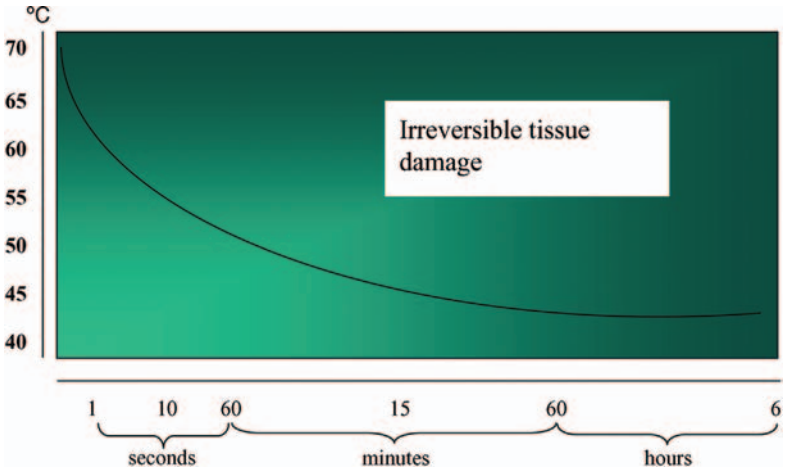

Figure 6.5 Reversible and irreversible damage of tissues as a function of the application time.

Depending on the applied wavelength and the intensity, these zones have different sizes. The longer the wavelength, the larger is the zone of irreversible damage. Further, the thermal damage depends on the application time, as shown in Figure 6.5.

As is clearly seen, increasing application times are connected with irreversible damage at lower temperatures, or the reverse: Short application times are connected with less damage of the tissue (skin effect). This effect is even more pronounced if the nanosecond time scale is reached because thermal diffusion times in tissues are in the nanosecond time scale (rate constants in the region of $10^{10}\,s^{-1}$). Shorter pulse lengths of the irradiation pulse lead to local effects in the tissue without thermal diffusion into the neighborhood. In this respect, ultrafast processes in light–matter interaction have minimal side effects (thermal damage effects) if the interaction process (and the resulting energy dissipation) proceeds faster than the diffusion time constants [4, 7]. In Figure 6.6, the laser beam penetrations as a function of the intensity and the respective treatment zones (thermal. optical, ablative) are depicted for comparison.

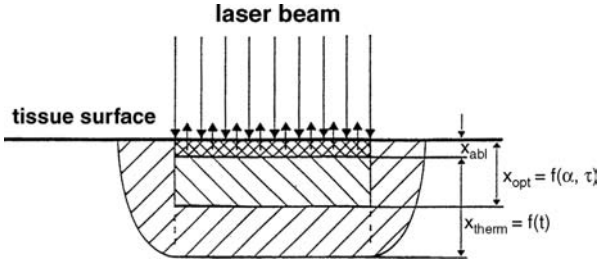

Figure 6.6 Influence of laser treatment on depth of tissue ablation, optical and thermal behavior. (with permission from Ringelhan 1992 [5]).

6.1.1.5 Nonlinear Processes in Light–Matter Interaction (Not to Be Confused with Nonlinear Optics)

In the late 1970s, Srinivasan and co-workers [8] were the first to show that under strong laser excitation in polymers a process occurs that is not longer explained by the action of one photon to create a single change in the material. It was shown that the cooperative action of multiple photons creates an avalanche process in the material which is energy dependent and has a well-defined threshold. This process was called "ablation" and has distinct different properties in comparison with the thermal treatment discussed before applying much lower intensities. Srinivasan and co-workers proposed the "photochemical model of ablation," which is based on the assumption that ablation proceeds above the bond energy by the cleavage of the chemical bond in the material (a process which is completed within picoseconds) and the fragments of the molecules are in the vapor phase, released from the irradiated area at high speed and without thermal dissipation into the surroundings. This model was proven by the ablation process in poly(methyl methacrylate) (PMMA) (see Figure 6.7). It was possible to show that the ablation process starts (threshold) if the loss effects are overcompensated by the production of molecule fragments in the irradiated volume. In this respect, the ablation process is a multi-photon process with single-photon excitation. This proceeds hold for the photoablation of tissue at high intensities with a UV laser, for example, an excimer laser. This process is used, for example, in ophthalmology (for more details, see [8]).

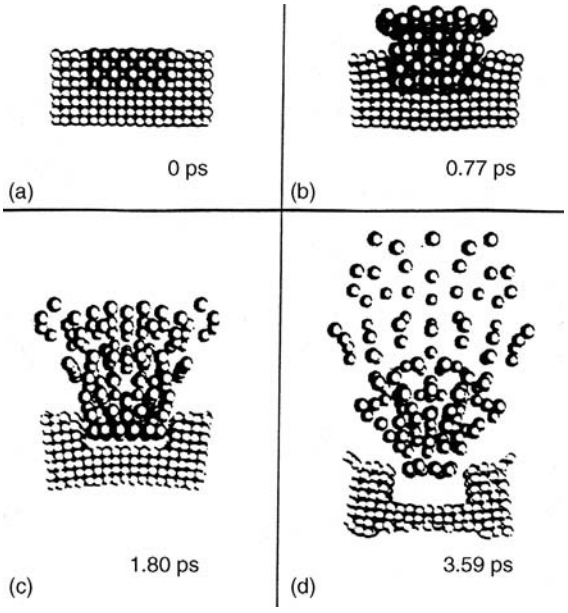

Figure 6.7 Photoablation scheme in PMMA [8]. (a) Starting point of ablation by irradiation of the ablated area; (b) release of the molecules from the layer, crystalline structure still unaffected; (c) build-up of the ablation bloom; (d) total release of the ablated material, finish of ablation process.

In addition to ablation by means of bond cleavage, it was shown that ablation can be achieved with the same minimized side effects (no thermal diffusion into the surrounding tissue) at wavelengths below the bond energy. In this case, the so-called *thermal model of ablation* provides an explanation of the effects that occur. The thermal ablation procedure is connected with multi-photon absorption at the surface. Under these multi-photon conditions, the heating of the irradiated region is connected with restricted thermal diffusion. This process holds for near-infrared (NIR) ablation with Nd:YAG and Er:YAG lasers. It was shown that this process is a cascade process of multi-photon absorption rather than a simultaneous absorption of more than one photon.

6.1.2
Minimally Invasive Diagnostics – Endoscopy

Endoscopy means looking inside the body for any medical reason using an optical-based medical device called an endoscope. The word endoscopy is derived from the two Greek words *endo* meaning "inside" and *skopein* meaning "to see."

Endoscopes can be inserted into the body through a natural opening, such as the throat, anus, or urethra. Alternatively, they can be inserted through a small surgical incision made in the skin.

Further, endoscopy permits minimally invasive surgery, making many operations simpler for the surgeon and safer, more effective, and often less painful for the patient, while significantly shortening the necessary stay in hospital.

For therapeutic reasons, the endoscope often has one or more channels for suction, which also serves as an instrument channel for the passage of biopsy forceps, retrieval forceps, cytology/culture brushes, and other accessories. Most endoscopes also have a separate channel for insufflations of air and water, thus enabling the endoscopist to distend the gastrointestinal tract during viewing and wash debris off the lens.

Endoscopic technology has advanced rapidly over the past 40 years, becoming an integral part especially in various fields of clinical and internal medicine. The utilization of endoscopy for both diagnostic evaluation and screening has markedly increased over the last two decades. Many innovations have extended indications for endoscopy. However, the largest factor to increase clinical endoscopic volumes in recent years has been the adoption of colorectal cancer screening through colonoscopy. The global endoscopy market is forecast to grow at a compound annual growth rate of 30% between 2008 and 2015 [9].

However, one major design problem with endoscopes remains – the necessary small external diameter. Within this small space, a lens system or a charge-coupled device (CCD) chip, a lighting fiber bundle, and useful instrument and flow channels have to be installed.

6.1.2.1 History

The first person in modern times to invent an instrument intended to illuminate the inner cavities of the human body was Philipp Bozzini. He published his first extensive medical report on his "light conductor" (*Lichtleiter*) in 1806. In 1960, Harold

H. Hopkins patented the rod lens system, which improved the previous Nitze system of a train of glass lenses by interspersing neutral gas between them instead of air. The optical features were improved ninefold by lowering the refractive index and increasing the functional diameter of the lenses. Fernando Alves Martins, from Portugal, invented the first fiber optics endoscope in 1963. Karl Storz in 1965 produced the first endoscope combining rod lenses for image transmission with fiber optics (fiber bundles) for illuminating (cold light) the biological object. The first solid-state camera was introduced in 1982. This was the basis for video endoscopy, starting with systems where the camera was mounted on the eyepiece of a traditional endoscope. The introduction of digital imaging with CCD image sensors in 1985 was a breakthrough. The chips could be miniaturized, and starting in the 1990s whole imaging procedure was placed at the tip of the endoscope. Interestingly, the CCD was first invented by researchers William S. Boyle and George E. Smith (awarded the Nobel Prize for Physics in 2009) at Bell Laboratories as a new type of computer memory. Soon it became apparent that it could be used as a light-sensitive element, which could capture images similarly to a film in a camera. The fiber bundles and optics used in fiber endoscopes to guide the light from the tip to the display could be replaced by simple wires.

Spectral endoscopy has evolved using different (no white light) illumination techniques and allows the detection or easy diagnosis of additional diseases. Fluorescence endoscopy is one example of the discriminative power of spectral endoscopy indicating tumorous growth on the bladder wall. In 2001, Given Imaging [10] introduced the first wireless pill-sized endoscopic capsule with a camera that is given to the patient for swallowing. With this technique, the small intestine can be examined, which was not possible before.

Finally, modern endoscopes are combined with other technologies such as endoscopic ultrasound or confocal endomicroscopy to enhance and optimize complex clinical investigations or treatments.

6.1.2.2 Types and Components of Endoscopes

Typical components of endoscopes are the following:

- tube (either rigid or flexible)
- light source (normally outside the body)
- light delivery system (fiber optics) for illuminating the organ or object under inspection
- in traditional endoscopes an optical lens or fiber optics system and/or in video endoscopes an information delivery system [images from CCD or CMOS (*complementary metal–oxide–semiconductor*) chip camera]
- a guiding system for additional manipulation (e.g., surgery, flushing) or diagnosing systems (e.g., biopsy probe sampling)
- image processing and documentation.

Light Sources Light sources for the illumination of the visual field of endoscopes (cold light) are typically connected to the endoscope via a flexible fiber-optic cable.

The most prominent light sources are the following:

- A halogen lamp cold light source is sufficient for most rigid endoscopy using the eyepiece.
- A metal halide lamp is an often used light source for fiber-optic scopes.
- Xenon is more powerful light source and is essential when dealing with video endoscopy and reduced light transmission of flexible endoscopes.
- Miniaturized light-emitting diode (LED) (in modern systems directly mounted at the tip of the endoscope).
- Laser light (for special applications such as fluorescence microendoscopes).

Imaging Depending on the visualization principle different imaging techniques are applied, such as

- white light imaging
- narrow band imaging
- fluorescence imaging.

The quality and sensitivity of imaging methods are strongly influence by features such as

- illumination of the region of interest (brightness)
- color fastness, depth of field
- resolution
- contrast
- vignetting
- depth of sharpness
- photosensitivity (electronic image transmission)
- signal-to-noise ratio of the implemented optical and electronic components.

Image Processing Systems in Video Endoscopes Image processing in endoscopy provides manipulation and enhancement of the video images. Image processing is a crucial part of the efforts to increase the quality and significance of medical images. Numerous filtering and image quality enhancement techniques (e.g., contrast enhancement, error reduction, distortion correction) have been introduced for various modalities and situations.

Visualization and Documentation Direct visualization of endoscopic images by eye is being more and more replaced by the introduction of video camera systems that present the images on a screen. This offers the opportunity for several observers to observe the endoscopic examination at the same time.

Modern video camera systems consist of an objective, a CCD or CMOS chip and a control unit mounted within a box. This kind of visualization provides analog or digital storage of endoscopic images and videos in modern documentation and clinical information systems. Image documentation is of high relevance for clinical follow-up and quality management of medical services. Further, the stored digital data offer new possibilities for digital signal processing, leading to increased quality

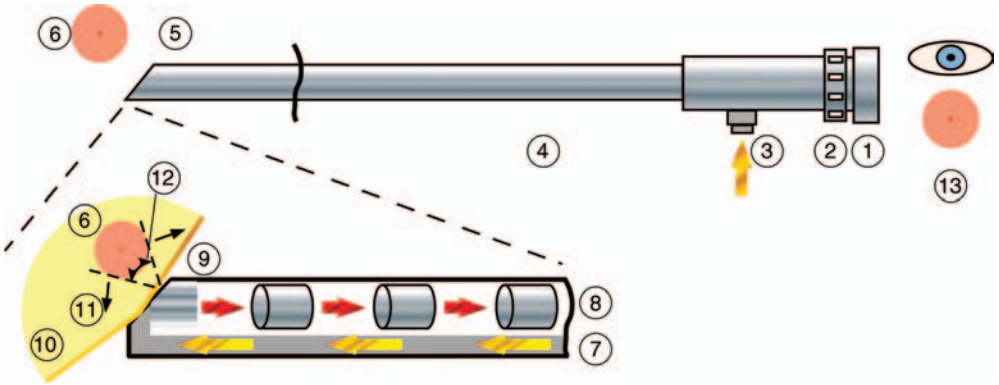

Figure 6.8 Rigid endoscope: 1, ocular; 2, focusing; 3, connector for fiber light guide cable; 4, telescope including fiber bundle for light transmission; optical lens system for image transmission and depending on application further channels for any manipulation; 5, endoscope tip; 6, object to be investigated; 7, fiber bundle for light transmission; 8, optical lens system (e.g., rod or achromatic) for image transmission; 9, objective lens; 10, illuminated area; 11, changeable direction of view (e.g., detectable tip); 12, lateral viewing angle (changeable, e.g., by type of included objective lens); 13, image of the object to be investigated within the field and angle of view.

of the images and extraction of new features from these images, increasing the precision of diagnosis that would not be possible with simple visualization.

Types of Endoscopes

Rigid Endoscope Rigid endoscopes (Figure 6.8) are small tubular telescopes to look inside the body and, in addition to diagnostic purposes, to carry out surgical procedures using special endoscopic instruments.

The optical element for rigid endoscopic systems is the telescope. It is an integral part of the system that provides both the image and the light transmission. The telescope is both the most expensive and most fragile part of the endoscope system. In rigid endoscopes, the optical lens train transfers the image to the eye of the user or to a video monitor. The lens train is comprised of precisely aligned lenses, spacers, and mirrors. Visualization occurs when light is transferred from a light source through the glass fibers distributed around the lens train. Rigid rod lens optics provides high-quality endoscopic images [11] (Figure 6.9).

The disadvantage of low light transmission in endoscopes with smaller diameter is compensated by the use of rod lens systems (Figure 6.9a). Endoscopes with an outer

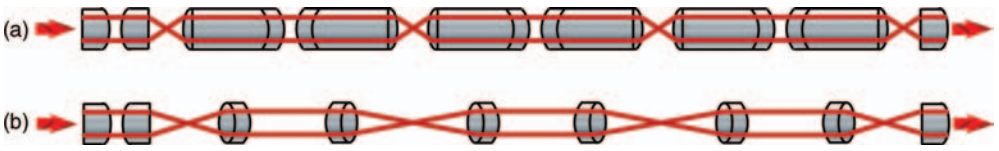

Figure 6.9 Lens systems in rigid endoscopes: (a) rod lens system; (b) achromatic lens system.

diameter of 6 mm and larger often include achromatic lens systems (Figure 6.9b), leading to higher stressability by holding nearly the same optical features.

The newest designed rod lens systems in combination with optimized glass fiber arrangements for lighting provide high-resolution images with sharpness up to the edges. Recent optical systems provide detailed recognition of the smallest visible anatomical structures.

A deflectable endoscope tip provides the maneuverability and access required for endoscopic single-site surgery.

Flexible Endoscope Flexible endoscopes are useful for viewing the inside of, for example, the stomach and intestines, where the endoscope may have to pass a long distance into the body, and around twists and curves. Flexible endoscopes are long, flexible tubes (Figure 6.10). In addition to visual and enhanced diagnostic purposes, flexible endoscopes enable (as rigid ones) surgical procedures to be carried out using special endoscopic instruments.

Fiber-optic lines are strands of optical glass (or special optical plastics) as thin as a human hair that carry digital information over long distances.

The single optical fibers (Figure 6.11) consist of three parts:

- **Core**: – Thin glass center of the fiber – transmits the light or optical information.
- **Cladding**: – Outer optical material surrounding the core – reflects the light back into the core.
- **Buffer coating**: – Plastic coating – protects the fiber from damage and moisture.

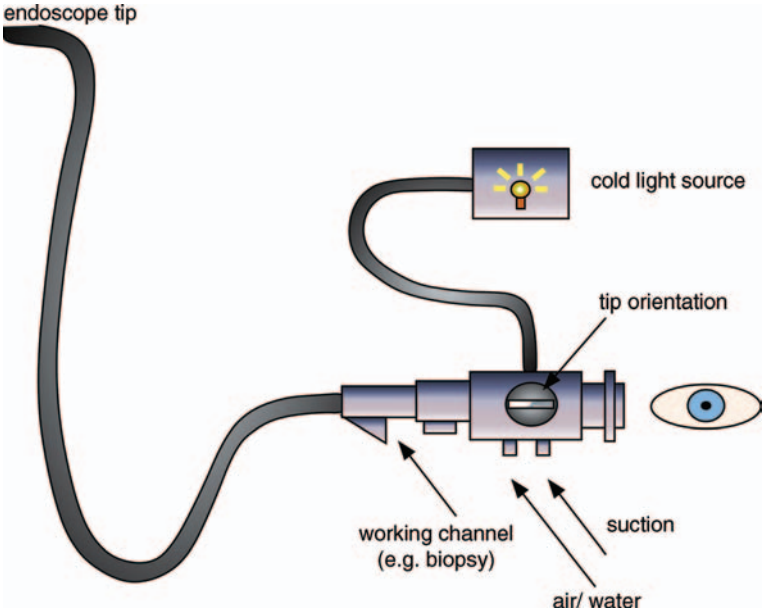

Figure 6.10 Flexible endoscope.

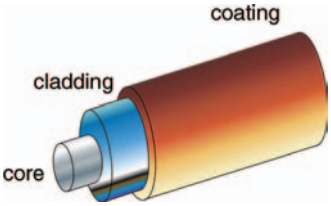

Figure 6.11 Single optical fiber.

The light in a fiber-optic cable travels through the core by constantly bouncing from the cladding based on the principle of total internal reflection (Figure 6.12).

The critical angle φ_C can be calculated from Snell's law, putting in an angle of 90° for the angle of the refracted ray φ_1. This gives φ_2, where n_1 and n_2 are the refractive indices of core and cladding material, respectively.

$$\varphi_1 = \arcsin\left(\frac{n_2}{n_1} \cdot \sin\varphi_2\right) \tag{6.1}$$

with $\varphi_2 = 90°$ and $\sin\varphi_2 = 1$ is $\varphi_C = \varphi_1 = \arcsin(n_2/n_1)$.

Thousands of these optical fibers are arranged in a bundle (Figure 6.13). This bundle is protected by an outer covering. Optical fibers come in two types depending on the type of light to be transmitted: single-mode and multi-mode fibers. A mode describes the distribution of light energy across the fiber (the patterns depend on the wavelength of light transmitted and on the variation in refractive index that shapes the core).

In fiber-optics endoscopes there are two separate fiber bundles, one for viewing and the other for transmitting light. The fibers in the viewing bundle are spatially

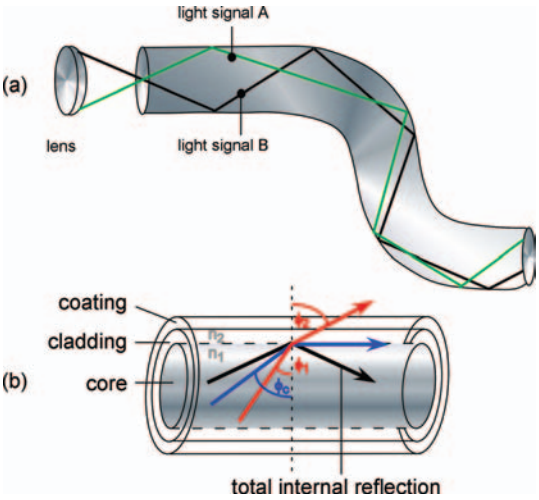

Figure 6.12 Schematic of (a) transmission in glass and (b) total reflection.

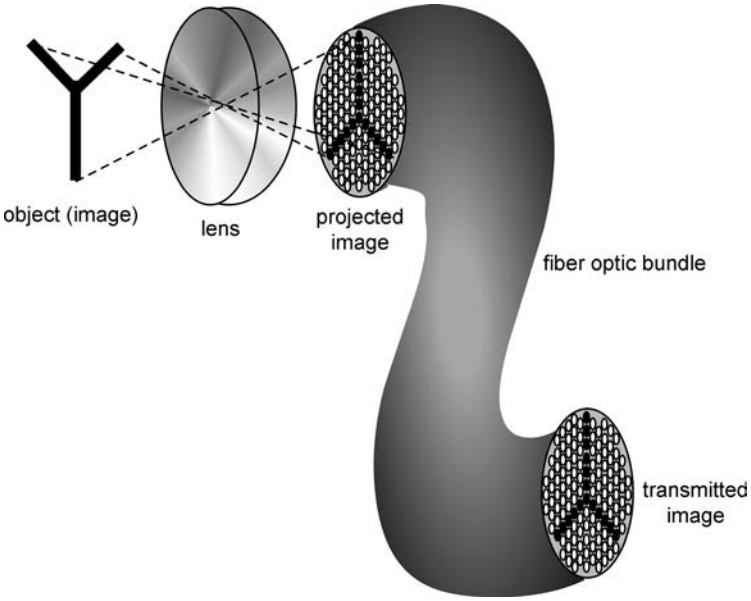

Figure 6.13 Fiber optic bundle (thousands of optical fibers are arranged in a bundle).

oriented so that the top of the object at one end corresponds to the top of the object at the other end (Figure 6.13). A lens focuses the image at the distal end and a magnifying lens enlarges the image at the eyepiece. Light is transmitted from a remote light source so that there is no heat at the end of the scope. The resolution of a fiber-optics endoscope is limited to about 100.000 pixels depending on the number and kind of bundled fibers (leading to an optical resolution of 1 pixel per fiber).

Video Endoscope The electronic video endoscope is based on a rigid or flexible endoscope and uses a computer chip camera as an imaging device. The most important part of the camera is a CCD or a CMOS sensor. These sensors convert the optical image into an electronic signal that is transmitted via wires to an external microprocessor, whose circuitry converts the signal to a video image, which is then processed and displayed on a high-resolution monitor.

CCD or CMOS sensors are composed of millions of photodiodes or photogates (Figure 6.14b), which convert photons into electric current that is later transformed into voltage, amplified, and converted to a digital form.

The signal path for a single pixel is as follows:

$$\text{photons}(\text{ph}\ \ \text{s}^{-1}) \Rightarrow \text{photocurrent}(\text{A}) \Rightarrow \text{charge}(\text{column}) \Rightarrow \text{voltage}(\text{V}).$$

CCD chips have a photoactive (photodiodes/photogates, Figure 6.14b) and a transmission region (yellow arrows in Figure 6.15). An image is projected through a lens on to the photoactive region, and each capacitor accumulates an electric charge proportional to the light intensity at that location. A control circuit then causes each photoactive region to transfer its contents to its neighbor. This circuit operates as

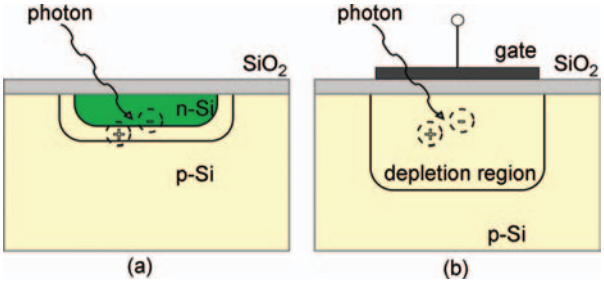

Figure 6.14 Schematic of (a) a photodiode and (b) a photogate of one silicon pixel from a CCD/CMOS image sensor (+ represents a hole and − an electron) (adapted from [11]).

a shift register (the original task of a CCD), transferring the electric charge sequentially, row by row, column by column, to a common output structure that converts the charge to a voltage. The color accuracy of the CCD camera allows enhanced visualization of reproduced images. Other advantages of the CCD camera are the improved resolution and quality of the images achieved when three chips are present (one each for red, blue, and green light). Most small endoscopes use a single chip in which these color distinctions are created by filters (e.g., Bayer filter).

CMOS chips, likewise, are capable of electronic registration of images projected on to their surface through the lens of a camera, and also provide image capture to a grid of pixels formed by photoelectric elements. The resultant electric charges are "read" by a sensor (Figure 6.15) and a process of analog-to-digital signal conversion is required to produce images that can be stored. In a CMOS sensor – in contrast to the CCD – each pixel acts as its own independent amplifier of the image signal, which limits noise as the charge-to-voltage conversion takes place within each pixel. However, these sensors are (still) less sensitive and noisier than CCDs. On both types of chips, the information is transferred to a controller box for image presentation or storage.

In comparison with CCD sensors, CMOS technology offers improved integration (more functions on the chip), lower energy consumption, faster processing, less heat

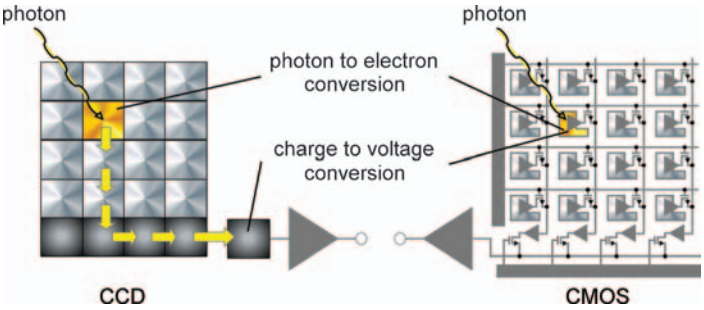

Figure 6.15 Schematic of CCD and CMOS image sensor arrays. CCDs (left) move photogenerated charge from pixel to pixel and convert it to voltage at an output node; CMOS (right) imagers convert charge to voltage inside each pixel (adapted from [11]).

production, and no smear effects. Additionally, CMOS technology requires fewer electronic components, which allows such chips to be smaller and more compact. However, to date, the advantages of CMOS chips often come at the expense of image quality and device cost. CMOS cameras still generally require companion chips to optimize image quality (e.g., to compensate for the lower light sensitivity and rolling shutter effects), which increases costs and power consumption.

Technological developments have allowed the production of CMOS sensors with high energy efficiency, high spatial resolution, high speed, low power consumption, and low cost. In the future, CMOS camera endoscopes might reduce device costs and facilitate the spread of distal sensor endoscopy. Sophisticated new microlenses with tiny gaps between them appreciably increase the efficiency of CMOS sensor light gathering [12–14].

Video endoscope with proximal camera: Conventional rigid and fiber-optic endoscopes can be converted to a video endoscope with a proximally mounted video camera on the eyepiece (Figure 6.16). Input to this sensor is the light transmitted either through a lens system or through fiber bundles (here the quality of the image is dependent on the quantity and quality of the fiber bundles).

Video endoscope with distal camera: Here the chip camera is mounted directly behind a lens system on the tip (distal) of the endoscope (Figure 6.17) and replaces either the lens system or the viewing fiber optic bundle in fiber-optic endoscopes. The quality of the image is dependent only on the quality of the CCD or CMOS chip (resolution). These image sensors are smaller than 2 mm in diameter. An optical magnification (zoom) can be added. With this technology, resolutions of $\gg$400 000 pixels are typical. The newest processors enhance the image to HD TV 1080i. The

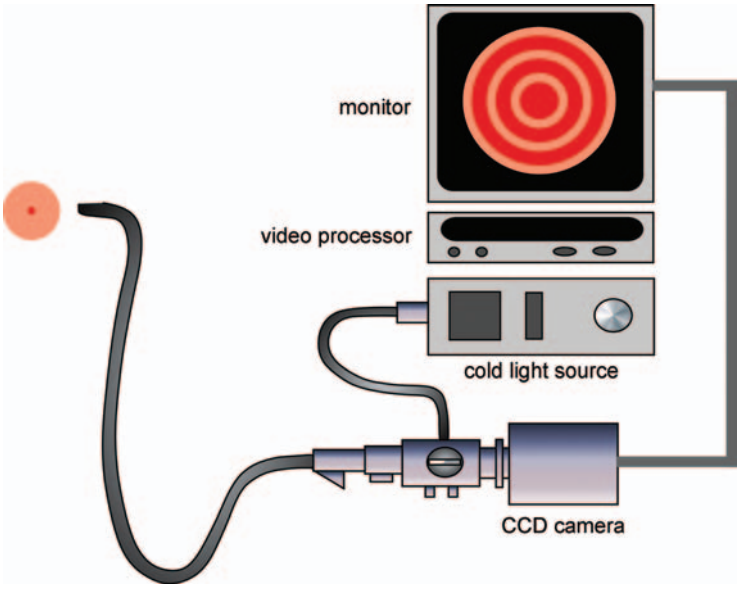

Figure 6.16 Schematic of a video endoscope with proximally mounted video camera.

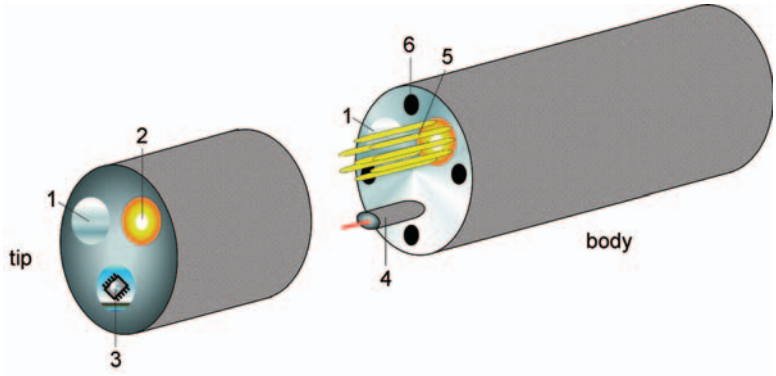

Figure 6.17 Schematic of flexible endoscope with distal mounted camera: 1, working channel/micro tools; 2, light; 3, tip-mounted camera with CCD/CMOS chip and lenses; 4, video cable; 5, light fiber bundle; 6, articulation control wires.

resolution of the newest Pentax CCD chip is 1280×1024 pixels (approximately 1.25 million pixels) and displays at native resolution [15].

High-resolution endoscopes are partly equipped with an optical zooming facility comprising a movable motor-driven lens in the tip of the scope that, controlling the focal distance, can move very close to the surface providing the magnified image. These scopes – magnification endoscopes – are referred to as magnifying endoscopes and increase the level of magnification, discriminating detail so that suspicious small lesions in the unmagnified overview image can be detected, reducing the surface area that is visualized [16].

The images can be further enhanced by the topical application of stains or pigments such as methylene blue, indigo carmine, and acetic acid, a technique known as enhanced magnifying endoscopy [17].

Capsule Endoscopy Esophageal capsule endoscopy is a new and exciting technique that uses a dual-camera wireless capsule endoscope [10], which offers an alternative approach to visualize the esophagus without the need for sedation, and without the discomfort and risks of conventional endoscopy. This technique may be helpful in finding the source of bleeding, pain, or other symptoms that may be coming from the small intestine, but it is also useful for looking at the colon and other parts of the body [18].

Capsule endoscopes are approximately 2.6 cm in length, the size of a large pill. The approved capsule [19] had a camera at one end that took two images per second as the capsule traveled through the digestive tract. The capsules were propelled from the mouth to the anus by the peristalsis of the digestive tract, and the images were transmitted to a recorder worn by the patient. Approximately 50 000 images were collected during the 8 h that the capsule was traveling through the body, and these were then downloaded to a computer. The associated computer program was configured to erase duplicate images, so that if the capsule was in

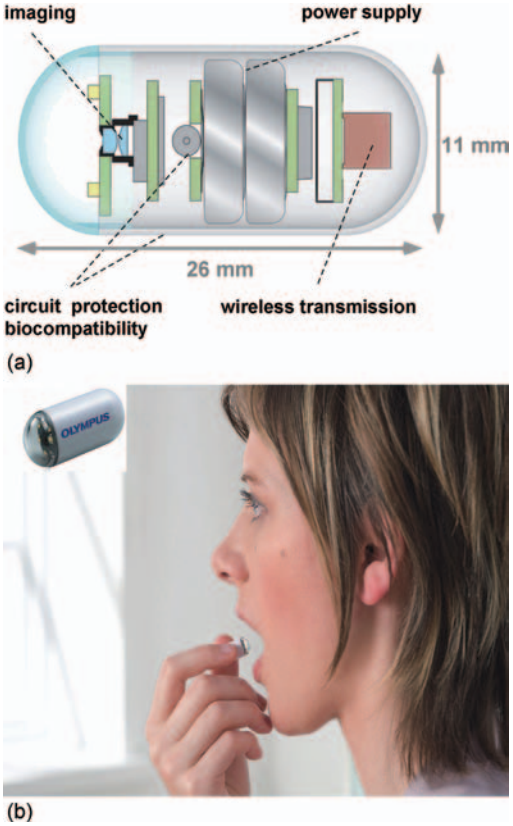

Figure 6.18 Capsule endoscope (Olympus EC Type 1). (a) Schematic diagram of the capsule endoscope; (b) the capsule endoscope and its ingestion.

one location for 15 min, not all of the images from that location would be downloaded. Figure 6.18 shows the scheme and the newest Olympus capsule endoscope.

Behind real-time monitoring of the capsule's transition, a system-integrated workstation contains software with overview and express viewing functions to shorten the time spent analyzing results (Figure 6.19). These functions are based on analysis of the motion grade between consecutive images to help decrease the number of redundant images for more efficient analysis (Olympus WS-1).

However, many of the already performed outcome studies have potential biases and confounding and do not provide sufficient evidence to determine the effect of capsule endoscopy on patient health outcomes. The use of capsule endoscopy of the colon allows visualization of the colonic mucosa in most patients, but its sensitivity for detecting colonic lesions is (so far) lower than with the use of optical colonoscopy [20].

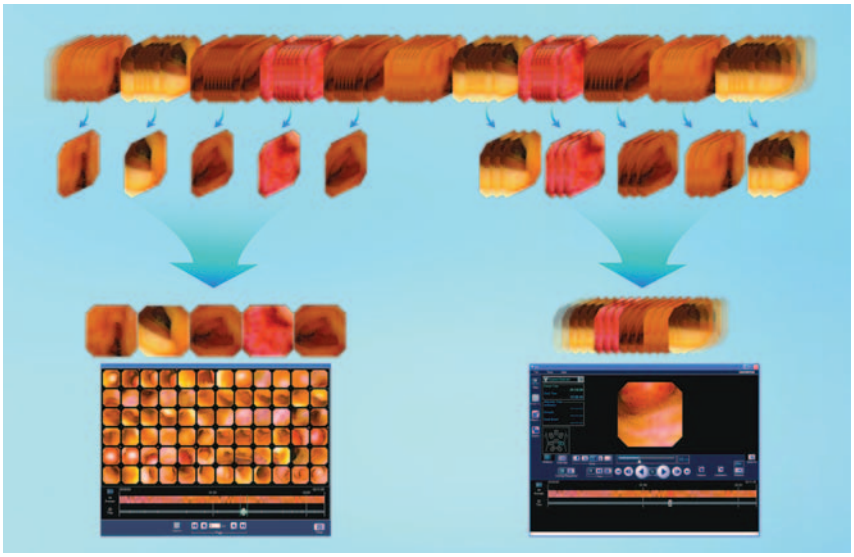

Figure 6.19 Workstation (Olympus WS-1) with overview and express-viewing facilities to optimize analyzing efforts.

6.1.2.3 **Advantages and Disadvantages of Endoscopy**

Advantages are:

- Enhances diagnostics (direct viewing interior of an organ often improves determination of the cause of disease or complication and is very helpful in establishing a diagnosis).
- Minimum stress and mortality.
- Faster recovery after intervention.
- Offers parallel interventions (e.g., biopsy probe sampling, endoscopic ultrasound).

Disadvantages are [21]:

- Requires rather expensive equipment and specialized setup.
- Biopsies are usually adequate but not as good as full thickness.
- Cannot examine every part of the organ (depending on diameters and bending radius) and lesions and other problems may be beyond the reach of the endoscope.
- Cannot determine if an ulcer is going to rupture or bleed.
- There is a small chance of herniation of abdominal contents after laparoscopy.
- There is always the possibility of the introduction of an unsterilized instrument into the body.
- Inexpert handling of the endoscope may lead to a punctured organ with variable effects.

- Reactions to the sedation can occur, although they are rare. For this reason, breathing, blood pressure, heart rate, and oxygen level have to be monitored during endoscopy.

6.1.2.4 **Application Fields**

The following conditions and illnesses are most commonly investigated or diagnosed with an endoscope:

- breathing disorders
- chronic diarrhea
- incontinence
- internal bleeding
- irritable bowel syndrome
- stomach ulcers and helicobacter
- urinary tract infections.

The choice of endoscope depends on which part of the digestive tract is to be examined. Some types of endoscopes and the areas of the body that they are used to view are listed in Table 6.1.

6.1.2.5 **Combination of Standard White Light Endoscopic with Other Diagnostic Methods**

Light interacts with tissue in a variety of ways, including absorption, fluorescence, elastic scattering, and Raman scattering. These interactions enable a number of promising technologies to be considered for endoscopic diagnosis. Other diagnostic procedures include cell and tissue sample collection by brush or biopsy forceps.

Some of the most promising newer methods combining with traditional endoscopy are briefly described below.

Fluorescence Endoscopy In contrast to the anatomical information provided by white light endoscopy (based mainly on the analysis of reflected light), fluorescence imaging provides biochemical and metabolic information [23] (Figure 6.20).

The principle of fluorescence diagnosis is based on the interaction between light at a specific wavelength and fluorophores in tissue. Light sources that can be used include incoherent light sources (e.g., xenon) and monochromatic laser light. When light penetrates tissue, it causes not only reflection and absorption, but also fluorescence. Depending on the fluorophore used, only light at a specific wavelength is maximally absorbed, and in turn variably emitted. As a result of the stimulation process, blue stimulation light, for example, loses some of its energy and is therefore given off as longer wavelength green or red fluorescence [24] (Figure 6.21). "Color differences" between, for instance, normal and neoplastic tissue arise here as a result of endogenous and exogenous fluorophores [25].

Fluorescence endoscopy is a wide-area imaging technique, with the ability to examine rapidly a large surface area of various organs such as gastrointestinal mucosa, bladder, or lung to detect small areas of dysplasia or cancer. It has potential in diseases such as Barrett's esophagus, ulcerative colitis, and gastric cancer, in which

Table 6.1 Types of endoscopes and their applications [18, 22].

Type of endoscope	Insertion	Body area(s) examined	Name(s) of procedures
Arthroscope	Incision near joint	Joints	Arthroscopy
Bronchoscope	Mouth or nose	Trachea (windpipe) and bronchi (tubes inside the lungs)	Bronchoscopy, flexible bronchoscopy
Capsule endoscope	Mouth	Upper and lower gastrointestinal tract	Capsule endoscopy
Colonoscope	Anus	Colon (large intestine)	Colonoscopy, lower endoscopy
Colposcope	Vagina	Vagina, cervix, and vulva	Colposcopy
Cystoscope	Urethra	Bladder, urethra, urinary tract, uteral orifices, and prostate (men)	Cystoscopy, cystourethroscopy
Esophagogastroduodenoscope	Mouth	Esophagus (swallowing tube), stomach, and duodenum (first part of small intestine)	Esophagogastroduodenoscopy (EGD), panendoscopy, upper endoscopy, gastroscopy
Hysteroscope	Vagina	Inside uterus	Hysteroscopy
Laparoscope	Incision(s) in abdomen	Space inside abdomen and pelvis	Laparoscopy, peritoneal endoscopy
Laryngoscope	Mouth or nose	Larynx (voice box)	Laryngoscopy
Mediastinoscope	Incision above sternum (breastbone)	Mediastinum (space between the lungs)	Mediastinoscopy
Nasopharyngoscope	Nose	Nasal cavity, maxillary sinus, nasopharynx, vocal cords	Nasopharyngoscopy
Neuroendoscope	Small incision, opening in the skull, supraorbital	Skull, brain, and spine	Neuroendoscopy
Otoscope, auriscope	Ear	Outer and middle ears	Otoscopy
Sigmoidoscope (flexible sigmoidoscope)	Anus	Rectum and sigmoid colon (lower part of large intestine)	Sigmoidoscopy, flexible sigmoidoscopy, proctosigmoidoscopy
Thoracoscope	Incision(s) in chest	Pleura, pleural spaces, mediastinum, pericardium	Thoracoscopy, pleuroscopy

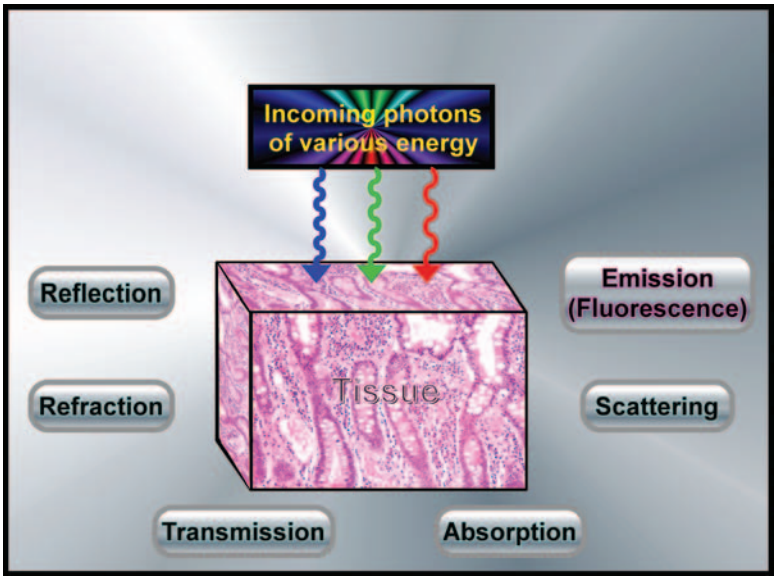

Figure 6.20 Interaction of light with tissue.

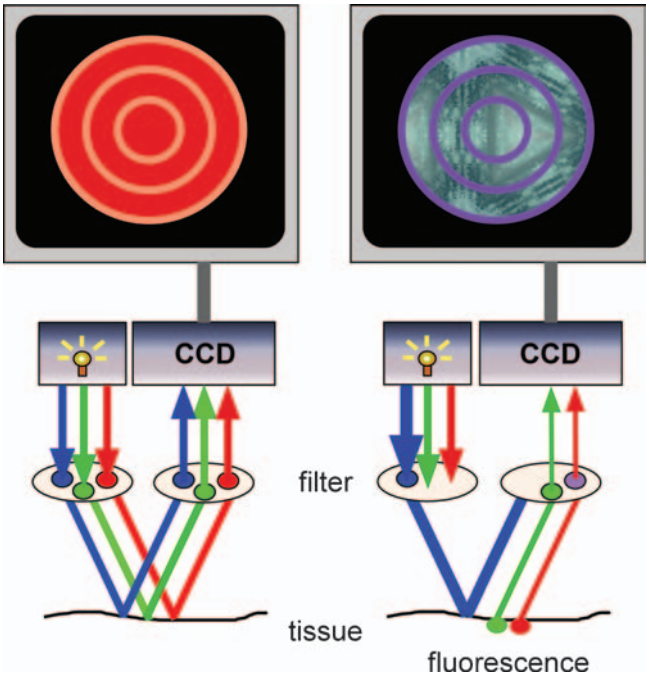

Figure 6.21 Schematic of fluorescence endoscope (adapted from [23]).

large areas of mucosa may harbor areas of dysplasia or superficial cancer not visible on conventional or high-definition white light endoscopy [26].

Fluorescence spectroscopic techniques are classified into two main types: autofluorescence diagnosis (using endogenous fluorophores), which utilizes inherent tissue autofluorescence, and photodynamic diagnosis (PDD) (exogenous fluorescence) using fluorescent drugs called photosensitizers, which react to various wavelengths of light [24].

When tissue is illuminated with UV or short-wavelength visible light from a laser source or a filtered lamp, fluorescence light of a longer wavelength is emitted by endogenous molecules (fluorophores) within the tissue. This "autofluorescence" arises from several components of connective tissues (collagen, elastin), cellular metabolism-related coenzymes, aromatic amino acids, by-products of heme biosynthesis, and lipopigments. Different excitation wavelengths activate different groups of fluorophores, each of which emits in a different range of wavelengths.

As their excitation and emission bands are fairly broad and often show spectral overlapping, it is still difficult to distinguish between these fluorophores. It is only when a suitable stimulation wavelength is selected that the individual fluorophores causing autofluorescence can be distinguished. A number of different pathological processes (neoplasias, inflammation, and ischemia) affect the metabolic, oxidative condition of the cells and thus their autofluorescence [24].

In contrast with autofluorescence, various exogenous photosensitizers (e.g., porphyrins) are used when fluorescence is induced by a drug in the PDD technique. However, the use of exogenous substances that produce a stronger and clearer fluorescence signal because of comparatively specific accumulation also has some disadvantages. In addition to the necessity to administer a chemical substance to the patient, it is often associated with brief but non-negligible photosensitization of the skin, so that the patient needs to be protected from sunlight for about a day [27].

The detection of abnormal lesions with autofluorescence depends on changes in the concentration or depth distribution of the endogenous fluorophores, changes in the tissue microarchitecture, or both, including altered mucosal thickness or blood concentration, that can affect the fluorescence intensity or spectrum because of wavelength-dependent light absorption. With exogenous fluorophores, lesion detection is based on selective drug uptake or retention by a target tissue relative to the uptake by normal tissue.

Endomicroscopy The Pentax confocal laser endoscope [28] and the Leica FCM1000 endoscopic confocal microscope (especially for animal experiments) [29] represent a fusion of endoscopy and confocal microscopy.

The components of a confocal laser endoscope are based on the integration of a confocal laser microscope in the distal tip of a conventional video endoscope, which permits confocal microscopy in addition to standard video endoscopy. The diameter of both the distal tip and the insertion tube is less than 13 mm. The distal tip contains an air and water jet nozzle, two light guides, an auxiliary water jet channel (used for topical application of the contrast agent) and a 2.8 mm working channel. Actuation of

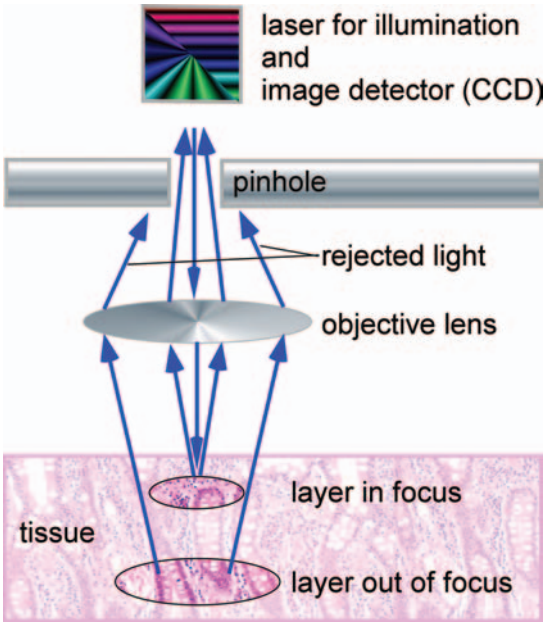

Figure 6.22 Schematic of confocal laser optical unit.

the imaging plane depth relative to the surface of the tissue is controlled using two additional buttons on the endoscope control body.

To create confocal images, blue laser light is focused on the desired tissue via the distal end. Applied fluorescent materials are excited by the laser light, and the special confocal optical unit (Figures 6.22 and 6.23) detects exclusively the fluorescing light in an exactly defined horizontal level. This produces high-resolution microscopic images, making it possible to assess structures down to the size of the cell nucleus (Figure 6.24).

In vivo confocal laser endomicroscopy is a newly developed diagnostic tool allowing virtual *in vivo* histology of the mucosal layer during ongoing endoscopy.

Summarizing the features of endomicroscopy, one can state the following characteristics and possibilities:

- *In vivo* microscopy during routine endoscopy.
- Real-time tissue diagnosis.
- Very high precision and correlation with histology.
- Simple pattern classification for diagnosis.
- Detection of neoplasias and *Helicobacter pylori* possible.
- Penetration into deeper layers (0–250 μm).
- Cell nucleus can be imaged in conjunction with topical staining.
- Vascular morphology can be assessed.
- Tissue can be examined over a greater area.
- No substantial material consumption (stains).

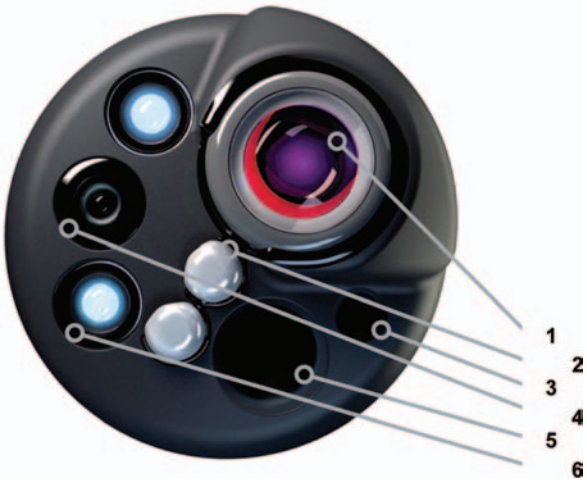

Figure 6.23 Distal part of a confocal laser endoscope [28]: 1, confocal microscope; 2, air/water nozzles; 3, water jet; 4, objective lens; 5, instrument channel; 6, light guide.

- Future (currently the only) technology platform for gastrointestinal molecular fluorescence markers.

The potential benefits can be summarized as follows:

- Early, improved tumor detection in a curable stage as a promising strategy for reduction of tumor mortality.
- Fewer conventional biopsies thanks to specific "smart biopsy."
- Optimized work processes in endoscopy (e.g., immediate therapeutic decision).
- Incorporation of progress from the fields of immunology and genomics in endoscopy (molecular markers).
- Efficient use of new, specific therapeutic measures (e.g., microscopic/molecular monitoring of efficacy).

Endoscopic Ultrasound Diagnostic procedures include the use of ultrasound-equipped endoscopes to evaluate blood flow or provide imaging of lesions. Endoscopic ultrasound can provide information (e.g., the depth and extent of lesions) that is not available via conventional endoscopy. Endoscopic ultrasound is increasingly used to assess gastrointestinal and lung diseases [30].

Further Approaches Chromoendoscopy still holds a place for detecting especially flat lesions in high-risk patients such as those with ulcerative colitis. Digital chromoendoscopy techniques such as narrow-band imaging (NBI), i-scan, and Fuji intelligent chromoendoscopy offer new possibilities of easily and reversibly obtaining enhanced tissue contrast. Autofluorescence imaging uses tissue function to yield a pseudocolored image, and has the potential to serve, for example, as a red flag technique for the detection of neoplastic lesions [31].

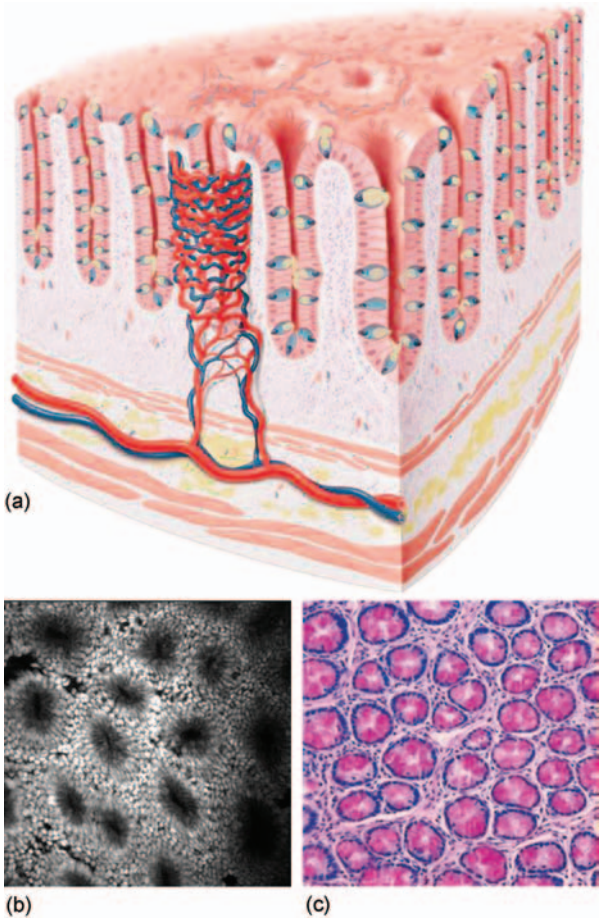

Figure 6.24 Colorectal cancer: screening with PENTAX 3618 endomicroscope. (a) Scheme of a horizontal slice; (b) conventional histology, horizontal slice; (c) endomicroscopy, horizontal slice (images courtesy of Uniklinik Mainz/Kiesslich).

Reflectance spectroscopy is an emerging technology which provides rapid and safe evaluation of tissue for dysplasia and ischemia. The probe-based devices can be passed through most endoscopes. Current applications include detection of dysplasia in Barrett's esophagus, colitis, and colon polyps [32].

6.1.2.6 **Some Trends in Endoscopy**

Colorectal cancer (CRC) is the second leading cause of cancer death, after bronchial carcinoma, in the West. Current estimates suggest that the disease affects in excess of 22 000 and 148 000 people annually in the UK and the US, respectively, where 50% die as a consequence of their disease [33]. New data suggest that early-stage disease (if diagnosed correctly in time) can be treated with "curative intent" using novel endoluminal resection techniques such as endoscopic mucosal resection (EMR)

and endoscopic submucosal dissection (ESD). Furthermore, novel adjunctive endoscopic imaging technology in the form of high-magnification endoscopy, colonic chromoscopy, confocal laser scanning endomicroscopy, NBI, "mini probe" endoscopic ultrasound, and autofluorescence now offer the endoscopist an unparalleled choice of diagnostic tools that improve early recognition of, for example, neoplastic disease and in general allow accurate *in vivo* morphological and now histopathological interpretation, in addition to "on-table" staging to enhance patient selection for further endoscopic surgical treatment. These technologies will be partly combined in the near future and enhanced by applying sophisticated imaging and image processing techniques.

NBI dramatically improves the detection of premalignant and early neoplastic lesions, particularly in combination with magnifying endoscopy. This allows the endoscopist to accomplish accurate diagnosis and better targeting of biopsy and improved and more appropriate treatment, and thereby contribute to optimal quality of life and patient survival [34].

Huang *et al.* [35] introduced integrated Raman spectroscopy and trimodal (white light reflectance, autofluorescence, and narrow-band) imaging techniques for real-time *in vivo* tissue Raman measurements with endoscopy. A special 1.8 mm endoscopic Raman probe with filtering modules was developed, permitting effective elimination of interference of the fluorescence background and silica Raman in fibers while maximizing tissue Raman collections. They demonstrated that high-quality *in vivo* Raman spectra of the upper gastrointestinal tract can be acquired within 1 s or less under the guidance of wide-field endoscopic imaging modalities, greatly facilitating the adoption of Raman spectroscopy into clinical research and practice during routine endoscopic inspections.

Advances in optical coherence tomography (OCT) may lead to a new class of endoscopic, image-guided therapies that target disease with microscopic precision. Fibered OCT in conjunction with natural orifice transluminal endoscopic surgery (NOTES) could provide a facility for rapid, *in situ* pathological diagnosis of intraperitoneal tissues in a truly minimally invasive fashion [36].

Further enhancements in software technology and image processing will lead to 3D surface reconstruction from endoscopic images [37] in combination with 360° forward life view (augmented reality) [38] and additionally displayed patient data for optimum (and automatic) navigation.

Lasher *et al.* [39] applied spatial modeling and analysis of living cardiac tissue based on 3D image data obtained by scanning confocal microscopy. For that purpose, they developed a novel method for the local delivery of fluorescent dye and labeling of cardiac tissue, which they characterized with standard inverted and catheter-based confocal microscopy systems. They introduced a methodology to process stacks of microscopic images and applied it to obtain detailed spatial models (Figure 6.25) and quantitative data on cardiac microstructure. These models and data promise to constitute an important input for tissue characterization and computational modeling of cardiac function.

Further, molecular imaging is a rapidly growing new discipline, for instance in gastrointestinal endoscopy. It uses the molecular signature of cells for minimally

Figure 6.25 Three-dimensional model of ventricular tissue shown from endocardial surface. The model includes 11 complete myocytes and 11 partial myocytes (scale: 50 mm) (courtesy of University of Utah, Salt Lake City/Sachse and © 2009 IEEE [35]).

invasive, targeted imaging of gastrointestinal pathologies. Molecular imaging comprises wide-field techniques for the detection of lesions and microscopic techniques for in vivo characterization. Exogenous fluorescent agents serve as molecular beacons and include labeled peptides and antibodies, and probes with tumor-specific activation. Most applications have aimed at improving the detection of gastrointestinal neoplasia with either prototype fluorescence endoscopy or confocal endomicroscopy, and the first studies have translated encouraging results from rodent and tissue models to endoscopy in humans. Even with the limitations of the currently used approaches, molecular imaging has the potential to impact greatly on future endoscopy in gastroenterology [40].

Virtual endoscopy is an imaging test. It uses a special computed tomography (CT) (or other modality) scan to look at the inside surfaces of organs such as the lungs (virtual bronchoscopy) or colon (virtual colonoscopy, also called CT colonography). Patients have the procedure just as they would any other CT scan – that is, they lie still on a table while a large ring (the CT scanner) passes over the part of the body being imaged. Unlike normal CT scans, which result in images in two dimensions, virtual endoscopy uses a computer to combine many images to create a 3D picture. Doctors can even use the images to create a black-and-white "fly-through" view on the screen, which looks much like it would if they were performing an actual endoscopy.

In recent years, endoscopic image quality has improved as the devices have advanced technologically. Although techniques such as chromoendoscopy, high-resolution and magnification endoscopy, narrow-band imaging, and autofluorescence imaging improve the visualization and detection of mucosal and other lesions, biopsy of the targeted lesion must still be performed for a formal histological diagnosis of cellular and architectural atypia. It would be ideal if a definite diagnosis could be made during endoscopy without a biopsy.

Virtual endoscopy has some advantages over standard endoscopy in that it is noninvasive and does not require any type of anesthesia. It also allows the doctor to change the angle or magnify the image, which can help with diagnosis. However, there are also some disadvantages. Although virtual endoscopy does show good detail, it is not quite as good at showing fine detail as standard endoscopy (for example, it cannot show color differences). It also exposes the patient to some radiation – about the same amount as a standard CT. Finally, because it is not invasive, it does not allow the doctor to take biopsy samples while it is being done. This means that if something abnormal is found, the patient may still need a standard endoscopy so that a biopsy sample can be taken.

6.1.3
Noninvasive Diagnostics – Photoplethysmography

6.1.3.1 Introduction

Photoplethysmography (PPG) is an optical measurement technique that can be applied to determine changes in blood volume in the microvascular bed of body tissue. It utilizes the optical characteristic of blood to absorb light strongly. It is applied on the surface of the skin, usually a finger tip or an earlobe, and working with light in the visible or NIR spectrum [41]. Therefore, it is an absolutely noninvasive and nonhazardous method.

There is a wide range of clinical applications, most commonly pulse oximetry to monitor blood oxygen saturation, but also various diagnostic methods to assess the cardiac and the vascular system. The technical effort and its handling are relatively small and simple compared with other assessment techniques such as vascular catheter or CT. Basically, the technical equipment consists of only two optical elements: a light source to illuminate the region of interest and a photodetector to measure the intensity variations of light beyond the volume. This correlates with the changes in blood volume in the examined body part, representing the peripheral pulse wave and therefore providing information about the cardiovascular system.

6.1.3.2 Characterization of the PPG Signal

The PPG signal consists of a pulsatile component, the AC component that results from the small variations in the blood volume during a heart period and a DC component that is related to the tissues surrounding the vessel and the basic average blood volume.

Hertzman, who was one of the pioneers in the field of PPG, and Spealman first described the characteristics of the pulse wave form in 1937 [42]. They defined two phases, first the rising edge of the pulse associated with the systole, and second the falling edge of the pulse associated with the diastole and the peripheral wave reflections (Figure 6.26). Also a dicrotic notch in the second phase is typical for subjects with normal compliance of arteries. The DC component can also vary, mainly due to respiration and vasomotor activities.

In several studies on the ability of PPG to assess the vascular system, many features of the pulse wave form have been investigated, such as the rise time, the pulse-transit

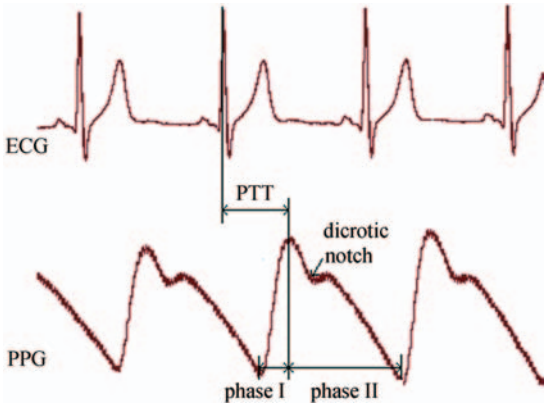

Figure 6.26 Typical PPG signal and extracted parameters in relation to ECG.

time (PTT) [time from the R wave in simultaneous electrocardiogram (ECG) recording to the maximum amplitude of pulse wave], the amplitude and shape, and also the variability of these parameters [43].

6.1.3.3 Signal Acquisition

Several studies [44–46] have found that the main factors affecting the amount of light received by the optical detector are the following:

- blood volume
- movement of blood vessel walls
- orientation of the red blood cells.

Another important aspect is the choice of wavelength that is used. There are three limiting considerations:

1) The optical characteristics of water, which is the main constituent of body tissue, need to be considered. It absorbs light strongly at the UV and long infrared (IR) wavelengths and therefore inhibits the light from passing on to the blood vessels. At the visible and NIR wavelengths the absorption of water is weaker, hence these wavelengths are usually used for PPG [47].
2) The isosbestic wavelengths play an important role, especially for the measurement of blood oxygen saturation. At these wavelengths compared with others there is no significant difference in the absorption between oxyhemoglobin and reduced hemoglobin. Hence the PPG signal is independent of the amount of oxygen in the blood volume [48].
3) The tissue penetration depth is also dependent on the operating wavelength [49]. It has been proven that light with longer wavelength can penetrate deeper into the tissue than light with shorter wavelength; for example, for a wavelength of 600 nm the penetration depth is 0.55 mm, whereas for a wavelength of 1000 nm it is 1.5 mm [50].

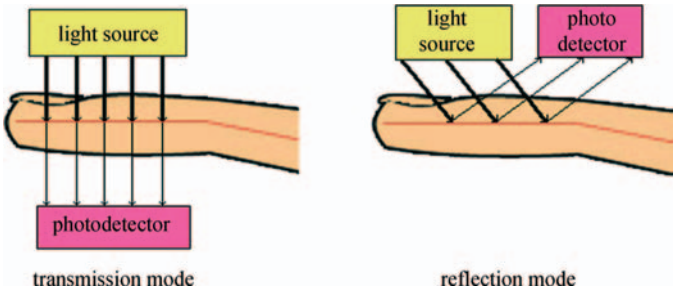

Figure 6.27 The principle of transmission mode and reflection mode.

Modern PPG sensors are usually built with semiconductor technology with LED and photodetector devices working at the red and NIR wavelengths (600–1000 nm). LEDs have several advantages compared with conventional illuminants:

- a narrow bandwidth
- compactness and robustness
- long operation time
- relative independence of temperature [51].

There are two different measuring realizations available (Figure 6.27). In the transmission mode, the tissue sample is placed between the light source and the photodetector. Therefore, its application is limited to only very few body parts that are thin enough to pass light. In the reflection mode, the light source and the photodetector are placed on the same side of the sample.

Several requirements have to be met to minimize measurement errors:

- Good contact with the skin.
- Movements between the sample and the sensor should be avoided.
- Probe attachment with a dark cuff and damping light in the measurement area, hence the signal is not influenced by ambient light interactions with the sensor.
- Filtering and artifact reduction by suitable electronic components and signal processing techniques.

6.1.3.4 Clinical Applications

Patient Monitoring – Blood Oxygen Saturation, Heart Rate The development of pulse oximetry is one of the most important improvements in the field of clinical monitoring in the last few decades. It involves the determination of the amount of oxygen in the blood and also the observation of the heart rate. Simple handling and rapid results acquisition allow application in many fields, such as in hospitals and in emergency medical care, and also in sports medicine and veterinary medicine.

For the calculation of the blood oxygen saturation, two different wavelengths are required, one in the red light and the other in the NIR light band. At these wavelengths, the absorption characteristics of oxyhemoglobin (HbO_2) and reduced

hemoglobin (Hb) are different. From the amplitudes at both wavelengths the oxygen saturation (SpO_2) can be calculated:

$$SpO_2 = \frac{HbO_2}{HbO_2 + Hb}. \tag{6.2}$$

To determine the impact of ambient light, a measurement without a signal of the light source as a reference is performed, and the resulting absorption amplitudes are subtracted from the original result of measurement. Usually an empirically derived calibration curve is needed [51, 52].

Since the AC component is synchronous with the heart beat, the PPG signal can be used to provide the heart rate, which is also an important parameter in monitoring of patients. A typical example of a pulse oximeter is shown in Figure 6.28.

Continuous Blood Pressure Measurement The determination of the arterial blood pressure is very important in the monitoring of patients, especially in intensive care units. Usually an invasive catheter is needed to provide this information. However, this method carries some disadvantages for the patient, such as the risk of infection or the dependence on hospitalization. Several studies have shown that a beat-to-beat evaluation of the changes in blood pressure [blood pressure variability (BPV)] is a potential tool for diagnosing cardiovascular diseases and for risk stratification.

The Finapres™ (now Portapres™) device (Figure 6.29) was one of the first medical instruments that provided noninvasive and continuous tracking of the blood

Figure 6.28 Pulse oximeter (Covidien-Nellcor™); transmission mode, display with blood oxygen saturation (left) and heart rate (right).

Figure 6.29 Portapres™ (Finapres Medical Systems BV) blood pressure monitor; inflatable finger cuff and control unit.

pressure wave form. It was developed in the 1980s and is based on the volume-clamp method that was first introduced by Penaz in 1967 [53]. With this method, the finger arterial pressure is measured using a finger cuff and an inflatable bladder in combination with an IR PPG sensor. The IR light is absorbed by the blood and the pulsation of arterial diameter during a heart beat causes a pulsation in the light detector signal. The first step in this method is determination of the proper unloaded diameter of the finger arteries, the point at which finger cuff pressure and intra-arterial pressure are equal. Then the arteries are kept at this unloaded diameter by varying the pressure of the finger cuff. Hence the cuff pressure provides an indirect measure of intra-arterial pressure [53, 54].

In several studies, parameters from the BPV provided by the Finapres were analyzed in order to examine the autonomic regulation system. For example, it was shown that measures from BPV analysis revealed highly significant differences discriminating patients with dilated cardiomyopathy from a reference group [55]. In another interesting study, it was found that the analysis of the baroreflex sensitivity is a potential tool in the prediction of pre-eclampsia, which is the most dangerous complication in pregnancy [56]. For the calculation of the baroreflex sensitivity, the determination of beat-to-beat changes in blood pressure is required. Furthermore, subjects with acute schizophrenia showed a reduction in baroreflex sensitivity (calculated from blood pressure and heart rate) accompanied by tachycardia and greatly increased left ventricular work index [57].

Assessment of the Peripheral Vascular System Arteriosclerosis and the resulting peripheral arterial occlusive disease (PAOD) play a significant role in arterial diseases, especially in elderly patients. It is also correlated with an increased risk of coronary artery disease and stroke. The PPG provides a potential diagnostic method as the peripheral pulse is usually damped, delayed, and diminished according to the stage of disease [58, 59]. In general, this is diagnosed through a site-to-site comparison, mostly performed at the lower limbs. A study by Simonson *et al.* [60] found significant changes in the rise time in impaired arteries. The potential of differences in PTT between the left and the right sides was further stated in recent

studied [61, 62]. It was also shown that frequency analysis of the PPG signal can reveal differences between healthy arteries and those with arteriosclerosis [63]. The shape of the pulse wave also contains diagnostic information. This was proven by Allen and Murray applying a neural network for classification [64]. They also introduced the shape index as a measure of the abnormal distortion of the pulse contour that provided a very high accuracy of >90% [65, 66].

A further new development is the application of photoplethysmography for the determination of the ankle brachial index (ABI). This is usually performed by using two pressure cuffs placed on the upper arm and lower limb (Figure 6.30) and a pocket Doppler ultrasound device. The ABI test is a potential method for the noninvasive assessment of PAOD [67]. Studies have shown a sensitivity of 90% with a corresponding 98% specificity for detecting hemodynamically significant stenosis (diameter of occlusion >50%) in major leg arteries [68]. The Doppler device registers the peripheral pulse while the pressure cuffs are inflated over the artery until the pulse

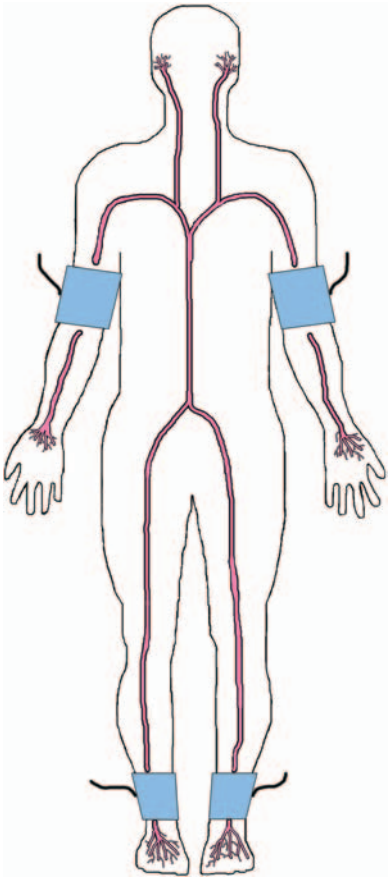

Figure 6.30 The principle of arrangement for measuring ABI.

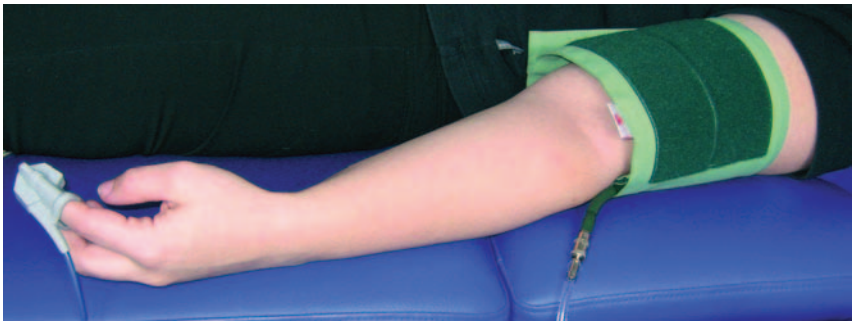

Figure 6.31 Placement of the pressure cuff and the PPG sensor on the left arm for determining the ABI (Vascular Explorer, enverdis GmbH, Jena).

ceases. The cuff is then slowly deflated. The corresponding pressure at the moment the pulse signal returns provides the systolic blood pressure reading for the given artery. A recently developed device (Figures 6.31 and 6.32) uses a PPG sensor instead of the Doppler device to detect automatically the diminishing and return of the pulse wave.

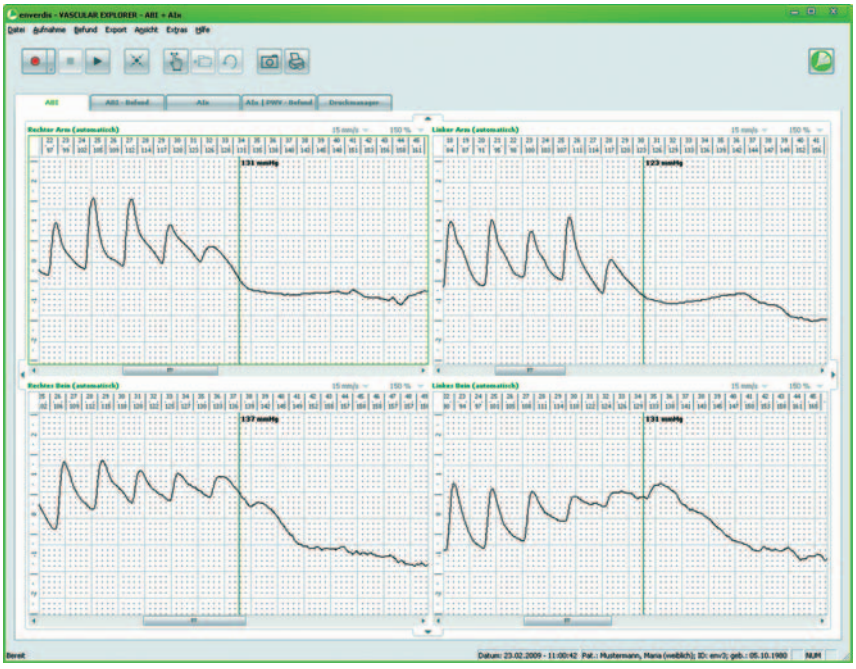

Figure 6.32 Display of the peripheral pulse wave in the measured limb: top left, right arm; top right, left arm; bottom left, right leg; bottom right, left leg. Marker represents the artery occlusion pressure which is the moment when the pulse wave disappears.

Further, chronic venous insufficiency can be detected with PPG by analyzing the DC component. The amount of blood increases in the venous system in a standing position due to the damaged valves in the vessels. This volume increase can be tracked with PPG. This method is also known as light reflection rheography [69, 70].

Assessment of the Microvascular Blood Flow In peripheral tissues, oxygen is distributed by the capillaries to the cells (Figure 6.33). Due to their small diameters, conventional techniques such as angiography and ultrasound are not capable of analyzing these vascular segments. "Tissue photospectrometry" is a technique to provide information on the condition of the microvascular system.

Measurement of the tissue perfusion is important for the assessment of, for example, viability and wound healing. A new technology which is realized in the O2C (Oxygen to See; LEA Medizintechnik, Giessen, Germany) (Figure 6.34) is a multiple-channel system which makes it possible to determine perfusion quantities and oxygen values within different tissue depths. This technology is a combination of laser Doppler spectroscopy for determination of blood flow and white light spectroscopy for determination of blood oxygen saturation and the amount of hemoglobin (Figure 6.35). Laser light determines perfusion quantities in tissue. A Doppler shift is caused by the movement of the red blood cells. This Doppler shift of the detected laser light is analyzed and displayed as the blood flow velocity (laser device class 3 B, protective class I, wavelength 830 nm, power <30 mW). The detected laser signal correlates with the number of moving red blood cells within the tissue. This quantity and the blood flow velocity are used to calculate the blood flow. Different applications

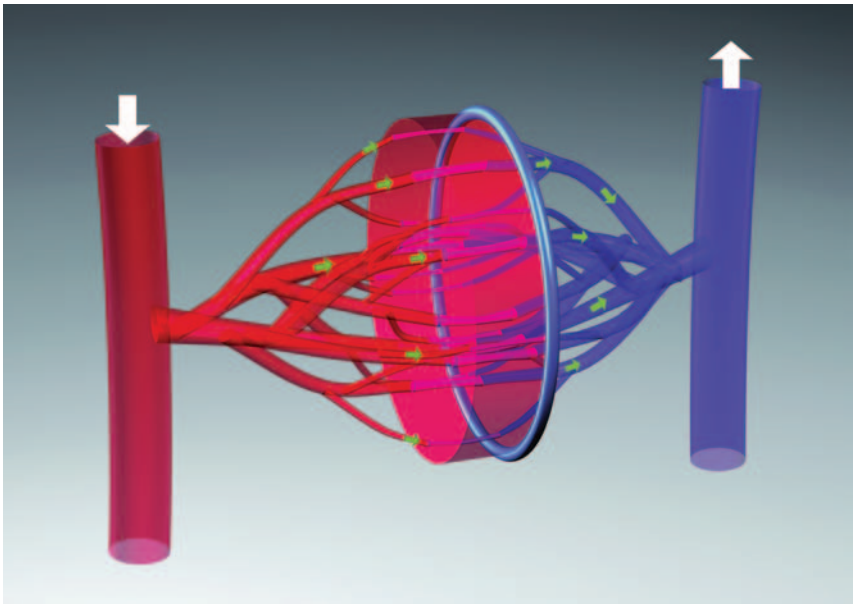

Figure 6.33 The capillary system.

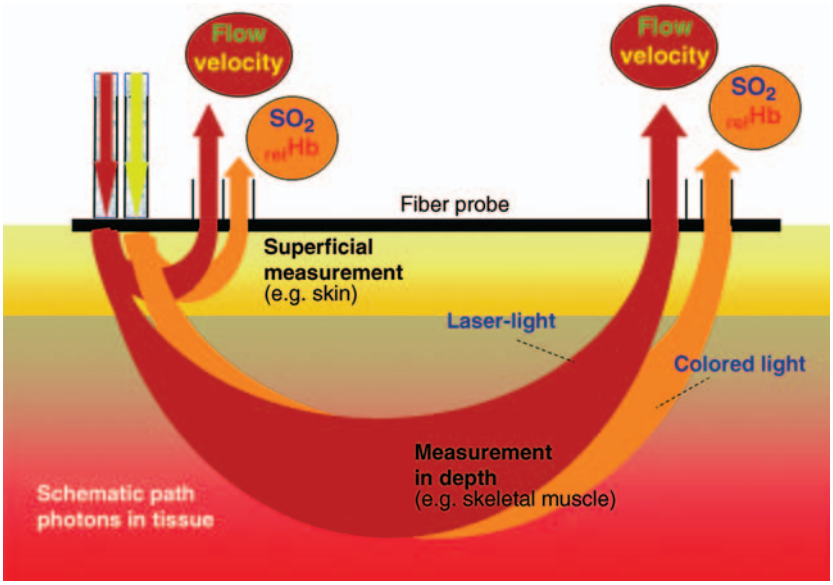

Figure 6.34 Principles of measurement of the microvascular blood flow and oxygen saturation (LEA Medizintechnik, Giessen). The O2C works simultaneously with white and laser light. The light in tissue is scattered at the mitochondria and reflected to the surface. There it is detected and analyzed. The white light allows the determination of the oxygen saturation. The shift in frequency of the laser light carries the information about the blood flow.

at the skin and in internal organs and the intestinal tract are possible using flexible glass fiber probes. Applying this technology allows the assessment of the healing of wounds, for example in patients with diabetic foot ulcers [71]. Another approach showed that the combined use of laser light spectroscopy and PPG allows continuous and noninvasive monitoring of organ reperfusion and oxygen metabolism during simultaneous pancreas–kidney transplantation [72].

Figure 6.35 (a) Display of the O2C: continuous data on oxygen saturation and blood flow over time (top); instantaneous values of oxygen saturation and blood flow in different tissue depth (right); spectrum and observation of signal quality (bottom left). (b) Sensor with white light and laser light source and detection unit.

6.1.3.5 Summary

Photoplethysmography is a technology that has a wide range of applications in the assessment of the cardiac and vascular system. It is a noninvasive, simple, and inexpensive method. The improvements in semiconductor optical components and computer-based signal processing have further increased its abilities. Conclusively PPG has great potential in the field of cardiovascular screening and monitoring of patients.

6.1.4 Noninvasive Diagnostics – Ophthalmology

6.1.4.1 Introduction

Ophthalmology is concerned with diseases and dysfunctions of the human eye, including structures surrounding the eye such as the retina, pupil, iris, vitreous body, and gland of the eye. The human eye is a complex photosensitive organ that enables analysis of the form, light intensity, and reflected light to be performed. Therefore, the eye contains different functional components: a lens system which focuses the image, a nervous system, and a layer with photosensitive cells that collect, process, and assign information to the brain [73]. The structure of the eye is shown in Figure 6.36. The eye consists of three layers, the outer, the middle, and the inner layer. The outer layer includes the cornea and the sclera and the middle layer consists of the iris, ciliary body, and choroid. The inner layer consists of the retina (nervous tissue), which is part of the optical nerve system and converts the light in electrical impulses.

The inner layer of the eye can be divided into different compartments: the anterior chamber, posterior chamber, and vitreous chamber [73, 75, 76]. The principle of image formation in the eye is demonstrated in Figure 6.37. A light beam is travels through the cornea, where the light is refracted and passes through the lens.

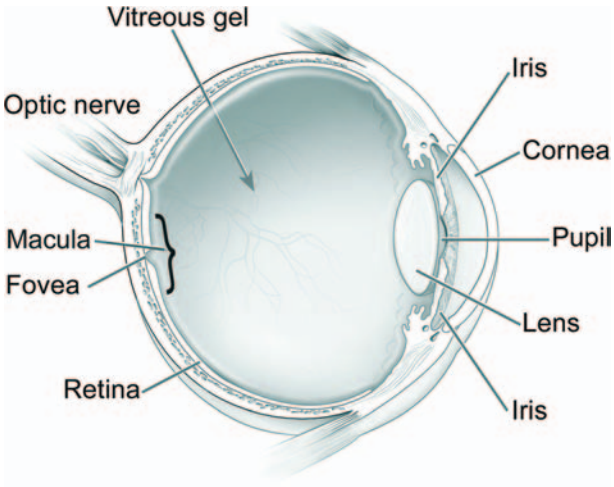

Figure 6.36 Structure of the eye [74].

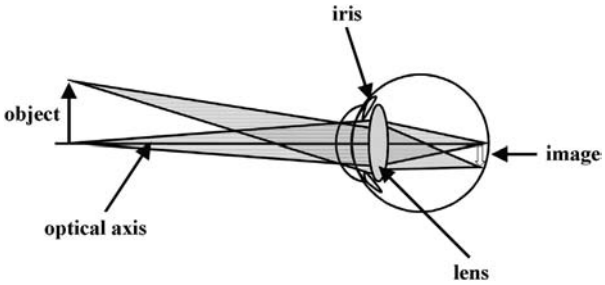

Figure 6.37 Process of a light beam in the eye (adapted from [76]).

The iris is located between the cornea and the lens and controls the size of the incoming light beam by the pupil. The lens focuses the light at the retina. The retina is a light-sensitive tissue where an inverted image of the visual field is formed [73].

Alterations in the eye are related to diseases such as hypertension and blinding conditions generated by glaucoma and macular degeneration [77]. In the following, some of the most important eye diseases are briefly described.

A scotoma is an area of partial or complete blindness within the visual field. The defect ranges from barely detectable loss of visual acuity to absolute blindness. It is due to retinal choroid or optic nerve disorder. There are three types of scotoma: absolute, relative, and scintillating scotoma [78].

A *cataract* is a gradual thickening of the lens that causes the lens to become so clouded that light is either distorted or cannot reach the back of the eye (the retina) for transmission to the brain [79]. It is opacity to different degrees of the lens of the eye [80]. Cataracts are the leading cause of treatable blindness in all areas of the world, especially in adults with an age of 55 years or more [81].

Glaucoma is a progressive disease of the optical nerve. Among other reasons it can be based on increased intraocular pressure (IOP). There are two main types of glaucoma: angle-closure glaucoma and open-angle glaucoma. For open-angle glaucoma, the risk increases with, for example, age over 45 years, family history of glaucoma, diabetes. or low blood pressure, and for closed angle glaucoma it increases with, for example, age over 55 years (especially in females), family history of glaucoma, or the use of certain drugs with cholinergic inhibition [82].

The macula is the part of the eye that is needed for seeing fine detail and central vision. Degenerative changes in the macula results in state known as macular degeneration. The disease is due to no apparent cause and usually occurs after the age of 50 years. The first symptom of macular degeneration is the painless loss of central visual acuity [83].

Keratoconus is characterized by a conical, usually bilateral, central deformation of the cornea with parenchymal opacification and thinning of the cornea. The risk of keratoconus increases with family history of the disease, and women are more likely to be affected than men [84].

There are different methods to diagnose the discussed diseases, outlined below.

One of the simplest methods for examining the anterior eye segmented is the slit lamp. The slit lamp (e.g., Slit Lamp SL 130, Carl Zeiss Meditec, Jena, Germany [85]) is

an instrument that consists of a high-intensity light source that can be focused to shine in a thin beam that is usually combined with a microscope. A variable narrow light beam (e.g., 1–2 mm) is focused on the curved surface of the cornea. This allows an optical section through the clear segments of the eye tissue. The split lamp is used for the examination of ocular tissue and surface, especially corneal injury. If the observer is using various handheld or split lamps equipped with lenses, it is possible to visualize the optic nerve, posterior vitreous, and retina [86].

The following sections discuss some of the common diagnostic methods (e.g., corneal topography, perimetry, scanning laser polarimetry, and wave front analysis) and their applications and give an overview of typical components, advantages, and disadvantages.

6.1.4.2 **Corneal Topography**

Corneal topography or videokeratography (see Figure 6.38) is a method for mapping the surface curvature of the cornea.

The patient is looking into a light bowl that consists of a pattern with concentric rings (placido disc). The light ring of the placido disc (Figure 6.39) shines on to the corneal surface. In the center of the placido disc an aperture measures the reflected rings from the cornea using a CCD camera.

The results are displayed in a color-coded topographic map of the cornea and computer software calculates different parameters characterizing the corneal surface [88–90]. An example of a pupil videokeratoscopic image is shown in Figure 6.40 and a color-coded topographic map is depicted in Figure 6.41 [87, 90].

Figure 6.38 Atlas Model 9000 (Carl Zeiss Meditec, Jena).

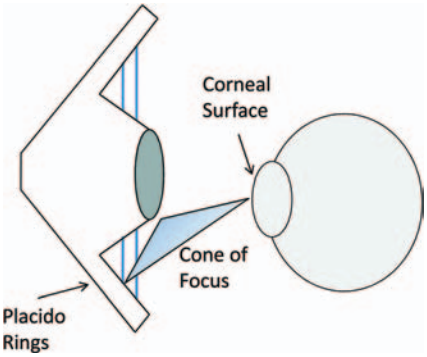

Figure 6.39 Structure of the placido disc with a cone of focus and the corneal surface where the placido rings are projected (adapted from [87]).

Applications Corneal topography is used for fitting contact lenses and identifying distortions such as keratoconus or scarring of the cornea. It is also needed for the evaluation of patients before and after surgical procedures. Another application of corneal topography is the analysis of the degree of corneal steepness [88, 91].

Typical Components of a Corneal Topographer A corneal topographer consists of a placido disc. The placido disc is a flat, lit disc and is composed of a pattern of concentric dark and light rings such as black and white rings. A placido disc can have

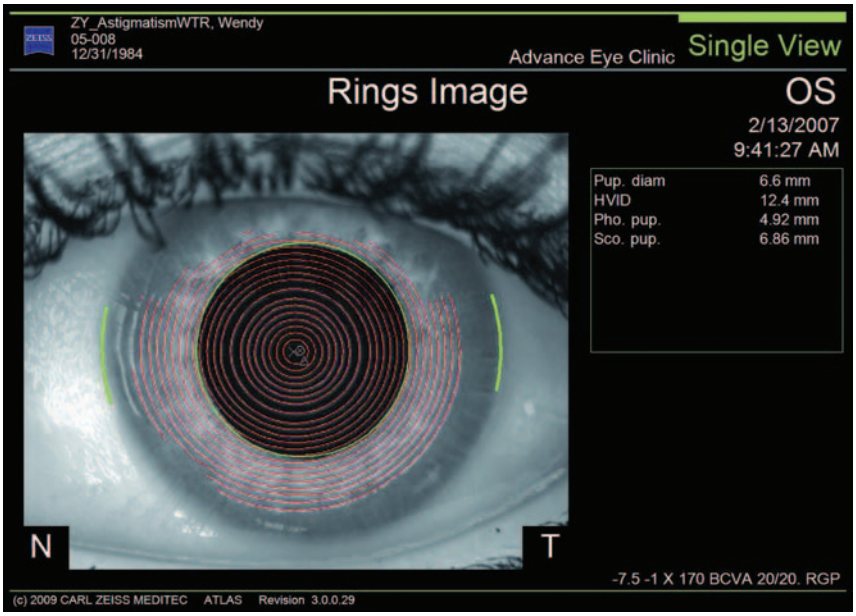

Figure 6.40 Videokeratoscopic image showing the projected rings from the placido disc on the corneal surface.

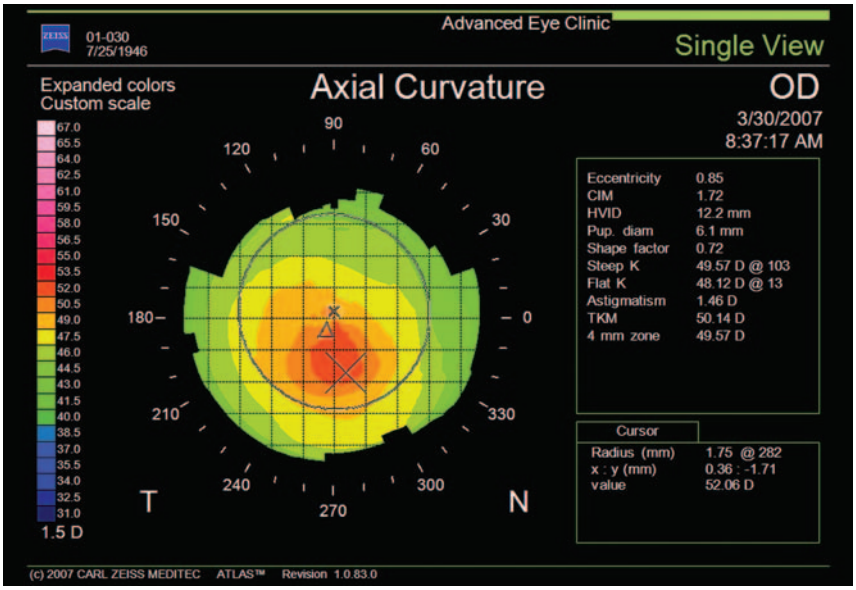

Figure 6.41 A color-coded topographical map displaying the curvature, elevation, and corneal wavefront. Blue represents the flattest area and red the mean steepness.

different sizes (a small or a large placido disc target) depending on the number of rings and the producer. In front of the placido disc the patient is held still by a chin rest. Another component of a corneal topographer is an imaging system with objective lens and a camera recording the reflected pattern of the cornea. The data analysis is performed by a computer system.

There are two approaches concerning the placido disc: on the one hand (I) the use of a large placido disc target and a long working distance to project images of mires on to the corneal surface and on the other (II) a small placido disc target with a short working distance [91, 92].

Corneal topography is a noninvasive, painless, and rapid method. The measurement has the ability to measure directly in the corneal height, detect irregular corneal surfaces, and perform analysis accurately across the whole cornea [91]. Approach I has the advantage of less critical focus whereas approach II has greater potential coverage of the corneal surface [92].

Corneal topography consisting of a large placido disc target and a long working distance (approach I) has the disadvantage of corneal shadows created by the brow and the nose. The disadvantage of the small placido disc target with a short working distance (approach II) is higher sensitivity to errors in focusing [92].

6.1.4.3 **Perimetry**

Perimetry uses different light sensitivities to verify the visual field. Here the patient is seated in front of the bowl and is held still with a chin and head rest. Figure 6.42 shows the principle of perimetry.

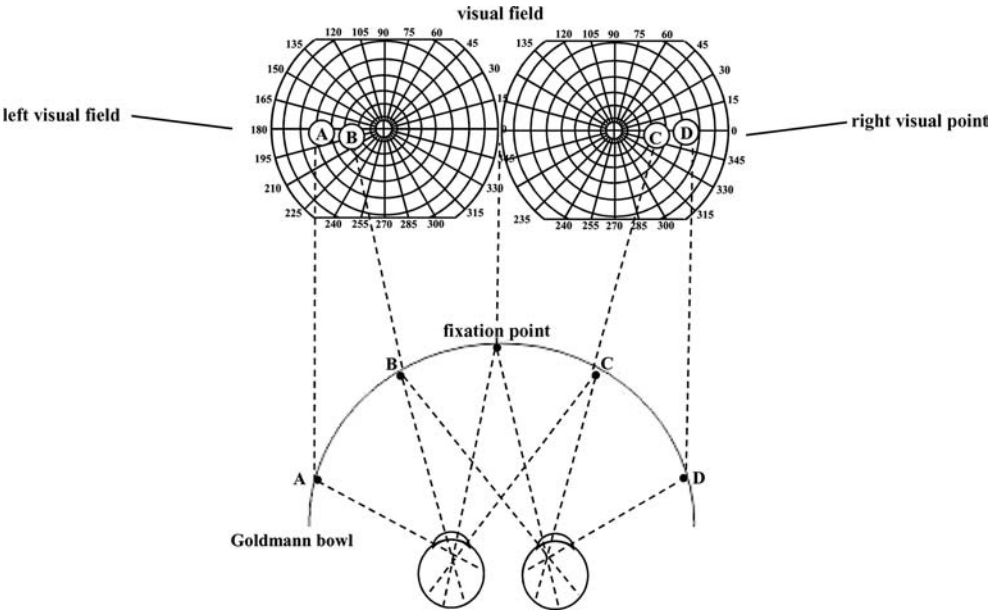

Figure 6.42 Scheme of perimetry with a Goldmann perimeter. The Goldmann chart represents the peripheral boundary of the visual field (adapted from [93]).

A light target is projected on a defined background (Goldmann perimeter). If the patient recognizes the light target he/she presses a button. This procedure is used for many light targets from different peripheral points. These recognized points are then plotted in the graph of the visual field [94].

Perimetry includes kinetic perimetry and static perimetry; both methods can be performed manually or automatically. In recent years, fundamental findings of automatic perimetry were reported [95, 96]. The Humphrey matrix perimeter was developed by Carl Zeiss Meditec AG (Figure 6.43) and is an example of an automated perimeter.

Applications Perimetry is used to explore the boundaries of the visual field, identifying visual abnormalities. Perimetry detects vision loss in the peripheral visual field caused by glaucoma and detects scotomas [97].

Typical Components of a Perimeter The major component of a standard perimeter is a hemispherical bowl with a white surface and a radius of 30 cm (Goldmann bowl). The patient is held still in front of the bowl by a fixation mechanism and in the back of the bowl is a telescope allowing the observer to adjust the patient's position. A light target is projected on to the inside of the white surface and its intensity and size are varied.

The basic equipment of an automated perimeter is a hemispherical bowl or a spherical Goldmann bowl, a patient fixation system such as a chin rest and head rest, a signal button, a monitor (flat-screen monitor) for real-time display, and

Figure 6.43 Humphrey Matrix™ Perimeter (Carl Zeiss Meditec, Jena).

a computer system. The automated perimeter can be used with different software solutions to analyze different states of glaucoma and scotomas, e.g., standard automated perimetry (SAP), frequency doubling perimetry (FDP), and short-wavelength automated perimetry (SWAP). SAP (or the so-called white-to-white perimetry) is the gold standard for testing functional changes in glaucoma. This technique measures light sensitivity thresholds at each retinal location. However, the method is not selective for the detection of particular glaucoma-related retinal ganglion cell (RGC) damage [98]. FDT perimetry is based on a frequency-doubled sinusoidal grating stimulus and was developed to detect damage to magnocellular ganglion cells, which are preferentially affected in glaucoma patients [98–100]. SWAP is used for the early detection of glaucoma. SWAP utilizes a bright yellow background and a large short-wavelength ("blue") stimulus to isolate and measure the sensitivity of short-wavelength chromatic mechanisms. From this basis the sensitivity of the middle ("green") and long ("red") wavelength mechanism is actuated [101].

Kinetic Perimetry A mobile light target (stimulus) is moved by a Goldmann perimeter from a non-seeing area to a seeing area of the visual field. When the spot light is noticed, the patient presses a button. Kinetic perimetry presents the visual field in a topographic map as depicted in Figure 6.44 [95, 102].

Kinetic perimetry is a noninvasive method to characterize an entire peripheral visual field [95].

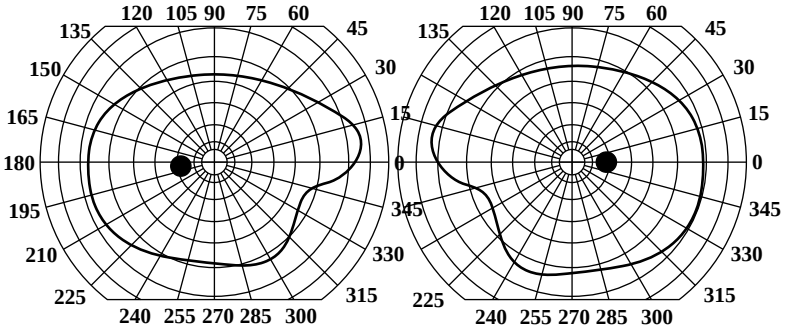

Figure 6.44 Perimetric results of a normal visual field. The optic disc makes a black point on the topographic map which is called the blind spot (adapted from [103]).

The results are dependent on the perimetrist because the exposure time is variable, there are different speeds of movement, and the point location of the stimulus is moved by hand. The measurement of the full field is time consuming, tedious, and requires good patient cooperation [95, 104]. Intensive training is necessary for the application of kinetic perimetry [105].

Static Perimetry Static perimetry is generally an automated method. The intensity and size of a light target will be increased or decreased until the patient notices. That means that the spot light does not move, in contrast to kinetic perimetry [102]. Figure 6.45 presents results for a defective visual field [106].

Static perimetry is a noninvasive method to characterize the central visual field. This computerized method uses a software package for fast data analysis, storage, and comparison with normative data [95]. The tests in static perimetry are performed by a computer, hence the measurements are reproducible, automatically calibrated, and performed under standardized conditions [107].

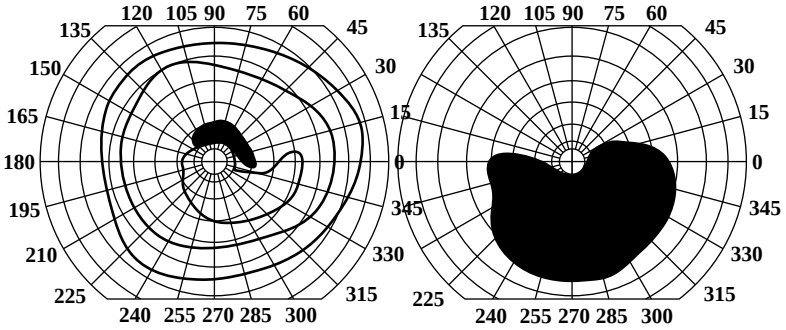

Figure 6.45 Perimetric results of defected visual fields. On the left side is an immediate visual loss and on the right is an advanced visual loss, e.g., due to glaucoma (adapted from [106]).

Static perimetry has increased cognitive demands and lack of flexibility for patients. Automated perimetry has high maintenance and acquisition costs [95, 97].

6.1.4.4 Optical Biometry

Optical biometry is a noninvasive optical biometric imaging technology which is based on the method of partial coherent interferometry (PCI). It measures directly biometric data such as the axial length along the eye's visual axis from the lens to the macula, as shown in Figure 6.46.

The measurement principle of optical biometry using a Michelson interferometer is demonstrated in Figure 6.47. A laser diode generates IR light (wavelength 780 nm) with a short coherence length. The laser beam passes through a beamsplitter, which produces two coaxial beams with mutual time delay by means of the interferometer mirrors (a fixed reference mirror and a moving measurement mirror).

These coaxial beams pass directly into the eye and are reflected on the surface of the cornea and the retina. A PCI signal is detected by a photodetector. The displacement of the moving mirror allows an accurate measurement of the axial length [108, 109]. The IOL-Master measures the anterior chamber depth (ACD), axial length, corneal radius, and white-to-white distance [110] (Figure 6.48).

Applications Optical biometry set a new standard for highly accurate, precise measurements of all ocular characteristics. Three measurements are executed for the calculation of intraocular implant lenses: the axial length of the eye, central cornea curvature, and ACD.

Figure 6.46 Optical biometry system: the IOL-Master (Carl Zeiss Meditec, Jena).

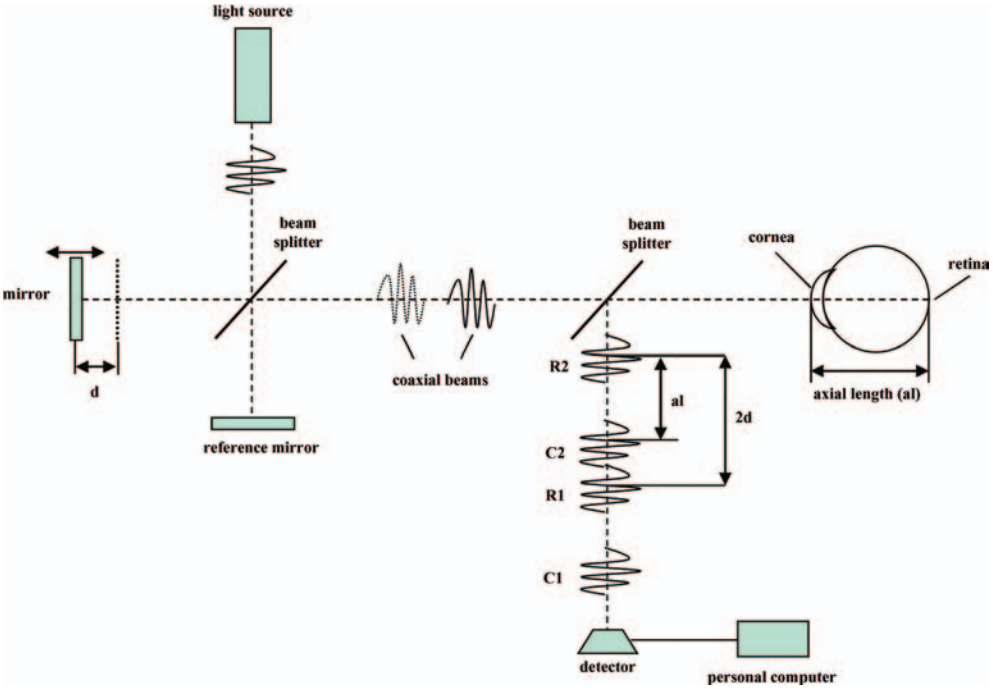

Figure 6.47 Operating principle of the IOL-Master device with a dual-beam partial coherence interferometer. The interferometer generates two coaxial beams with a mutual time delay (interferometer arm length differences *d*). Both coaxial beams pass through the eye and are reflected at the anterior surface of the cornea (C_1, C_2) and at the retinal (R_1, R_2) interface. An interference signal is detected at the photodetector with the help of the displacement of the moving mirror which is related to the coherence of the light source and the reflected signal (adapted from [108]).

Typical Components of the IOL-Master Optical Biometry System An optical biometry system such as the IOL-Master consists of a measurement aperture including an IR laser diode (wavelength 780 nm), beamsplitter, photodetector and video camera. A joystick is used for raising and lowering the IOL-Master scanning device. A patient module (chin rest and head rest) for the patient's positioning and a computer system

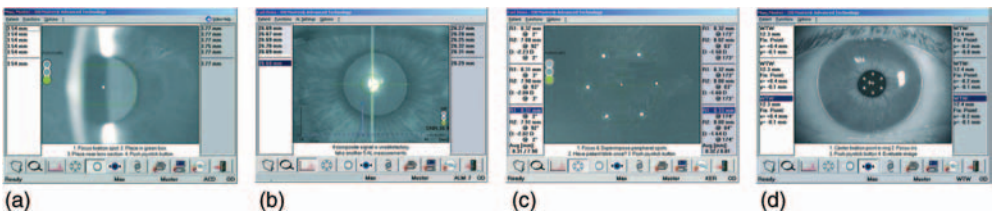

Figure 6.48 Measurements with the IOL-Master: (a) anterior chamber depth; (b) axial length; (c) corneal radius; (d) white-to-white distance.

with an integrated software package for data analysis, storage, and documentation of the results are also included [111].

Optical biometry is a noninvasive procedure that is easy to use for the operator and with less discomfort for the patient. The measurement is made without any anesthesia [112].

Optical biometry is not applicable in various cases, such as severe tear film problems, corneal scarring, mature cataract, respiratory distress, tremor, membrane formation, keratopathy, lid abnormalities, vitreous hemorrhage, and retinal detachment [112]. A new generation of optical biometry device is the Lenstar LS900®all-in-one optical biometer (Haag-Streit AG, Koeniz, Switzerland). The Lenstar LS900 measures nine different eye parameters: corneal thickness, ACD, lens thickness, axial length, keratometry, white-to-white distance, pupillometry, eccentricity of the visual axis, and retinal thickness at the point of fixation (macula). The measurement is based on the principle of optical low-coherence reflectometry (Michelson interferometry) [113].

6.1.4.5 **Retinal Imaging and Glaucoma Diagnostics**

Optical imaging is a standard method for detecting changes in the optic nerve head and retinal nerve fiber layer (RNFL). Some optic diagnostic imaging methods specialized for glaucoma management are scanning laser ophthalmoscopy (SLO), scanning laser polarimetry (SLP), optical coherence tomography (OCT), and the retinal thickness analyzer (RTA) [105], and are discussed in the following.

Scanning Laser Ophthalmoscopy (SLO) SLO is based on the technique of confocal scanning laser microscopy. The principle of SLO is shown in Figure 6.49. A laser beam passes through a pinhole aperture and is situated in a conjugate plane with a small focus point that scans the retina surface horizontally and vertically.

The scanning depth is adjusted by shifting the confocal aperture. The detector measures the reflected light and records this on a fundus camera [115, 116].

The Heidelberg retina tomograph (HRT) (Figure 6.50) generates two-dimensional images Figure 6.51 by an array of pixels and is also designed for acquisition and analysis of three-dimensional images of the posterior segment. It allows the quantitative assessment of the topography of ocular structures and the precise follow-up of topographic changes [114].

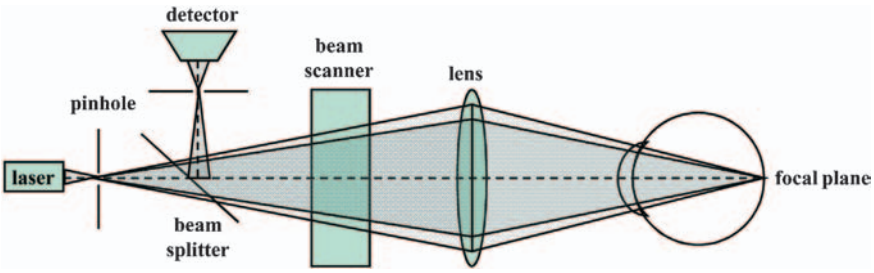

Figure 6.49 Scheme of a scanning laser ophthalmoscope (adapted from [114]).

Figure 6.50 HRT 3 scanning laser ophthalmoscope (Heidelberg Engineering GmbH, Heidelberg).

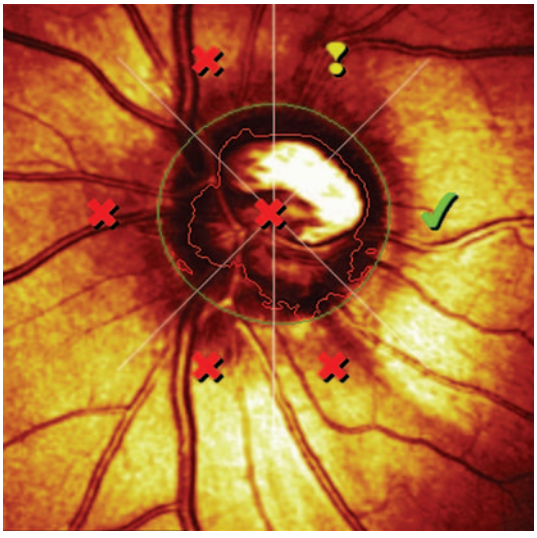

Figure 6.51 HRT image: reflectance map image of an optic nerve head [117].

Application SLO imaging is used for diagnostics of the retina or cornea and glaucoma, macular degeneration, and other retinal disorders. Some topographic parameters are estimated such as disc area, RNFL thickness, cup depth, and shape [105, 116].

Typical Components of SLO The light source of the HRT is a diode laser (wavelength 670 nm). The patient is held still with a patient module such as head rest and chin rest. A standard personal computer is used with a software package including data analysis and storage of the results [117].

HRT is a noninvasive method and the topography image is acquired without pupil dilation. HRT images are of high contrast and are available in real time [105].

Some HRT measurements require a reference plane for the exact calculation of some diagnostic parameters. Further, it needs some expertise to draw a initial contour line to define the optic disc margin. Another limitation of HRT is the influence of the intraocular pressure [105].

Scanning Laser Polarimetry (SLP) SLP uses polarized light to determine the thickness of the RNFL. The method is based on the property of birefringence of nerve fiber layers. The scanning laser polarimeter [118] (Figure 6.52) is based on confocal scanning laser ophthalmoscope [119].

Figure 6.53 shows the basic principle of SLO. A polarized laser beam is projected into the eye and is reflected by the retina. The amount of light reflected is detected and analyzed. The RNFL produces birefringence, changing the state of polarization. This

Figure 6.52 Scanning laser polarimeter: the GDx™ (Carl Zeiss Meditec, Jena) measures the birefringence of the RNFL and includes analysis for glaucoma. Some instruments have a variable corneal compensation (VCC), reducing the anterior segment birefringence of the eye and eliminating RNFL inaccuracies in the image.

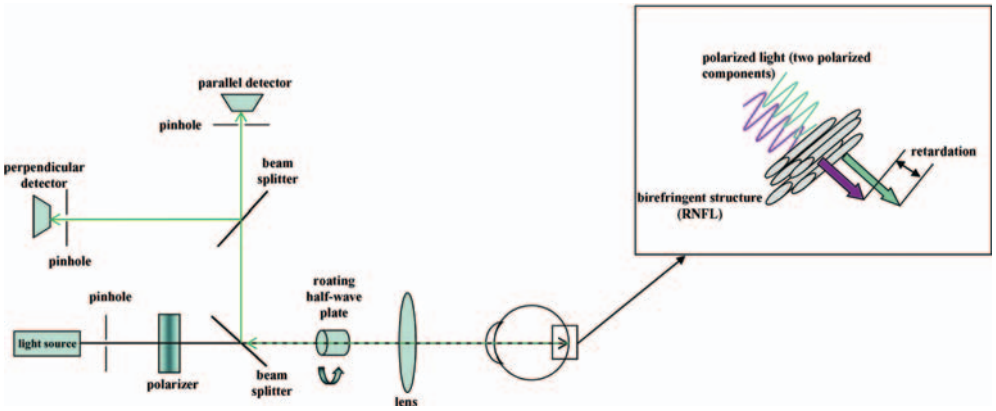

Figure 6.53 Principle of scanning laser polarimetry (adapted from [120, 121]).

procedure, called retardation, is detected by an analyzer. The value of retardation directly correlates with the thickness of the nerve fiber layer and is displayed in the retardation map [120]. Some scanning laser polarimeters have variable corneal compensation (VCC) for adjusting the corneal birefringence.

Figure 6.54 presents the standard GDx printout with the fundus image, the thickness map or retardation map, the deviation map and TSNIT (temporal–superior–nasal–inferior–temporal) graph and RNFL parameter. The fundus image displays

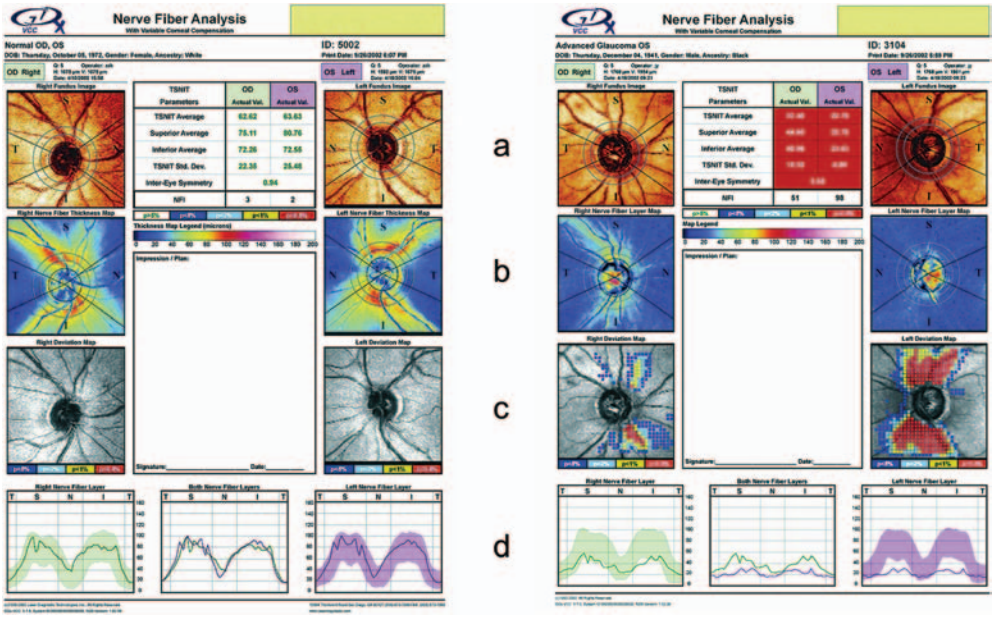

Figure 6.54 Standard GDx printout of a healthy eye (left) and a glaucoma eye (right): (a) fundus image; (b) thickness map or retardation map; (c) deviation map; (d) TSNIT graph.

a color intensity map of the reflectance. The retardation map shows a color-coded RNFL thickness, which means that thicker areas are displayed in warm colors (yellow, orange, and red) and thinner areas in colder colors (blue and green).

The deviation map compares each RNFL scan with a normative database. A color scale characterizes the locations and magnitudes of the RNFL defects. The TSNIT graph represents the RNFL thickness values along the calculation circle; normal values are in the shaded area and abnormal values are below the shaded area [105].

Application SLP detects structural changes and defects of the RNFL and enhances the diagnostics of early glaucoma.

Typical Components of an SLP The light source of an SLP is a helium–neon diode (wavelength 632.8 nm) or argon laser (514 nm). A polarization modulator changes the polarization states of the laser beam. The laser beams are moved horizontally and vertically on the retina by a scanning unit. The polarization detector detects the reflected polarized light from the cornea. A computer analyzes and stores the results. Some instruments have a joystick for pupil alignment [119].

A measurement can be performed without pupil dilation and is independent of a reference plane and magnification effects. SLP is a noninvasive method and easy to handle [105, 122].

Erroneous images and measurements could be obtained in the case of eyes with peripapillary embossment. It is not possible to generate images from eyes with nystagmus. Other problems in SLP imaging are atypical birefringence patterns and abnormal polarization at the anterior segment [105, 122].

Optical Coherence Tomography (OCT) OCT generates high-resolution images of the ocular structure. The principle of this optical technology is similar to that of ultrasound, but low-coherence light is used instead of sound. OCT is based on the Michelson interferometer technique (Figure 6.55).

In Figure 6.56, a schematic OCT setup is shown. Low-coherent light (consisting of a finite bandwidth of frequency) is focused through a Michelson interferometer. A beamsplitter in the interferometer breaks the light into a reference beam and sample beam. The sample beam passes directly through the retina and the light is reflected from structures at different depths. The reference beam is reflected on the reference mirror. The two reflected beams are recombined at the same beamsplitter and transmitted to a photosensitive detector.

OCT generates a final image which is a color-coded map with the help of a special image processing software package. A printout of an OCT scan is shown in Figure 6.57, including the RNFL thickness [105, 123].

There are different basic principles of OCT: time domain optical coherence tomography (TDOCT), frequency domain optical coherence tomography (FDOCT), which is also called Fourier domain OCT or spectral domain OCT, and polarization-sensitive optical coherence tomography (PS-OCT).

In contrast to FDOCT, where the mirror is kept stationary, in TDOCT the mirror moves to match the delay in various layers of the sample. The resulting interference

Figure 6.55 Optical coherent tomography with Stratus OCT (Carl Zeiss Meditec, Jena).

signal is processed to produce the axial scan waveform. The reference mirror must move one cycle for each axial scan, which limits the speed of the image acquisition. In FDOCT, the mirror is stationary and the spectral pattern of the interference between the sample and the reference reflections is measured and the interferogram is Fourier transformed to provide an axial scan. FDOCT offers higher resolution than TDOCT (5 μm versus 10 μm axial resolution) [125–127].

PS-OCT uses depth-dependent changes in the polarization states of backscattered light. Its application is to measure the birefringence of the RNFL. The reference arm consists of a quarter-wave plate (polarization modulator) and a moving mirror. In the

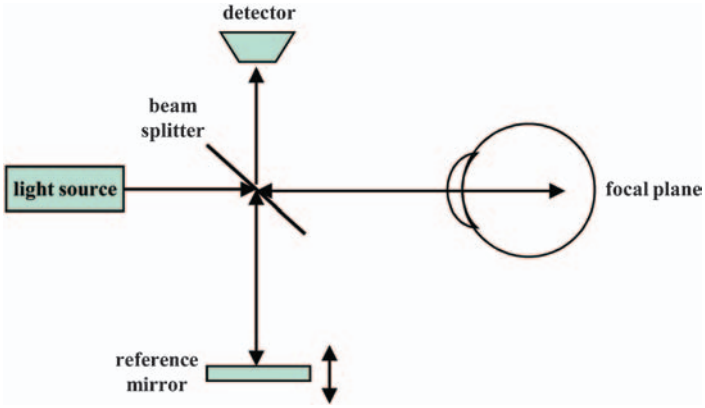

Figure 6.56 Operating principle of an OCT using an interferometer (adapted from [123]).

sample arm is also located a quarter-wave plate and a lens. The backscattered light of the reference arm is combined with the light of the sample arm and the resulting interfered beam is split by a polarization beamsplitter. The resulting beams are detected by two separate detectors [125, 128].

Application OCT is used to diagnose posterior segment and anterior segment disorders of the eye. The application of OCT in the posterior segment has contributed to the understanding of macular holes and vitreomacular traction. It is also a quantitative method of detecting changes in retinal thickness due to diabetes, cystoid macular edema, and epiretinal membrane.

The use of OCT in the posterior segment is helpful in imaging and measuring complex details of corneal pathologies and structural changes of the chamber angle and iris. OCT supports research on and treatment of glaucoma [123].

Typical Components of OCT The light source in OCT is a super-luminescent diode (wavelength 830 nm for the posterior segment and 1310 nm for the anterior segment) [122]. A photodetector records images. The patient is held still with a patient module such as head rest and chin rest and a joystick is needed for pupil alignment. A computer includes software packages for storage, analysis, viewing and importing of the OCT data [124].

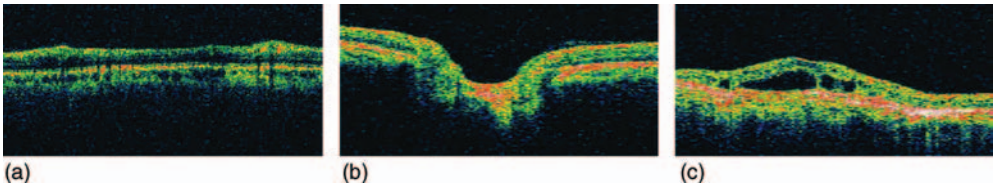

Figure 6.57 OCT scan with (a) thickness of RNFL; (b) optic nerve head; (c) macula [124].

OCT is a noninvasive diagnostic method which produces high-resolution images. It does not need a reference plane for measuring the RNFL thickness. It is possible to measure without pupillary dilation [105].

The measurements with OCT are dependent on the position of the individual scans and their overlap [129]. Many patients need pupillary dilation for good-quality images [105].

A problem with the OCT tomogram is to establish an accurate segmentation and layer thickness measurement of the retinal layer. Mishra *et al.* [130] developed an image processing method for the segmentation of all intra-retinal layers. The algorithm was performed on retinal images from healthy and diseased rodent models. The study presented a new method allowing much more accurate segmentation even in sub-optimal conditions of low image contrast and the presence of irregularly shaped structural features in the OCT images. The recently developed spectral domain OCT allows the image speed to be increased 100-fold compared with the first-generation TDOCT and allows three-dimensional imaging and real-time imaging of fast-moving structures. OCT has the potential to improve the precision of surgical interventions and may provide new interventions [131].

Retinal Thickness Analyzer (RTA) The RTA (Figure 6.58) is a device for mapping and quantitative measurement of the thickness of a selected retinal area in various regions of the fundus disc topography. The method is based on the principal of slit lamp biomicroscopy. A green helium–neon laser (543 nm) projects narrow light slits

Figure 6.58 RTA 3 retinal thickness analyzer (Talia Technology Ltd., Israel).

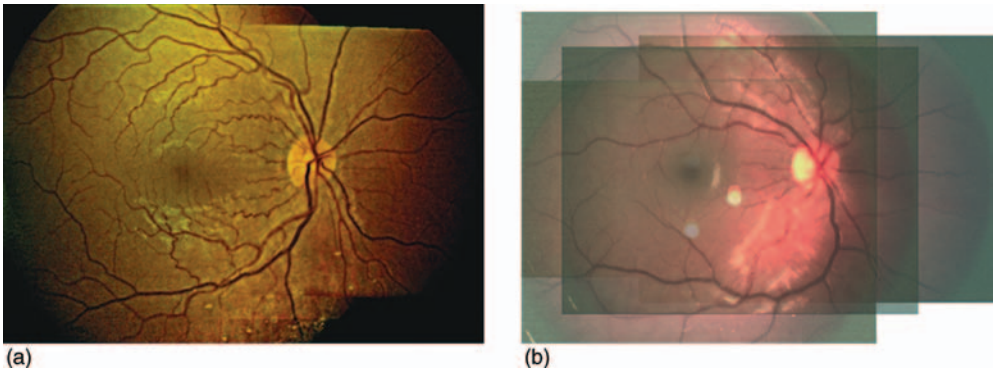

Figure 6.59 Standard RTA fundus image: (a) stand-alone fundus image; (b) overlapping of high-resolution fundus images.

on the retina and scans, in steps, across the retina. A CCD camera records the reflected light from the retinal pigment epithelium (RPE) and RNFL [105, 132, 133].

The recorded fundus images (Figure 6.59a) were analyzed by using an image registration algorithm. Thereby subsequent scans are overlaid (Figure 6.59b) while a color-coded retinal thickness mapping is performed. This allows an accurate follow-up of the vasculature of the fundus.

Furthermore, the RTA data provide information about topography maps, deviation probability maps from a normative database, quantitative numerical values, optical cross-sections, and unique interactive 3D cut sections [133].

Application The RTA is used for detection and follow-up investigations of glaucoma, diabetic retinopathy, age-related macular degeneration, and other retinal pathologies [133].

Typical Components of an RTA The RTA consists of a laser source such as a solid-state laser (wavelength 532 nm), a CCD camera which records the backscattered light, and a computer system including a software package for automatic registration, analysis and storage of high-resolution fundus images from the camera.

RTA is a noninvasive method and scans a wide area of the retinal tissue in a short acquisition time [105, 134].

Pupillary dilation is needed to obtain acceptable RTA images such as a macular scan. It is also possible to obtain optic disc images without pupillary dilation. For a continuous retinal thickness map an interpolation is necessary, but focal defects in retinal thickness or disc topography could be overlooked [105]. Furthermore, the image is adversely affected by media opacities [135].

6.1.4.6 Fluorescein Angiography

Fluorescein angiography (Figure 6.60) uses the dye tracing technique for examining the blood circulation within the retinal vessels.

Figure 6.60 Fluorescein angiography system combined with spectral-domain OCT: Spectralis HRA + OCT (Heidelberg Engineering GmbH, Heidelberg).

A fluorescent dye is injected into a vein in the patient's arm. After the dye injection, a series of photographs are taken and an angiogram is obtained for documentation. An exemplary fluorescein angiogram is presented in Figure 6.61. The fluorescein angiogram can be divided into six phases (choroida, arterial, capillary, venous, recirculation, late phase) with normal transit times [136, 137].

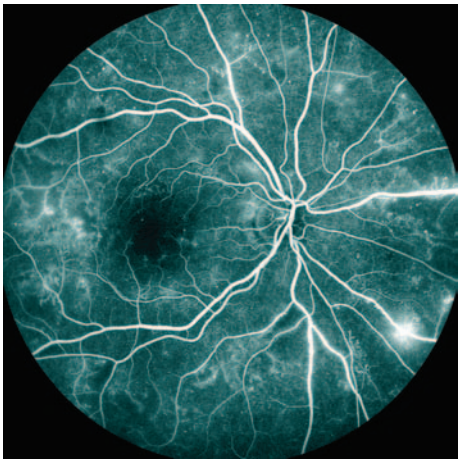

Figure 6.61 Fluorescein angiogram of retinal blood vessels.

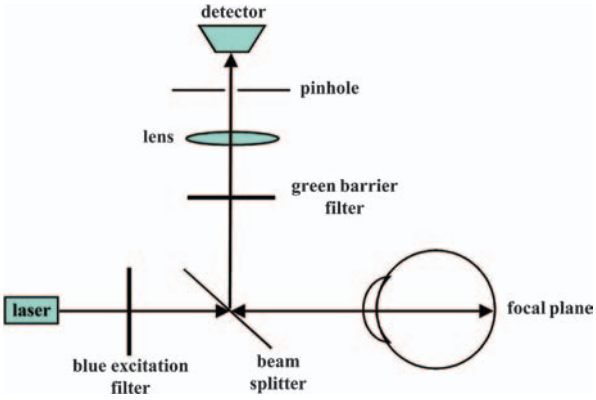

Figure 6.62 Principle of fluorescein angiography (adapted from [140]).

Sodium fluorescein has the property to fluoresce, which is the absorption of light with a specific wavelength inducing emission of light with a higher wavelength. A wavelength between 485 and 500 nm (blue) is the suitable for stimulating sodium fluorescein that consequently emits light with a wavelength between 520 and 525 nm (yellow–green). In the following, the basic principle of a fluorescein angiography system is described.

A monochromatic laser beam passes through an excitation filter that is only transparent to blue light. Accordingly, this blue light enters the eye and excites the fluorescein present in blood vessels. This procedure is called the excitation phase. Subsequently yellow–green and blue light emerge from the eye and pass through another barrier filter. This filter is only transparent to yellow–green light, which is detected by the camera (emission phase) [138, 139]. In Figure 6.62 the basic form of fluorescein angiography is shown.

Another type of fluorescein angiography is indocyanine green (ICG) angiography. ICG dye is a fluorescent substance which produces a weaker fluorescence. In this context, the wavelength of the excitation light ranges from 780 to 805 nm while light with a slightly higher wavelength (820–850 nm) is emitted. ICG is a useful method for investigating the choroidal circulation [140, 141].

Application Fluorescein angiography is used for the diagnosis of various posterior segment diseases such as macular diseases, retinal vascular diseases, optic nerve disorders, inflammatory retinal/choroidal diseases, and tumors [139].

Typical Components of a Fluorescein Angiography System The Spectralis HRA fluorescein angiography system consists of an optical system with a laser source (diode laser, wavelength 790 or 820 nm) and filter system. The angiography images can be recorded with a camera. A patient module (e.g., chin rest and head rest) is used to keep the patient still. It also has a computer system with an integrated software platform for image acquisition, processing, and archiving [142]. The fluorescent agent supports the ability to visualize dynamic processes in the retina [129].

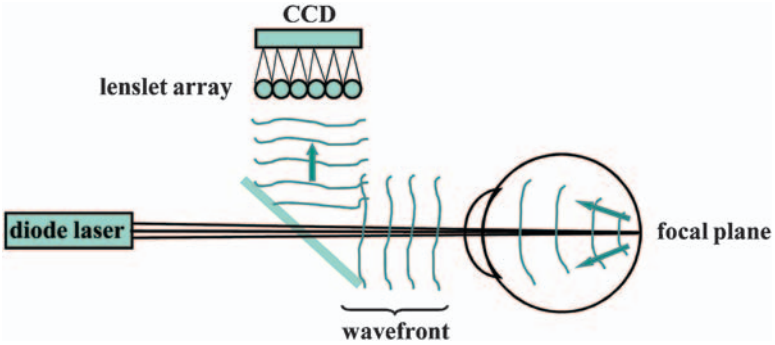

Figure 6.63 Schematic diagram of the Shack–Hartmann aberrometer (adapted from [144, 145]).

Fluorescein angiography is a less invasive imaging method with pupillary dilation [129]. Side effects of fluorescent dye injection are nausea, emesis, pruritus, and vasovagal symptoms. Further, the fluorescent dye stains the skin (yellow) and the urine [136].

6.1.4.7 **Wavefront Analysis**

The wavefront measures and treats small vision errors (higher order aberrations) that scatter light in a pattern that is unique to every person. Aberrations of the eye are results of optical contradictions within media and local irregularities of the optical surfaces. A wavefront analyzer (aberrometer) is based on a Shack–Hartmann sensor or a Tscherning sensor [143]. The working principle of both aberrometers is to measure the reflected wavefront of light that is coming out of the eye [144].

A Shack–Hartmann aberrometer consists of an aperture where the beams of a diode laser are focused to a point on the retina. The reflected wavefront that returns out of the eye passes through a lenslet array and subdivides the wavefront into multiple beams. All the reflected light generates multiple images of the retinal spot and is detected by a CCD camera. Figure 6.63 shows the principle of a Shack–Hartmann aberrometer [144–146].

The Tscherning aberrometer is a device where the laser beam (wavelength 670 nm) passes through a dot mask which forms a bundle of thin parallel beams [147] (Figure 6.64). This light beams are projected into the eye and a retinal spot pattern is generated of the eye's aberrations. The retinal spot pattern image is recorded with a CCD camera. The differences between the original image and the reflected image are analyzed mathematically. The basic principle of a Tscherning aberrometer is shown in Figure 6.65 [144, 148].

Application The wavefront analysis diagnoses lower and higher order vision errors represented by the way the eye refracts or focuses light. Lower order aberrations are more typical vision errors such as nearsightedness, farsightedness, and astigmatism whereas higher order aberrations are more complex vision errors.

Figure 6.64 Tscherning aberrometer:ALLEGRO Analyzer (WaveLight AG, Erlangen).

Typical Components of an Aberrometer An aberrometer typically consists of a light source, beamsplitter, lens system, and camera recording the returning wavefront from the eye. A patient module is used to keep the patient still and a computer analyzes and displays the measurement data.

Shack–Hartmann aberrometry [144,149]: The principle of Shack–Hartmann aberrometry is the generation of images with high resolution, accuracy, and reproducibility. The method needs a short measuring time and fast performance

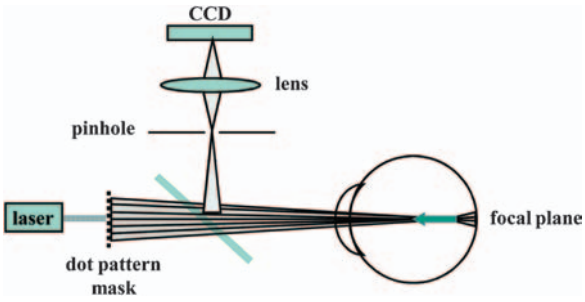

Figure 6.65 Schematic diagram of the Tscherning aberrometer (adapted from [144]).

of data analysis is possible. Furthermore, it is less sensitive to scattering and provides information about the central cornea. Shack–Hartmann aberrometry uses the outgoing path and an expensive sensor technique. Another disadvantage is the deeper penetration in the macula.

Tscherning aberrometry [142,147]: Tscherning aberrometry has a low penetration into the fovea and is a fast measuring technique. It is limited in the imaging resolution and also in the patient setup, and the analysis is more time consuming. Furthermore, it is sensitive to scattering due to the diffraction of the laser beam caused by the pinholes which affects the results. There is also a disturbing visible ash for patients during the measurement.

6.1.5
In Vitro Diagnostics – Microscopy

Microscopes are devices that are used to magnify small objects that are too small to be viewed by the unaided human eye. Objects with a size from millimeters down to nanometers can be visualized. The limits of resolution are shown in Figure 6.66.

In the following we consider only microscopes with a biophotonic background (other existing technologies, such as electron microscopes, are not considered).

There are different types of microscopes classified by shape, size, functional principle, illumination source, and image processing. Some major application fields of microscopy are hematology, pathology, cytology, gynecology, cancer research, brain research, analysis of samples, and *in vitro* fertilization.

Microscopy is an essential tool for functional studies on specimens of biological structures, molecules, and pathways in living organisms. Major innovations in microimaging technology during recent decades (e.g., confocal microscopy, fluorescent proteins) improved the resolution and sensitivity of microscopes. This enabled scientists to understand cellular functions and to determine the molecular

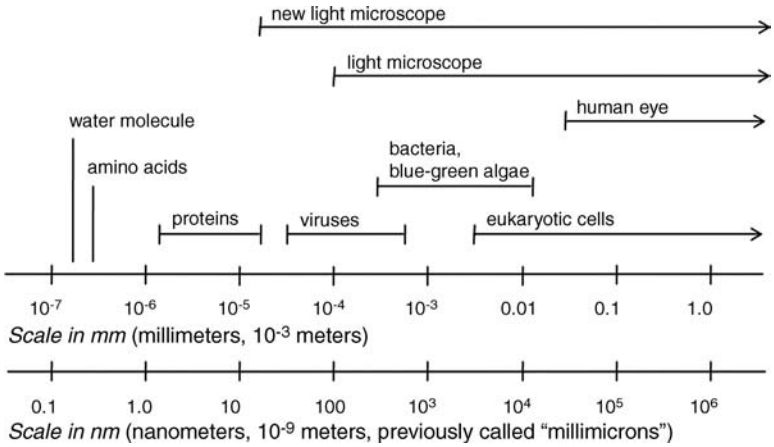

Figure 6.66 Limits of resolution in microscopy. In cell biology, the micrometer and nanometer scales are of most interest (adapted from [152]).

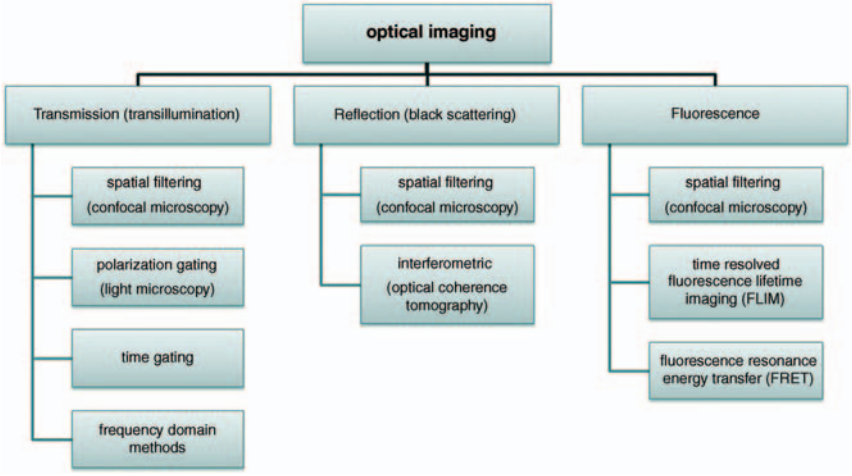

Figure 6.67 Optical methods of imaging (adapted from [153]).

mechanisms of diseases such as cancer and Alzheimer's disease [150]. We can differentiate different basic principles of optical imaging (Figure 6.67) suitable for microscopy:

- Transmitted light microscopy (with is based on the transmission by light of thin specimens, for example, cell cultures or biopsy samples).
- Reflected light microscopy (which is based on examination of the light reflected by thicker specimens).
- Fluorescence microscope (which is based on the phenomenon that certain materials emit energy detectable as visible light when irradiated with light of a specific wavelength) [151].

Further, we can differentiate between the following:

- "**Wide-field" microscopy**: The entire specimen is bathed in light and the image can be viewed directly by the eye or with a detector (e.g., CCD camera).
- **Laser scanning microscopy**: Only a disc-shaped area of the fluorescently labeled or autofluorescent sample is illuminated by a focused laser beam via a pinhole and the sample is scanned point-to-point. A detector pinhole focused on the same plane eliminates light scattered outside the focus plane. The image is reconstructed electronically by computer [151].

Due to this wide variety of existing microscopy techniques, detailed descriptions of each application would go beyond the scope of this chapter. Therefore, only a few techniques (light microscopy, fluorescence microscopy, confocal microscopy, Raman microscopy) have been selected for a more detailed description. In Section 6.2.2.5 on advanced microscopic techniques, some further important microscopic techniques for biotechnology are described.

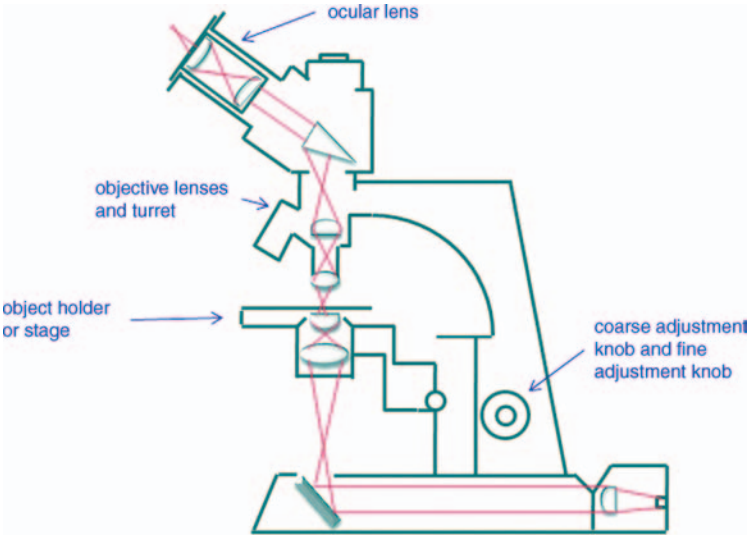

Figure 6.68 Basic components of a light microscope (adapted from [155]).

6.1.5.1 Light Microscope

The light microscope is a type of optical microscope which uses visible light and a system of lenses to magnify images of small samples. The basic components and the light path are illustrated in Figure 6.68 [154].

The main disadvantage of a standard light microscope is the limited spatial resolution of 200 nm. Other types of light microscopes include the inverted microscope (a microscope with its light source and condenser on the top, above the stage pointing down, while the objectives and turret are below the stage pointing up; it is useful for observing living cells or organisms at the bottom of a large container) and the stereomicroscope (which uses two separate optical paths with two objectives and two eyepieces to provide slightly different viewing angles to the left and right eyes).

6.1.5.2 Fluorescence Microscope

A fluorescence microscope is a light microscope used to study the properties of organic or inorganic substances using the phenomena of fluorescence and phosphorescence instead of, or in addition to, reflection and absorption [156]. Fluorescence microscopy the most frequently used microscopy procedure in biology and medicine [151].

In addition to the basic components (Figure 6.69) of a light microscope, typical components of a fluorescence microscope are the following [158]:

- a light source (xenon arc lamp, mercury vapor lamp, or laser)
- an excitation filter
- a dichroic mirror (or dichromatic beamsplitter).

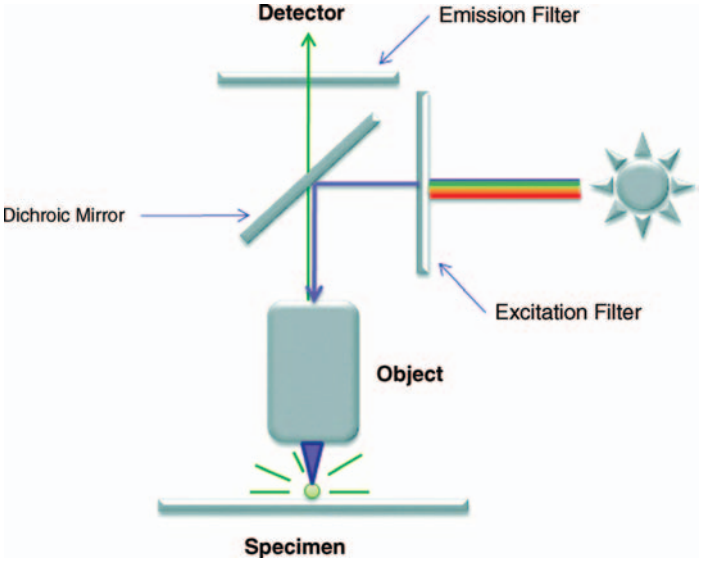

Figure 6.69 Light path in a fluorescence microscope. The specimen is illuminated with light of a specific wavelength (selected with excitation filters) which is absorbed by the fluorophores. The fluorescent light can be separated from surrounding light with special (emission) filters. The observer views only the part of tissue that is fluorescing (adapted from [157]). Copyright Spectrum Akademisches Verlag/Springer – Verlag Gmbtt

With total internal reflection fluorescence (TIRF) microscopy (see also Sections 6.1.2.2 and 6.1.2.5), extraordinarily sharp and detailed images of the cell surface are possible by eliminating fluorescence from within the cell. This allows researchers to study cellular signaling processes, exo- and endocytosis, the principles of cell adhesion, and cell-to-cell interactions.

The analysis of images acquired with conventional wide-field fluorescence excitation near the cell membrane is difficult due to the background fluorescence from other planes which are not in focus. Only under TIRF conditions can a resolution of $<$200 nm on the z-axis be achieved by selective illumination. This resolution is not achieved by either epifluorescence or confocal microscopy. The problem is solved by a technique in which fluorochromes are excited within a thin layer only. TIRF microscopy is particularly suited to the task, as the principle allows only those molecules to be excited which are in a layer of typically 100–200 nm above the cover-slip [159, 160].

For the transition from the glass cover-slip (refractive index $n_1 = 1.518$) into water ($n_2 = 1.33$), a critical angle of 61° results (Figure 6.70). With total reflection, a stationary evanescent (= decaying) wave is formed at the interface between the two media. The intensity of this wave decays exponentially with increasing distance from the interface:

$$I_z = I_0 \cdot \exp\left(-\frac{z}{d}\right) \tag{6.3}$$

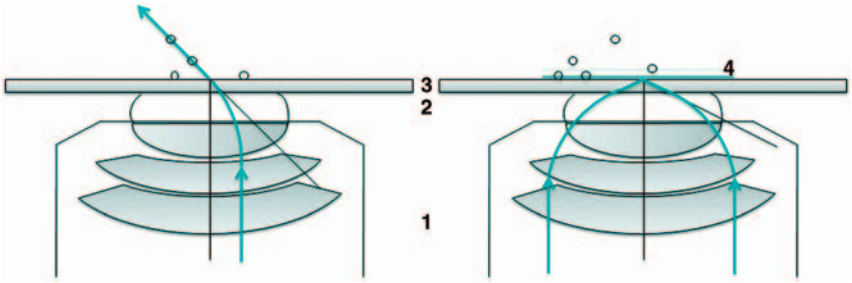

Figure 6.70 Beam path of incidence at less than the critical angle (left pathway) and beam path of total reflection (right pathway): 1, objective; 2, immersion oil, $n = 1.518$; 3, cover-slip, $n = 1.518$; 4, evanescent field (adapted from [160]).

where I_z is the intensity at a distance z from the interface and I_0 the intensity at the interface.

The penetration depth of the evanescent field is defined as the distance d from the interface at which the energy of the light has dropped to 37% of the original level. This distance depends on the angle of incidence and the wavelength of the light used. The distance d is calculated by

$$d = \frac{\lambda_0}{4\pi n_2 \sqrt{\left(\frac{\sin\alpha_1}{\sin\alpha_g}\right)^2 - 1}}. \tag{6.4}$$

6.1.5.3 New Fluorescence Microscope Techniques

The resolution limitation of light microscopy is overcome by several new microscopy technologies which allow structures smaller than 200 nm to be studied. Various approaches of microscopy techniques and different characteristics are listed in Table 6.2.

Table 6.2 Summary of the various described approaches and comparison of the different characteristics [161].

Method	Acquisition method	Lateral resolution (nm)	Axial resolution (nm)	Time required per image acquisition	Time required per image processing
Confocal laser scanning	Scanning	200	500	<1 s	
Structured illumination	Wide-field	50–120	150–350	<1 min	1–10 min
PALM	Wide-field	20–40		5–10 min	<1 h
TIRF	Wide-field	200	<100	0.2–0.4 s	

Photoactivated localization microscopy (PALM) offers biomedical researchers effective lateral resolution down to 20 nm. The technology employs photoswitchable dyes to enhance the resolution significantly.

With the method of structured illumination microscopy (SIM), researchers can image any fluorophore in living cells with twice as much lateral and axial resolution as with current light microscopes [150].

PALM and SIM enable scientists to analyze functionally even smaller cellular structures without the applicative limitations of electron microscopy (disadvantage: no colored picture) and other high-resolution techniques. For example, neuronal synaptic vesicles are about 50 nm in size and were previously not visible under the light microscope. The same is true for visualizing interactions between single pairs of proteins in living cells [150].

In addition to laser scanning microscopy, a wide range of other optical sectioning technologies is available addressing the needs of specific biological applications [161].

3D Structured Illumination Microscopy (3D-SIM) SIM can image any fluorophore, fixed or live, with up to twice the resolution possible using deconvolution or confocal microscopy. This is made possible by combining precise spatial modulation of the excitation light with an algorithm that computes super-resolution information from interference patterns in the raw data.

Super-resolution structured illumination microscopy (SR-SIM) provides up to double the resolution in all dimensions, without compromising on dyes and without special sample treatment. It relies on state-of-the-art algorithms to reconstruct a super-resolution image in 3D (see Figure 6.71).

Considering the two overlapping grids in Figure 6.72, tilted at 5° against each other, one can observe a real and visible pattern of approximately perpendicular dark and light bands superimposed on the parallel lines. This is a phenomenon called Moiré fringes, originating from the interaction of the optical patterns of lines. The fringes contain super-resolution information that otherwise escapes detection.

This is exactly the principle that is used in SR-SIM. A known pattern is projected into the image plane and interferes with sample structures, creating Moiré fringes. Super-resolution information can now be captured by the microscope from these structures. All that remains to be done is to restore this information into a super-resolution image by high-end algorithms.

Photoactivated Localization Microscopy (PALM) PALM (Figure 6.73) allows scientists to produce light microscopic images with effective lateral resolutions down to 20 nm. This is achieved by successively localizing single molecules with high precision. A wide range of fluorophores can be visualized in this way, from special GFP (green fluorescent protein) mutants to organic dyes such as Cy5. For uncompromised results, it is of paramount importance to achieve the highest system sensitivity and precise optical sectioning [150].

PALM permits scientists to visualize cells with far more detail than with conventional light microscopes, which are inherently limited by the wavelength of light. To achieve this resolution, PALM uses different fluorescent labels that can be turned on

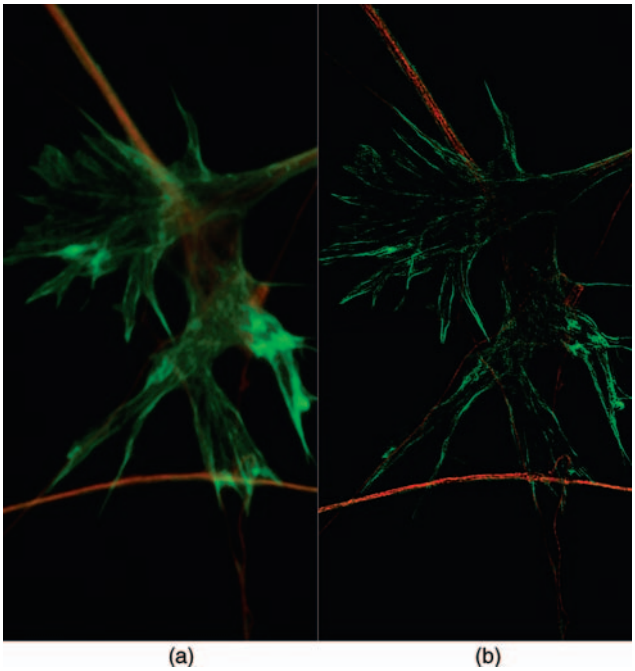

Figure 6.71 (a) Widefield image and (b) SIM image of neuronal growth cones. Staining for tubulin (red) and F-actin (green) (specimen: M. Fritz and M. Bastmeyer, University of Karlsruhe, Germany [150]).

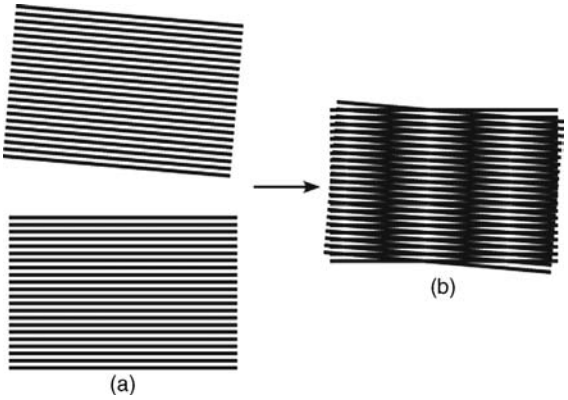

Figure 6.72 Moiré patterns formed by superimposed grids. (a) An image and the same image turned 5°; (b) the overlapped grids generated Moiré fringes, which contain super-resolution information [162].

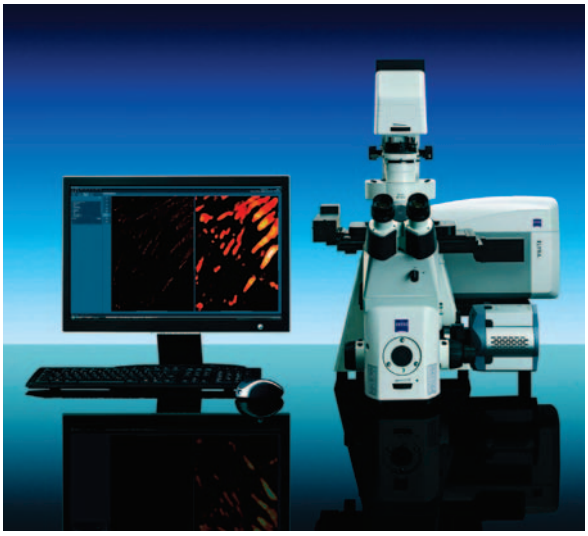

Figure 6.73 ELYRA P.1 photoactivated localization microscope (Carl Zeiss MicroImaging GmbH, Jena) offers fluorescence imaging with single-molecule discrimination, down to effective resolutions of 20 nm [164].

and off with a pulse of light. Cells whose proteins are tagged with these labels are imaged repeatedly with PALM, with only a tiny subset of the fluorescent molecules turned on in each image. PALM records many thousands of these images to illustrate each fluorescently tagged protein. Hence PALM creates a complete picture of the structure under study. As a result, the observer obtains a much clearer picture than the overlapping haze that results when all of the tagged proteins are lit up at the same time, as in traditional fluorescence microscopy [163, 164] (see Figure 6.74).

6.1.5.4 **Confocal Microscopy**

The principle of confocal microscopy (see Figure 6.75) was originally patented by Marvin Minsky in 1957. The development of lasers for confocal laser scanning microscopy (CLSM) became a standard technique towards the end of the 1980s. Thomas Cremer and Christoph Cremer designed in 1978 a laser scanning process which scans point-by-point the three-dimensional surface of an object by means of a focused laser beam and creates the overall image via a photomultiplier (similar to those used in scanning electron microscopes). The key feature of confocal microscopy is its ability to acquire in-focus images from selected depths (a process known as optical sectioning); images are acquired point-by-point and reconstructed with a computer. As only one point in the sample is illuminated at a time, 2D or 3D imaging requires scanning over a regular raster (i.e., a rectangular pattern of parallel scanning lines). The thickness of the focal plane is defined mostly by the inverse of the square of the numerical aperture of the objective lens, and also by the optical properties of the specimen and the ambient refractive index. The thin optical sectioning possible

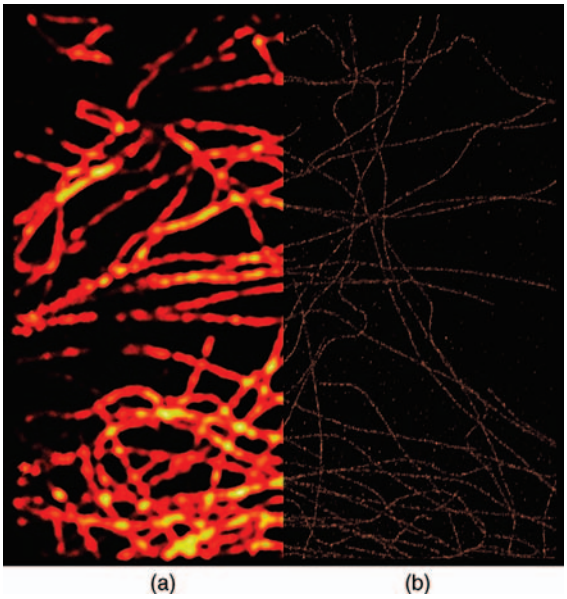

Figure 6.74 (a) Total internal reflection microscope image and (b) PALM image of antibody staining for tubulin in a cultured cell (specimen: S. Niwa, University of Tokyo, Japan [150]).

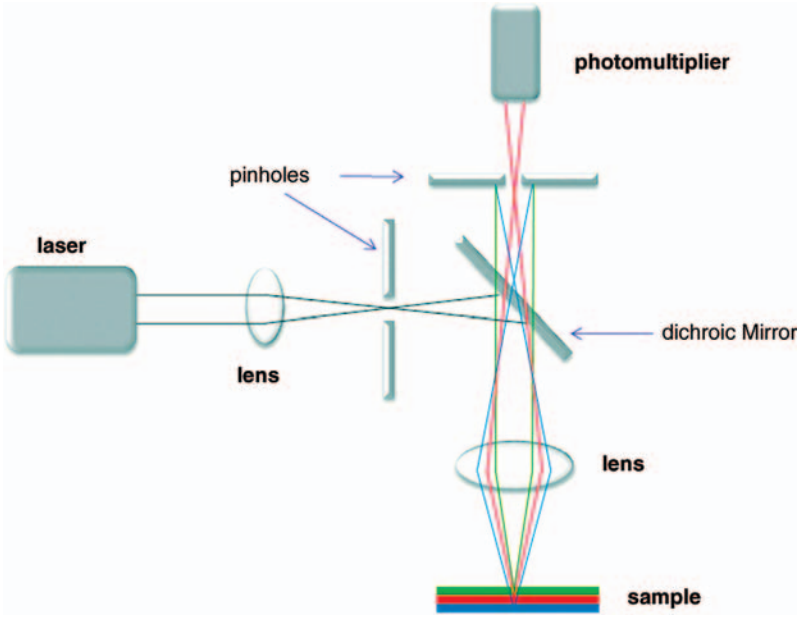

Figure 6.75 Light path and components in a simple confocal laser microscope. Interfering intensity from outside this plane is canceled out by a pinhole. Therefore, it is possible to obtain spatial resolution and additionally very detailed intensity information not only in the *xy*-direction but also in the *z*-direction (adapted from [167]).

makes these types of microscopes particularly suitable for 3D imaging of samples [165, 166].

In comparison with the conventional "wide-field" microscope, the following advantages result [151]:

- improved lateral resolution
- increased contrast
- electronic zoom
- increased sensitivity
- information in the *z*-direction (for 3D imaging).

Traditional fluorescence microscopes can focus on a certain region of the specimen, but the fluorescence background from the out-of-focus part distorts the in-focus signal. Historically, the only way to obtain a clearer and sharper image of a thicker sample was physically to cut thin sections of the sample, a technique which was time consuming, likely to introduce artifacts, and not suitable for imaging living samples.

During the last few decades, a large number of techniques have been developed that allow the contributions from these out-of-focus regions to be removed. This led to a much clearer image of the specimen in the focal plane without any sample manipulation.

The best known optical sectioning method is confocal or laser scanning microscopy (LSM) (see also Section 6.1.2.5); for an example, see Figure 6.76. Confocal microscopy systems enable researchers to study living, 3D samples with significantly improved sensitivity and higher resolution images compared with conventional fluorescence microscopy [150, 166].

Confocal microscopy allows the tracking of specifically labeled (e.g., GFP or fluorescent antibodies) proteins in living cells and organisms. The simultaneous

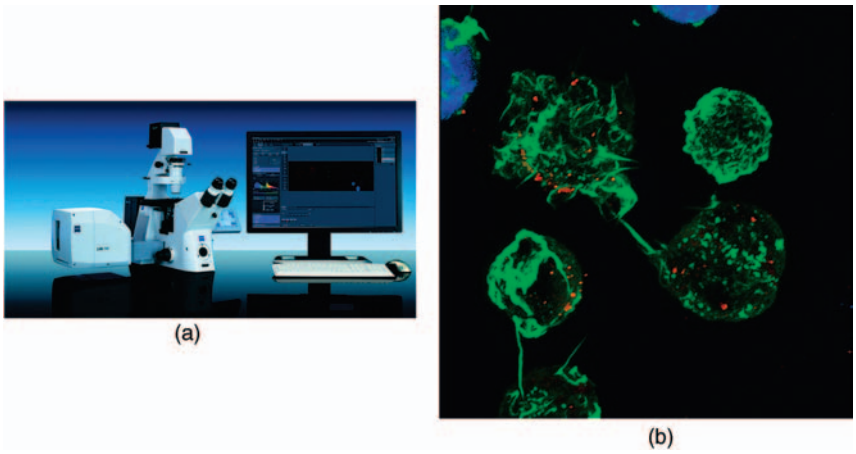

Figure 6.76 (a) LSM 700 confocal laser microscope (Carl Zeiss MicoImaging GmbH, Jena): (b) human lymphocytes transmitting the HIV virus from cell to cell [168].

spectral imaging capabilities and low signal-to-noise ratios of modern LSM systems allow the interactions of several different proteins to be observed at the same time. With such analyses, fundamental cellular pathways can be discovered and morphology can be linked to function. By combining several confocal images with 3D images, unprecedented insights into the molecular morphology and function of cells, tissues, and organisms have become possible [150].

6.1.5.5 **Raman Microscopy**

In addition to the fluorescence microscope, Raman-based techniques have became increasing evident in recent years. Raman spectroscopy allows one to derive detailed and specific information on a molecular level that other laser spectroscopic methods can provide to only a limited extent, and is a technique used to study vibrational, rotational, and other low-frequency modes in a sample [169, 170]. Confocal Raman microscopy combines the 3D optical resolution of confocal microscopy and the sensitivity to molecular vibrations which characterizes Raman spectroscopy (Figure 6.77).

Raman spectroscopy is based on the inelastic scattering of monochromatic light when the frequency of photons changes upon interaction with a sample. The photons of the laser light are absorbed by the sample and subsequently re-emitted. The frequency of the re-emitted photons is shifted up or down in comparison with the original monochromatic frequency, which is known as the Raman effect and provides molecular fingerprints.

The advantages of Raman spectroscopy are that it can be applied to any optically accessible sample, pretreatment of the sample is not or almost not necessary and in contrast to fluorescence spectroscopy it works completely without external markers.

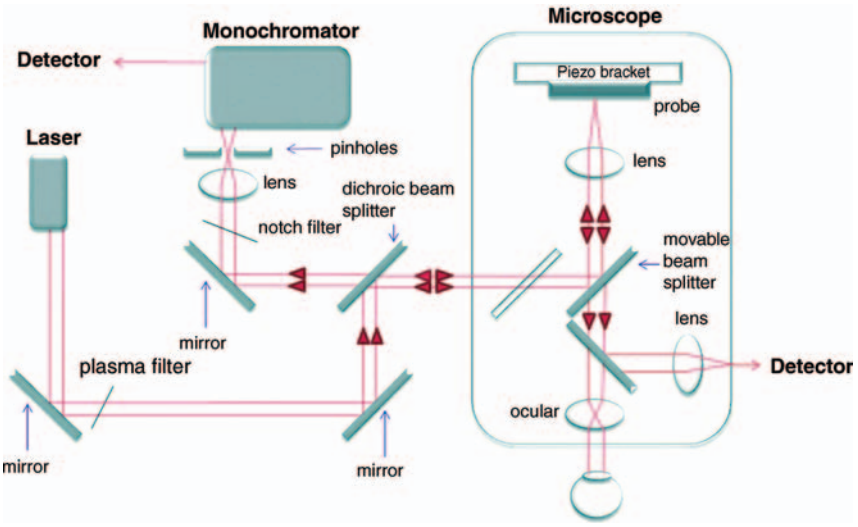

Figure 6.77 Raman microscopy: light path and components (adapted from [171]).

(d) 59 × 59 Raman map with a step size of 2.5 µm; the colors within the Raman maps correlate with group classifications performed by cluster analysis. (e) Zoomed ganglion from (c) [170]. Copyright Spektrum Akademischer Verlag/Springer Verlag GmbH.

An example of Raman spectroscopy of a dried intestinal sample is shown in Figure 6.78.

However, although the specificity of Raman spectroscopy is very high, its sensitivity, that is, the conversion efficiency of the Raman effect, is rather poor. Since only a small number of the incident photons are inelastically scattered, the detection of molecules present in very low concentrations is limited. To circumvent such problems, special Raman signal-enhancing techniques can be applied [169], such as resonance Raman spectroscopy, surface-enhanced Raman scattering (SERS), coherent anti-Stokes Raman scattering (CARS), and tip-enhanced Raman spectroscopy (TERS).

The use of SERS continues to be increasingly important for analytical applications of Raman spectroscopy. Patel *et al.* [172] used a combination of SERS with principal component analysis (PCA) to provide a barcoding methodology for pathogen identification in bacterial cells and to show how this approach potentially provides a rapid diagnostic tool for bacterial pathogens.

A key biological molecule is DNA. Benevides *et al.* [173] used NIR laser excitation to probe drug–DNA interactions. They compared the Raman spectra of complexes of ethidium bromide, 9-aminoacridine, and proflavin with DNA and showed that the Raman signatures reveal the specific structural changes induced at the drug–DNA intercalation sites. The results were discussed in relation to frameshift mutagenic activities of the intercalating drugs. Another theme in this context is the use of Raman spectroscopy to address medically related problems. Pawlak *et al.* [174] reviewed results from a program designed to investigate the potential of Raman microscopy as

a probe technique to address important problems in ophthalmology, looking at the disease age-related macular degeneration (AMD), the leading cause of irreversible blindness in the West.

Downes *et al.* demonstrated the integration of Raman spectroscopy and CARS into one instrument, to combine the benefits of both techniques for stem cell differentiation [175]. In the future, multiplex CARS promises to be the technique of choice for all platforms, due to its combined attributes of speed, full spectral analysis, and applicability to individual live cells.

6.1.6
In Vitro Diagnostics – Digital Slides and Virtual Microscopy

In the last few years, telepathology has benefited from the progress in the technology of image digitization and transmission through the World Wide Web. The applications of telepathology and virtual imaging are more current in research and morphology teaching. In the daily practice of surgical pathology, this technology still has limits and is more often used for case consultation. Many of the limitations of virtual imaging for the surgical pathologist reside in the capacity for storage of images, which so far has hindered the more widespread use of this technology. Overcoming this major drawback may revolutionize the surgical pathologist's activity and slide storage [176].

At present, telepathology serves as a promoter for a complete new landscape in diagnostic pathology, the so-called virtual pathology institution. Industrial and scientific efforts will probably allow the implementation of this technique within the next 2 years, with exciting diagnostic and scientific perspectives [177].

A digital slide in pathology is a digital scanned image of a specimen. The advantages of digital slides are their global management (access, storage, image processing, distribution) with the help of a picture archiving and communication

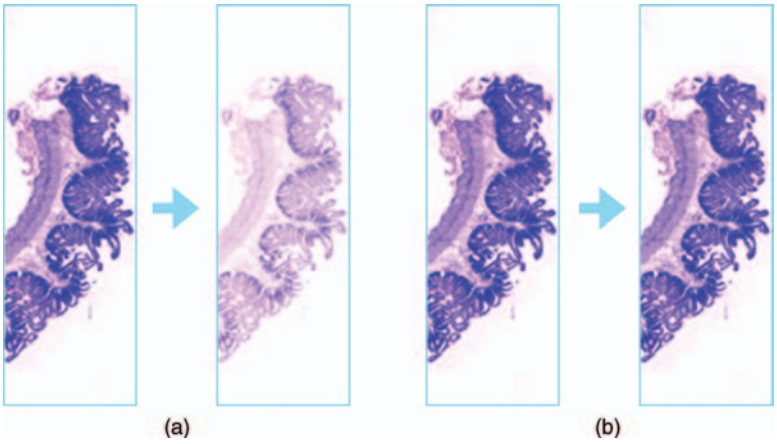

Figure 6.79 Digital slides: a stained specimen on a glass slide will fade over time (a) , whereas a digital slide does not change at all (b) [179].

system (PACS), no fading over time (Figure 6.79), and very fast access for teleconsultation services [178].

The main applications of digital slides are the following:

- **Teleconsultation**: Pathologists are able to view and discuss histology with other colleagues via the Internet.
- **Computer-aided diagnosis**: Interactive quantification allows pathologists to quantify immunohistochemical (IHC)-stained histology sections.
- **Education**: Gives medical students the opportunity to navigate even through rare cases like viewing them under a "real" microscope.

6.1.7
In Vitro Diagnostics – Optical Methods in Clinical Analysis System

6.1.7.1 Optical Spectroscopy of Blood and Urine Components

In addition to electrode measurements in clinical analysis, optical methods have been applied for many years. Usually a chemical reaction is used to convert the component of interest in the analytical solution (blood, urine, or other body liquids) into a colored species. For example, in the case of creatinine the well-known Jaffe's method is used, where the creatinine is converted into a complex which shows good discrimination against other blood components. In such commercially available creatinine detection kits, the absorption of the reaction product at an appropriate wavelength (here 530 nm) is a direct measure of the analyte concentration [180].

More sophisticated methods use more selective reactions to discriminate between the analyte of interest and other components in the highly complex investigation solution (see Table 6.3). First there are enzymatic reactions that can be used. Very often these enzymatic reactions do not lead to a colored species for optical detection. In this case, a side product is usually used to account for the analyte concentration. Commonly used side products for optical detection are oxygen (production or consumption), carbon dioxide, and pH changes. In some cases, when the main products have no significant absorption or absorb only in the deep-UV region (e.g., if NADPH or $NADP^+$ analogs are side products), a secondary reaction is used to detect the analyte concentration via an absorption or fluorescence measurement of the secondary products (see Figure 6.80).

6.1.7.2 Optical Spectroscopy of Tissues and Vessels

Optical spectroscopy of tissues and vessels is a long- and well-established method to detect and analyze components inside and outside cells. Problems arise if the absorption of these native chromophores is in the UV or deep-UV range, because in theses cases direct imaging using one-photon excitation is severely limited by photodamage to living specimens, in addition to indiscriminate background absorption or fluorescence. In these cases, multi-photon excitation can be used to overcome these problems. In fluorescence microscopy (see Section 6.1.5.2), either the fluorescence (autofluorescence) of the native components is visualized or the tissue is labeled selectively with fluorescence markers (such as labeled antibodies

Table 6.3 Clinical chemical blood parameters (selection) and the possibility of their optical detection.

Blood parameters	Detection method	Optical detection methods
Total and direct bilirubin	Complex building reaction with diazotized sulfanilic acid	Red colored azobilirubin detection wavelengths 578 nm (total), 546 nm (direct)
Total protein	Antigen reaction	Colored with 4-chloro-1-naphthyl
Alkaline phosphatase (AP)	Hydrolysis of a phosphate ester substrate [e.g., 2′-(2-benzothiazolyl)-6′-hydroxybenzothiazole phosphate (BBTP)] to a benzothiazole [e.g., 2′-(2-benzothiazoyl)-6′-hydroxy-benzothiazole (BBT)]	Detection of the BBT fluorescence
Lactate dehydrogenase (LDH)	Surface plasmon resonance (SPR) sensing	Measurement of intensity changes of light in an optical fiber
Glutamate dehydrogenase (GLDH)	Interaction with rhodamine–dextran substrate (e.g., SNARF 1-dextran)	Fluorescence detection
Creatine kinase (CK)	Fluoroimmunoassay	Fluorescence detection
Metabolites		
Lactate	SPR sensing	Measurement of intensity changes of light in an optical fiber
Glucose	Interferometric detection	Measurement of refractive index changes
Urea	Enzymatic reaction with urease in a polypyrrole matrix	Absorption measurement
Creatinine	Jaffé method	Absorption measurement
Minerals		
Calcium (Ca) Magnesium (Mg) Phosphorus (P) Sodium (Na) Potassium (K)	Insertion in calixarene receptors with fluorescence markers	Fluorescence measurements
Serum iron (Fe)	Serum transferrin receptor (TfR) measurements	Absorption measurement
Triglycerides	Enzymatic detection	Measurement of secondary products

or by transfection with fluorescent proteins) to discriminate between different components and to localize them. One of the advantages of direct imaging via fluorescence labeling is the visualization of intrinsic chromophores such as nicotinamide adenine dinucleotide (NADH), tryptophan, and serotonin. Especially investigations with endogenous fluorophores of the skin such as tryptophan,

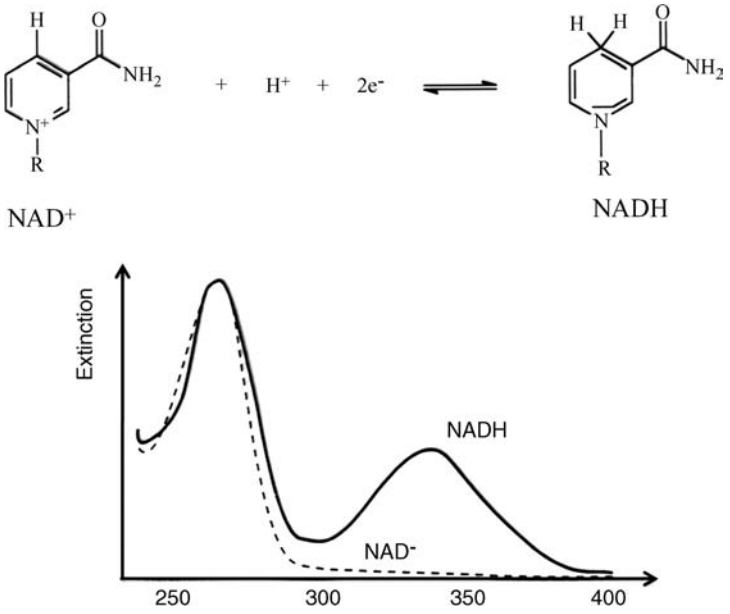

Figure 6.80 NADH transformation and the corresponding spectra.

collagen, elastin, keratin, flavins, melanin, and porphyrins have been discussed in the literature [181].

Two-photon-excited cellular autofluorescence from intrinsic chromophores such as NAD(P)H has been used to study the cellular metabolic state. As an

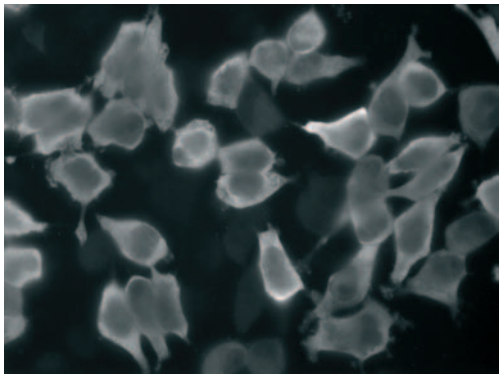

Figure 6.81 NADH autofluorescence. Intrinsic NADH autofluorescence is visualized by using 700 nm pulsed excitation. In this image, the NADH localization in HeLa cells is shown.

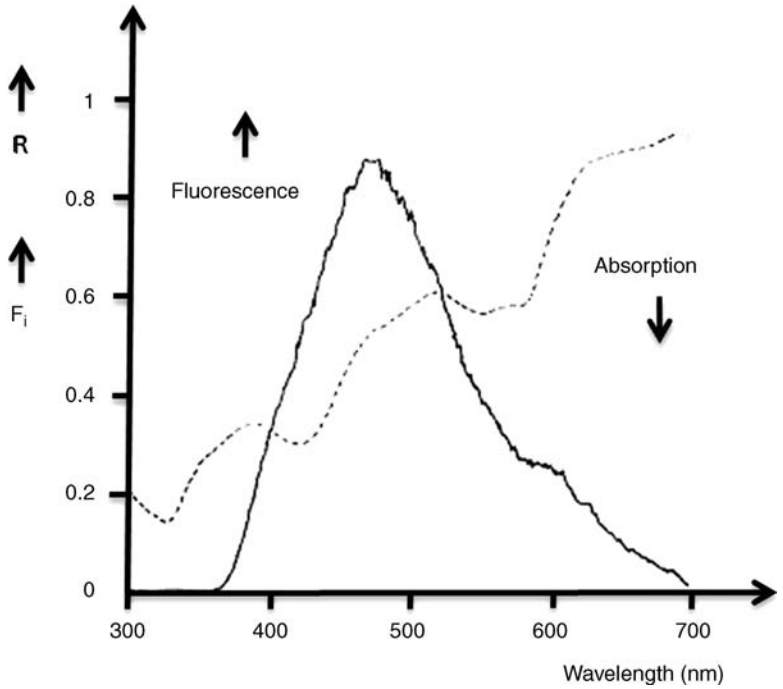

Figure 6.82 Fluorescence and absorption spectra (diffuse reflectance spectrum) of a human hand palm in arbitrary units [184].

example, Figure 6.81 shows two-photon-excited NADH autofluorescence in living cells [182].

In the case of labeling, maintenance of the native biochemical character of the tissue has to be taken into account. Therefore, fluorescent dyes are usually introduced into the biological system at neutral pH, in mild isotonic salt buffers. It must be ensured that the probe is soluble in the labeling buffer and that it can penetrate the hydrophobic membrane of the cells [183].

A noninvasive approach is shown in Figure 6.82, which represents an example of the investigation of autofluorescent tissue. The spectrum was recorded *in vivo* by the reflectance mode of irradiation of the palm of a human hand [184]. Fluorescence originates mainly from NADH, but often its spectrum is overlaid by additional long-wavelength absorbers, as can be seen in the diffuse reflectance absorption spectrum of the palm presented in Figure 6.82.

It is very useful to apply NIR fluorimetry (up to 1600 nm) in tissues, because this technique enables a greater penetration depth of the (NIR) radiation in organic matter to be used to obtain a well-defined region of excitation, for example, in single cells or mammalian tissue.

Other advantages afforded by NIR over UV–visible fluorescence techniques include the following:

- reduced Rayleigh scattered excitation (this being proportional to the inverse fourth power of wavelength)
- low absorption coefficient in many organic media, for example, tissue (results in less background)
- increased photochemical stability.

Additionally, longer absorption and emission wavelengths allow the use of inexpensive light sources such as LEDs and diode lasers, which are available mainly in the red and NIR region. Due to the reduced absorption of human tissue at wavelengths longer than 600 nm, this spectral region is very relevant to clinical applications [185].

Thus a laser beam of around 400 nm might be expected to penetrate only a few micrometers into the skin of a subject due to strong scattering and absorbance by hemoglobin (see below), whereas a light beam of about 830 nm would penetrate some centimeters due to the 16-fold lower scattering and also much reduced absorbance. We can imagine interrogating implanted fluorophores through the skin for a variety of diagnostic purposes, such as blood glucose monitoring [186]. In mammalian tissue at visible wavelengths, the principal absorbing species is, of course, hemoglobin, due to its strong absorbance and high concentration. All derivatives of hemoglobin exhibit significant absorbance at wavelengths longer than 700 nm; absorbance spectra are depicted in Figure 6.83. The measurement principle is used in the well-known noninvasive pulse oximetry. Every species (hemoglobin derivative) has its own optimal detection region. The calculation of the concentrations of the components can be made with respect to isosbestic points (e.g., at 805 nm) [187].

Other NIR applications of tissue and vessel imaging include optical time-domain reflectometry and photon migration in tissue [188, 189]. Furthermore, laser-induced autofluorescence studies of human tissue are widely used in modeling of human cutaneous tissue using spectroscopic measurements. This is possible simply because human tissue contains many components that fluoresce. This creates a readily

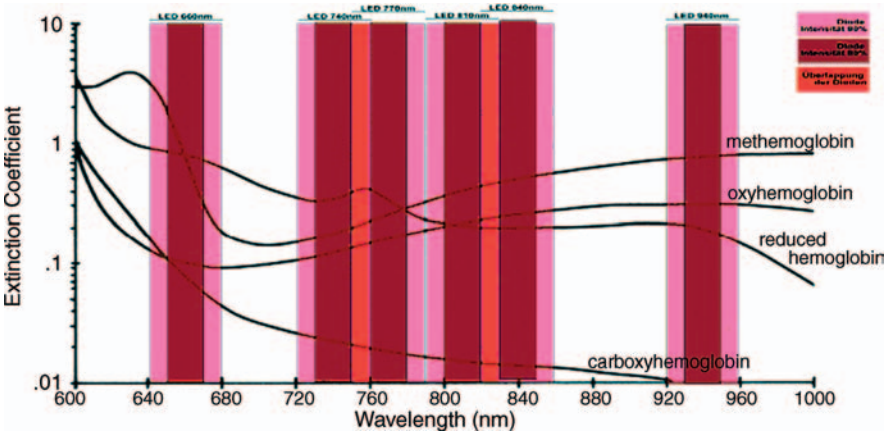

Figure 6.83 Absorbance of hemoglobin derivatives in the red and near-IR region.

detectable fluorescence background, but on the other hand is an important feature that limits the sensitivity of labeled fluorescence applications in tissue characterization. In this respect, laser-induced autofluorescence spectroscopy provides excellent possibilities for medical diagnostics of different tissue pathologies, including cancer, because cancer cells have a different metabolism than healthy cells and exhibit a much stronger fluorescence background than healthy reference tissue [23].

Another very important method for the investigation of cells and other tissue components is flow cytometry. Flow cytometry is a method of fluorescence-activated cell sorting (FACS) and is widely used in the diagnosis of cell diseases such as leukemia [190, 191]. In flow cytometry, the sample is irradiated with a continuous-wave laser light beam and the fluorescence light is detected as an indicator of cell type-specific antigens, cell–cell interactions, cell diseases, and mutagenic changes (see Figure 6.84). Most applications of flow cytometry are based on the presence or absence of cell-surface antigens, or the presence of one or two copies of the DNA, as determined by measurement of the fluorescence intensity of cells labeled with fluorescent antibodies or nucleic acid stains such as 4′,6-diamidino-2-phenylindole (DAPI). Multidimensional slit-scan flow cytometers have also been developed and used successfully for the automated detection of different types of cancer cells [190, 191].

In general, the time resolution of the fluorescence light is a very powerful tool for investigating environmental effects upon the cells and other components in tissues and vessels. This is due to the high sensitivity of the fluorescence lifetime to the

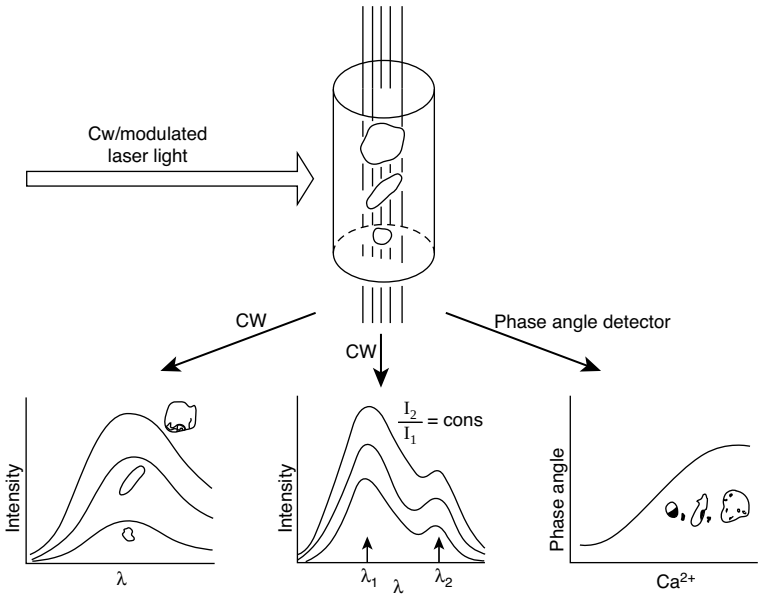

Figure 6.84 Principle of cell-by-cell measurements in flow cytometry (cw = continuous wave) (adapted from [192, 193]).

solvent or the viscosity and polarity of the surroundings of the cell. Therefore, lifetime imaging and fluorescence lifetime measurements play an important role in the optical characterization of human tissues.

Fluorescence lifetime imaging (FLIM) allows image contrast creation based on the lifetime of the probe at each point in the image. There is significant interest in creating 2D or even 3D fluorescence lifetime images, and for this purpose several techniques have recently been described. If the probe lifetime is sensitive to a naturally occurring analyte, one now has the ability to create (chemical and biochemical) images of cells and tissues (for more details, see [192, 193] and the references therein).

6.1.7.3 Optical Spectroscopy of Agglutination and Precipitation – Nephelometry, Turbidimetry

In addition to absorption of electromagnetic radiation, we observe scattered radiation if photons impact on matter (e.g., Raman scattering).

In the case of elastic light scattering, the relative molecular mass M_r of the scattering particle can be calculated from the analysis of the scattered radiation. Furthermore, information can be obtained about the molecular dimensions and the interaction between macromolecules, and parameters such as the diffusion coefficient of the scattering particle can be estimated.

In general, various scattering processes have to be taken into consideration:

- **Elastic light scattering**: Incident and scattered light have the same frequency.
  - –If the dimensions of the scattered particles are small in comparison with the wavelength, $d \ll \lambda/2$, Rayleigh scattering is observed.
  - –If the dimensions of the scattered particles are large in comparison with the wavelength, $d \gg \lambda$, Mie scattering occurs.
- **Quasi-elastic scattering**: Change in the frequency of the scattered light due to translational movement of the scattered particle (Doppler effect, frequency chirp).
- **Inelastic scattering**: Excitation of molecular vibration due to interaction with the incident light (Raman scattering).

Nephelometry is an optical analysis method to determine the concentration of colloidal dispersed small particles, in most cases in solution.

In the following, the scattering behavior of particles in solution is considered. This is necessary to understand the kind of representation of the results usual in nephelometry and the parameters deduced from the plots. The scattering of monochromatic polarized light at an isolated, isotropic molecule with the field strength leads to the induction of an electrical dipole moment (see Figure 6.85):

$$E = E_0 \cos\left[2\pi\nu\left(t - \frac{x}{c}\right)\right]. \tag{6.5}$$

The resulting oscillating dipole emits radiation, the field strength of which is proportional to

$$\frac{d^2\mu}{dt^2} = f(\varphi). \tag{6.6}$$

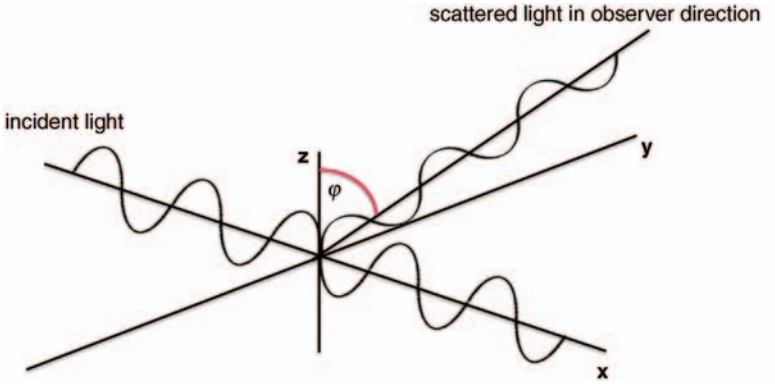

Figure 6.85 Scheme of scattering of incident irradiation at an object at (0, 0, 0) indicating the scattering angle φ under which the scattered light occurs.

For isolated molecules in solution, the resulting equation for the relative scattered light intensity is

$$\frac{I_s}{I_0} = \frac{2\pi^2(1+\cos^2\varphi)n_0^2}{r^2 \cdot L \cdot \lambda^4} \cdot \left(\frac{dn}{dc}\right)^2 \cdot cM_r \tag{6.7}$$

where I_s is the scattered light intensity, I_0 is the incident light intensity, φ is the angle of detection, n_0 is the refraction index of the solvent, n the refraction index of the solution, r is the radius of the particle, L is the Loschmidt number, c is the concentration of the molecules and M_r is the relative molecular mass.

With the help of some abbreviations like the Rayleigh rate R_0 and a constant K

$$R_0 = \frac{I_s}{I_0} \cdot \frac{r^2}{1+\cos^2\varphi} \tag{6.8}$$

and

$$K = \frac{2\pi^2 n_0^2}{L\lambda^4} \cdot \left(\frac{dn}{dc}\right)^2 \tag{6.9}$$

Equation 6.7 can be transformed. For ideal solutions, Equation 6.7 results in [194, 195]

$$\frac{K \cdot c}{R_0} = \frac{1}{M_r} \tag{6.10}$$

Taking into consideration a real solution with the experimentally determined concentration dependence of the scattered light intensity, the following equation results:

$$\frac{K \cdot c}{R_0} = \frac{1}{M_r} + 2Bc + \ldots \tag{6.11}$$

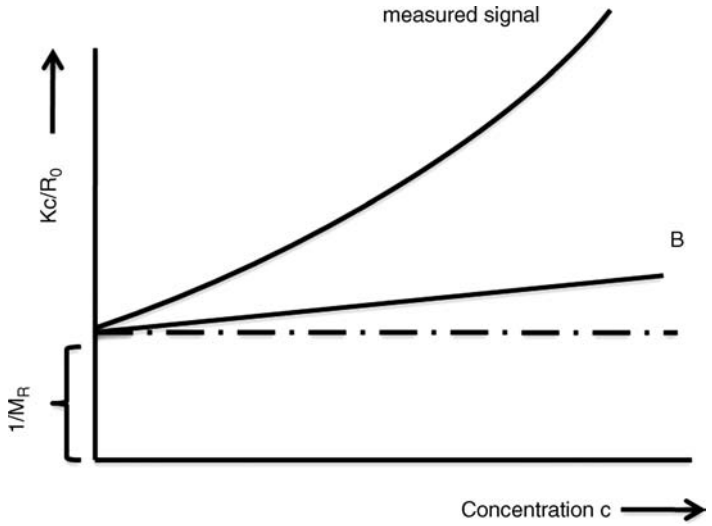

Figure 6.86 Typical measuring curve for $K \cdot c/R_0$ as a function of the concentration c of scattering particles. The ordinate section gives the molecule mass; the ascent of the curve at low concentrations gives the second virial coefficient B (with permission of H.-J. Galla [194]).

From this dependence, the molecular mass and the second virial coefficient B (the interaction strength between the particles) can be deduced (see Figure 6.86).

In the case of Mie scattering, the particle can no longer be handled as a point; the phase of the interacting light has different values at different places in the particle. In general, the contributions to the overall scattered light intensity must be summarized. This procedure is very time consuming and involves the calculation of so-called Mie integrals. Even more sophisticated is the application of a correction function which involves all aberrations of the Mie scattered light intensity behavior depending on the measuring angle compared with the Rayleigh scattered light intensity [194, 195]:

$$P(\varphi) = 1 - \frac{16\pi^2 R_G^2}{3\lambda^2} \sin^2\left(\frac{\varphi}{2}\right). \tag{6.12}$$

This correction term goes to zero if the wavelength becomes large, the radius of gyration R_G becomes small, and the detection angle becomes zero. On the other hand, this correction term fully describes the shape of the scattered light intensity in the case of Mie scattering from the detection angle. Equations 6.11 and 6.12 give

$$\frac{K \cdot c}{R_0} = \frac{1}{P(\varphi)} \left(\frac{1}{M_r} + 2Bc\right). \tag{6.13}$$

The abbreviated equation for the scattered light intensity in this case becomes [194, 195]

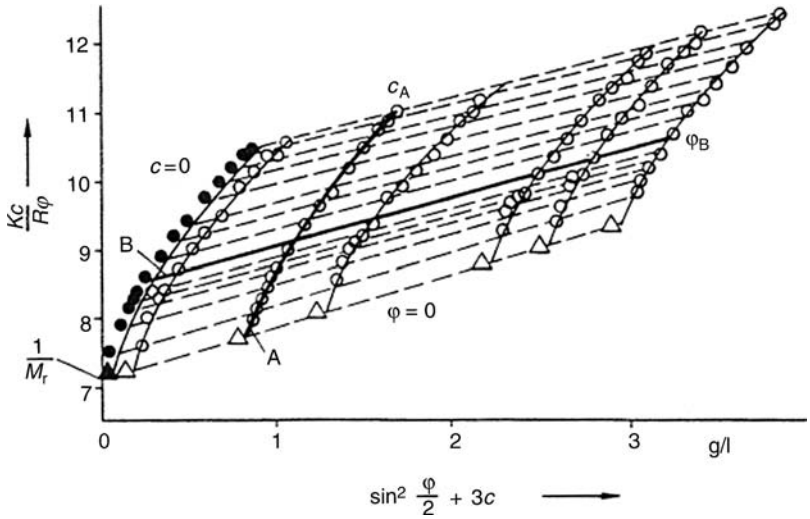

Figure 6.87 Zimm diagram (adapted from [194, 195]).

$$\frac{K \cdot c}{R_0} = \frac{1}{\left[1 - \frac{16\pi^2 R_G^2}{3\lambda^2} \sin^2\left(\frac{\varphi}{2}\right)\right]} \left(\frac{1}{M_r} + 2Bc\right). \tag{6.14}$$

In the case of Mie scattering, it is no longer sufficient to measure the scattered light intensity at one angle only. At least the detection of the scattered light intensity of a half circle is necessary (see Figure 6.87).

Measurement of the scattered light intensity as a function of the concentration and the detection angle leads to the well-known Zimm diagram (see Figure 6.88).

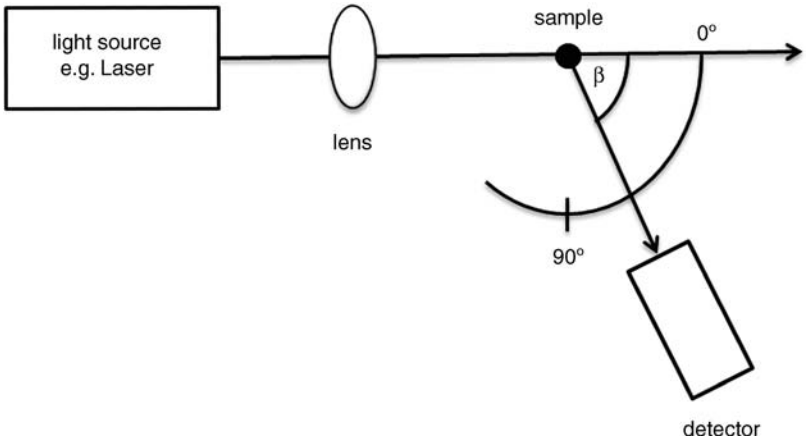

Figure 6.88 Scheme of half-circle detection for detecting scattered light intensity (with permission of H.-J. Galla [194]).

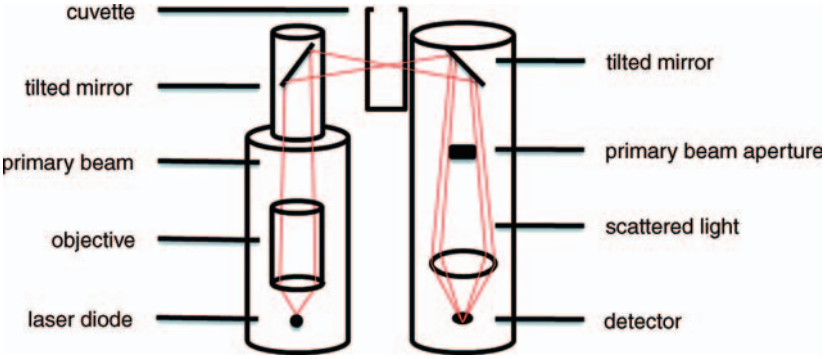

Figure 6.89 Principle of turbidimetry. Only scattered light intensity as an overall signal is detected.

Mie scattering delivers, in addition to the molecular mass and the virial coefficient via the radius of gyration, information about the dimension and the shape of the scattering particle.

In the case of turbidimetry, only the scattered light intensity as an overall signal is detected, as can be seen in the measuring scheme in Figure 6.89. The primary beam is blended out after the samples, and with a lens the whole of the scattered light is directed on to the detector. The scattered light intensity is in this case directly proportional to the concentration of the sample.

Typical precipitation reactions in clinical analysis can be checked by means of scattered light analysis. In the simplest case, the "apparent absorption" is measured and plotted against time to obtain a kinetic description of the precipitation reaction. Plotting the apparent absorption against the concentration leads to the well-known nonlinear form of the calibration curve of immunological reactions (see Figure 6.90).

6.1.8
In Vitro Diagnostics – Blood Gas Pressure Measurements

6.1.8.1 Optical Detection of pO_2 in Blood

In addition to the amperometric detection of gas pressure (oxygen gas pressure in blood), gas components in human blood can also be detected by means of optical methods. In this case the optical fiber connected with the light source (usually a diode laser in the green or blue region) is covered on the tip with an immobilized dye embedded in a polymer which is gas permeable and cleanable with respect to contamination of the analyte solution (blood, urine). The dye is irradiated with the excitation light and fluorescence emission is obtained in the red-shifted wavelength region [196] (see Figure 6.91).

As oxygen is an effective quencher, the permeated oxygen in the analyte solution quenches the fluorescent light. Plotting of the fluorescence intensities in a Stern–Volmer plot leads to a straight-line dependence between the fluorescence intensities (I_0/I) and the oxygen concentration:

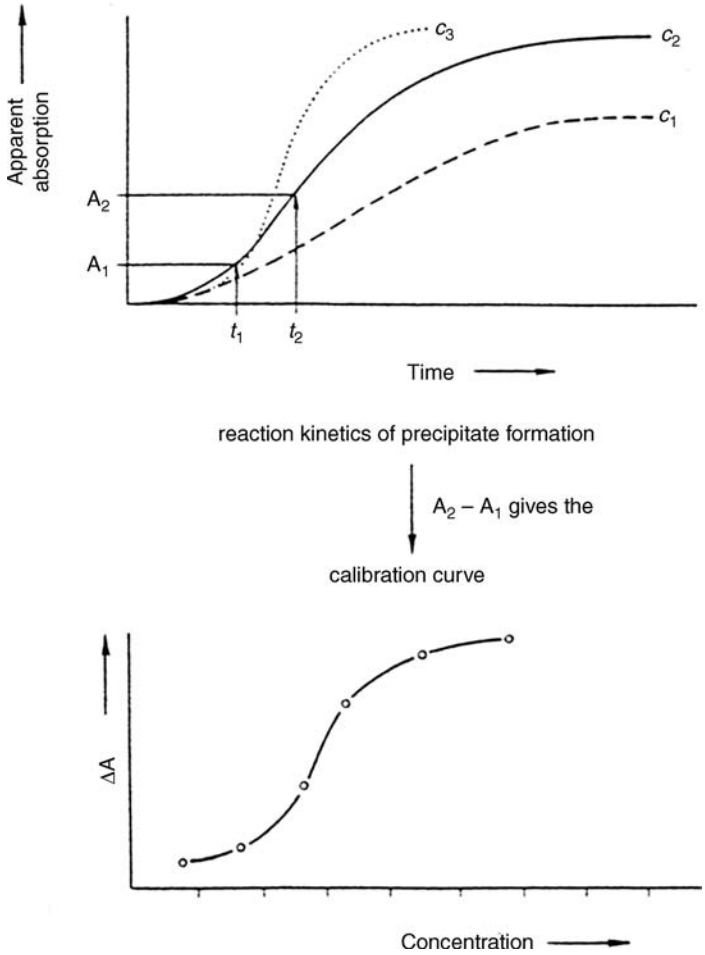

Figure 6.90 Scheme of kinetic–turbidimetric measurements of immunological reactions and transformations in a calibration curve.

$$\frac{I_0}{I} = 1 + k_q \tau_F [Q] \tag{6.15}$$

where k_q is the quenching rate constant, τ_F is the fluorescence lifetime, and [Q] is the quencher (oxygen) concentration. The term $k_q\tau_F$ is the "half quenching concentration," which is the quencher concentration at which the quenching effect is 50%.

With the help of the linear dependence between fluorescence intensity and quencher concentration, the oxygen concentration in blood can be determined.

The great advantage of the optical system is the possibility of minimally invasive permanent monitoring of the oxygen (and carbon dioxide) partial gas pressure in intensive medical monitoring.

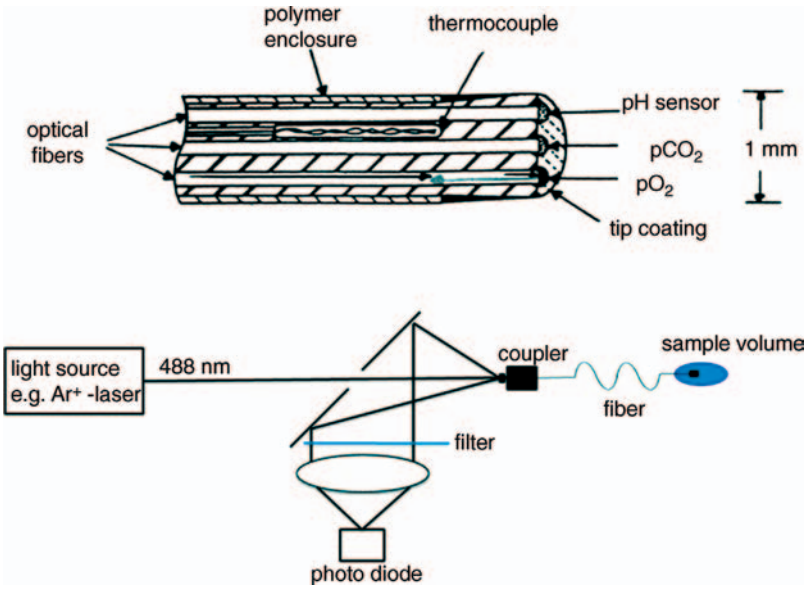

Figure 6.91 Experimental set-up of the fiber-optic partial gas pressure measuring system.

6.1.8.2 Optical Detection of pCO_2 in Blood

The basic principle of the pCO_2 measurement method adapts the Lambert–Beer law and the embodied system using the nondispersive infrared (NDIR) method. Since CO_2 gas reacts to a 4.3 μm wavelength, this wavelength is selected using an optical filter, and the energy decrease due to molecule oscillations is used. The CO_2 concentration is then measured by a mass flow controller (MFC) using basic steps, instead of collecting pCO_2 gas by applying heat to the outer skin. The measuring system consists of an IR lamp, optical filter, optical reaction chamber, pyroelectric sensor, and signal processor. To make the sensor system portable, the length of the optical reaction chamber is minimized to 1 mm using an Si wafer based on MEMS (microelectromechanical systems) technology. When CO_2 gas is injected into the optical reaction chamber, a result of 4.3 mV was confirmed when using a photoreaction path of 1 mm with a CO_2 gas reaction. The response time of the system was within 2 s, which is fairly fast [197].

6.1.8.3 Optical Detection of Further Monitoring Parameters in Intensive Care (Temperature, pH)

Novel methods of temperature measurement use optical fibers and luminescent materials to convert absorption into a temperature-dependent luminescent signal. For example, the delay time of an excited state in an inorganic material has been shown to vary with temperature, and this is readily measured via the phase-shift technique [198]. Other approaches use the creation of an acoustic wave due the conversion of excitation energy into heat and sensitive detection by a microphone for

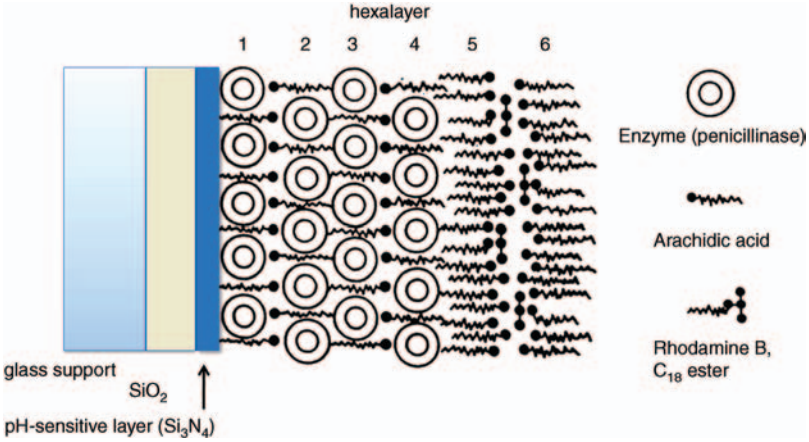

Figure 6.92 Scheme of an optical pH meter composed of Si_3N_4 semiconductor material and a potential-sensitive dye in the layer.

temperature measurement. This method is rather similar to photoacoustic spectroscopy (for more details, see Section 6.1.9).

Optical pH measurements combine the use of semiconductor materials such as Si_3N_4 to create potential changes in the medium with the incorporation of a potential-sensitive fluorescent dye in the layer (see, e.g., [199] and Figure 6.92).

6.1.9
In Vitro Diagnostics – Photoacoustic Spectroscopy

Photoacoustic spectroscopy goes back to Alexander Graham Bell in 1880, who observed that modulated sunlight directed into a gas chamber or on to a thin membrane emits sound. He further discovered that the sound became louder if the sample in the gas chamber was darker (higher light absorption) or the surface became larger. One year later, Tyndall and Röntgen discovered that the sound is also emitted without a solid component in the gas chamber if modulated heat radiation (IR radiation) is directed into the chamber. H_2, O_2, and air gave no sound whereas illuminating gas (CH_4, CO) and ammonia were connected with a loud tone [200–203].

The reason for this effect is that periodic light absorption leads to thermal oscillations in the gas chamber. These thermal oscillations are connected with density oscillations which in its part create sound (sonic) waves that can be detected by a microphone.

In principle, the photoacoustic spectrometer (Figure 6.93) measures the heat production in the sample or, in other words, the contribution of nonradiative deactivation channels in the molecules to the overall relaxation process after absorption. The advantages of the photoacoustic spectroscopy are manifold. First, photoacoustics needs no transmittive sample. The heat and therefore the signal are produced from the front side of the sample. Furthermore, with photoacoustics very

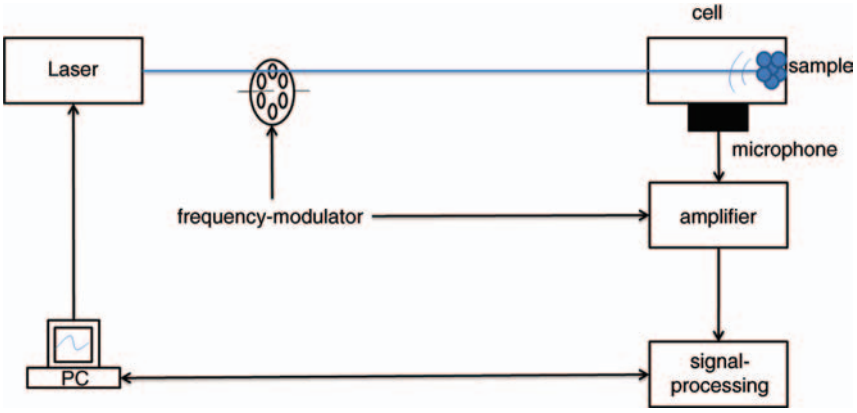

Figure 6.93 Scheme of photoacoustic spectrometer.

high and also very low absorption can easily be detected. The signal is directly proportional to the absorbed power (in solids: absorbed power within the thermal diffusion length). Hence there are decisive advantages in comparison with conventional absorption spectroscopy:

- direct measurement (no difference)
- no transmitted light beam necessary.

The application of photoacoustic spectroscopy in medicine is directed to the investigation of non-transparent samples, for example

- biological samples such as leaves, apple parings, and flowers
- medical samples such as blood, skin, and vessels.

Information given by the photoacoustic spectrum, in addition to the concentration and the spectral characteristics of the samples, includes

- demolition-free depth profiles, material defects
- fluorescence quantum yield, heat capacity, thermal conductivity.

6.1.10 Therapy

6.1.10.1 Introduction

Today, a multitude of therapeutic applications based on the biophotonics concept are available in the medical and cosmetic surgical fields, for example:

- Photodynamic therapy (PDT) [202–207] is used in dermatology for the treatment of viral warts, acne, psoriasis, actinic keratoses, Bowen's disease, basal cell carcinoma, and so on; in oncology for the treatment of cancer of the skin, bladder, breast, stomach, oral cavity, and so on; in ophthalmology for the treatment of wet macular degeneration, subfoveal choroidal neovascularization, pathological

myopia, and presumed ocular histoplasmosis syndrome; in cosmetic surgery as therapy for photoaging, cosmetic skin improvement, oily skin, enlarged sebaceous glands, wrinkles, rejuvenation, and so on; see Section 6.1.1.3.

- Refractive surgery [208–212] alters the curvature of the cornea to improve the focusing characteristics of the eye and can be divided into flap surgery [laser-assisted *in situ* keratomileusis (LASIK), intralase-LASIK, femto-LASIK, intra-LASIK, laser-LASIK, all-laser-LASIK] and surface surgery [photorefractive keratectomy (PRK), laser epithelial keratomileusis (LASEK)] and epithelial *in situ* keratomileusis (epi-LASIK).
- Laser-induced photothermolysis [213–215] is used for removing abnormal cutaneous vessels (telangiactasias, port wine stains, capillary hemangiomas, etc.), for laser skin resurfacing (e.g., treatment of fine wrinkles, photodamaged skin, acne and surgical scars, melasma, uneven skin coloring, stretch marks, keloids, xanthelasma), for laser removal of tattoos and permanent makeup, and for laser removal of undesired hair.
- Photobiomodulation (low-level laser therapy, cold or soft laser therapy, laser biostimulation) [216–218] is applied for the therapy of, for example, wound management, soft tissue injuries, inflammation, arthritis, chronic pain, dermatological conditions, myofascial trigger point therapy, acupuncture, allergy, and tinnitus.
- Photoactivated disinfection (PAD) [219] is an antibacterial dental treatment of, for example, endodontics, periodontics, caries, peri-implantitis, and so on.
- Laser conization [220, 221] is used for cervical intraepithelial neoplasia.
- Laser tonsillotomy [222, 223] is applied for tonsillar hyperplasia.
- Laser interstitial thermal therapy (LITT) [224, 225] is used for the treatment of, for example, brain and spinal cord tumors and breast cancer.
- Percutaneous laser disc decompression (PLDD) [226, 227] can be used to treat back and neck pain caused by a herniated disc.
- Photoselective vaporization of the prostate (PVP) [228, 229] (also known as GreenLight HPS, GreenLight PV, laser prostatectomy, laser TURP) is used to treat benign enlargement of the prostate gland.
- Laser lithotripsy [230, 231] is a surgical procedure to remove a kidney stone, urethral stone, or bladder stone.

Due to this wide variety of existing biophotonics applications in therapy, detailed descriptions of each application would go beyond the scope of this chapter. Therefore, as just one example, refractive surgery, as a widely used laser light therapeutic application in ophthalmology, is described in a more detailed manner in the following section.

6.1.10.2 **Laser Therapy in Ophthalmology – LASIK (Refraction Correction by Cornea Treatment)**

Laser therapy for refraction corrections goes back to Trokel *et al.* [232],who reported the first laser application in ophthalmology in 1983. In 1987 the first commercial cornea surgery laser (>250 000 patients) was introduced.

Direct cornea ablation (photorefractive keratectomy) is preferentially carried out with an excimer laser at a wavelength above the photodecomposition energy of 3.5 eV

(XeCl, ArF, etc.) and the mechanism is ablation by photodecomposition with a precision of $<0.5\,\mu m$ and a typical ablation depth of $100\,\mu m$.

Radial Keratectomy (RK) The idea of surgical vision correction is not new. In the early 1970s, Svyatoslav Fyodorov, a Russian ophthalmologist, developed a procedure called radial keratotomy (RK). He noticed that after removing splinters of glass from a patient's eye, the patient's distance vision improved. In 1978, the procedure was introduced in the US. Surgeons perfected the procedure by creating incisions in the cornea to flatten the front of the eye and to refocus light on to the retina. Unfortunately, it was not a good procedure for patients with higher prescriptions, so surgeons started to search for a new procedure to reshape the cornea.

RK involves the placement of microscopic incisions outside the central optical zone. This weakens the outer perimeter of the cornea and causes it to flatten, thereby moving the point of focus from in front of the retina to the periphery of the retina [233].

Photorefractive Keratectomy (PRK) The next procedure to be developed, photorefractive keratectomy (PRK), approved by the US Food and Drug Administration (FDA) in 1996, uses an excimer laser to resurface the cornea. Because of pain receptors in the surface of the cornea, PRK turned out to be a painful procedure and surgeons looked towards a new approach. Furthermore, the surface of the cornea changed by creating cicatrices in the long term, which reduced the effect of cornea resurfacing dramatically (see Figure 6.94).

Laser-Assisted *In Situ* Keratomileusis (LASIK) Finally, LASIK surgery was developed. LASIK combines the creation of a corneal flap with laser resurfacing. Because there are no pain receptors in the under-layers of the cornea, the creation of the flap proved to eliminate pain involved in the procedure and led to a quicker recovery (see [209] and references therein, and Figure 6.95).

LASIK is a procedure that permanently changes the shape of the cornea, the clear covering of the front of the eye, using an excimer laser. A knife, called a microkeratome, which is better with femtosecond laser pulses (Carl Zeiss Meditec, Jena, Germany), is used to cut a flap in the cornea. A hinge is left at one end of this flap. The flap is folded back, revealing the stroma, the middle section of the cornea. Pulses from a computer-controlled laser vaporize a portion of the stroma and the flap is replaced.

6.2
Photonic Instruments in Biotechnology

6.2.1
Introduction

Much attention has been devoted recently to defining biotechnology. The European Federation of Biotechnology defined biotechnology as the integration of natural sciences and engineering sciences in order to achieve the application

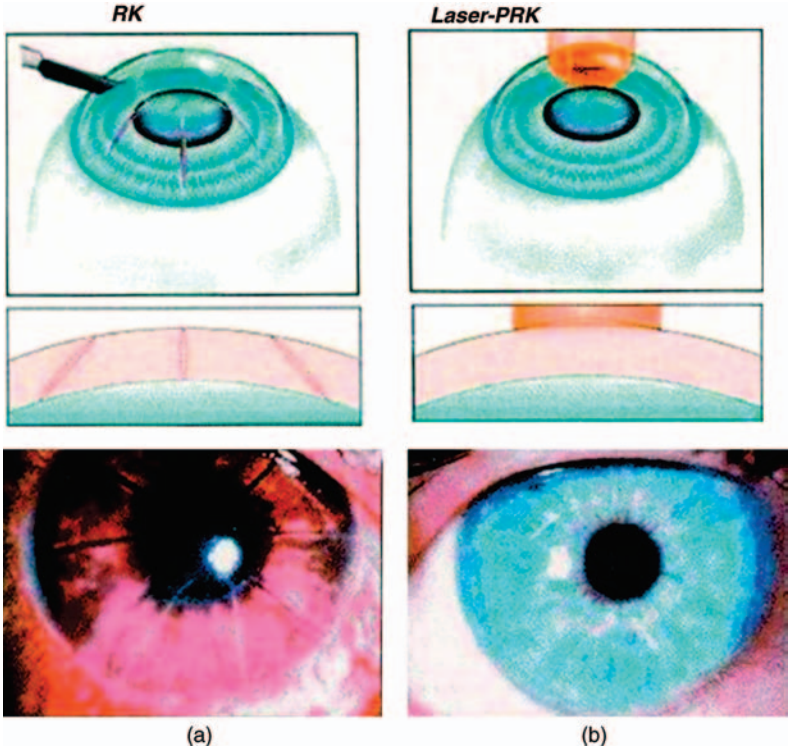

Figure 6.94 Eye after RK (a) and eye 1 day after laser PRK (b).

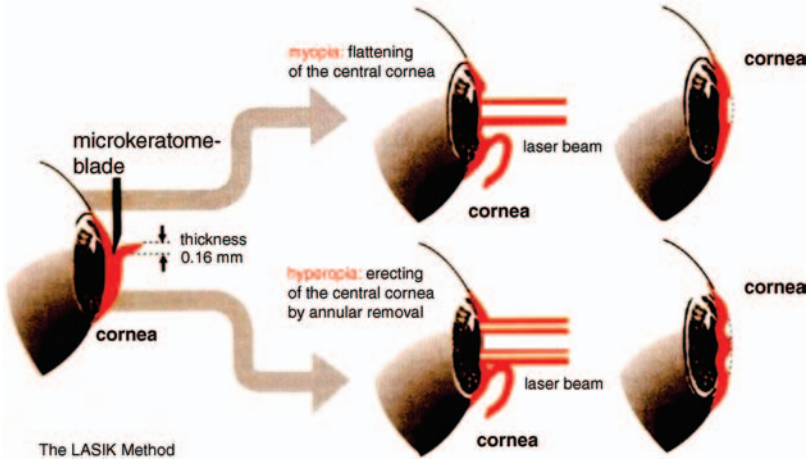

Figure 6.95 LASIK ablative surgery in cases of myotropia and hypermetropia.

of organisms, cells, parts thereof, and molecular analogs for products and services [234].

The interrelation between chemistry, chemical engineering, and the burgeoning areas of molecular biology is especially important as chemical industrial processes incorporate recombinant DNA techniques. In a wider community of chemists, an understanding of the so-called "new" biology enhanced research opportunities and communication in related fields. Frequently, the language of a given discipline creates a barrier to interactions with other disciplines. Rapid developments, such as micro- and nanotechnology have been witnessed in the last few years in the multidisciplinary field of biotechnology, exacerbate this problem [235].

Despite this discussion, biotechnology is one of the oldest technologies of mankind. Depending on the point of view and with consideration of different incisive scientific and technological developments, several steps can be defined [236].

The production of early foodstuffs such as bread, cheese, and sour milk products and also alcoholic beverages such as beer and wine was for thousands of years often characterized by the unwitting use of the metabolism of microorganisms.

The second developmental stage is characterized by biotechnological treatments without prevention of foreign microorganisms. Louis Pasteur (1822–1895) and other microbiologists investigated the metabolic reactions in microorganisms and Robert Koch (1843–1910) developed the technology for the production of microorganisms in monoculture, but often in corresponding processes infections by microorganisms different from those being cultivated could not be excluded. This period was marked by the production of primary metabolic substances such as lactic and citric acid, ethanol, and butanol and the development of the first waste water treatment plants at the end of the nineteenth century.

The next step is to consider the biotechnological manufacture of products with exclusion of foreign microorganisms. The discovery of the antimicrobial action of penicillin by Alexander Fleming (1881–1955) stimulated large-scale production. Sophisticated process technology made the growth of microorganisms under optimal conditions possible. Sterilizability of plant components which are in contact with the fermentation medium was a necessary condition. Following the discovery of further antibiotics, a wide range of secondary metabolic products such as vitamins and pharmaceutical substances came into biotechnological production. This period is still continuing.

One important turning point was, of course, the discovery of the genetic code by James Watson (born 1928) and Francis Crick (1916–2004) in 1953. This fourth period is denoted, in general, by the transfer of knowledge from basic research to biotechnology. Many results in microbiology, biochemistry, enzyme research, molecular biotechnology, genetic engineering, and process engineering are combined into modern biotechnology. All of these disciplines use photonic instruments for the investigation of biological objects and organic and inorganic substances.

On the other hand, material research is also increasingly influencing biotechnology and biotechnological production processes. The selected material itself as well as the interactions between technical/inorganic phase and biologic system/organic material are of considerable importance for optimized biotechnological processes

and technical systems, respectively. Much research work is done with respect to the functionalization of material surfaces and interfaces. The control of structure and surface-relevant interactions at this interface is an essential requirement for innovative developments and products in biotechnology. Examples are the cultivation of adherent cells with ceramic or polymer materials and also modern biosensors and biochips.

Biotechnology today provides products in various application fields with growing markets, employment, and turnover [237]. Meanwhile, a classification by colors has been introduced (e.g., red, medicine/pharmaceuticals; green, agriculture, plant biotechnology; gray, waste management; white, biotech products, industrial processes [238]).

Biotechnological production processes are highly sophisticated and specially adapted and optimized to the relevant biological system (microorganisms, cells, biomolecules) and the desired product [236, 239]. In general, and in brief, the first step is the screening, investigation, and optimization (among others by genetic engineering, and the independent field of Research Technology & Development) of the biological component including the exploration of the optimal process conditions. This is a wide field of application of photonic instruments.

The basic production step, fermentation, involved the transformation of raw material (substrate) into the desired product by microorganisms, cells, or biomolecules or the cultivation of the biomass as the product itself. The technical device used, the fermenter, is a highly sophisticated system. To realize the optimal biochemical change, optimized cultivation conditions (e.g., temperature, pH, dissolved oxygen, stirrer speed for mixing, ion concentration, concentration of substrate and product components, and many more) are controlled by the fermenter. Therefore, fermentation is also an important field of application for analytical and photonic instruments.

Fermenters are available with a broad range of special equipment adaptable for every organism, strain, and metabolic product and therefore for different kinds of processes (see Section 6.2.4). Its volume can vary from a few milliliters to thousands of cubic meters. In parallel with the first step mentioned above, the selection and composition of the nutrient broth, the substrate, is realized. The substrate contains all the necessary components for the maintenance of the microbial or cellular metabolism or for an optimal biochemical reaction.

After sterilization and filling of substrate (or vice versa), the fermenter is inoculated with the organism that will be cultivated.

As result of the fermentation process, the fermentation broth contains the desired final product in a mostly very complex substrate. For this reason, treatment steps are normally necessary to isolate the end product (e.g., by filtration in different forms, centrifugation, digestion, evaporation extraction, crystallization). The monitoring of the product quality and purity is a further field of application for photonic instruments.

However, sensors and analytical systems for the huge range of all biotechnological process steps and every signal level are necessary in general and are widely available for in-line, on-line and off-line measurements. In addition to others, especially

electrochemical devices, numerous optical photonic systems are used. Process coupling is increasingly at the center of attention but the problems of sampling are often neglected.

6.2.2 Selected Analytical Methods

6.2.2.1 Introduction

In biotechnology, a broad range of different measuring systems is used. They can be discriminated by different criteria. One important classification describes the series of steps of the analytical process with respect to the prespecified problem of the measurement [240] (Figure 6.96). An important aspect of this consideration is related to the sampling problem, which is often disregarded.

The analytical principle as the first step of the measurement is quantitatively describable by the underlying natural law. For example, light is absorbed by molecules of a solution; the Lambert–Beer law describes the extinction as a function of concentration.

The analytical method furthermore comprises parts of the sample preparation and the evaluation of the measured value. It realizes a strategic concept for extracting the optimal information content from the object. With respect to the absorption of light, the method includes, for example, rules about how to dilute the sample and how to fill and handle the cuvette, and also instructions about the calculation of the result.

The analytical procedure contains complex protocols including, on the one hand, instructions about the sampling from the measured object or the process and, on the other, sample preparation, the arrangement of measuring equipment, the calibration functions, the possible errors, and so on. In the case of a fermentation process, it could be important, for instance, to prescribe the sample port and the sterile interface to obtain a sample for flow through the cell of a photometer and also the use of calibration curves for the determination of the biomass content from the extinction of the photometer.

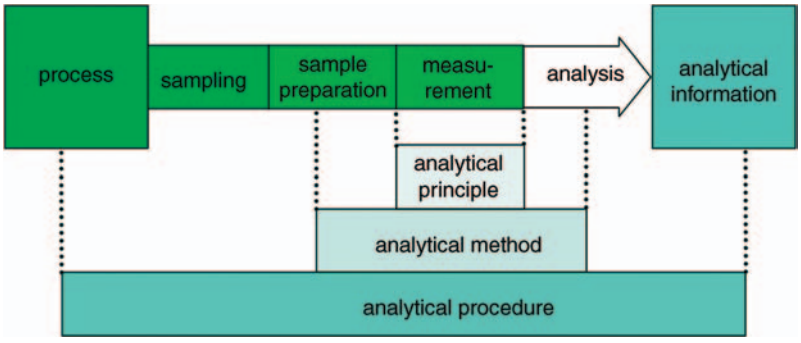

Figure 6.96 Analytical principle, analytical method, analytical procedure.

It is important to state that sensors cannot be classified in this system. In contrast, sensors are in direct contact with the object or the process. In combination with data recording and acquisition by electronics, they are independent systems which are able to record physical or chemical properties of the environment qualitatively and/or quantitatively.

On the other hand, the underlying principles are used both in analytical systems and in sensors. In the context of this chapter, we distinguish here between the methods and the sensors. However, it is important to state that in real practice the relationship is smooth.

6.2.2.2 **Reflectometric Interference Spectroscopy (RIfS)**

Reflectometric interference spectroscopy (RIfS) is based on the multiple reflection of white light at interfaces between thin transparent layers with different refractive indices. The basic principle is Fabry–Pérot interferometry. It is suited to the determination of the thickness of thin transparent layers [241].

At each interface, the light beam is partly transmitted and partly reflected (Figure 6.97 [242]). The reflected beams cover different optical paths. Any change

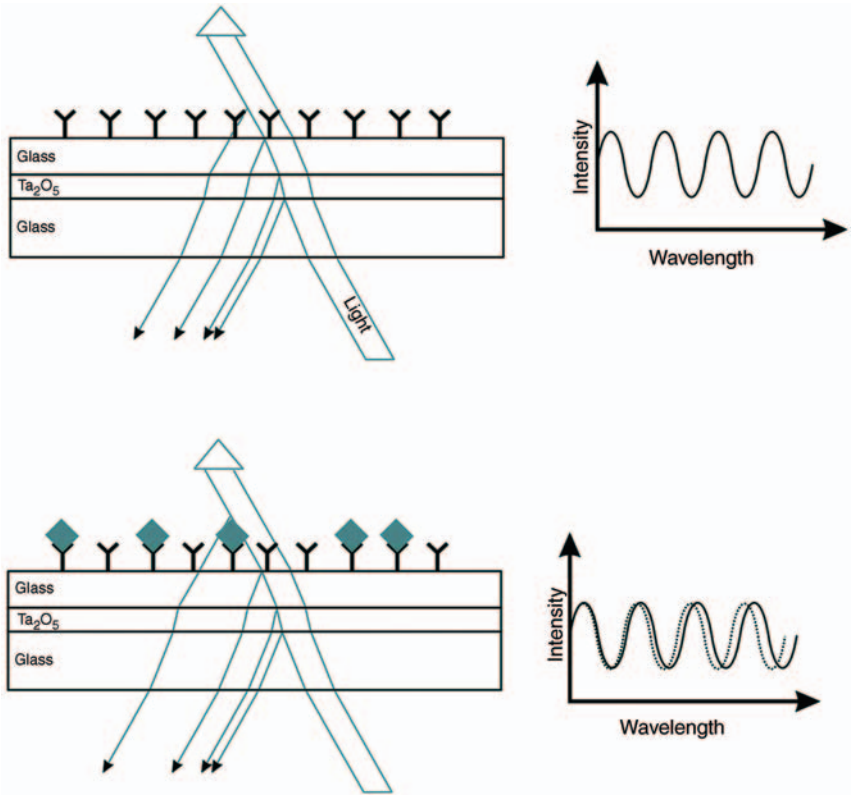

Figure 6.97 RIfS: light is partly reflected and partly transmitted at the glass–antibody layer and also at the antibody–antigen layer.

in optical thickness (represented by *nd*, where *n* is the refractive index and *d* the thickness) will lead to changes in the interference spectrum of the recombined fractions of the reflected light due to constructive and destructive interference of the individual single beams.

Reflection also takes place at biologically activated surfaces (receptors) and at receptor–analyte complexes (e.g., antibody–antigen system). The temporal shift of the position of a selected extremum provides information about interactions between surface-immobilized biomolecules and molecules of the analyte. In combination with a fluidic system, RIfS permits time-resolved, label-free measurement of the real-time kinetics of analyte binding to a surface-immobilized sensor molecule.

As a laboratory method RIfS has also been evaluated for use in different experiments, for example, for bacterial infections [243], testing of biocompatibility [244], and coupling with other highly sophisticated methods {e.g., matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry for the determination of binding interaction of antibiotics [245]}, in addition to being used as a bridging technology for different high-content screening approaches in the development chain of leading structures for the pharmaceutical industry or during the identification and validation processes of new biomarkers [246].

The RIfS method is widely used in biosensors (see below), but analytical systems are also commercially available. Analytik Jena (Jena, Germany) offers the BIAffinity® system [247] for the measurement of concentrations (10^{-3}–10^{-10} M), kinetics (association rate k_a 10^3–$10^6\,M^{-1}\,s^{-1}$, dissociation rate k_d 10^{-5}–$10^{-1}\,s^{-1}$), and affinities (10^4–$10^9\,M^{-1}$). Label-free real-time detection of interactions is possible with simultaneous presentation of the interference spectrum.

Depending on the application, different materials are usable as transducers. Glass slides are coated with niobium pentoxide, titanium dioxide, indium tin oxide and TOPAS® (a cyclic olefin copolymer). The use of a wide range of "classical" bioreceptors has been described (e.g., antibodies, antigens [248], cells [249], oligonucleotides). Modern analytics also applies bioanalogs (e.g., aptamers) and synthetic molecules [e.g. prepared by molecular imprinting (MIP)] [250, 251].

6.2.2.3 **Surface Plasmon Resonance (SPR)**

Label-free interaction analysis is of increasing importance for scientists in the academic, pharmaceutical, biotechnology, and diagnostic markets. SPR, in addition to RIfS, is such a label-free interaction analytical technique. SPR was first demonstrated in 1983 [252, 253].

Plasmons are quantized density oscillations of charge carriers in metals and semiconductors. On irradiating the interface between a glass substrate coated with a thin gold layer and a liquid medium, total reflection can be observed (Figure 6.98) [254]. Normally the gold layer has no influence if it is thin enough. However, at a definite angle and under special conditions of polarization (use of totally internally reflected parallel polarized light) of the incident monochromatic wave, the evanescent field goes into resonance with the electrons of the gold layer and light energy of the reflected light is absorbed. The diffusion and immobilization of a layer of analyte molecules or analyte receptor complexes at the gold surface

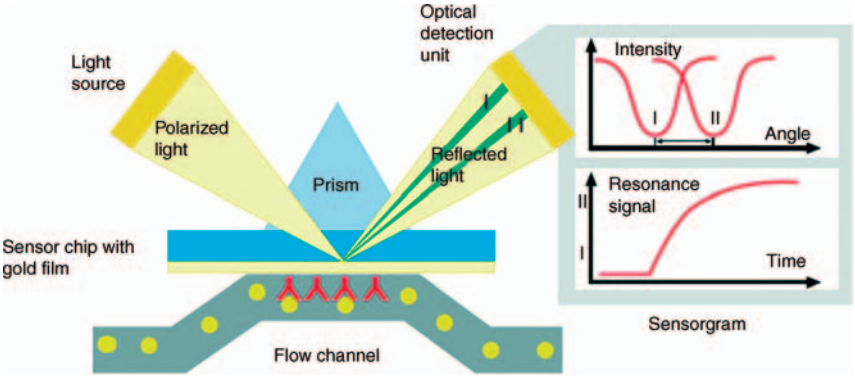

Figure 6.98 The Biacore detector with sensor chip and integrated microfluidics cartridges. © 2010 General Electric Company. Reproduced by permission of the owner.

influence the resonance condition and the maximum signal is detectable at a different angle. The deviation is a measure of the concentration of the substances. Together with a selected receptor, this principle allows specific and quantitative detection. A good overview of SPR is given in [255].

In the same way as RIfS, SPR was developed only as biosensor technology. However, in current biotechnology it is mostly used as sophisticated analytical system using a flow system for sample transport (Figure 6.98) [256]. Biacore (Uppsala, Sweden) commercialized its SPR systems in 1990 [257]. The systems permit label-free interaction analysis in real time and are applicable for concentration measurement in the nanomolar range, compound-target-binding assays in the range 50–2000 ng ml^{-1}IL-6 (interleukine-6), and anti-drug-antibody (ADA) detection. The data give insights into protein functionality, elucidate disease mechanisms, and play a key role in the critical decisions needed for efficient development and production of therapeutics. Numerous research articles deal with special applications [258].

SPR is particularly interesting if more than one receptor is immobilized at the surface. Using a variety of different molecules, for example, by application of biochips with numerous receptor dots, a CCD matrix scans the signals and the interaction analysis of potential binding partners is possible. Some further interesting developments are the extension to complex analytical systems, for example, combination with MALDI-TOF mass spectrometry [259, 260] (see Section 6.2.2.2), miniaturization, the detection of whole cells, the option of remote sensing (by coupling with light fibers), the use of gold nanoparticles in solution instead of a gold layer (which allows, for instance, tumor diagnostics), and multichannel analysis. For future trends, see also [255]; selected applications are described in [261].

6.2.2.4 Fluorescence Methods

Application of Green (GFP) and Other Fluorescent Proteins Since its incidental discovery in 1962 [262], green fluorescent protein (GFP) has become one of the most important tools [263] of molecular biology (Nobel Prize in Chemistry, 2008).

The oxoluciferase aequorin from the jellyfish *Aequorea victoria* fluoresces after excitation by blue or ultraviolet light with the same emission spectrum as the tissue of the jellyfish itself and is associated with a green fluorescent protein. This shows that the GFP is excited by the aequorine. Additionally, no cofactors are necessary for fluorescence. It has two absorption maxima (395 and 475 nm) but only one emission maximum (509 nm). GFP is very stable over a broad pH range and denatures only at temperatures higher than 65 °C. In jellyfish, the excitation energy is provided by radiationless energy transfer from the aequorin protein.

It was found that GFP can be gene-specifically fused with different proteins without loss of fluorescence. Since 1994, GFP has been used as marker for these proteins [264, 265] and this technology has become a standard method in cell biology and genetic engineering, because genetic expressions can be viewed.

GFP can be expressed by numerous organisms and many variants (seven different groups, additionally enhanced variants; see Chapter 7) with different emission spectra have been synthesized by mutagenesis. Today, further proteins obtained (e.g., from corals or *Escherichia coli* [266]) with very different emission spectra (e.g., blue 440 nm, red 610 nm) are available. With these proteins it is possible to monitor the spatial and temporal distribution of different proteins of living cells to which the fluorescent proteins are bound.

Förster/Fluorescence/Bioluminescence Resonance Energy Transfer (FRET, BRET) Fluorescence resonance energy transfer (FRET) and bioluminescence resonance energy transfer (BRET) are useful tools for investigating molecular interactions, biochemical reaction kinetics and their location in living organisms.

FRET (described in 1948 by Thomas Förster and often referred to as Förster resonance energy transfer [267]) is a distance-dependent interaction between excited electronic states of two dye molecules with energy transfer and without transfer of photons. In a typical FRET experiment, the regions of interest are labeled with different fluorophores [e.g., blue fluorescent protein (BFP), cyan fluorescent protein (CFP), and yellow fluorescent protein (YFP)] [268], the donor and the acceptor. It is performed with a fluorescence spectrometer by observing the fluorescence intensity of the donor, and if possible also that of the acceptor, or by specially adapted microscopes, offered by different companies, for example [269]. More complicated but more convincing is the measurement of the fluorescence decay time.

The absorption of the donor takes place at a shorter wavelength than that of the acceptor and the FRET efficiency E_{FRET} can be detected by the appearance of sensitized fluorescence of the acceptor by quenching of donor fluorescence. The efficiency of this process depends on the inverse of the sixth power of the intermolecular distance [270]:

$$E_{FRET} = \frac{1}{1 + \left(\frac{R}{R_0}\right)^6} \tag{6.16}$$

where R is the distance between fluorophores and R_0 is the Förster radius, which is the distance at which 50% of the donor fluorescence is quenched.

The spatial resolution of a conventional fluorescence microscope is limited by the Rayleigh criterion to about 200 nm. FRET permits the determination of the closeness of the molecules within a few nanometers (Förster radius), depending on the fluorescence quantum yield of the donor (e.g., 4 nm for BFP–GFP, 5 nm for CFP–YFP). The process can take place when the donor fluorophore in the electronically excited state transfers its excitation energy to the nearby acceptor. If the fluorescence emission spectrum overlaps the absorption spectrum of the acceptor molecule, the donor transfers the energy by long-range dipole–dipole intermolecular coupling.

A limitation of FRET is the requirement for external illumination to initiate the fluorescence transfer, which can lead to background noise in the results from direct excitation of the acceptor or to photobleaching. To avoid this drawback, BRET was developed. This technique uses a bioluminescent luciferase rather than CFP to produce an initial photon emission compatible with YFP.

FRET has become a standard tool in molecular biology {e.g., real-time quantitative polymerase chain reaction (PCR) [271–273]}, biochemistry (e.g., hetero- and oligodimerization, reconnaissance of signal transduction pathways [274]) and cell biology [275, 276] for the detection of protein–protein, protein–nucleic acid, and nucleic acid–nucleic acid interactions [277]. It is also used for spectroscopy and in combination with confocal microscopy. FRET and BRET in research are also used for the study of molecular motors, that is, the molecular machines for the movement of living organisms. Furthermore, by labeling different ends of a molecule, the kinetics of fragmentation can be observed in real time.

Flow Cytometry/FACS The key technology of cytometry was developed in 1968 by Wolfgang Göhde and Wolfgang Dittrich [278, 279] and has been commercialized by several companies. Flow cytometry combines fluorescence and stray light measurement into a powerful technique which can be used for the analysis of multiple parameters, especially for counting and examining microscopic particles. In biotechnology it is used for a wide range of applications from individual cells within populations, chromosomes, and ploidy analysis to GFP expression analysis [280, 281]. For descriptive introductions see [282–284].

Cells are suspended in a fluidic stream (Figure 6.99 [282]) until thousands per second are passing a laser beam and the fluorescent and forward- and side-scattered light emerging from each cell is captured and statistically evaluated in real-time. Relevant parameters are, for example, size, components, complexity, and phenotype.

The sample is transported to the interrogation point by a flow system. Lasers are used as light source. The optics gathers and directs the emerging light to the detectors. The operation and data evaluation are substantially computer controlled.

Laser light and the sample intersect at the interrogation point. The sample stream containing the cells is injected into the fluid stream by hydrodynamic focusing. Due to the higher pressure of the outer sheath stream, the inner sample stream is formed into a thin thread. In consequence, the cells pass through the laser beam one at a time. In practice, cytometers can detect cells with diameters between 1 and 15 μm. Specialized systems can detect particles outside this range.

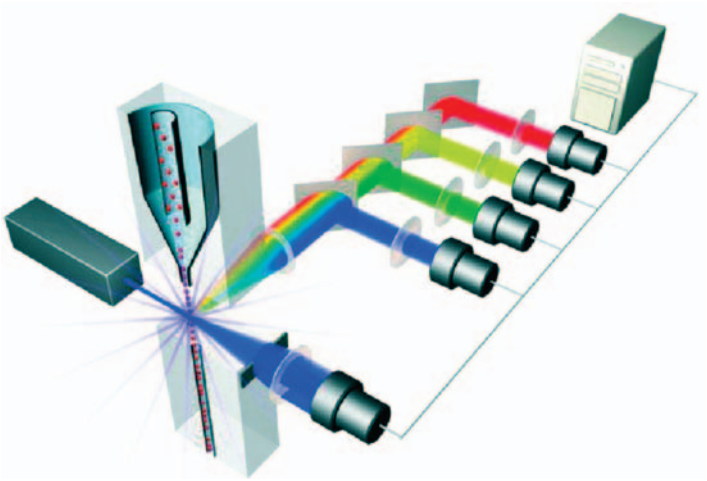

Figure 6.99 Basic design and optical path of the flow cytometer (Invitrogen).

Stray light from the interrogation point can be measured at different angles. Routine devices besides fluorescence are designed to measure low-angle scattered light and/or light scattered at a right-angle. The forward-scattered light is nearly proportional to the cell size. Hence the scattered light received by the detector is proportional to the cell size and results in a histogram of the diameter distribution. The side-scattered light characterizes the granularity and structural complexity inside the cell. Separate detectors sample this light as a function of the wavelength also as histograms. The combination of both measurements is a 2D histogram with patterns characterizing the different particles of the sample.

A third signal, the fluorescence of different marker molecules (dyes) applied to label cells is measured as a function of wavelength by the same detectors again as a one- or two-color histogram. Using two dyes, a two-color histogram can be evaluated as a two-color dot plot. Dichroitic filters separate the different emission wavelengths of the different markers. The spectral overlap of the filters depends on their characteristics and on the fluorescence spectra.

Because it is possible to sort cells according to the measured characteristics, cytometers are often also termed fluorescence-activated cell sorters (FACS), despite the fact that this is a registered trade mark of the Becton-Dickinson [285] company. Separation is possible by tagging of cells of interest with an antibody linked to a fluorescent dye. This antibody must be bound to a protein expressed in the cells of interest. Ultimately cells are sorted by electrical charge, which is computer controlled, applied to the drops before being formed at the end of the flow stream. These charged drops are then deflected to sample tubes.

In addition to biotechnology, there are also numerous applications in medicine, for example, blood analysis [286, 287], bone marrow diagnostics [288, 289], immune phenotyping [290, 291], and AIDS research [292].

Fluorescence *In Situ* Hybridization (FISH) Fluorescence *in situ* hybridization (FISH) is a special form of *in situ* hybridization, a molecular method to detect nucleic acids (DNA or RNA) in tissues, cells, or metaphase chromosomes by fluorescence. It rests on the pairing of complementary bases of single nucleic acid strands. One of these is previously labeled (e.g., with haptens, in the case of FISH directly with fluorescing molecules) and the other is the strand to be detected.

6.2.2.5 Advanced Microscopic Techniques (Selection)

Some of the available advanced microscopic techniques are also based on fluorescence. According to classical physics (Abbe's theory of image formation, Rayleigh criterion of resolution; see below), until not very long ago it was accepted that two objects limited by diffraction can be resolved only if they are not closer than about half of the wavelength of light, that is, about 240 nm.

The lateral two-point resolution is calculated by

$$\Delta r = \frac{0.61\lambda}{n \sin \alpha} \tag{6.17}$$

where n is the refractive index and α half the aperture angle. The product $n\alpha$ (n sinα) is called the numerical aperture.

The axial two-point resolution is given by

$$\Delta z = 2\frac{n\lambda}{(n \sin \alpha)^2}. \tag{6.18}$$

Many biological objects of interest are smaller. By the end of the last century, new concepts and technical developments overcame the diffraction criterion and allowed the transition from microscopy to nanoscopy. Some ideas that emerged from scanning and fluorescence microscopy (e.g., labeling) recently resulted in a large number of microscopic methods. To present them all would go beyond the scope of this chapter (see [293, 294]) and here are only a few principles are mentioned.

Confocal Laser Scanning Microscopy (CLSM) Confocal laser scanning microscopy (CLSM) is distinguished by enhanced lateral resolution (about 200 nm) and depth selectivity. In contrast to classical fluorescence microscopy, only a disc-shaped area of the fluorescently labeled or autofluorescent sample is illuminated by a focused laser beam via a pinhole and the sample is scanned point-to-point (Figure 6.100 [295]). A detector pinhole focused to the same plane eliminates light scattered outside the focus plane. The image is electronically reconstructed by computer. By the reduction of the out-of-focus blur, the image definition of opaque samples is enhanced, allowing better surface profiling and to a certain extent (non-opaque samples, light absorption) virtual 3D images with a depth penetration from some tens to a few hundred micrometers are possible. Comprehensive image processing software supports this option [296, 297]. Although already patented in 1957, it needed further technical developments in other fields to make this system suitable for research and routine uses, especially lasers and computer technology.

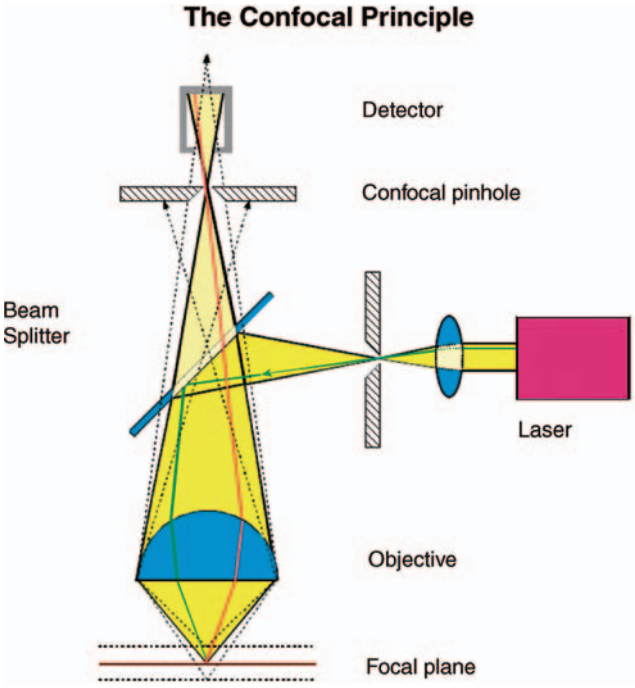

Figure 6.100 Principle of CLSM. Copyright (2010) Leica Microsystems CMS GmbH.

CLSM is used for innumerable applications. Especially in biotechnology and medicine [293], new options are opened up for the investigation of cells and tissues [298–301].

Two-/Multi-photon Laser Scanning Microscopy (TPLSM, MPLSM) In multi-photon laser scanning microscopy (MPLSM), the fluorescence of the (labeled) sample is excited by a pulsed solid-state laser. In CLSM, the energy of the excitation light corresponds to the difference in the energetic levels of the ground and excited states of the fluorescing molecules (one-photon excitation). whereas in MPLSM, the energy of the exciting electron due to quantum effects can be smaller than the energetic distance of the two levels provided that the excitation of the two or more photons takes place nearly simultaneously (the excitation probability is proportional to the reciprocal pulse duration) and with high intensity. Both requirements are fulfilled by femtosecond lasers (pulses of 10^{-15} s, e.g., titanium sapphire laser).

A major advantage of these nonlinear processes is the limitation of the excitation to the focus volume. As a consequence, the fluorescence is also generated mainly in this focus region. A second result is the excitation of the fluorescence with (in the case of two photons) half of the energy, which is especially advantageous for the investigation of sensitive samples such as biological objects. By both effects the unobserved

regions of the sample are less charged with energy and the bleaching of the fluorescent dyes is reduced. Further, the longer wavelength used in two-photon laser scanning microscopy (TPLSM) penetrates the sample up to five times deeper. Because the signal is generated only in the focus, no pinhole is necessary. Therefore, photons from the focus scattered by other sample compartments can contribute to the image.

As in CLSM, in TPLSM the sample is scanned and the signal of every scattered focus point contributes to the computer-generated 3D image. Different scanning modes are available [302] (Figure 6.101). Derived from theoretical considerations, the lateral resolution of the TPLSM is about 1.5–2 times better than that of the CLSM and typically reaches about 300 nm; the axial resolution is of the order of micrometers. It should be mentioned that in addition to the use of labels [303] and of autofluorescence, the application of the above-mentioned fluorescent proteins is common.

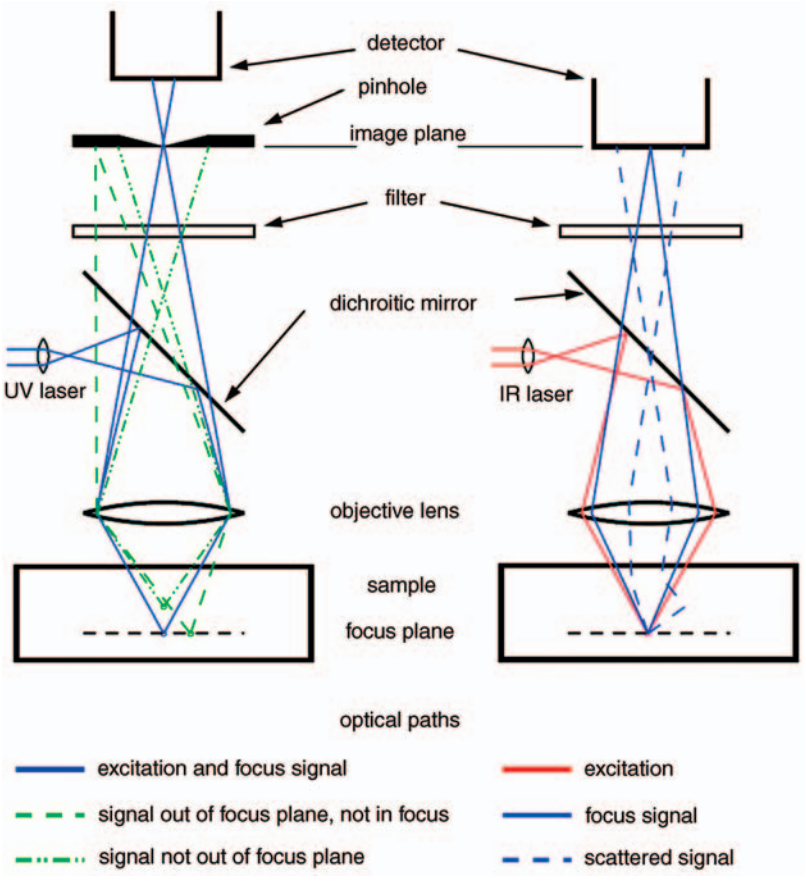

Figure 6.101 Comparison of CLSM and TPLSM: in both cases a laser beam (UV or IR) is focused via a dichroitic mirror and the objective on the sample. Fluorescence is projected on detector. The filter blocks the excitation light.

Applications in biology and medicine are numerous, for example, the investigation of cell interactions [304], imaging of neurons [305], tissue remodeling [306], and tumor research [307].

Resulting from the advantage that the exciting energy is generated only in the focus, TPLSM is used for other working methods. The option to adjust the energy in the focus point, on the one hand, enables one to destroy structures specifically. This can be used, for instance, for the investigation of structure–function relations of macromolecules or cells. On the other hand, it becomes possible to dose energy, for example, for the triggering of polymerization reactions on the nanoscale, for instance to generate predetermined structures.

4Pi Microscopy (4Pi) 4Pi microscopy (4Pi) is a far-field fluorescence 3D microscopic method and a version of confocal microscopy. In consequence of the previously mentioned Abbe criterion and because many biological objects (cell organelles, viruses, genes) are smaller than the minimal resolution in fluorescence microscopy, objects are with increasing regularity observed indirectly by fluorescence labeling (e.g., GFP). The lens projection of a point light source to a focus point caused by the wave character of light does not result in a point image but in an intensity distribution around this point, which has a greater extension in the z-direction than in the x,y-directions. If the projection of the complete solid angle 4π were possible, the resolution could be increased. It could be shown that it is possible to minimize the spread of the focus to the minimal distance given by Abbe by the so-called point spread function engineering [308].

Using a beamsplitter cube [309] (Figure 6.102), the excitation light of the laser source is split into two beams with the same intensity and projected by two opposing lenses of high numerical aperture. The counterpropagating spherical wavefronts are

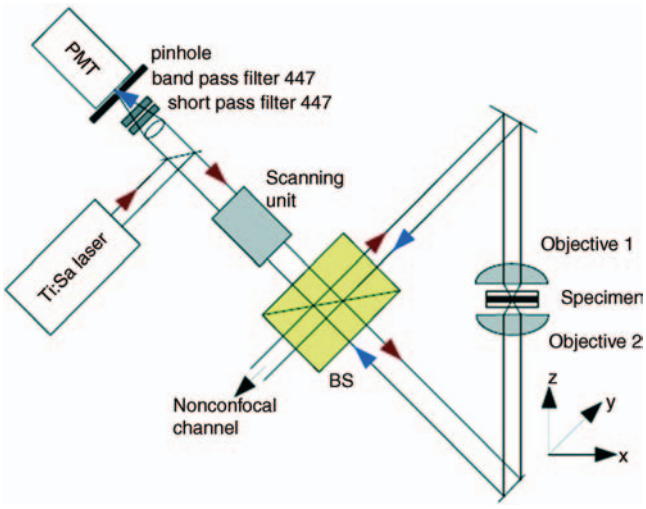

Figure 6.102 Principle of beam path of 4Pi microscope. BS, beamsplitter.

coherently summed at the focal point. The sample is scanned in the axial direction. The fluorescent light is recorded by both objectives, recombined by the beamsplitter and back-reflected to the confocal scanner, where it is spectrally detected.

As a result, the axial resolution is improved 3–7-fold down to 100 nm. 4Pi is mostly applied in cell imaging for biology and medicine [310–312].

Stimulated Emission Depletion (STED) Microscopy Stimulated emission depletion (STED) microscopy is another variant of non-diffraction-limited far-field fluorescence microscopy [294, 313] that has recently found application in biology and medicine [314, 315]. Fluorescence markers are applied for labeling of small components of the sample. When irradiated by a focused laser beam, molecules emit [316] (Figure 6.103) light within a few nanoseconds. In STED microscopy the effective excitation is limited to a small spatial extent. This is facilitated by a second laser beam which is focused like a donut with central zero intensity. Its wavelength and energy are in the red region and therefore too low to excite the molecules, but it is adapted to de-excite molecules by stimulated emission.

The donut shape of the laser beam de-excitation of the molecules in the outer zone of the excitation beam is achieved to confine molecules in the ground state whereas the molecules in the middle of the donut remain excited and fluorescent. In this way, resolutions of better than 20 nm ($\sim \lambda/50$, 15 times better than confocal microscopy) are possible. Excitation and de-excitation are realizable by synchronized laser pulses of shorter than 100 ps and longer than 300 ps, respectively.

It should be mentioned that several different methods and variants of STED microscopy have been reported, for instance, reversible saturable/switchable optically linear fluorescence transition (RESOLFT) and ground-state depletion (GSD) microscopy [294].

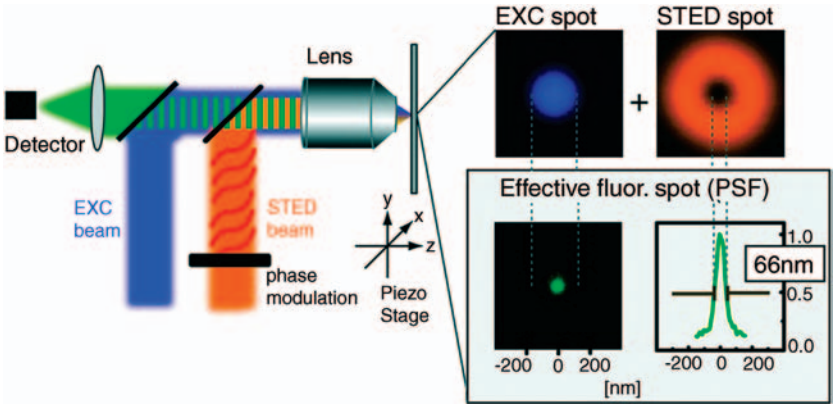

Figure 6.103 STED: exciting and de-exciting light pulses are coupled in simultaneously. The exciting laser generates a diffraction spot of >250 nm whereas the wave front of the STED beam is modified by a phase shift and generates a "donut." in this way, at the edge of the donut fluorescence is prevented. In the middle of the spot fluorescence can be observed.

Scanning Near-Field Optical Microscopy (SNOM, NSOM) Compared with the microscopes mentioned above, scanning near-field optical microscopy (SNOM or NSOM) is a near-field technique. SNOM yields high-resolution topographic and optical images and is an important technique for visualizing biological systems.

The theory was originally proposed in 1928. The Abbe diffraction limit is circumvented by SNOM because the light is generated, scattered, and detected in the near-field. Illumination of the sample is realized through an aperture with a diameter significantly smaller than wavelength of the light. Resolutions of 50 nm can be realized.

A point light source is placed within nanometers of the surface of interest, different modes are known (transmitting, reflecting, collecting, and illumination/collection mode imaging, depending on the illumination and the detected light [317]; see Figure 6.104). A few different light sources are available (tapered optical fibers, cantilevers used in atomic force microscopy with a centered hole for laser illumination, pipets filled with light-emitting or luminescent compounds). The tip is positioned within a few nanometers above the surface and controlled by special feedback mechanisms. The sample is scanned.

Changes in refractive index, reflectivity, transparency, and polarization, and also fluorescent and excited molecules (e.g., Raman) are usable for image generation [317].

Combinations with atomic force microscopy, laser tweezers, and immunolabeling, among others, extend the opportunities for application in life sciences from single fluorescently labeled molecules such as DNA or proteins up to whole cells and chromosomes (for examples, see [317–322]). SNOM is particularly suited to labeling cell surface membrane proteins, since the illumination depth is limited to tens of nanometers. This allows good discrimination between proteins at the cell membrane and those in the cytoplasm [323]. Fluorescent labeling of chromosomes is also

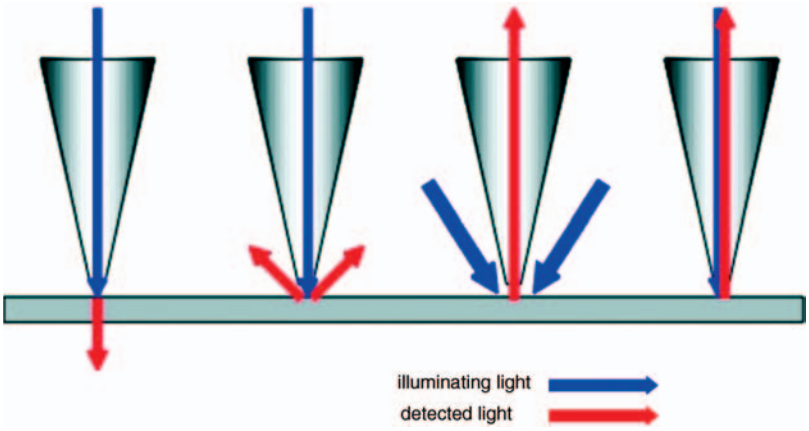

Figure 6.104 SNOM: modes of illumination of the sample and detection of light (for explanation, see text).

common, using FISH or other techniques to label particular areas, which can then be identified in the topography images.

6.2.2.6 Enzyme-Linked Immunosorbent Assay (ELISA)

Enzyme-linked immunosorbent assay (ELISA) is a common serological test for the presence of particular antibodies or antigens. It was developed simultaneously with but independently of enzyme immunoassay (EIA) [324]. It is based on the principle of immunoassay, that is, the interaction of antibodies and antigens of the immune system, and can measure their concentrations sensitively. The principle is similar to radioimmunoassay (RIA), which needs a radioactively labeled detection reagent for quantitative measurement.

In principle, the examined substance (e.g., the antigen) is bound to a solid surface of a microtiter plate, which is immobilized with a specific antibody. Subsequently a second enzyme-labeled antibody is added. The enzyme is used for colorimetric or fluorimetric detection.

Today ELISA represents a standard method in biotechnological and medical laboratories and is applied in numerous detection applications, for example, for low molecular weight compounds (hormones, toxins, pesticides) and also for proteins and viruses [325–328].

Several different technologies have been developed over time. The basic technology is the sandwich ELISA in which, complementary to the basic principle, a secondary antibody bounds at a different site of the antigen [329] (see (4) in Figure 6.105). The method is more universal because this secondary antibody is usable for several different detections.

Competitive ELISA as a further method uses a labeled structural analog, a synthetic antigen, instead of the antibody that competes with the analyte for the binding site.

The indirect ELISA test determines whether a specific antibody is present in the sample. This technique first immobilizes the appropriate antigen to the walls of the microtiter plate [330].

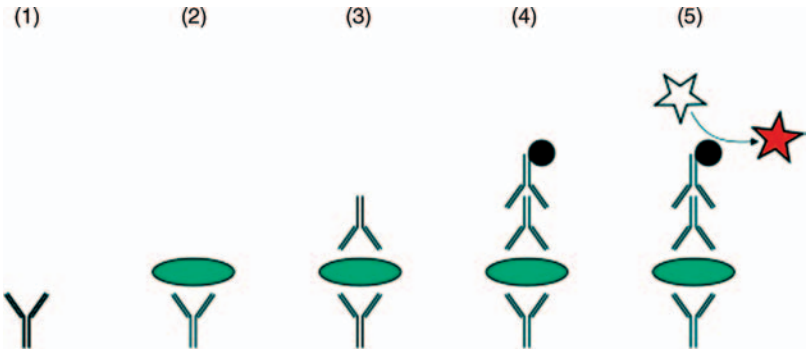

Figure 6.105 Sandwich-ELISA.

6.2.2.7 Optical Biosensors, Biochips, Miniaturized Analytical Systems

Optical Biosensors Chemoreceptors of cells have binding sites for specific substances. Following a binding reaction of this substance with the receptor, the protein structure is changed and an ion channel is opened for transporting ions.

Biosensors are technical analogs of the chemoreceptors of cells. They are defined [331] as self-contained integrated devices which are capable of providing specific quantitative or semiquantitative information using a biological recognition element (biochemical receptor) that is in direct spatial contact with a technical transduction element. The biological recognition element has to identify a substance specifically (key–keyhole principle) and to generate a signal resulting from the contact with this analyte (see Figure 6.106). The technical component has to transduce this signal into a technically processable signal.

This definition is partially outdated because of two developments. Today, the recognition elements are not only biological receptors but increasingly also biotechnological, biomimetic, and synthetic substances. The second reason is that the receptor and transducer are no longer just in direct spatial contact, they are highly integrated, for example, in the form of biochips.

In general, biosensors are classified into two main groups: bioaffinity and metabolism biosensors [332, 333]. This reflects what happens between the receptor and the analyte. Not discussed further here, sometimes one encounters additionally the group of coupled and hybrid sensors and also biomimetic biosensors.

At the surface of a *bioaffinity sensor*, the analyte A is bound with a receptor R as a stable complex characterized by the alteration of the electron density:

$$A + R \Leftrightarrow AR \tag{6.19}$$

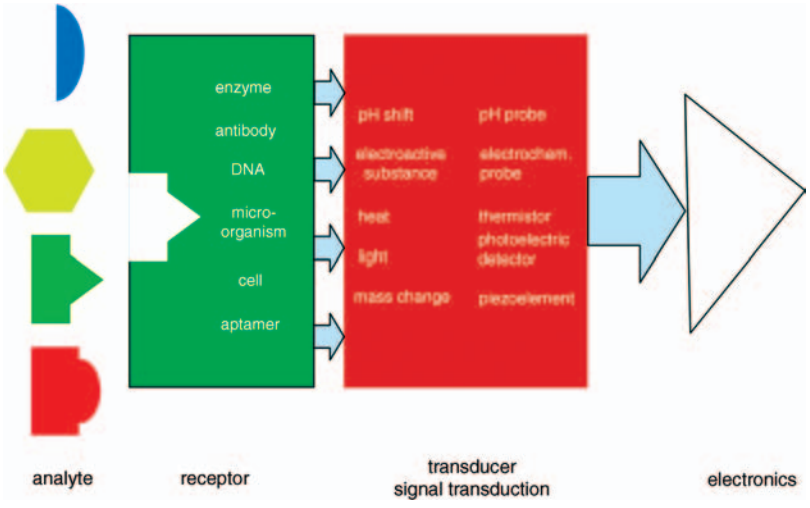

Figure 6.106 Schematic principle of a biosensor.

A typical example is an immunosensor. The related physico-chemical alteration, for instance, layer thickness, refractive index, light absorption, or electrical charge, can be measured by different optoelectronic sensors, based on a quartz microbalance, by surface acoustic waves, and others. The initial state has to be recovered by splitting of the complex.

In the case of *metabolism biosensors* the molecular recognition of analytes by the receptor is coupled with the chemical conversion of the analyte into a product:

$$A + R \Leftrightarrow AR \Leftrightarrow P + R. \tag{6.20}$$

Here an enzyme biosensor typically represents the principle. Mostly electrochemical transducers are used, sometimes also thermometric biosensors, and less frequently optical sensors. It is important to state that the analyte is consumed and the receptor is available in the initial state again.

Other classifications [332] (Table 6.4) distinguish between the different kinds of receptors (e.g., enzymatic, immuno, cell-based, synthetic biosensors, molecular imprinted) or transducers (e.g., electrochemical, optical, piezoelectric, thermal biosensors) [334, 335].

Table 6.4 Recognition elements and transducers of various configurations generate data which are differently analyzed (selection).

Recognition element	Transducer	Measured data/ evaluation	Configuration
Biologic Enzymes Antibodies Nucleic acids Cells *Biotechnological* Designed enzymes Transgenic cells Variants of antibodies *Biomimetic* Highly affine aptamers Peptide nucleic acids *Synthetic* Synzymes Molecular imprints	*Electrochemical* Amperometric Potentiometric Conductometric Capacitive Impedance Microelectrodes ISFET's *Optical* Photometric Interferometric Fluorimetric Optical light guides *Mechanical/ Thermodynamical* Thermistors Piezoelements (Quartz micro balance) Surface acoustic wave	Threshold values Digital single Concentrations Biological effects Pattern recognition	Sensor/probe Microanalytical system Microfluidic systems Micro-total analysis Systems (μ-TAS) Micro-electro-mechanical systems (MEMS) Highly parallel systems (biochips)

In biosensors, three processes proceed successively:

- specific recognition of the analyte
- transformation of the physico-chemical alteration caused by the interchange with the receptor into an electrical signal
- signal processing.

Applications of biosensors are very diverse [334, 336], extending from biotechnology to food technology and from environmental monitoring to forensic and human medicine.

Probably the first and most important stimuli for the development of biosensors arose from medicine. In 1962, Clark and Lyons [337, 338] developed the first biosensor for the determination of glucose in blood. Based on the electrochemical oxygen probe, invented by Clark, the enzyme glucose oxidase was immobilized between two membranes on top. The glucose concentration could be measured from the change in the oxygen concentration due to the oxidation of glucose by the catalytic action of the enzyme. As a result of investigations in different scientific disciplines (e.g., biochemistry) and technological developments (e.g., biotechnology, sensor technology), a vast number of biosensors have now been developed. This progress has culminated in the presentation of modern biochips and microanalytical systems (see the subsections Biochips and Miniaturized Analytical Systems below) with incorporated (bio)sensors.

In medicine, point-of-care testing (POCT) [339] means the use of small, robust, and simple to handle instruments with less consumption of substance and without sample preparation. Instruments in this class allow fast analysis, need no sample transport, and are not integrated in the time flow of the laboratory. Short turnaround times (TATs) permit optimization of therapy [340] (Table 6.5).

One of the goals with the glucose sensor mentioned above was the improvement of the monitoring of diabetes patients. Especially the monitoring of critical states and self-control of patients were targeted. During the last decades, numerous of new and especially miniaturized sensors were developed. These miniaturized sensors based on electrochemical transducers are often combined with other sensors and integrated in analytical hand-held systems, and some of these developments are suitable for patient self-control [341].

Table 6.5 Typical turnaround times (TATs).

POCT parameter	TAT (min)
Metabolic (glucose, bilirubin, lactate)	30
Coagulation	30
Fertility	
Hematology	30
Cardiology [troponine, CK-MB (creatine kinase muscle–brain)]	Immediately
Kidney function	<60
Blood gas	Immediately
Electrolytes	30
Infection serology	<60

With respect to the subject matter of this book, in the following only biosensors based on optical effects (e.g., diffraction, interference, total refraction) or transducers will be discussed. Sometimes more than one effect is used in this kind of biosensor (e.g., diffraction and SPR).

- **Evanescent field biosensors, total internal reflection fluorescence (TIRF)**: Inside an optical waveguide, light is totally or partially reflected at the interface between the core (with lower refractive index) and the surrounding cladding (with higher refractive index). However, the amplitude outside the core does not decrease discontinuously to zero, it decays exponentially. This evanescent part of the wave can be used for the detection of binding events between analytes (e.g., pure or labeled antigens) and a receptor (e.g., antibody), which is immobilized at the surface of the core without the cladding. One option is to compare the light absorbed by the receptor with and without bound analyte. The other opportunity is the excitation of fluorescence of the (labeled) analyte and the measurement of the fluorescent light irradiated back into the waveguide.
- **Interferometric biosensor, reflectometric interference spectroscopy (RIfS)**: Another group of biosensors is based on the principle of interference. In a basic type, light from a waveguide is split into two arms, a sensing arm with the appropriate immobilized receptor and the reference arm (Mach–Zehnder interferometer). In the sensing arm, interaction between light and receptor–analyte complex takes place by evanescent waves. After passing the arms, recombination of the waves allows the observation of constructive and destructive interferences depending on the concentration of the analyte. The principle of RIfS is more often used. The label-free multiple reflection of light at interfaces between thin transparent layers with different refractive indices is the underlying principle of this biosensor type. The principle is described above. RIfS systems provide measurement of real-time kinetics of a bioanalyte binding to a surface-immobilized sensor molecule (see Section 6.2.2.2) and also the investigation of conformational changes in the receptor, leading to the activation or inhibition of the receptor-dependent pathways [342] and much more (see the references in Section 6.2.2.2). Application to fermentation control has also been described [343].
- **Grating couplers**: Often the variation of the refractive index is used to monitor the reaction between analyte and receptor. The grating coupler (in addition to the prism coupler, which is not discussed here) offers a method to determine the refractive index via the evanescent field of the waveguided light. A surface grating is used to couple or decouple light into the waveguide. The effective refractive index influences the grating constant and therefore also the interference characteristics of the electromagnetic wave. Depending on the wavelength, constructive interference only takes place at well-defined angles, that is, only at these angles can light be coupled in or decoupled out of the waveguide. The evanescent wave is influenced by the addition of the analyte and the subsequent shift of the coupling angle is detectable. Different types of grating couplers are used (input, output, reflected mode, wavelength-interrogated couplers).

- **Surface plasmon resonance (SPR)**: This type of biosensor is mostly used as a complete analytical system. The principle is described in Section 6.2.2.3. SPR biosensors are used in drug discovery [344] for some hundreds of assays per day.

Biochips Biochips are small sample carriers constructed from different materials (glass, plastics, silicon). At their surface in parallel hundreds or thousands of sensitive spots with immobilized biological material are arranged as sensitive elements (targets), comparable to the receptor of a biosensor. Each spot realizes a biochemical detection reaction. For this reason, advantageous parallelized and miniaturized analysis is possible.

For the interpretation of the results, it is necessary to know which analyte from the sample is bound at which spot or was detected with which receptor. Therefore, the target spots are structured as an array, with respect to their dimensions often also denoted as microarray. Optical and electrical biochips can be distinguished depending on the method of signal acquisition and processing. For detection of a certain molecule, the characteristic molecular interaction with its target is used, for example, the sequence-specific hybridization of nucleic acids or the affinity of antigens and antibodies.

Huge quantities of target molecules can be generated by synthetic procedures, for instance by amplification of clones sampled in DNA libraries in a PCR.

There are many methods for coating the spots with the target molecules. Sometimes they are similar to microfabrication processes developed by the electronics industry (photolithography), but it is also possible by, for example, piezoelectric (like an air jet) or micro contact printing. In a few square centimeters one can generate some tens of thousands of these spots.

In the past, by combining biochips with flow cells an increase in the probe number was possible because of the relatively high sample concentration in the small chamber volume and hence by the acceleration of the hybridization reaction. Another advantage of flow systems is that the applicability of different fluorescent dyes with similar quantum efficiency opens up the possibility of competitive hybridization for labeling of different targets (e.g., oligonucleotides of different tissue types), which allows the direct comparison of their relative amounts.

For optical detection, the analyte molecules are labeled with a dye, for instance with a fluorescent label. Because the binding of the analyte to the target is specific (e.g., between DNA strands), the binding position at the biochip can be recorded by a sensitive microarray scanner (CCD) or photomultiplier) with high spatial resolution. Another method is the use of glass fiber bundles which read out the spots of the biochip. Furthermore, the waveguides used are similar to those mentioned earlier. The detected signals are analyzed by specific software with pattern recognition.

Since the beginning of this century, many biochips have become commercially available. Their development boomed particularly after the first encodings of the genome of microorganisms starting in the mid-1990s. The first yeast DNA chip possessed a sequence motive of more than 6000 genes in an area of 18×18 mm. The basic principle of biochips was applied to different target molecules such as biomolecular probes (oligonucleotides, cDNA, DNA, RNA), peptides, proteins, and cells.

Biochips are widely used in biological, molecular biological, and biomedical research and also in pharmaceutical drug screening. By miniaturization, automation, and parallelization the throughput efficiency, sensitivity, and reliability are improved, which is not possible with conventional serial methods of biotechnology. Biochip-based analytical systems are being progressively used in clinical and diagnostic fields, for example, for genotyping, mutation analysis, and infection diagnosis.

Miniaturized Analytical Systems These previously mentioned examples present a cross-section of the versatile opportunities for biosensor and biochip applications. However, biosensors suffer from one important bottleneck: because of their biochemical nature, receptors are very sensitive to extreme ambient conditions such as temperature, pH, high salt concentrations, high viscosity, and so on. For this reason, they are often used in the protected surroundings of fluidic systems [e.g., flow injection analysis (FIA); see Section 6.2.3], which are complete analytical systems allowing preconditioning of the sample.

Generally (and independently of the need for biosensors), as a result of the progress in science and technology, miniaturized analytical systems were developed for several advantageous reasons, among others faster response time and analysis, saving of reagents, lower sample and waste volumes, and the compactness of the analytical system.

Micro electromechanical systems (MEMS) are a consequence of the progress in modern microelectronics in the middle of the twentieth century that made sub-micrometer-sized mechanical structures in silicon wafers possible. Subsequently, a further logical step was the consequent integration of fluidic channels and fluid handling modules (dosing devices, valves, pumps) into miniaturized CMOS-compatible systems, denoted lab-on-a-chip (LOC) [345, 346] (Figure 6.107).

Other materials used are glass, ceramics, and polymers. For example, one of the first systems was a gas chromatograph for environmental application [347, 348]. The dimensions of LOCs are in the square millimeter to square centimeter range, liquid volumes down to picoliters are handled, and single or a few functions are integrated. Although the terminology is not consistent, micro total analysis system (μTAS) is used mostly synonymously, whereas the microfluidic systems [349] further also integrate pretreatment steps of the laboratory to a complete laboratory analysis. In microfluidic systems (Figure 6.108), the samples and fluidic elements are mostly handled serially, except that the different components are supplied to points of reaction. Sophisticated systems are able to process some tens of thousands of samples per day.

Related to the numerous applications, a differentiation and systematic classification into the above-mentioned groups is not always possible – the boundaries are fluid. Such miniaturized analytical devices are applied in a wide range of scientific and technological fields, for example, biotechnology [350], medical research [351–353], centralized laboratory analysis, POCT, and pharmaceutical high-throughput screening (HTS) (see Section 6.2.2.8). Optical systems are integrated advantageously, for example, as sensors [354] or for the manipulation [355] of cells and particles.

6.2.2.8 High-Throughput Screening (HTS)

In contrast to microfluidic systems, HTS is a highly parallelized automatic method for liquid handling. Up to millions of samples per day can be processed [for more than 10^5 per day the process is termed ultra-high-throughput screening (UHTS)]. Developed for pharmacological, genetic, and biochemical applications, HTS is mostly used in pharmaceutical research to identify new lead compounds for drugs. The center piece is the microwell or microtiter plate (Figure 6.109) with 96–1536 or more wells in which the assays take place. Especially the interaction of test substances with pathogenic target structures (proteins, cells, microorganisms) is investigated as a (competitive) binding assay with labeled ligands resulting (predominantly) in an optical signal.

HTSs are partly or fully automated systems for liquid handling with statistical data evaluation. Microplates can be supplied by stackers to the system. Corresponding to the highly parallel sample handling and data acquisition, the measurement of the optical signals must also be highly parallelized.

Highly sophisticated microplate readers are filter- and/or monochromator-based detection systems [356] (Figure 6.110) which can address the necessary microplate-based applications to detect the reaction events in the wells. Depending on their special application, they are equipped with suitable optical modules for sample excitation and measurement of sample emission (color intensity, absorbance, polarization, time-resolved fluorescence and luminescence) in the UV–VIS–NIR spectral range. The measuring time necessary is in the range from a few to tens of seconds, depending on the measurement method and the number of wells. However, many variations of detection methods are available, from label-free measurement to the use of imaging of the wells or the whole well plate.

6.2.3
Sample Preparation: Flow Injection Analysis

Parallel to the progress of modern analytical measurement techniques due to technical developments in the twentieth century arose the demand for automation of test routines. However, in general it is important to state that sampling is an often

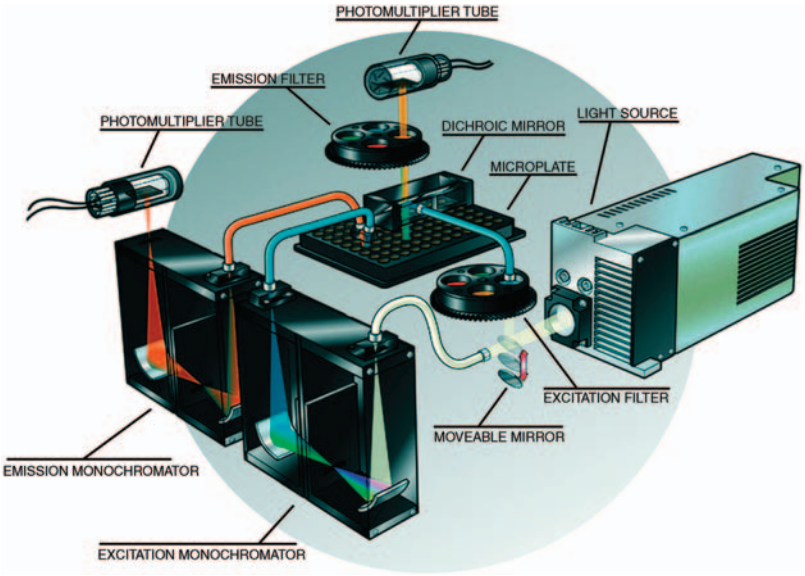

Figure 6.110 Combined filter-based system with monochromator-based optics of the BioTek Synergy 4 Hybrid Multi-Mode Microplate Reader (BioTek, Winooski, VT, USA).

underconsidered field of analytics, above all in process monitoring. In addition to cost efficiency, automation, and some other aspects, a general problem is to separate different samples taken at different times, at different sites, or from different patients for an unambiguous correlation at every later time. Additionally in other applications, it can be important to protect the sample or the process or to condition the sample (e.g., chemical reaction, dilution, preconcentration, and debubbling).

Parallel to autoanalyzers used in clinical laboratories and resulting from their particular disadvantages (use of bubbles for sample segmentation and carryover between the different samples), FIA was developed, defined by three criteria:

1) sample injection into the flow stream by a special injection valve
2) reproducible timing of all processes by computer control
3) controllable dispersion.

A basic FIA system consists of two pumped fluidic lines, the carrier (C) and the reagent (R) line (Figure 6.111) [357]). The sample (S) is injected into the carrier as a plug, undergoing dispersion on the way to the detector and leaving the FIA system as waste (W). A myriad of setups differing from this basic mode are used, depending on the special application of the system.

Dispersion takes place because the center of the flow zone is moving faster than the edges against the wall, as wall drag slows the molecules.

The dispersion coefficient D is defined [358] as the amount by which the chemical signal is reduced by dispersion in an FIA system according to

$$D = \frac{C_0}{C_{\max}} \tag{6.21}$$

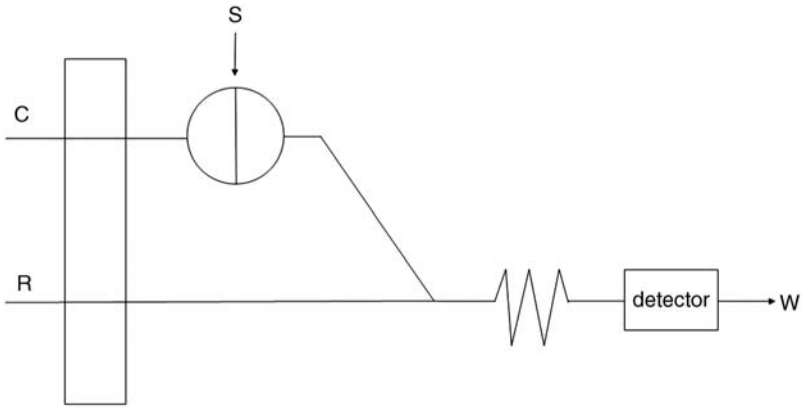

Figure 6.111 Schematic diagram of the basic FIA system.

where C_0 is the maximum signal without dispersion, determined experimentally by filling the FIA system with a pure dye, and C_{max} is the concentration of the same dye injected in a nonreactant carrier flow.

Because of the physical FIA characteristics, it was shown that the flow stream has a reproducible spectrum of corresponding concentrations in the ascending and the descending parts of the curve, depending on the time after injection, that is also at the detection point (if the design of the FIA is not changed). In practice, this so-called gradient method has some advantages, for example, for measuring concentration as a function of the injection time or for providing concentrations beyond the measurement range of the detector.

However, in addition to reproducible sampling, another important advantage of FIA is the usability of numerous highly sophisticated analytical systems as detectors (e.g., high-performance liquid chromatography HPLC). Of course, optical systems can also be coupled to FIA systems, for example, luminometers [359], spectrometers [360, 361], and fluorimeters [362].

6.2.4
Fermentation as a Central Process of Biotechnology

6.2.4.1 General Aspects

Fermenters are bioreactors available with a broad range of special equipment adaptable for every organism, strain, and metabolic product and therefore for different kinds of processes. Fundamentally, depending on their construction, fermenters with mechanical stirrers, pneumatic agitation, and membrane separation between the sensitive biomass and the agitated fermentation broth are used (e.g., aerobic, anaerobic, stirred, air-lift, tower-loop, bubble columns, submerged or adherent cultivation). Fermenters are operated in continuous, batch, and fed-batch mode depending on whether the substrates are supplied and the products are downstreamed.

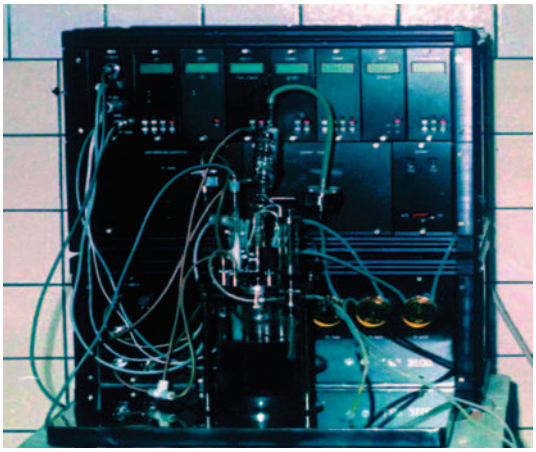

Figure 6.112 Bench-top laboratory-scale stirred-tank fermenter of 1 l volume.

The volume ranges from a few milliliters (mostly laboratory scale and research; see Figure 6.112) to thousands of cubic meters (production scale), depending on the particular process (organism, product, application). By means of today's microsystem technology, it is already possible to use microfluidic-generated droplets in the nanoliter range (Figure 6.113) to cultivate and handle single cells inside for special purposes, for example, testing of individual cells against chemical stress or encapsulation to protect the cells against surrounding media [363, 364]. They are often termed microbioreactors.

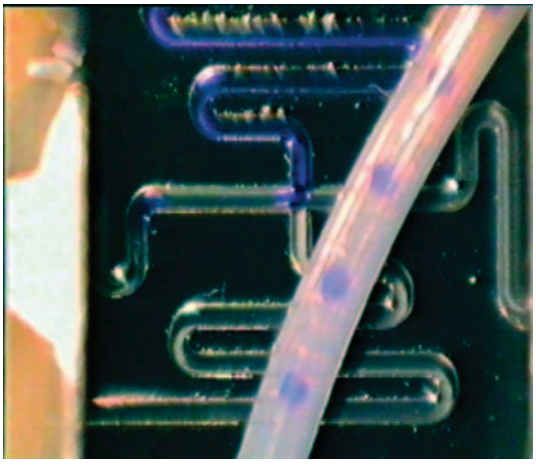

Figure 6.113 Microfluidic system for sterile handling of single or a few cells inside droplets (blue points) of some tens of nanoliters.

Apart from a few exceptions (unsterile processes such as biogas production and waste water treatment), the necessity for sterilization of fermenters to exclude germs in competition with the production organism is an aggravating constraint. The most common method to avoid foreign organisms is heat sterilization by steam at 125 °C. This requires all components to be resistant to steam contact. Often it excludes the in-line application of otherwise reliable analytical systems and sensors and demands sample taking and off-line measurement. The problem can mostly be solved only by help of a sterile interface in a coupling system (sample port, flow systems such as FIA [357, 365]) providing protection against the harsh conditions (on-line mode). Among others (financial pressure, accepted materials), this condition also resulted in the use of disposable bioreactors (characterized by a cultivation chamber or bag made of plastic materials), especially in cell cultivation for the development of biopharmaceutical products [366].

After sterilization and filling with substrate (or vice versa), the fermenter is inoculated with the organism to be cultivated. The system is operated by highly sophisticated digital systems for measurement and control. Different operating modes are usual (batch, fed-batch, repeated fed-batch, semicontinuous, continuous fermentation) depending on the kind of system used (e.g., closed, open, partly cyclic).

As a result of the fermentation process, the fermentation broth contains the desired final product in a mostly very complex substrate. For this reason, treatment steps are normally necessary to isolate the product (e.g., filtration in different forms, centrifugation, digestion, evaporation extraction, crystallization). The monitoring of the product quality and purity is a further field for application of photonic instruments.

In both process development and biotechnological production it is necessary to obtain information about the state of the process by the measurement of characteristic variables. In contrast to more or less calculable chemical processes, in fermentation the biomass and its growth often influence the process unpredictably. For this reason, in addition to temperature, pH, substrate and product concentrations, masses, mass flow rates, and impeller speed, especially biomass concentration, dissolved oxygen, and intermediates are examples of typical process characteristic variables to be taken into consideration.

With respect to measurement, general consideration of the hierarchical signal level in a biotechnological process is necessary. The example of the fermentation process shows how it is obvious to differentiate.

First one can gain information at the level of the substrate mixture. It contains all the necessary feed components (carbon and nitrogen sources, carbon hydrates, organic acids, oxygen, etc.), the inoculated organisms, and its products. The substrate shows physicochemical parameters typical for the process state. Measurement parameters are temperature, pH, ions, dissolved oxygen, glucose, biomass concentration, secondary metabolites, antibiotics, and so on.

The metabolic level is the second item of information. The measurand is the metabolic activity of the microorganism or cell, characterizable by different parameters such as adenosine triphosphate (ATP), NAD(P)H, intermediate metabolites, enzymes, and coenzymes.

Third, subcellular epigenetic level nucleic acids and their components (nucleosides, nucleotides, nucleic acid bases) are observed. Modern biochips have improved the possibilities to measure this group of substances.

The delays between external influences and the measurable reaction (minutes to days) are often too long for effective process control because exertion of the influence is no longer possible. This illustrates the necessity to control biotechnological processes as early as possible after process-changing incidents. The problem of nonsterilizability of most sensors and measuring systems and the resulting necessity to use sampling ports and/or flow systems or to measure off-line magnify the problem.

6.2.4.2 **Fermentation Control**

Measurement systems, probes, and sensors are available for all three hierarchical signal levels. With respect to the content of this book, only examples of sterilizable and in-line or on-line coupled systems [367] are mentioned here.

Biomass is an important parameter because it allows insight to be gained into the process by the activity of cell growth and the optimization of the process. Different systems are commercially available, from electrical impedance spectrometers to especially optical probes. Probably the most widespread are sterilizable turbidimetric probes for real-time monitoring of cell growth, measuring the absorption in the NIR spectrum and calibrated with the cell number or optical density of laboratory analyses. By varying the optical pathlength, a wider concentration range can be measured. The biomass concentration is directly monitored in grams per liter, percent dry matter, or optical density (OD) [368]. This approach is used for active control of the fermentation. Another example if the use of optical detection at this level is nephelometric biomass detection by scattered light measurement [369].

Recently, new emphasis has been placed on the use of optical oxygen sensors, but they are temperature sensitive and not sterilizable. In the biotechnological and medical fields, the measurement of the oxygen partial pressure by these sensors is a standard diagnostic tool (e.g., for blood and tissue). One reason for the increasing interest in optical sensors is the ready availability of fiber-optic technologies and of oxygen-sensitive dyes. These sensors use oxygen-sensitive molecules immobilized in oxygen-permeable and nonpolar polymers. Oxygen quenches the luminescence or lifetime of numerous dyes. In this way, the intensity of the emitted light and the relaxation to the ground state depend on the oxygen concentration [370, 371]. The probes of dissolved oxygen measurement in the parts per million (milligrams per liter) range show percentage-level accuracy, for example [372].

On-line monitoring of intracellular proteins and enzymes is an important factor with regard to fermentation process development and optimization. Disintegration of cells under sterile conditions is required. The necessary sample preparation and disintegration of cells (e.g., by ultrasonics) under sterile conditions can be performed by FIA. Using special reaction protocols, for example, the quantification of intracellular lactate dehydrogenase (LDH) during fermentation is possible [373]. LDH oxidizes lactate to pyruvate enzymatically with simultaneous reduction of NAD^+ to NADH. Nicotinamide adenine dinucleotide (NADH, oxidized as NAD^+, reduced as

NADH) is a coenzyme of living cells and is involved in redox reactions as an electron carrier. However, NADH itself also presents an example of measurement of fluorescent substances at the metabolic level. The oxidized and reduced states differ in their fluorescence (NADH is fluorescent at 460 nm, NAD^+ is nonfluorescent) and the fluorescence changes with binding to protein [374]. Despite the option of coupling a fluorimeter with FIA, in the past several attempts have been made to develop *in situ* fluorosensors [375].

Another example is the measurement of ATP concentration. All living cells contain intracellular ATP needed for the regulation of stored metabolic energy, for the maintenance of enzyme systems and for biosynthesis of cellular constituents during all phases of growth. In dead cells, ATP is broken down by autolysis within a few minutes. ATP can therefore be used as a measure of microbial biomass. Linear relationships have been found between intracellular ATP levels and the total number of colony-forming units (CFUs) with bacteria and with yeast. In addition to the more conventional measurement of the intracellular ATP level mediated by the luciferin–luciferase reaction and detection with an (FIA-coupled) luminometer [376], in other reports [377, 378] microorganisms were genetically modified, for example, by inserting cDNA for firefly luciferase resulting in specific activity of luciferase during different growth phases due to ATP utilization in the presence of added D-luciferin. Using fiber optics, the luminescent light emitted inside the fermenter is guided to a photometer.

6.2.4.3 **Photobioreactors**

About 400 000 different algae populate very diverse biotopes on earth. Worldwide about 16 million tonnes of algae were produced in 2007 [379] and processed into foodstuffs, feeds, cosmetics and fertilizers. By use of light, chlorophyll of phototropic microorganisms such as algae and cyanobacteria in photosynthesis produce energy-rich substances and biomass from CO_2.

Bioenergy from biomass can contribute to solving the global energy problem. Biomass can be converted into biofuel (fuel of the third generation), for example, by alcoholic fermentation. Their light conversion effectiveness differs but in general especially microalgae offer a 10-fold higher biomass yield than terrestrial plants.

At present, open land and offshore systems for algae production dominate. However, various different types of closed photobioreactors have been developed by numerous companies and research institutions [380]. They provide an artificial environment for the chemical conversion on the scale of liters to cubic meters. Attempts have also been made to use micro system technology for this process [381]. In addition to the availability of carbon dioxide in huge quantities (1.8 tons for 1 ton of biomass), one of the technical problems is the optimization of photobioreactor design with respect to the light regime necessary for optimal growth of algae [382]. The general objective is to avoid artificial lighting. Because absorption takes place according to the Lambert–Beers law, the light intensity decreases exponentially with depth and with the algae concentration. Hence flat planar or tubular systems of different types (e.g., flat plate, airlift, column; see Figure 6.114 [383]) and materials (e.g., glass, PVC foil) are mostly used.

Figure 6.114 Column photobioreactor (Hielscher Ultrasonics GmbH, Teltow, Germany).

6.2.5
Optical Trap/Optical Tweezers

Already in the 1970s lasers were used to trap various atoms and particles. The first optical traps used visible light. Starting in the mid-1980s, optical traps were used to trap biological particles. Arthur Ashkin [384, 385] is thought to be the pioneer of optical tweezers. His group at AT&T Bell Laboratories trapped individual viruses and *E. coli* bacteria as early as 1985. In a study performed in 1987, the viruses were able to resist the power created by a 1064 nm laser, whereas the *E. coli* bacteria always exploded at around 100 mW. In order to reduce biological damage, using IR lasers in the 780–950 nm range proved to be useful, especially for bacteria which under these conditions can survive the trap for hours without damage [386].

Microscopic objects are moved in the laser light in the direction of the optical axes. The change in direction of the light is connected with a change in the momentum transferred to the biological cell. In Figure 6.115, in partial beam "a" the light has the momentum F_a (inwards) out of the whole beam, and in partial beam "b" the momentum F_b (outwards) is effective. In a homogeneous laser profile this would result in a movement in the beam direction. Because the field is inhomogeneous (see the laser profile), the resulting force is directed in the direction of the beam center.

In principle, light acts as force on an object (impact of photon and object, like a pressure model in a gas cell). For an illustration of the scale of the effect, two examples can be given:

- A car in sunlight is ~1 mg (better millipond) heavier than in the shadow.
- The tail of a comet is "pushed away" on approaching to the Sun.

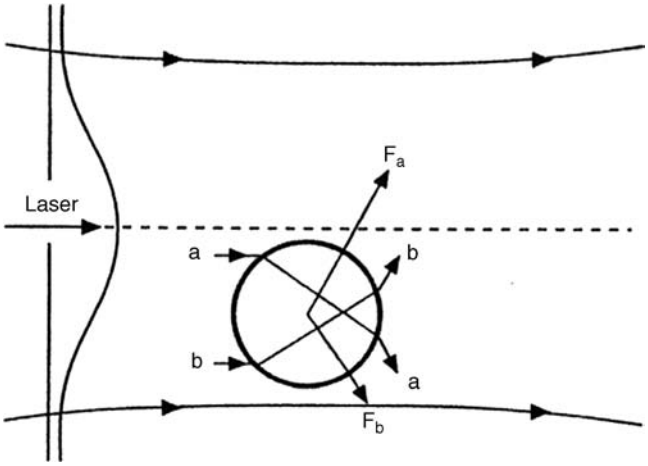

Figure 6.115 Scheme of laser irradiation of a spherical particle and the resulting momentum (F_i) as a function of the beam intensity (a larger than b).

The force of a laser F with power P in watts is given by

$$F = \gamma P/c \tag{6.22}$$

where γ is the gravity constant and c is the velocity of light.

If laser light of 1 W is focused on to a cell of 10 μm diameter, a pressure of ~5 bar acts on the cell. Due to its small mass, the cell will be accelerated to extremely high speeds (700 000 times the acceleration due to gravity). The acceleration is connected with the pressure in the following way:

$$p = \frac{F}{A} = \frac{m \cdot a}{A}. \tag{6.23}$$

Hence the velocity is

$$v = a \cdot t = \frac{p \cdot A \cdot t}{m}. \tag{6.24}$$

The speed of the acceleration cell results in Equation 6.24. Taking a 100 kW laser instead of a 1 W laser will result in catapulting of microscopic objects. In such cases, the speed can be as high as 1one-tenth of the speed of light [387].

6.2.5.1 Basic Scheme of Laser Tweezers and Micromanipulation

The realization of laser tweezers is achieved by a combination of a UV laser (diffraction limited) with a powerful NIR laser. In normal cases, this pair consists of an Nd:YAG laser (as the NIR laser) and an N_2 laser (or even better is an excimer laser) as the UV laser; in some cases green lasers are also used. The NIR laser acts as an optical tweezer and due to the wavelength has a small (or vanishing) absorption with a large penetration depth. Whereas the UV laser acts as an optical treatment

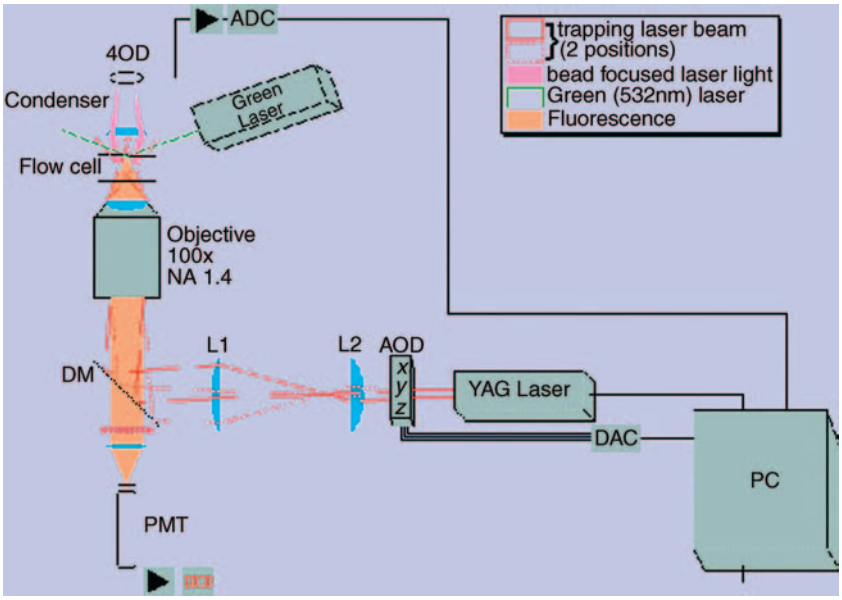

Figure 6.116 Scheme of optical tweezers [3].

(cutting) tool, UV light is absorbed by the cell. Short, powerful pulses lead to extremely high local temperatures. Of decisive importance is that the surrounding tissue is not or only marginally damaged by the laser energy. The requirements for achieving this effect are the possibility of high focusability and an excellent beam profile with low thermal diffusion effects [388].

The basic equipment is an optical microscope (e.g., Zeiss Axiovert) with UV lenses as shown in Figure 6.116. Via the in-coupling of the illumination light, the two laser beams are also coupled in. With the microscope the image is zoomed into the object cell and the laser tweezers and the UV laser are aligned with respect to the object. The object is captured, the UV laser vaporizes cell parts, drills microholes, and destabilizes the cell walls, as shown in Figure 6.117.

6.2.5.2 Applications of Optical Tweezers

Optical tweezers have been used since 1987 for medical purposes. For example, the manipulation of red blood cells (see Figure 6.118) can be performed by rotating them. They can also be stretched, moved, and even dissected using an optical tweezer/scalpel.

Helical modes of light can be focused into toroidal optical traps known as optical vortices, which are capable of localizing and applying torques to small volumes of matter. Measurements of optical vortices created with dynamic holographic optical tweezers (see Figure 6.119) reveal an unsuspected dependence of their structure and angular momentum flux on their helicity. There is novel optical ratchet potential in practical optical vortices [389].

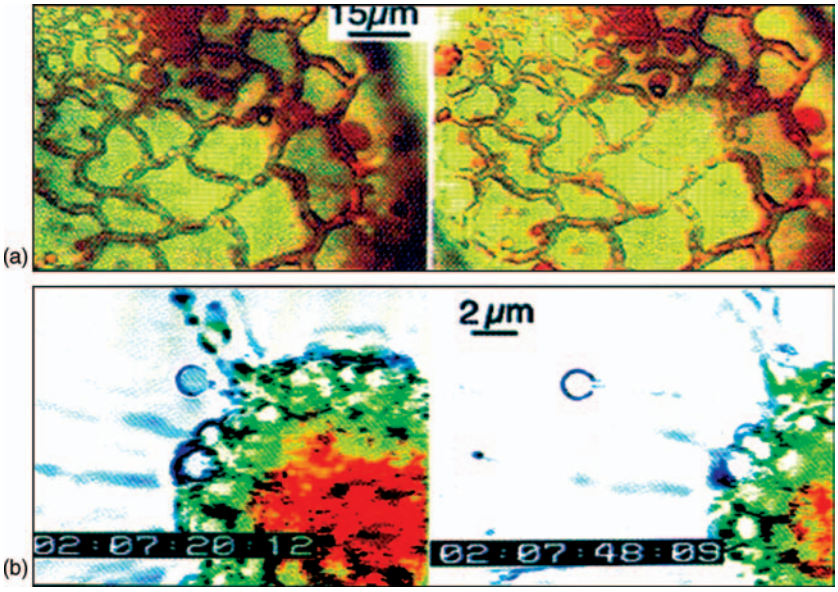

Figure 6.117 (a) Modification of the surface structure of a lily pollen. The resolution of the laser beam is $>1\,\mu m$, so it is possible to modify the structure of the pollen surface without influencing the cell wall. (b) Movement of subcellular structures through optical tweezers in unopened cells of the alga *Pyrocystis noctiluc*. The cell is irradiated from below through the cell wall (no absorption) and subcellular structures at the opposite wall are accelerated so strongly that they are catapulted out of the cell and can be caught in microreaction vessels and prepared as single subcellular structures (courtesy of K. O. Greulich, Leibniz-Institut für Altersforschung, Jena).

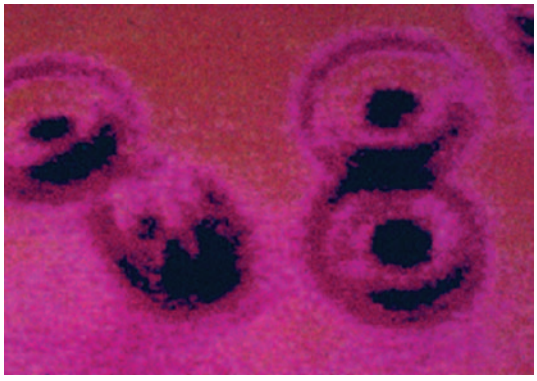

Figure 6.118 Red blood cells manipulated with optical tweezers [389].

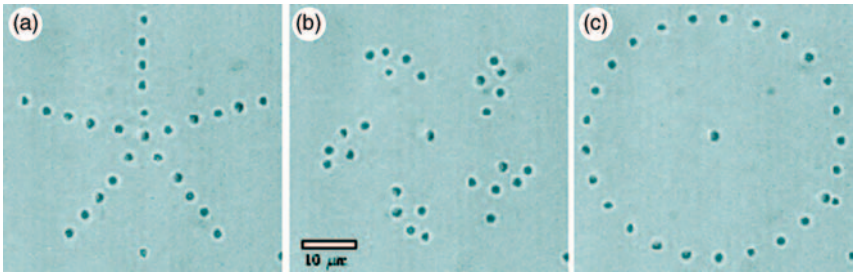

Figure 6.119 A pentagonal pattern of 26 colloidal silica spheres 0.99 μm in diameter is transformed into a circle using dynamic holographic optical tweezers. (a) The original configuration; (b) after 16 steps; (c) the final configuration after 38 steps of illumination [390].

Beams of light with helical wave fronts focus to rings, rather than points, and also carry orbital angular momentum that they can transfer to illuminated objects. When focused strongly enough, such helical modes form toroidal optical traps, whose properties present novel opportunities for scientific research and technological applications. For example, optical vortices should be ideal actuators for MEMS, and arrays of optical vortices have shown a promising ability to assemble colloidal particles into mesoscopic pumps for microfluidic systems.

Further applications of optical tweezers are shown in Figure 6.120, where the fusion of two lymphoblast cells after perforation of the cells by a strong UV laser and transportation of one of the cells via laser tweezer to another is shown in (a). In (b), laser-supported fertilization is shown where the optical tweezer guides the sperm cell to the perforated egg cell. In (c), laser microcutting of a chromosome is depicted where the two chromosomes indicated an arrows are cut along their long axes to separate the two chromatides [391].

The list of possible applications of optical tweezers could in principle be almost infinite. Optical tweezers can be calibrated for position measurements because of the 3D force is quantitative. Therefore, it is possible to measure movements and forces generated by single motor proteins.

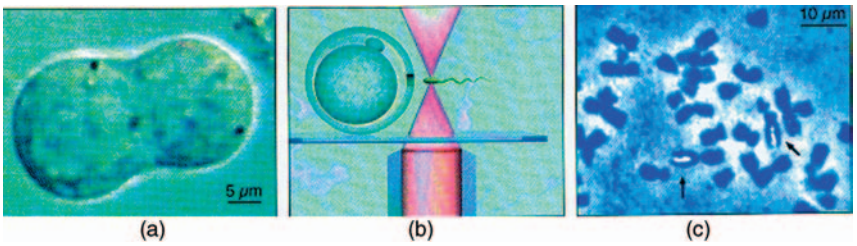

Figure 6.120 (a) Fusion of a long-living lymphoblast cell with a B-cell lymphoblast of a mouse for antibody production. (b) Principle of laser-supported fertilization: the egg cell is already perforated and the optical tweezer/trap is used to guide the sperm cell to the entrance of the perforation channel. (c) *In vitro* laser microcutting of a chromosome: two chromosomes are cut along their long axes to separate the two chromatides (courtesy of K. O. Greulich, Leibnitz-Institut für Altersforschung, Jena).

Biology

Stefan H. Heinemann, Roland Schönherr, and Toshinori Hoshi

Biophotonics comprises several scientific and technological disciplines that have in common an interaction of light, photons, with biologically relevant material. A prerequisite of research and development in the field of biophotonics is a firm understanding of the structure, function, and organization of organisms and their components, both as a whole and in isolation – a wide area collectively summarized by the term biology. Since a large branch of biophotonics applications involves the diagnosis and treatment of human diseases, knowledge of some fundamentals of medicine is also helpful.

Living material is always organized in cells and a biophotonics experiment most often must extract information from light–cell interactions. Although cells can be extremely diverse in their appearance and function (see Section 7.2), a prototypical cell model as depicted in Figure 7.1a may serve to indicate some common cellular features. Cells are always separated from the environment by a very thin lipid bilayer (about 4 nm), the plasma membrane. Cells also contain a large nucleus (often 5 μm in diameter), which contains the chromosomes holding the genetic information. The power plants of cells are mitochondria; these organelles have a size comparable to that of bacteria (about 1 μm in length). Whereas cell bodies typically range in diameter between 10 and 50 μm, some nerve cells can have very long fiber-like axons, for example, reaching from the spinal cord to the little toe.

Biologically relevant processes span a very wide range of length and time scales and, hence, pose a challenge to the experimenter. As illustrated in Figure 7.1b, biophotonics employs a relatively narrow spectrum of electromagnetic radiation including visible light to gain information about length scales ranging from individual chemical bonds, proteins, and organelles to long cellular structures. The range of time scales of interest in biology is even more impressive, as illustrated in Figure 7.1c. Whereas biologically relevant chemical bonds may be broken and formed in less than 1 ns, molecules holding the genetic information may last for the entire lifespan of an organism.

This chapter on biology provides quick access to the most relevant aspects of the life sciences, with particular reference to potential biophotonics applications. It is primarily intended for students and researchers from outside the field of life

Handbook of Biophotonics. Vol.1: Basics and Techniques, First Edition.

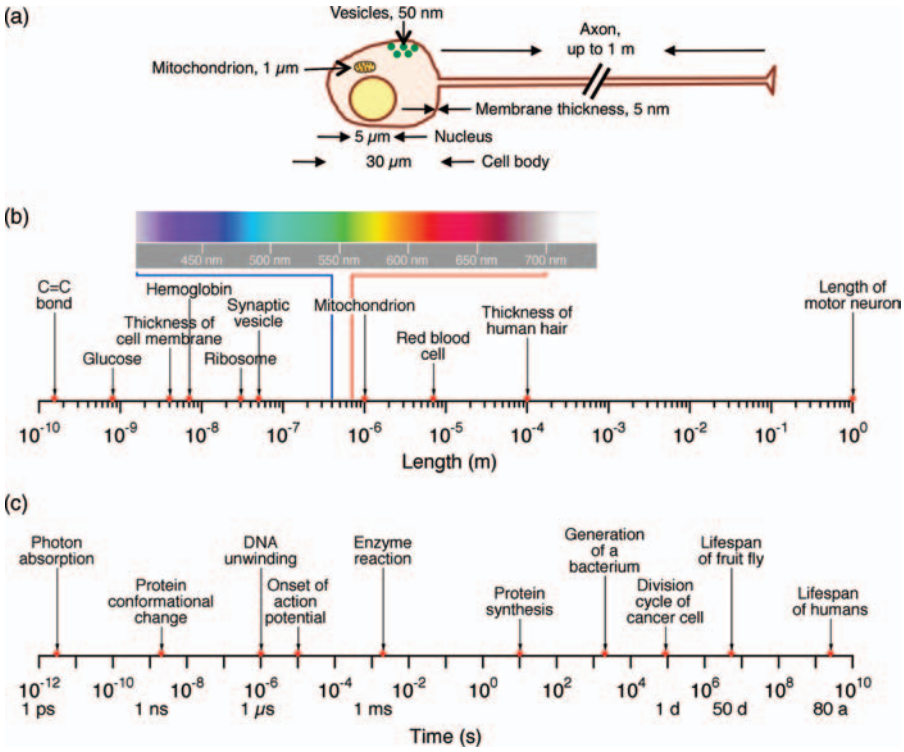

Figure 7.1 Overview of length and time scales. (a) A prototypic neuronal cell with a cell body and a long axon with some typical length scales indicated. (b, c) Selected length and time scales of biological material and processes [parts (b) and (c) adapted from Stryer [1]].

sciences, such as physicists, chemists, and engineers. It is not meant to be a comprehensive source of biology, which can be found in numerous excellent textbooks. Instead, we have attempted to cover selected topics to provide illustrative access to general biological problems and the language of biology, thereby facilitating communication between biophotonicists and biomedical scientists. We are aware that several exciting aspects of biology cannot be discussed in depth here. Nevertheless, summarizing in a somewhat naive way how life works from an engineer's perspective may be a suitable starting point for examining some fascinating aspects of biology and medicine.

We start with a description of the most relevant biomolecules and their properties. Section 7.1, providing a quick reference to biochemistry, will be essential because the biomolecules are the ultimate targets for light–matter interactions. We continue with a presentation of various cell types and the organization of cells in Section 7.2, topics that are usually found in textbooks on cell biology. In Section 7.3, we discuss several ways in which cells communicate with each other and how communication takes place inside cells. Such communication processes are usually termed cell signaling and the corresponding textbooks are on molecular cell biology. The reader may notice the complete absence of references to physiology, organs, and whole organisms –

essentially the most important aspects of biology. Such topics are far beyond the scope of this chapter. Therefore, to illustrate how molecular and cellular dysfunctions alter the whole organism, we discuss in Section 7.4 a few human diseases, their pathomechanisms, diagnosis, and possible therapies. Given the obvious link of biophotonics to biotechnological applications, we present a few standard methods for the handling of biological material in information Boxes. Insight into such methods will help the biophotonicist to evaluate the feasibility of experimental plans.

7.1
Biomolecules: Building Blocks of Living Matter

Even a relatively simple organism, such as the intestinal bacterium *Escherichia coli*, consists of several thousands of different types of molecules. In a typical human cell, there are certainly more than 100 000 types of molecules and many more remain to be identified. Therefore, obtaining information from a spectroscopic experiment in which the light–matter interaction is studied in living cells must appear a tremendously complicated task. However, the situation is not hopeless because the molecules of living material are organized in a hierarchical manner, ranging from free protons, metal ions, and water to macromolecules with a size greater than 1000 Da (the dalton is a unit commonly used in biology. 1 Da is one-twelfth the mass of a ^{12}C atom, that is, 1.66×10^{-27} kg. Proteins mostly have a mass of several thousand daltons, usually abbreviated as kDa). By means of self-aggregation, even greater complexes, so-called molecular aggregates such as membranes and fibers, are formed.

As shown in Table 7.1, about 70% of the mass of a bacterial cell consists of water, and macromolecules account for about 25%. The latter are polymers; chain-like molecules formed from a limited set of smaller units, the monomers. Hence there are many thousands of different types of macromolecules inside a cell, but the unitary elements are always the same, somewhat simplifying the situation. As depicted in Figure 7.2, the most important polymers are nucleic acids built of only eight different

Table 7.1 The approximate chemical composition of a bacterial cell (after Alberts *et al.* [2]).

Component	% of total weight	Number of types of each molecule
Water	70	1
Inorganic ions	1	20
Sugars and precursors	1	250
Amino acids and precursors	0.4	100
Nucleotides and precursors	0.4	100
Fatty acids and precursors	1	50
Other small molecules	0.2	~300
Macromolecules (proteins, nucleic acids, polysaccharides)	26	~3000

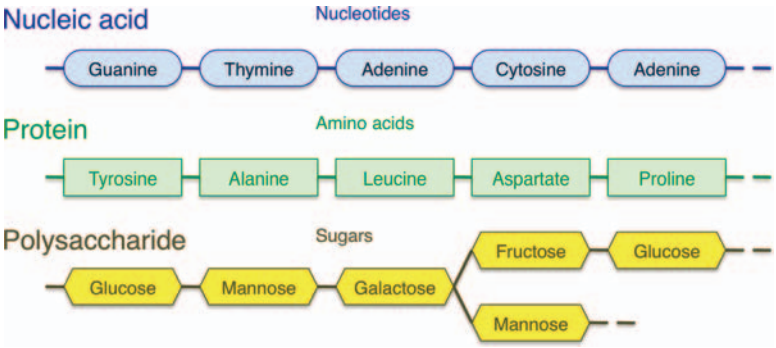

Figure 7.2 Polymeric biomolecules. Whereas nucleic acids and proteins are linear chains of monomers, polysaccharides can form branched chains.

nucleotides (see Section 7.1.1), proteins typically built of 20 different amino acids (see Section 7.1.2), and polysaccharides consisting of different types of sugar molecules (Section 7.1.3). Membranes are formed by various types of lipids (Section 7.1.4); they are more heterogeneous in structure but also harbor modular fatty acid components. The relatively stereotypical structure of polymers can be diversified by specific chemical modification of their components, as discussed below for proteins. Proteins made solely of amino acids cannot achieve some tasks, such as the light harvesting of the protein rhodopsin in the eye. Such special-purpose proteins therefore contain specific prosthetic groups or cofactors, many of which are of particular interest to biophotonics research (Section 7.1.5). Finally, in Section 7.1.6 we address some important nonpolymeric molecules.

7.1.1
Nucleic Acids: Storage of Genetic Information

Virtually all mammalian cells are composed of many proteins, lipids, and sugars, and some nucleic acids (Table 7.2). Since the latter are the storage medium for genetic information and, hence, they contain the information necessary to produce all the other biomolecules and to replicate itself, we start with a description of these very long polymeric molecules.

The key type of macromolecule is deoxyribonucleic acid (DNA); it forms two intertwined chains, each built of individual nucleotides (see Figure 7.4). The nucleotides themselves consist of a sugar moiety, the deoxyribose, a phosphate moiety, and one of four bases: adenine (A), thymine (T), guanine (G), or cytosine (C) (Figure 7.3). Genetic information is encoded by the sequence of these four nucleotides. Since there are four nucleotides, the number of possible combinations of a chain of n nucleotides is 4^n. In molecular biology, the length of DNA typically is expressed in units of bases, that is, one kilobase (kb) or one megabase (Mb) is a nucleic acid molecule 1000 or 1 000 000 nucleotides in length, respectively. Since DNA in the nucleus is a double-stranded molecule, one often refers to base pairs (bp) instead of just bases. In order to distinguish between computer storage (measured in

Table 7.2 Approximate chemical compositions of a bacterium and a typical mammalian cell[a].

	E. coli	Mammalian cell
Water	70	70
Inorganic ions	1	1
Miscellaneous small metabolites	3	3
Proteins	15	18
RNA	6	1.1
DNA	1	0.25
Phospholipids	2	3
Other lipids	—	2
Polysaccharides	2	2

[a]Numbers represent percentage of total cell weight (after Alberts *et al.* [2]).

kilobytes and megabytes) and genetic information, kbp and Mbp are also used. The entire human genome comprises about 3 billion base pairs (3000 Mbp or 3 Gbp). Since nearly every human cell carries its genome in duplicate, having one copy of each chromosome from the father and mother, the total cellular DNA content is 6 Gbp in the so-called diploid cell. In eukaryotic cells, most DNA is organized in 8–60 chromosomes in the cell nucleus, while a very small fraction of DNA exists in the

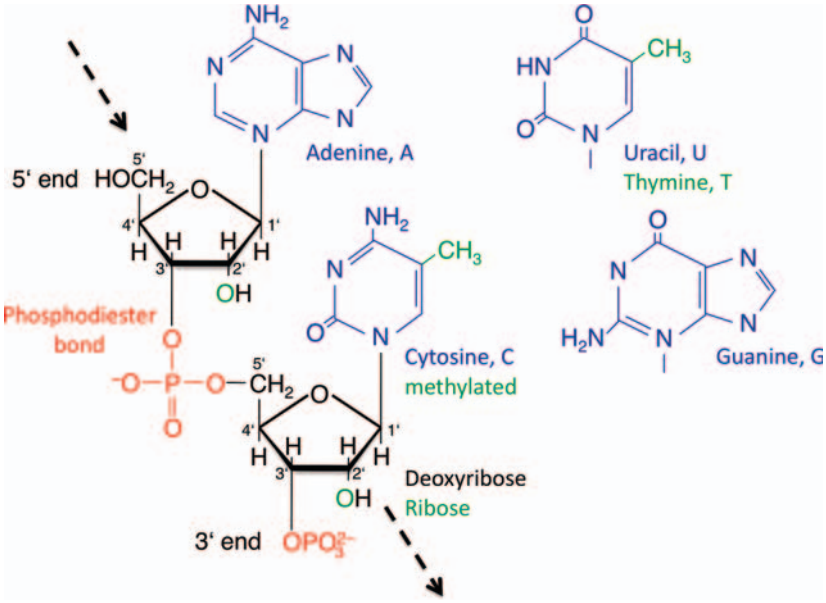

Figure 7.3 DNA and RNA are made by linking individual nucleotides via phosphodiester bonds (red). The coupling occurs between the 3′ and the 5′ carbons of a sugar moiety, a ribose for RNA and a deoxyribose for DNA (black). The nucleotides differ in the structure of their bases (blue). In RNA, uracil is used instead of thymine (5-methyluracil). Also shown is the methylated form of cytosine (5-methylcytosine).

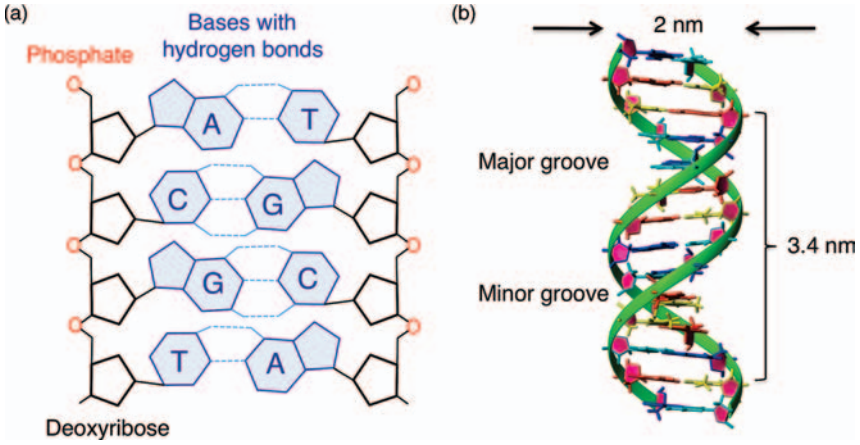

Figure 7.4 Double-stranded DNA. (a) Base pairing by formation of hydrogen bonds between the bases A/T and G/C. (b) Model structure of B-DNA (courtesy of Dr. Matthias Görlach, Jena).

mitochondria, intracellular membrane-bound compartments within a cell (in humans, mitochondrial DNA comprises only 16 569 nucleotides).

The sequence of nucleotides in one DNA chain determines the sequence of the other, complementary, chain. This is because both chains bind to each other via hydrogen bonds between the bases. Two hydrogen bonds can be formed between adenine and thymine, and three between guanine and cytosine (Figure 7.4). Therefore, only the pairs A–T and G–C are allowed when two nucleic acid chains hybridize to form double-stranded DNA. The unambiguous coupling of the nucleotides ensures that one chain is an exact complementary copy of the other. When cells divide, all constituents and also the DNA must be replicated. In this phase, the double-stranded DNA opens, and both chains are the templates for the synthesis of new complementary offspring chains. Therefore, in a daughter cell the DNA consists of one newly synthesized nucleic acid chain and one "inherited" from the parent cell.

The interpretation of the information stored in the DNA sequence implies the definition of so-called genes – regions of the DNA that actually contain the blueprint for the formation of proteins or for functional ribonucleic acid (RNA) molecules, including flanking regions with regulatory function. Surprisingly, there are only a fairly limited number of genes in the human genome (about 20 000–25 000). Moreover, the number of genes is not a good indicator of the complexity of an organism, as exemplified by the worm *Caenorhabditis elegans* (18 300 genes), the fruit fly *Drosophila melanogaster* (13 300 genes), and the plant *Arabidopsis thaliana* (25 700 genes). The largest parts of all DNA sequences have either regulatory function or can be allocated to so-called introns, noncoding regions that are interspersed between the coding regions called exons. In most cases, genes are composed of several exons, linked at later stages by a process termed gene splicing. Only about 2% of the total human genome sequence contains such blueprint information. The remaining part of the DNA sequence does not appear to code for known functional products.

Roughly half of the human genome is covered by so-called *repetitive sequences*, short repeating stretches of nucleotides. Such repetitive regions have a structural role both at the ends and in the central region of each chromosome, the centromere.

According to the so-called *central dogma of molecular biology*, the amino acid sequences of all proteins are unambiguously determined by the gene sequences. For the expression of genetic information, the translation of a gene into a protein sequence, a copy of the DNA is made for a specific gene only. During this process of transcription, a complementary copy of one DNA chain is formed to generate a chain of RNA. This nucleic acid typically is a single-stranded molecule. It has strong similarity to DNA, but the sugar moiety of the monomers is a ribose instead of a deoxyribose; at the 2′ (read as "two prime") position of the sugar ring there is an OH group instead of a proton (Figure 7.3). In addition, in place of the base thymine, a uracil (U) is used. As a consequence, an adenine (A) in the DNA is transcribed to uracil (U) in the RNA. The information stored on the RNA is then translated into a sequence of amino acids to form a protein. In this process, *three* succeeding nucleotides inside a coding reading frame (triplets or codons) always code for *one* amino acid (see Figure 7.7).

Because translation of genetic information from RNA into a protein sequence takes place outside the nucleus, one task of the RNA molecules is to send the message from the DNA to the site of translation, and therefore this type of nucleic acid is called messenger RNA (mRNA). Another form of RNA is transfer RNA (tRNA). On the one hand, they expose a triplet of ribose nucleotides coding for a specific amino acid. On the other, they bind that amino acid as cargo. By means of the triplet-encoded codon, the tRNA *transfers* the amino acid to the correct position of the template mRNA during the process of protein synthesis. In addition, there are regulatory forms of RNA that play a role in how genes are translated into proteins (siRNA and miRNA) (see the following information Box). In general, DNA is largely a stable storage molecule for genetic information, whereas RNA serves more diverse functions and, in some cases, even exhibits enzymatic activity. Regulatory RNAs can be very small and their functional role is only beginning to be elucidated.

Downregulation of Genes by RNA Interference (RNAi)

One mechanism of post-transcriptional gene regulation is based on double-stranded RNA molecules derived from genomically encoded micro-RNAs (miRNAs). After processing in the nucleus and in the cytosol, double-stranded RNA fragments of ~20–25 bp are generated. These small interfering RNAs (siRNAs) inhibit complementary mRNA and, hence, prevent the production of the encoded protein. Using synthetic siRNA molecules, molecular biologists can thus disable the expression of specific genes, referred to as gene silencing or gene knock-down. In an alternative approach, genetically modified viruses can be used to express siRNA precursors that are processed to functional siRNA by the endogenous RNA interference (RNAi) machinery. RNAi technology provides important tools for cell biology and the potential for therapeutic applications in molecular medicine is being evaluated.

7.1.1.1 Structure

The nucleotides used for storage of genetic information harbor bases with either a pyrimidine ring (C, U, T) or a purine heterocycle (A, G).

The bases in DNA can be chemically modified slightly without any fundamental change in the nucleotide sequence to regulate gene expression, a process collectively referred to as epigenetics. One well-known example of an epigenetic phenomenon is methylation of cytosine and adenine.

Individual nucleotides are linked by means of phosphodiester bonds connecting the ribose ring at the 3′-position with the CH_2 group at the 5′-position (Figure 7.3). According to commonly accepted convention, genetic sequences are read from left to right, that is, from the 5′ to the 3′ end, and this is also the direction of synthesis. A sequence coding for a protein read in this direction is referred to as *sense* sequence, and that of the complementary strand as *antisense* sequence.

At a physiological pH of about 7.2, the phosphodiester groups are negatively charged such that DNA and RNA migrate in electric fields, an important feature used for electrophoretic analysis of these molecules (see the following information Box).

Gel Electrophoresis

Most biological macromolecules are charged and, hence, in an electric field they will move according to their overall charge. The average distance moved depends on the electric field and also on the charge, the size, and the surface structure of the molecules. Hence a given mixture of biomolecules exposed for a certain time to an electric field will be separated according to their molecular properties. The resolution power of standard electrophoresis systems is strongly increased by meshed or porous matrices, such as agarose or polyacrylamide gel, through which the biomolecules are forced to move. The electrophoresis of biomolecules through various types of gels is a powerful and inexpensive method commonly used in molecular biology to analyze and separate RNA, DNA, and proteins. Depending on the type of molecule to be analyzed, various staining methods to visualize the biomolecules under study are applied, such as fluorescent ethidium bromide for DNA/RNA and Coomassie Brilliant Blue stain for proteins. As all nucleic acids have identical densities of negative charge, their electrophoretic mobility directly reflects the molecule size if they are assumed to be in the same conformation, such as the linear double-stranded form. By contrast, proteins are much more heterogeneous in size and charge and typically analyzed using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). The anionic detergent SDS unfolds the proteins and provides a uniform charge density on the surface such that the electrophoretic mobility of a protein is roughly linear to the logarithm of its molecular weight.

The long DNA molecules adopt specific three-dimensional structures. The most important form, predicted by James Watson and Francis Crick in their pioneering work awarded the Nobel Prize in Physiology or Medicine in 1962, is a double-helical

right-handed spiral, also called B-DNA (Figure 7.4b). This configuration is stabilized by the hydrogen bonds formed between the matching bases A–T and G–C. These so-called Watson–Crick base pairs result in a very stable DNA configuration with the bases, that is, the moieties carrying the information on the DNA, pointing to the center of the strand, and the negatively charged phosphate backbone facing the outside so as to minimize electrostatic repulsion between the individual chains. The helical double strand has a thickness of about 2 nm, and 10 bp are required for one helical turn. The stacked bases are rotated by 36° with respect to the immediate neighbor. The distance from one ribose to the next is about 0.34 nm. Thus, a single copy of the entire human genome would correspond to a linear DNA molecule of about 1 m in length. The binding of complementary single DNA strands to form a double-stranded DNA is referred to as hybridization. The stability of the double-stranded DNA depends strongly on the temperature. Heating beyond a certain critical "melting" temperature results in the separation of the strands.

As the DNA strands wind around each other, they leave gaps between each set of phosphate backbones, revealing the sides of the bases inside. There are two of these grooves twisting around the surface of the double helix: the major groove is 2.2 nm wide and the other, the minor groove, is 1.2 nm wide. The greater accessibility in the major groove means that DNA-interacting proteins such as transcription factors that can bind to specific sequences in double-stranded DNA usually make contacts with the sides of the bases exposed in the major groove.

The double-stranded DNA is stable, but for the synthesis of mRNA, the DNA template must be present as single strands to expose the bases. Specific enzymes are required to open the double strand and to initiate the transcription. The propensity that this actually happens itself is encoded in the DNA sequence using multiple mechanisms. One strategy is based on the difference in binding energy between the base pairs. Because the C–G pair is more stable than the A–T pair, DNA sequences with a high AT content are less stable and easier to "open." Such TATA boxes then often provide access for transcription factors – proteins that regulate (activate or inactivate) the transcription of specific genes.

There are additional, less common forms of DNA whose physiological roles are not yet clear. The A form is a wider right-handed spiral, with a shallow, wide minor groove and a narrower, deeper major groove. The A form occurs under nonphysiological conditions in dehydrated samples of DNA, whereas in the cell it may be produced in hybrid pairings of DNA and RNA strands, and also in enzyme–DNA complexes. Segments of DNA where the bases are methylated may undergo a larger change in conformation and adopt the Z form. Here, the strands turn about the helical axis in a left-handed spiral.

Densely packed DNA strands form chromosomes, which are large structures visible with conventional microscopy. Mammals are typically diploid; every mononucleated somatic cell contains two copies of the set of chromosomes. In humans there are 22 autosomal chromosomes plus the X and Y chromosomes, which determine the gender (female, XX; male, XY). Some individuals with chromosomal disorders carry an extra chromosome, the most common case being trisomy 21, also referred to as Down syndrome. In an extended fashion the helical DNA strand of a

typical human chromosome would have a length of about 50 mm; it would by far not fit into a cell. Moreover, in this configuration the DNA would be inherently unstable. Therefore, in the nucleus the DNA is further condensed with the aid of specialized proteins, the histones. The double-stranded DNA makes two turns while wrapping around a complex of eight histones, thus forming a unit called a nucleosome. These units are cross-linked with H1 histones to form a fiber about 30 nm in diameter. The complex of histones and condensed DNA is referred to as chromatin. The chromatin fiber of a typical chromosome would still have a length of 1 mm. The chromatin is therefore further folded to form the structure of a chromosome. In a configuration in the metaphase of cell division a chromosome can have a length of about 5 μm.

7.1.1.2 Enzymes for DNA and RNA processing

DNA in a chromosome is densely packed with proteins and specific enzymes play key roles in regulating gene transcription. Therefore, under *in vivo* conditions DNA is rarely found in isolation but typically associated with complex clusters of proteins, some of which may have enzymatic activity, facilitating specific chemical reactions. Such enzymatically mediated reactions are necessary to maintain the organization of the supercoiled structure of the very long DNA molecules. DNA pieces need to be cut out and pasted together again to avoid the formation of knots. Replication and transcription are finely regulated and they require the synthesis of new strands of nucleic acids. In particular, because many of these enzymes are valuable tools in molecular biological research, we will briefly address some of them.

Cut and Paste of DNA Nucleases are enzymes that cut DNA or RNA strands by catalyzing the hydrolysis of the phosphodiester bonds (DNAses and RNAses, respectively). Endonucleases cut within a strand whereas exonucleases only remove single nucleotides from the ends. The physiological purpose of DNAses and RNAses is the degradation of the nucleic acids. Experimentally, these enzymes are powerful tools in molecular biology for the targeted isolation of RNA or DNA, respectively. Because of the inherent instability of RNA, trace amounts of RNAses in the laboratory pose a serious problem in handling large RNA molecules. Two DNA strands are rejoined or concatenated (ligated) with the aid of ligases.

Topoisomerases combine the activities of both nucleases and ligases. Thus, they cut a DNA double strand, rotate it, and paste it together again. Topoisomerases therefore reduce the degree of supercoiling when double-stranded DNA is unwound and solve the complex topology problem arising from the helical DNA structure.

Some endonucleases are very specific for the sequence motif at which they cleave the DNA. Such *restriction* endonucleases are indispensable tools in molecular biology as they allow site-specific fragmentation of DNA, for example, for the generation of restriction maps. In addition, restriction enzymes are used to extract specific stretches of DNA from larger DNA structures (e.g., plasmid DNA) for further processing. Most restriction endonucleases originate from bacteria and the enzyme names indicate the origins. For example, the enzyme *Eco*RV comes from *E. coli* and it recognizes the 6-base sequence 5′-GAT|ATC-3′ and cuts at the vertical line, thus leaving "blunt" DNA ends. Other restriction enzymes cut in an asymmetric manner.

The restriction enzyme *Hin*dIII from *Haemophilis influenzae* cuts at the sequence 5′-G|AATTC-3′, leaving single-strand overhangs of four nucleotides, so-called "sticky ends."

Synthesis of New DNA or RNA DNA replication and gene transcription, that is, the synthesis of mRNA, require access to the base sequence of the DNA. The inner-facing hydrogen-bonded bases are not accessible from the outer perimeter in double-helical DNA and the double strand must be "opened." This task is achieved with the aid of energy-consuming enzymes, the helicases; they break the hydrogen bonds between bases and unwind the double-helical DNA into single strands.

The exposed bases are used to synthesize a new complementary strand of DNA or RNA by DNA or RNA polymerases, respectively. These polymerases bind to the single-strand DNA template and join individual nucleoside triphosphates, always working from the 5′ to the 3′ end. DNA replication catalyzed by DNA polymerase is a critical step in biology because a perfect complementary copy of the genome must be synthesized in every cell division. Therefore, many polymerases have a so-called proofreading activity to check and correct for mistakes in DNA synthesis. Transcription or RNA synthesis requires DNA-dependent RNA polymerases; they take single-stranded DNA as a template but synthesize the complementary RNA sequence. Transcription is initiated by binding of the RNA polymerases to specific promoter sequences preceding the actual coding region of a gene and by unwinding the DNA. Transcription terminates at termination sequences encoded in the DNA.

Polymerase Chain Reaction (PCR)

The polymerase chain reaction (PCR) is a fast and simple method to amplify specific parts of a DNA strand. This is important because standard molecular biology techniques such as DNA sequencing, gel electrophoresis, or the recombination of DNA fragments are not applied to single molecules, but typically require at least picomolar DNA concentrations. The power of PCR is based on the fact that both strands of any double-stranded DNA can be used as templates to generate new double strands; n repetitive steps of strand separation (*denaturation* step), hybridization of specific starting oligonucleotides (primers, *annealing* step), and synthesis of new complementary strands (*elongation* step) lead to an exponential amplification of the starting material according to $f(n) = 2^n$. Denaturation typically is performed at around 95 °C for 20 s; annealing occurs, depending on the length of the primers, at 50–65 °C, and thermostable DNA polymerases synthesize the new strands at about 70 °C. PCR is used to produce identical copies of DNA sections for later use (*preparative* PCR) or for the analysis of trace amounts of DNA in modern diagnostics or forensics (*analytical* PCR). Quantification of analytical PCR is achieved by instruments measuring the time course of DNA synthesis (*real-time* PCR). RNA molecules can be subjected to PCR methods subsequent to a reverse transcription into DNA (*RT*-PCR).

The synthesis and analysis of DNA *in vitro* are an indispensable step in most molecular biological experiments. By means of the PCR, DNA sequences are amplified for preparative and analytical/diagnostic purposes (see the information Boxes on PCR and DNA sequencing).

DNA Sequencing

Many experimental steps in molecular biology require the knowledge of the exact sequence of bases in DNA molecules. Various methods to determine DNA sequences exist, but the one most commonly used relies on a combination of DNA synthesis and gel electrophoresis according to Sanger. A template DNA to be sequenced is incubated with a short sequence-specific oligonucleotide and a DNA synthesis reaction mix composed of a polymerase and the four nucleotides (A, T, G, C). The polymerase starts to synthesize new DNA strands by adding complementary nucleotides to the priming oligonucleotide that binds to the template. Instead of performing one reaction with standard A, T, C, and G nucleotides only, the reaction is split into four, each one being supplemented with small amounts of one of the four modified nucleotides (A^*, T^*, C^*, G^*) that cannot be linked to additional nucleotides and, hence, will terminate the chain reaction. At the end, each reaction tube will contain a mixture of oligonucleotides of various lengths, always terminating at either A^*, T^*, C^*, or G^*. Electrophoresis of these four reaction mixes in parallel then reveals a correlation of "size" and "terminating nucleotide," providing the complementary sequence of the template.

A special form of DNA polymerase frequently used in molecular biology is reverse transcriptase. This enzyme takes RNA as a template and synthesizes a complementary DNA (cDNA). It is a valuable tool for the cloning of intron-free coding sequences from processed mRNA molecules isolated from cells.

DNA Propagation in *E. coli*

One of the practical challenges in molecular biology is to identify and isolate specific DNA macromolecules in a mixture with numerous other known and unknown molecules. For example, if a DNA fragment is amplified by a PCR reaction, how is this fragment isolated and produced in large amounts? Typically, such fragments are inserted into a circular DNA (plasmid) by a ligation reaction. The plasmids are subsequently incorporated into bacteria, typically *E. coli* – the bacteria are transformed. Plasmids replicate within the bacteria and amplify with the bacterial culture. However, since bacterial transformation is a very inefficient process, untransformed bacteria without plasmids must be eliminated. This is achieved by a gene on the plasmid coding for a protein that makes the bacteria resistant to an antibiotic. Hence, in the presence of the selection antibiotic, only the transformed bacteria will survive. When bacteria are seeded at very low

concentration on a solid substrate (agar dish), individual colonies of bacteria – all originating from the same "mother bacterium" – will appear. As a result, identical copies of one original DNA molecule – a clone – can be isolated from the descendants of a single bacterial colony.

7.1.1.3 **Mutations, Damage and Repair of DNA**

The DNA sequence remains essentially constant throughout our lives. However, surprisingly, the DNA molecule itself is one of the least stable molecules in the cell. *In vivo*, DNA is always accompanied by water molecules, making the nucleic acid prone to hydrolytic cleavage. In fact, cleavage of the backbone phosphodiester bonds (single-strand break) is a very common reaction under physiological conditions. About 50 000 events of this type are estimated to occur per genome in 24 h. However, also the glycosidic bonds of the purine bases (A, G) are very susceptible to hydrolytic attack and so-called depurinations have an estimated daily frequency of 10 000. The pyrimidines (C, T) are more stable, with cleavage events about 20-fold lower than purine removal. These are just examples of the most common challenges to DNA integrity, but other modifications are also known, including those caused by oxidation.

Oxygen is required for cell survival, especially for energy production, but the oxygen usage itself creates highly reactive oxygen-derived species capable of damaging cell constituents, including DNA. One oxidative damage to human DNA is estimated to occur every 9 s. The DNA stability is further compromised by alkylating agents and electromagnetic radiation such as X-rays and ultraviolet (UV) light. In addition, several chemicals have a tendency to bind to DNA and affect replication and transcription, ultimately leading to changes in nucleotide sequence. Such chemical mutagens are usually planar aromatic substances that fit into the space between two adjacent bases. This process of intercalation may alter transcription and DNA replication and manifest itself as a mutation.

The long list of DNA modifications, either spontaneous or induced by mutagens, raises the question of how DNA can serve as a blueprint of life. In fact, the system would not work without the existence of an elaborate DNA repair machinery. Several independent repair mechanisms are known, including base excision repair and nucleotide excision repair. The *base* excision repair system comprises glycosylases, endonucleases, and polymerase activity, which allow the replacement of a single incorrect *base*. By contrast, enzymes involved in *nucleotide* excision repair remove short nucleotide stretches containing multiple bases in a single DNA strand, followed by a fill-up reaction guided by the sequence of the complementary strand.

The balance between DNA damage and repair, which together define the net mutation frequency, is the basis of all evolutionary processes. Under some conditions, the repair mechanisms are not sufficient and may leave a mutation unrepaired. A DNA mutation occurring in a germ cell can be propagated to the offspring where it has potential to cause a functional or developmental change. In an extreme case, the mutation may be so detrimental that the offspring may not be able to develop properly. In other cases, the consequences of a DNA mutation may not hamper

immediate survival and the mutation may persist and spread among the offspring. One example is single-nucleotide polymorphisms (SNPs); some individuals harbor DNA sequences that vary only at specific single bases. Such SNPs may cause a predisposition for the development of an inherited disease. When located in a noncoding region, it may not have an immediate impact on health, but it can contribute to a diversification of DNA and, hence, might be used for forensic identification.

In contrast to the mutations in germ cells, in cells whose genetic information is not inherited to the next generation, the so-called somatic cells, mutations often affect the process of controlled cell division (see also Section 7.4.1). Thus, chemical mutagens are potentially carcinogenic and must be handled with great care. An example is ethidium bromide, routinely used in molecular biology to visualize DNA in an electrophoresis (see the information Box on electrophoresis). Others are benzopyrenes and aflatoxin. Some intercalating substances, such as the chemotherapeutic drug daunomycin, are used specifically to combat cancer cells, which rely heavily on the replication machinery due to their rapid growth.

Of particular importance for biophotonics applications in living systems is the inherent risk of photons directly damaging DNA. UV light, for example, can induce a cross-linking reaction between adjacent pyrimidine bases, thus producing thymine dimers. Maybe even more importantly, reactive species generated by light, such as free radicals and hydrogen peroxide, also damage DNA by chemically modifying bases or by breaking the DNA double strand. Whereas damage occurring in only one strand can be repaired efficiently by the DNA repair systems, double-strand lesions are difficult to repair and often lead to adverse consequences. Therefore, when using photons for clinical applications, it is imperative to evaluate the photodamage risk carefully.

Detection of Molecules in Cells/Tissue

Despite the immense number of different molecules inside a cell, various methods are available to "visualize" molecules in a very specific manner. DNA and RNA molecules typically are detected by binding cDNA molecules (probes) to them, a process termed hybridization. Such probes are detected either via a fluorescent moiety that they carry or by means of an enzymatic activity with which they are equipped. The cytogenetic technique to localize specific DNA sequences on chromosomes is termed fluorescence *in situ* hybridization (FISH). For the detection of proteins or other molecules the use of antibodies is instrumental (see the information Box on antibodies below). Visualization of specific antigens in biological tissues using antibodies is referred to as *immunohistochemistry* (IHC).

7.1.1.4 UV Absorption and Fluorescent Nucleic Acids

DNA strongly absorbs UV light of wavelength 260 nm. This absorption characteristic is utilized to measure the DNA concentration and purity. In addition, a change in light absorption when DNA molecules are denatured provides information on the melting temperature of DNA and on its content of guanine and cytosine (GC content).

As mentioned in the previous section, some substances show a strong propensity to intercalate into DNA. Such compounds are potentially carcinogenic; however, they have proven to be useful tools in detecting and quantifying DNAs in a variety of manners. For example, the DNA-binding dye ethidium bromide is routinely used to visualize DNA in gel electrophoresis experiments aimed at measuring the size of DNA fragments. For the analysis of the exact DNA sequence various methods exist. Mostly they rely on the synthesis of cDNA from the DNA template to be sequenced. Such reactions are performed four times, each one with a small fraction of a specific variant of the nucleotides (A, T, C, G) such that the reaction is terminated once one of those nucleotides is incorporated. Hence a mix of DNA of various lengths is generated. For the measurement of these lengths, and consequently the association of the terminating nucleotides, the DNAs are separated by electrophoresis and identified by means of fluorescently labeled nucleotides.

The use of fluorescently labeled nucleotides is also the basis of the detection of specific DNA sequences (or specific gene) in cells. Small complementary stretches of single-stranded DNA (oligonucleotides) are labeled with specific dyes. Upon binding of these oligonucleotides to DNA in a cell, the process called hybridization (see above), DNA harboring the matching sequence is detected by fluorescence microscopy. With the FISH technology mentioned earlier, many different genes (or chromosomes) can therefore be detected in cells simultaneously when using oligonucleotides with different fluorescent properties (colors). In a somewhat similar fashion, modern chip technology uses fluorescently labeled RNA probes to evaluate the expression of entire genomes (e.g., measurements of the relative concentration of DNA coding for about 20 000–40 000 genes are performed for pan-genomic human arrays).

7.1.2
Proteins: Scaffolds and Molecular Machines

Proteins are probably the most diverse group of biomolecules in cells. Likewise, their functional roles range from structural scaffolds to ensure cell shape and integrity, to cell communication, catalysis of numerous biochemical reactions, and energy-harvesting and energy-consuming molecular machines. In short, proteins participate in almost all functions required for life.

7.1.2.1 Amino Acids

Amino acids, the building blocks of proteins, are diverse in structure, but have in common a carboxylic acid group and an amino group linked by a central carbon atom (α-carbon) (Figure 7.5). The third bond of this α-carbon is made to a hydrogen atom. The fourth bond is to a variable group (side chain), specifying the type of amino acid (an exception is proline; see below). The tetrahedral arrangement of bonds to the α-carbon confers optical activity on amino acids; the amino acid is chiral and will change the polarization of light on interacting with photons. The mirror-image L-isomer and D-isomer forms exist, but nearly all amino acids in naturally occurring proteins are L-isomers.

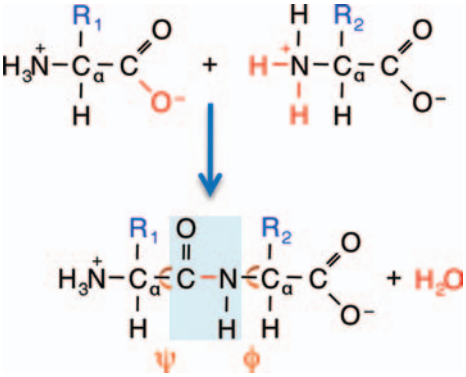

Figure 7.5 Peptide bond formation. Two amino acids with side chains R_1 and R_2 form a dipeptide with the concomitant release of water. The peptide bond is indicated in red and the plane formed by the peptide bond and the carbonyl oxygen in blue. Also indicated are the dihedral angles of rotation, ψ and φ.

The side chain (R_1 and R_2 in Figure 7.5) can be small such as the proton in glycine or large such as the indole group in tryptophan. The chemical nature of this side chain largely determines the properties of the amino acid and, hence, the properties of the proteins made of them. Although there are many different types of amino acids, in nature only 20 L-amino acids are commonly used to build proteins (there are modifications of such amino acids, some of which will be discussed in Section 7.1.6), no matter whether in bacteria, plants, or humans. The strong diversity of the chemical properties of these 20 standard amino acids provides an immense variability of protein structures and therefore functions. At the same time, it is remarkable that the standard amino acids, and therefore most native proteins – without considering modifications occurring after protein synthesis in Section 7.1.2.5 or cofactors (Sections 7.1.2.6 and 7.1.6) – consist of only five chemical elements: carbon (C), hydrogen (H), oxygen (O), nitrogen (N), and sulfur (S) [a few proteins contain selenocysteine instead of cysteine and, therefore, selenium (Se) is another naturally occurring element in native proteins].

Three nomenclature systems, the full names (e.g., arginine), the three-letter code (Arg), and the single-letter code (R) (see Figure 7.6), are in place to describe different amino acid residues. The single-letter code is often used for the description of protein sequences because they can contain more than 1000 amino acid residues.

Amino acids can be classified according to various parameters, as illustrated in Figure 7.6. Among them are the mass, the volume, the electric charge, the pH value at which the residues are half-protonated (pK_R), and a measure of how the side chain interacts with water, hydropathy. According to the last aspect three groups can be defined:

1) non-polar side chains (Gly, Ala, Val, Ile, Met, Pro, Phe, Trp)
2) uncharged but polar side chains (Ser, Thr, Gln, Tyr, Cys)
3) charged polar side chains (Lys, Arg, His, Asp, Glu).

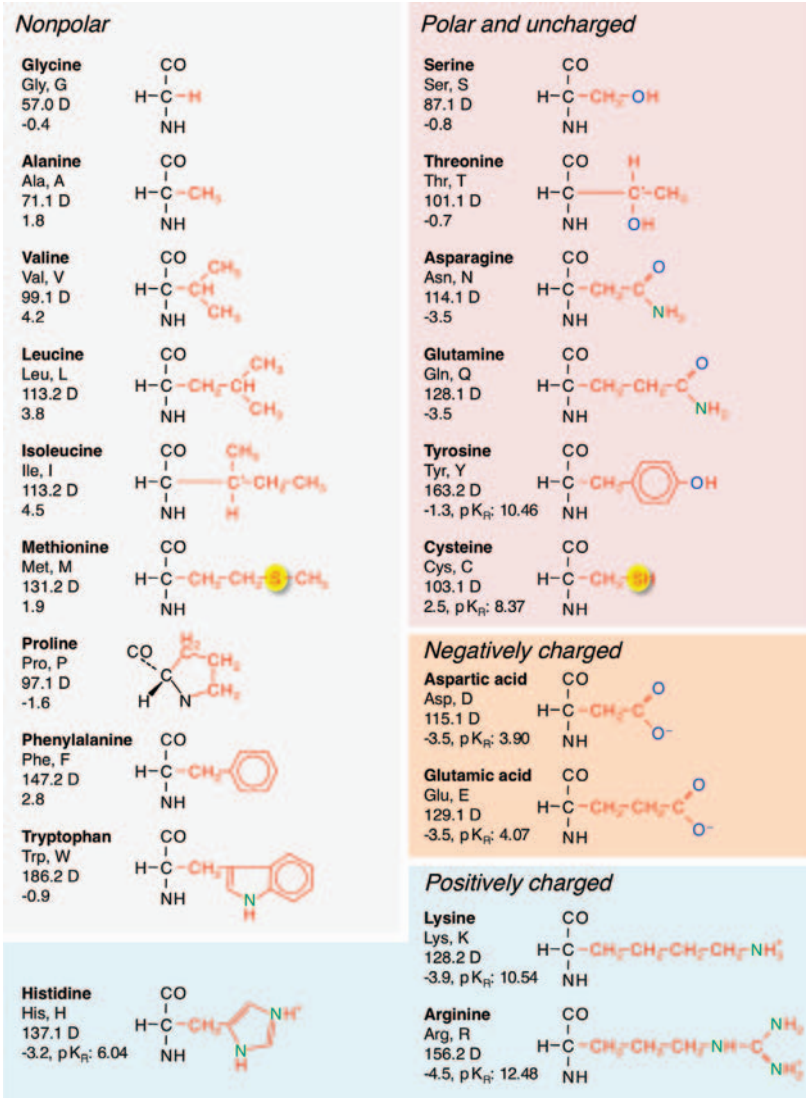

Figure 7.6 The 20 natural amino acid residues as they occur in a polypeptide. Full name, three-letter code, single-letter code, molecular mass of the residue, hydropathy index, and pK_R values for charged residues are indicated. In the chemical structures, the backbone atoms are drawn in black, the side chain atoms are colored. Side-chain atoms sulfur, oxygen, and nitrogen are highlighted (numeric values from Voet *et al.* [3]; hydropathy values from Kyte and Doolittle [4]).

Typical pK_R values of the protonatable side chains are indicated in Figure 7.6. The histidine side chain is partially protonated at physiological pH between 7.2 and 7.4. It is important to note that exact pK_R values vary markedly depending on temperature, ionic strength, and the immediate environment of the ionizable group. For example,

inside a protein the effective pK_R value of a histidine can deviate considerably from 6.04 if there are charged residues nearby.

The amino acid proline is a special case because the hydrogen atom at the backbone is replaced by a bond to the side chain (Figure 7.6). Therefore, proline residues introduce a "kink" in the polypeptide backbone structure (see Section 7.1.2.3). Glycine's side chain is only a proton and, hence, the amino acid glycine is not chiral. Subsequently, glycine exhibits greater structural flexibility than other amino acids (Section 7.1.2.3).

7.1.2.2 Protein Translation – the Standard Genetic Code

Proteins are linear chains of amino acids covalently bonded together and the amino acid sequences contained therein are specified by the genes consisting of DNA base sequences. To synthesize a protein from the corresponding DNA sequence, the first step is to transcribe the DNA into mRNA, which is then transported outside the nucleus to the cytosol, the site of protein synthesis. Here, mRNA binds to ribosomes, large subcellular structures designed to comprise a complex machinery that "reads" the mRNA sequence and then "synthesizes" a protein by linking the correct matching amino acids loaded on to tRNAs ("charged tRNAs"). Since there are only four bases in the DNA or RNA sequence but 20 amino acids, three base positions are utilized to describe an amino acid, defining the so-called standard genetic code. A triplet of bases, a so-called codon, "codes" for an amino acid in mammals according to the scheme illustrated in Figure 7.7. Some features of the genetic code are readily apparent:

- Some amino acids are coded for by four different codons (Leu, Val, Ser, Pro, Thr, Ala, Arg, Gly), some by three, two, or only one codon (Met, Trp).
- Some codons do not code for any amino acid; they are called missense or stop codons.

One consequence is that those amino acid residues coded by four codons are less prone to amino acid-altering mutations because the base at the third position is redundant. A mutation of the base sequence that does not lead to a change in the translated protein sequence is referred to as a "synonymous" mutation or a type of "silent" mutation. Because only a single codon exists for Met or Trp, any change in base sequence coding for Met or Trp will necessarily lead to a coding (non-silent) mutation.

The RNA codon AUG (or ATG in DNA sequence) is of particular importance. It not only codes for the amino acid methionine (Met) but is also the so-called eukaryotic start codon; translation can only start at a base triplet AUG. In this way, the interpretation of the following base triplets – the reading frame – is defined. The structure of the ribosome ensures that, once initiated at an AUG element, the reading frame is maintained; the mRNA always advances by exactly three bases before the next amino acid is attached to the protein sequence. Another consequence is that directly after synthesis all proteins start with a methionine residue.

Pos 1		Pos 2							Pos 3
		U		C		A		G	
U	Phe	UUU	Ser	UCU	Tyr	UAU	Cys	UGU	U
		UUC		UCC		UAC		UGC	C
	Leu	UUA		UCA	stop	UAA	stop	UGA	A
		UUG		UCG	stop	UAG	Trp	UGG	G
C	Leu	CUU	Pro	CCU	His	CAU	Arg	CGU	U
		CUC		CCC		CAC		CGC	C
		CUA		CCA	Gln	CAA		CGA	A
		CUG		CCG		CAG		CGG	G
A	Ile	AUU	Thr	ACU	Asn	AAU	Ser	AGU	U
		AUC		ACC		AAC		AGC	C
		AUA		ACA	Lys	AAA	Arg	AGA	A
	Met	AUG		ACG		AAG		AGG	G
G	Val	GUU	Ala	GCU	Asp	GAU	Gly	GGU	U
		GUC		GCC		GAC		GGC	C
		GUA		GCA	Glu	GAA		GGA	A
		GUG		GCG		GAG		GGG	G

Figure 7.7 Standard genetic code describing how RNA codons are translated into amino acid residues. Coding sequences always start with AUG, also coding for methionine residues. Translation is terminated whenever one of the stopcodons is encountered. Coloring denotes nonpolar (gray), polar and uncharged (pink), negatively charged (orange), and positively charged (blue) residues.

In many cases, however, such leading sequences are removed in subsequent protein processing steps.

Translation is terminated once a stop codon is encountered. In the standard genetic code there are three stop codons: UGA determines the end of about 50% of all human protein sequences and UAA or UAG are found in the rest of the mRNAs.

The fact that organisms as different as a human, an oak tree, and a tiny bacterium virtually "speak" the same genetic language may seem surprising, but it reflects that all organisms are derived from a common ancestor. During the enormous number of generations that separate the mentioned species, very many small variations have occurred and accumulated, and have since been conserved in individual genetic codes. Such deviations from the standard code are particularly evident in mitochondria, small endosymbionts in animal and plant cells (Section 7.2.1.5) that carry some of their own genetic material. In the human mitochondrion, unlike the universal code, UGA codes for tryptophan instead of terminating the translation. AUA codes for methionine instead of isoleucine, and AGA and AGG are stop codons. In addition to such alterations in the meaning of individual codons, the selection of redundant codons for the same amino acid is not identical in different organisms. Depending on the species, the translation machinery prefers some codons over others. Thus, in a given organism the presence of individual tRNA molecules reflects the frequency at which the respective codon is used in the genome of this species. This so-called codon

usage is of practical importance if a gene from one species is to be expressed in a host system of another species; this can result in a very small protein yield if the codon usage is incompatible. For example, the codons AGG and AGA, both encoding arginine, occur with very low frequencies of about 1.5 per 1000 in the genome of the bacterium *E. coli*. In the human genome, each of these codons occurs at a higher frequency of about 12 per 1000 codons. This corresponds to a probability of 42% that one of the two codons appears in the mRNA sequence, whenever an arginine occurs in the protein sequence. As a consequence, efficient production of a human protein in *E. coli* may require adapting the codon usage such that rare tRNAs of *E. coli* will not limit the yield of the translation process.

Genome Projects and Protein Sequences The amino acid sequences of all proteins are specified by the mRNA sequences, which reflect the corresponding complementary DNA sequences. Thus, the information obtained from mRNA has been used to deduce the amino acid sequences of proteins and also to gain additional information about the genome. Typically, mRNA sequences are reverse transcribed or copied into cDNA and used for standard DNA sequencing approaches. Although this approach provided a wealth of information, the sequence coverage for humans and other species was far from being complete. With the development of new shotgun sequencing methods, very large stretches of genomic DNA could be sequenced. With the successful sequencing of the complete human genome, the public availability of gene sequences reached a new quality. In addition, the genomes of many important model organisms and also pathogenic organisms have been sequenced completely. *In principle*, this allows the prediction of all proteins that can be made by cells of these organisms.

Naming genes and gene products (proteins) often has a historical background and it is no rare event that identical genes have various different names. Recently the Human Genome Nomenclature Committee has introduced the standardized HUGO nomenclature of human genes, facilitating searches for genes of specific properties (http://www.genenames.org/). There are several Internet-based resources where information on genes and proteins can be found, for example, http://www.ncbi.nlm.nih.gov/ and http://www.ebi.ac.uk/embl/.

7.1.2.3 Peptide Bonds, Polymerization, and Secondary Structure

Two amino acids are joined to form a dipeptide by a peptide bond between the carboxy group of the first and the amino group of the second amino acid (Figure 7.5). The carbonyl oxygen, its carbon, the nitrogen, and the proton of the amide group are in a plane, mostly in a *trans* configuration, so that the oxygen and the proton point in opposite directions. The bond between the carbonyl carbon and the nitrogen is rigid. The bonds of the α-carbon to the carbonyl carbon and the nitrogen, however, are single bonds and therefore can rotate along the axis. The respective angles of rotation, the dihedral angles ψ and φ, thus provide a considerable degree of rotational freedom.

As a consequence, the side chains of two succeeding amino acids typically point in different directions. Addition of another amino acid yields a tripeptide, and so forth.

Short sequences of amino acid chains are called peptides (or oligopeptides). Starting from a somewhat arbitrary size of about 40 residues, one refers to such polypeptides as proteins. The linear sequence of a protein, the list of amino acid residues starting from the amino-terminal end, is called the *primary sequence* or *primary structure* of the protein.

Upon peptide bond formation, a linear chain of amino acids consists of the backbone, formed by two carbons and one nitrogen atom per residue, one proton of the amide group, one of the α-carbons, a carbonyl oxygen, and the side chain.

Based on the nature of the peptide bond and the available side chains, there is only a limited set of structural configurations that a polypeptide can adopt. A presentation of the dihedral angle ψ plotted versus the dihedral angle φ – the so-called Ramachandran plot – provides a prediction for the formation of secondary structural elements and shows that only relatively small domains of ψ−φ combinations give rise to secondary structural elements. Such structural modules have a low potential energy and therefore form larger building blocks inside protein structures.

The α-Helix The first secondary structure identified was the α-helix (Figure 7.8a). This common structure forms spontaneously and is stabilized by hydrogen bonding between amide nitrogens and carbonyl oxygens of peptide bonds spaced four residues apart. Thus, in an α-helix all CO and NH groups of the backbone are hydrogen bonded. The orientation of the hydrogen bonding produces a helical coiling of the peptide backbone such that the side-chain groups lie on the exterior of the helix and perpendicular to its axis. Typical figures for an α-helix are a diameter of the backbone of about 0.5 nm, a height per turn of about 0.54 nm, and approximately 3.6 residues per turn. Along the helix axis the residues are thus separated by 0.15 nm and are rotated by 100° with respect to the next neighbor. The helical twist in proteins is right-handed. In three-dimensional space, residues separated by three or four positions on the primary sequence are in close proximity.

Not all amino acids favor the formation of the α-helix due to steric constraints of the side-chain groups. Amino acids such as Glu, Met, Ala, Leu, Lys, and Phe favor the formation of α-helices, whereas Gly and Pro favor disruption of the helix. This is particularly true for Pro since it is a pyrrolidine-based imino acid whose structure significantly restricts movement about the peptide bond, interfering with extension of the helix. The disruption of the helix is important as it introduces additional folding of the polypeptide backbone to allow the formation of globular proteins.

Another helical secondary structure much less frequently found is the 3_{10} helix. This is a right-handed helix with three residues per turn and a translation of 0.2 nm along the helical axis. Some protein segments may exhibit transitions between the 3_{10} and α-helical secondary structures.

β-Strands and β-Sheets Whereas an α-helix is composed of a single linear array of helically arranged amino acids, β-sheets are composed of two or more different β-strands, that is, regions of stretches of at least 5–10 amino acids. The folding and alignment of stretches of the polypeptide backbone beside one another to form β-sheets are stabilized by hydrogen bonding between amide nitrogens and carbonyl

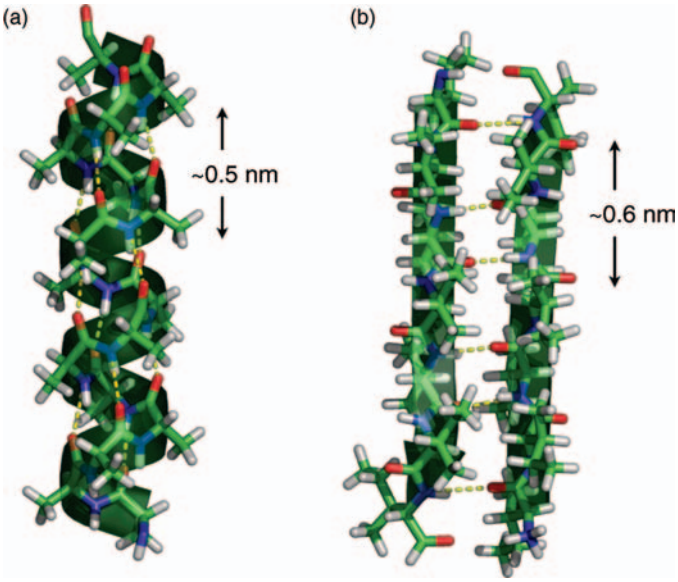

Figure 7.8 Secondary structural elements. (a) α-helix; (b) β-sheet. The hydrogen bonds stabilizing these structures are indicated in yellow.

carbons, thereby using the full hydrogen-bonding capacity of the polypeptide backbone (Figure 7.8b). However, the hydrogen-bonding residues are present in adjacently opposed stretches of the polypeptide backbone in contrast to a linearly contiguous region of the backbone in the α-helix. β-Sheets have a rippled appearance and they are said to be pleated. This is due to positioning of the α-carbons of the peptide bond, which alternates above and below the plane of the sheet; as a consequence, the β-sheet is slightly shorter than an extended polypeptide. Neighboring side chains point in opposite directions and a typical distance between one and the next residue is about 0.7 nm.

β-Sheets are either parallel or antiparallel. In parallel sheets, adjacent peptide chains proceed in the same direction (i.e., the direction of N-terminal to C-terminal ends is the same), whereas in antiparallel sheets adjacent chains are aligned in opposite directions. In proteins, β-sheets can contain between two and 22 strands, with each strand up to 15 residues in length. The average length is six residues. The amino acids Val, Ile, Tyr, Trp, and Leu are most frequently found in β-sheets; Pro and Gly are rarely found in β-sheets.

Coiled Coils α-Helices are perfectly suited to form fibrous proteins: long fiber-like structures that play a supportive and connective role in living organisms. A prominent example is α-keratin, a protein that occurs in hair, nails, and other relatively hard biological structures. Two α-helices wind around one another to form a left-handed coiled-coil structure. Depending on the type of keratin, this structure is stabilized by disulfide bridges. Chemical cleavage of these bonds can result in weakening of the structure; re-formation of disulfide bonds in a curled configuration

can stabilize such a curled structure, as practiced to generate a "permanent wave" of hair. Another example is collagen, forming a coiled-coil structure of three helices twisted around one another. Collagens are stabilizing proteins found in connective tissue such as bone, cartilage, tendons, and skin. They consist of about one-third of glycine and 15–30% of proline and 4-hydroxproline (Hyp). The latter is the result of a post-translational modification of proline with the aid of prolyl hydroxylases, an enzyme that requires vitamin C (ascorbic acid) for its activity. Deficiency of vitamin C can thus result in an impairment of collagen formation as found in scurvy.

Turns, Loops and Random Coils In proteins that do not form long fibrous structures, so-called globular proteins, individual secondary structural elements (α-helices and strands of β-sheets) must be interconnected. The common feature of such structures is that they cause abrupt changes in direction, such as in reverse turns or β-turns connecting strands of β-sheets. Some protein segments, mostly found at the surfaces, form loops. They play important roles in how proteins are recognized by other proteins. In addition, there are countless structural configurations that appear totally disordered or random and cannot be associated with a well-defined structural class, thus referred to as random coil or intrinsically disordered structures. Although such structures appear "random," this characteristic may be well suited for the functions of the proteins.

7.1.2.4 Tertiary and Quaternary Protein Structure

The globular structure of a single polypeptide chain (protein) is referred to as tertiary structure. In many cases, specific function can only be acquired when several identical or different polypeptides or protein *subunits* form homomeric or heteromeric protein complexes, respectively. The overall structure of such complexes is called *quaternary structure*. An example of a protein structure and an illustration of various ways of its visualization are given in Figure 7.9.

Owing to the tremendous number of degrees of freedom, a protein with a given primary sequence can theoretically adopt countless structural configurations and yet in nature, its structural appearance is limited and reproducible; a polypeptide with a given sequence always folds into the same or at least a small number of tertiary structures. Which factors thus determine the final three-dimensional structure of a protein? We have already seen that, mostly by formation of a dense network of hydrogen bonds, secondary structural elements adopt low-energy states and, hence, are fairly stable. Another important driving force is the so-called hydrophobic force, largely expressing how nonpolar residues are stabilized by avoiding contact with water. This tendency is expressed by the hydropathy index (see Figure 7.6) of side chains. Hydrophobic areas will be largely buried inside the protein, whereas hydrophilic parts may face the surface and, hence, may interact with water molecules. In addition, formation of salt bridges, that is, electrostatic interactions of electric charges, contributes substantially to the overall energy of a protein structure. Quantitative descriptions of these physical forces form the basis of molecular dynamics simulations of proteins. Nevertheless, just by these physical forces alone – electrostatics,

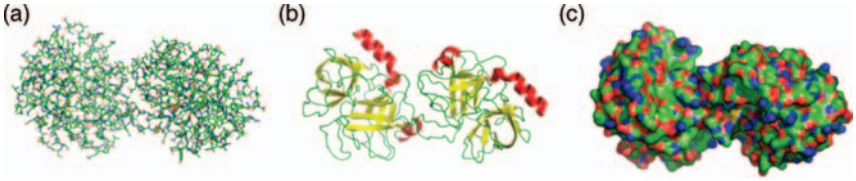

Figure 7.9 Tertiary structure of trypsin represented in three ways: (a) ball and stick, (b) cartoons, and (c) surface. PDB ID: 1TRN.

hydrogen bonds, and hydrophobic forces – most linear polypeptides will not spontaneously assume a tertiary structure with a desired function.

Disulfide Bonds The formation of reversible covalent bonds between the nucleophilic thiol groups (−SH) of two cysteine residues (Figure 7.10) helps to stabilize globular structures. In particular, large extracellular protein loops often require such stabilization in order to adopt the correct structure. The intracellular milieu, with the exception of the ER, is a more reducing environment and therefore the overall likelihood of disulfide formation is lower. However, some intracellular disulfide bonds may be formed and broken, depending on the local redox environment. Disulfide bonds can be formed within the same polypeptide chain, but they are also used to link different chains within a protein complex. During folding of a protein, the formation of disulfide bridges is often catalyzed by protein disulfide isomerases (PDIs).

For *in vitro* analysis, it is often necessary to disrupt the protein structure without destroying the peptide chain. This process is called denaturation and is achieved in part by the addition of strong reducing agents such as mercaptoethanol to break disulfide bonds.

Chaperones Chaperones are proteins that assist the noncovalent folding/unfolding and the assembly/disassembly of other protein structures by transiently interacting with the target protein during synthesis. Some chaperones provide steric information for the new protein to fold. More frequently, however, chaperones prevent both newly synthesized polypeptide chains and assembled subunits from aggregating into nonfunctional structures. These chaperones are typically so-called heat shock proteins. They are synthesized when the temperature is elevated and, hence, when there

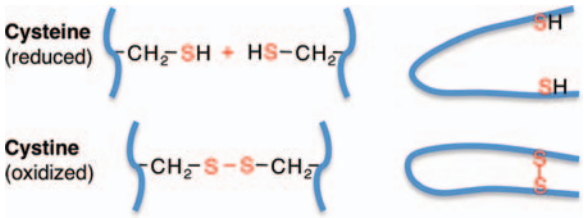

Figure 7.10 Protein stabilization by the formation of disulfide bridges between two cysteine residues. The typical S–S distance is about 0.2 nm.

is an increased tendency for proteins to be denatured by stress. The exact molecular function of chaperones is only beginning to be understood.

Structural Classification of Proteins – Folds The tertiary structures of proteins are much less variable than expected from the vast number of naturally occurring primary sequences. This is because proteins often adopt structures that have an overall similar topology, albeit varying in sequence and function. Since the two well-defined secondary structural units of helices and sheets are abundant in proteins, families of protein structures have been classified by a system based upon the α-helix and β-sheet and their general topological properties. Each different topology may be considered as a fold. Current thinking suggests that there are a limited number of folds, about 1000, in naturally occurring proteins.

Thus, the tertiary structure of a protein can be thought of as a composition of structural modules. Starting from the secondary structural elements discussed above, one defines so-called *supersecondary structures*. These are small structural motifs composed of combinations of α-helices and β-sheets. Prominent examples are antiparallel βαβ-motifs, antiparallel β-hairpin motifs, and antiparallel αα-motifs. A long β-hairpin folded over in the middle results in a Greek key motif.

A single protein can harbor several folds or areas of specific structure and function. Such protein *domains* play a pivotal role in their classification and they are often used when a protein is to be characterized by simpler means than the three-dimensional structure. In particular in the cell biological literature, proteins are often presented in a simplified fashion by denoting such domains without referencing to the real three-dimensional structure. An example is shown in Figure 7.11.

β-Barrels Very common folds are so-called β-barrels – proteins in which β-strand elements are arranged to form a cylindrical structure. These can be arrays of β-strands with alternating directions or more complicated constructs in which the neighboring sheets are not necessarily neighbors in sequence (e.g., jelly roll or Swiss roll barrel). A TIM (triosephosphate isomerase) barrel or α/β-barrel is a complex fold of eight β-strands forming an inner barrel surrounded by eight α-helices forming an outer barrel. The green fluorescent protein (GFP) adopts a fold called β-can – a cylinder of 11 β-strands with a central α-helix holding the chromophore (see Figure 7.20a).

There are various theoretical approaches for the classification of protein structures. The most common ones are SCOP (Structural Classification of Proteins), which defines a hierarchy of "class–fold–superfamily–family–protein–species" and CATH (class, architecture, topology, homology), which uses the four attributes listed as

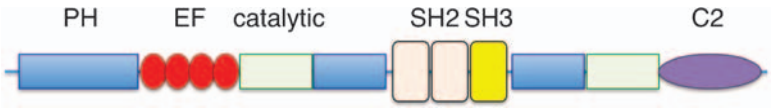

Figure 7.11 Functional domains of phospholipase γ1 (PLCγ1). PH, pleckstrin homology domain; EF, Ca^{2+}-binding EF-hand domains; SH, Src homology domains; C2, Ca^{2+}-dependent phospholipid binding domain (after Cockcroft [5]).

order criteria [6]. For a detailed description and classification of protein folds, see also [7] and [8].

More general classifications of protein structures are guided by their overall appearance of localization: globular, structural, and membrane proteins. Globular proteins are mostly found in the cytosol; typically they are soluble and adopt a compact structure. Structural proteins often tend to aggregate or to polymerize to form large filamentous structures. Membrane proteins are characterized by a hydrophobic core with which they are stabilized in the lipid bilayer membrane.

7.1.2.5 Post-translational Modifications: Dynamics of Protein Structure and Function

A protein, with a three-dimensional structure defined by its primary amino acid sequence coded by DNA, performs specific functions in a cell. If the cellular environment changes, such as a change in oxygen level, the cell may respond by changing gene expression, leading to the synthesis of new proteins with different properties. This strategy, transcriptional regulation, requires an expenditure of cellular energy to synthesize new molecules and it is often slow. In contrast, existing proteins may be modified to regulate their functions rapidly, a process termed post-translational modification. Numerous such modifications have been documented and a few selected examples are presented below. A more detailed treatment of the topic can be found in textbooks on biochemistry.

Cleavage by Peptidases Peptide bonds linking amino acid residues in proteins can be cleaved by specific enzymes, referred to as proteases or peptidases, with varying degrees of specificity to the amino acid sequence. Peptidases are present in the cytosol, in intracellular organelles, or are even secreted to the extracellular space. The secreted peptidases, such as matrix metallo-proteinases (MPPs), are essential in structuring the tissue by modification of those proteins forming the extracellular matrix, playing critical roles in development, remodeling, and cell migration.

The first residue to be synthesized in most proteins is methionine. Following this N-terminal methionine, some proteins may contain special-purpose sequences that are required to target the proteins to specific sites inside a cell, for example, into the mitochondria. Such *signal sequences* are address labels that may not be needed any longer once the desired location has been reached. Therefore, specialized peptidases cleave off such sequences. Other proteins, such as the peptide hormones insulin and enkephalin and the amyloid precursor protein, remain inactive until they are processed via peptidases.

Protein Phosphorylation By far the most important structural and functional regulator of proteins is the covalent attachment of negatively charged phosphate groups (PO_4^{3-}) to specific amino acid residues. This phosphorylation process is catalyzed by protein kinases, which transfer phosphate moieties most commonly from ATP (adenosine triphosphate) to the target proteins, often causing noticeable changes in their functions. The reverse process, removal of phosphate, is catalyzed by phosphatases. Both the phosphorylation and dephosphorylation processes are

subject to fine tuning, and kinases and phosphatases themselves may be phosphorylated.

Protein phosphorylation usually occurs at serine, threonine, and tyrosine residues in eukaryotic proteins. In addition, the basic amino acid residues histidine, arginine, and lysine in prokaryotic proteins may undergo phosphorylation. Histidine and aspartate phosphorylation in eukaryotic cells is less frequent but is receiving increasing attention. Structurally, the addition of a phosphate molecule to a polar group of an amino acid side chain can turn a hydrophobic portion of a protein into a polar and extremely hydrophilic moiety, causing a conformational change in the structure of the protein via interaction with other hydrophobic and hydrophilic residues. In Figure 7.12, phosphorylated serine, threonine, and tyrosine are illustrated.

Antibodies

Antibodies are large molecules generated by the immune system that specifically bind to (mostly) small sections of proteins, also called *epitopes*. While in the immune system antibody binding is a signal for the destruction of the respective target, scientists make use of antibodies to label proteins specifically on or inside cells. Antibodies to a protein of interest are generated in animals (e.g., rabbit, mouse, sheep, horse, chicken) in response to injection of the whole or a small fragment of the protein. The resulting antibodies are diverse in nature, recognizing different aspects of the protein, and are referred to as polyclonal antibodies. By fusion of cancer cells with antibody-producing B-cells in cell culture, permanent hybridoma cell clones can be generated that produce antibody molecules of only one type (monoclonal antibodies). For optical detection, antibodies are often labeled with fluorescent dyes. Since the labeling process is expensive, one often first binds a specific primary antibody (e.g., from mouse) to the target protein and subsequently a secondary, fluorescently labeled antibody that recognizes mouse antibodies is bound to the first one. Fluorescently labeled antibodies can be used

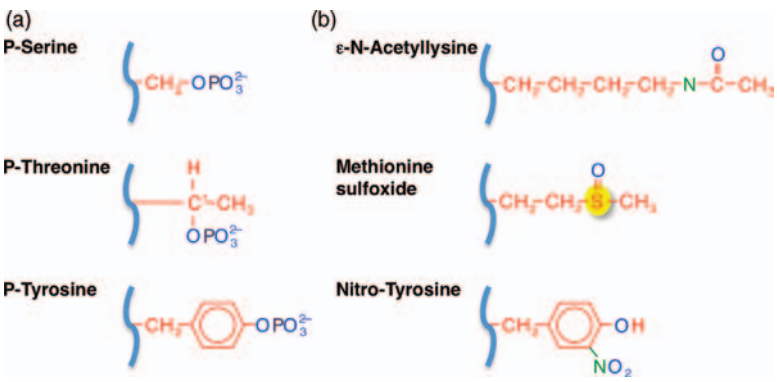

Figure 7.12 (a) Protein phosphorylation: *O*-phosphoserine, *O*-phosphothreonine, and *O*-phosphotyrosine. (b) Acetylated lysine, one epimeric form of methionine sulfoxide, and 3-nitrotyrosine. The side chains only are illustrated.

to detect surface proteins on living cells and to separate such cells in a fluorescence-activated cell sorter (FACS). If antibodies are used to label proteins that have been separated upon gel electrophoresis, this is referred to as Western blot.

A high degree of sequence specificity for protein kinases exists. For example, a given kinase does not phosphorylate every serine residue in a protein. The selectivity arises because most kinases require the target side chains, such as those of serine and threonine, to bind the enzymes transiently as specified by the three-dimensional structure imposed by the neighboring residues. Such phosphorylation *consensus sites*, typically described using the primary sequence, are known for several kinases, but they are much less stringent than, for example, recognition sites for DNA endonucleases. For instance, many kinases specific for serine and threonine residues require positive charges (Arg, Lys) being located N-terminal to the target residue. The mitogen-activated protein kinase (MAPK) prefers the consensus site P–X–S/T–P, where X is any residue. It should be noted, however, that such recognition motifs are an oversimplification as they cannot take into account the three-dimensional structure of the motifs. Experimental evidence is necessary to prove that a specific residue is indeed phosphorylated. For the detection of phosphorylated protein moieties, antibodies specific for a protein structural element encompassing the phosphorylated site (epitope) are instrumental. In particular, antibodies raised against phosphotyrosine are very important because consensus sites for tyrosine kinases are not well defined.

Protein Acetylation Most proteins undergo acetylation as a co-translational modification and/or as a post-translation modification. Most importantly, the N-terminal amide is often acetylated by the aid of *N*-α-acetyltransferases. Of the protein side chains, lysine is a typical target of histone acetyltransferase (HAT), an enzyme that modifies histones and thereby regulates gene transcription. Acetylated lysine (Figure 7.12) is modified back to lysine by histone deacetylase (HDAC). Both HAT and HDAC also exhibit activity with respect to proteins other than histones.

Protein Oxidation Almost all protein side chains can be oxidized, but the sulfur-containing residues cysteine and methionine are most susceptible and enzymes for their reduction exist. Oxidative modification of cysteine with a thiol group (−SH) was discussed in Section 7.1.2.4. Methionine is also oxidized by the addition of an oxygen atom to the sulfur atom, resulting in two epimeric forms of methionine sulfoxide: Met-(*S*)-sulfoxide (Figure 7.12), and Met-(*R*)-sulfoxide. Specific enzymes (methionine sulfoxide reductases A and B, respectively) reduce such moieties back to methionine and thereby play an important role in the antioxidant mechanism.

Protein Nitration Under oxidative conditions, nitric oxide (NO) can lead to formation of peroxynitrite ($ONOO^-$), which then reacts with tyrosine to form nitrotyrosine (Figure 7.12). Tyrosine nitration is speculated to play a role in degenerative phenomena under nitrosative stress conditions.

7.1.2.6 Noncovalent Structural Regulation

In addition to the covalent protein changes discussed in Section 7.1.2.5, more subtle modifications of the protein or its environment can have a consequence for its structure and function. One such regulatory mechanism is reversible binding of a ligand to the protein. Among the diverse ligands, ions, often metal ions, are very commonly utilized.

The smallest ion ligand is the proton, H^+. As illustrated in Figure 7.6, several amino acid side chains harbor structural groups whose degree of protonation depends on the local pH value. For example, the imidazole side chain of histidine has an apparent pK_R value of ~6, and its electric charge varies according to the pH. The functional consequence of the protonation may be dramatic. Some proteins acquire a certain function under the matching proton concentration whereas other proteins are kept in an inactive state while being stored in acidic intracellular organelles; once released to neutral pH media (e.g., the cell cytosol or the extracellular space), they obtain their full function.

Another biologically important ligand is Ca^{2+}. The importance of Ca^{2+} as a regulator is indicated by the existence of specialized, often small, Ca^{2+}-binding proteins. Such proteins undergo substantial conformational changes upon binding of one or more Ca^{2+} ions and they transmit the binding signals to other specific interacting proteins by physical association. The most prominent example of such a Ca^{2+}-binding protein is calmodulin. This small protein, with <150 amino acid residues, is ubiquitously present in eukaryotic cells and harbors four so-called EF-hand domains that bind Ca^{2+}. Two of the domains are half-saturated with Ca^{2+} at about 100 nM and the other two domains at about 1 μM. By physically interacting with other proteins, Ca^{2+}-binding proteins, such as calmodulin, confer robust Ca^{2+} sensitivity to the resulting protein complexes.

In other proteins, binding of metal ions such as Zn^{2+} plays an important role for the establishment of the correct 3D structure. Moreover, metal ions integrated into the protein structure are often essential for the establishment of the catalytic activity of some enzymes.

7.1.2.7 UV Absorption and Fluorescence of Proteins

Polypeptides strongly absorb light in the UV region of the spectrum. The peptide groups of the protein backbone absorb in the far-UV range (180–230 nm). The major contribution of the side chains comes from the aromatic residues Trp, Tyr, and Phe (in that order). Their molar extinction coefficients are as follows Trp, 5050 $M^{-1}\,cm^{-1}$ (at 280 nm); Tyr, 1440 $M^{-1}\,cm^{-1}$ (at 274 nm); and Phe, 220 $M^{-1}\,cm^{-1}$ (at 257 nm). Therefore, from the absorbance at 280 nm the content of aromatic residues can be estimated in protein samples; the maximum absorbance of nucleic acids is at about 260 nm, hence the ratio of the absorbance at 260 nm to that at 280 nm provides an estimate for the purity of a DNA or RNA sample.

Tryptophan is fluorescent with a peak of emission at about 355–360 nm at pH 7.4 and can therefore be utilized for experiments relying on autofluorescence of proteins. Above ~400 nm, proteins do not generally absorb appreciably unless they harbor chromophores (see Section 7.1.5.1).

Owing largely to the absorbance of the aromatic residues, proteins are sensitive to UV light. Molecular damage of residues or cross-linking reactions induced by photons may cause loss of protein function. In addition, secondary reactive species generated by absorption of UV photons in living cells may oxidatively modify proteins, in particular by reacting with the sulfur-containing Cys and Met residues. Therefore, great care must be taken when assaying proteins in a photonic experiment using short-wavelength excitation.

Pigments Biophotonics experiments can be compromised when the object under study contains autofluorescent materials or pigments that markedly absorb light. The most prominent pigment in humans is melanin, a class of compounds derived from the amino acid tyrosine. Among the several melanin-related compounds present in biological samples, eumelanin is a brown–black polymer of dihydroxyindole, dihydroxyindolecarboxylic acid, and their reduced forms. Another common form of melanin is pheomelanin, a red–brown polymer of benzothiazine units largely responsible for red hair and freckles. In human skin (see Section 7.2.2.3), the production of melanin is stimulated by UVB radiation, leading to the development of a tan. Since melanin absorbs UV light and converts its energy to heat, it is a very effective photoprotectant, diminishing DNA damage. The central nervous system also contains melanin-related pigments in selected areas, such as the substantia nigra, giving the areas a dark-brown appearance. Neuromelanin in the substantia nigra may play an important role in the pathogenesis of Parkinson's disease (see Section 7.4.5), by interacting with the neurotransmitter dopamine in a redox-sensitive manner.

In many macroscopic biological preparations, however, the strongest light absorption is due to the content of red blood cells (see Section 7.2.2.6) via the hemoglobin (see Figure 7.19b). Depending on the saturation level with oxygen, hemoglobin strongly absorbs light up to about 620 nm. Therefore, any blood contamination of samples may pose a serious problem. If it is inevitable to perform experiments in the presence of blood/hemoglobin, if possible wavelengths above 620 nm should be used to limit the interference. The absorbance of water sets the limit towards longer wavelengths, thus defining an "optical window" of about 620–1100 nm.

7.1.3
Carbohydrates: Energy Storage and Structural Elements

Carbohydrates or saccharides are polymeric macromolecules formed from individual carbohydrate units, the monosaccharides. Unlike DNA, these sugar-related molecules cannot replicate themselves and they do not have enzymatic functions as found with some proteins. Nevertheless, saccharides are of vital importance not only as an energy source for the cellular metabolism but also as structural materials. In addition, they can be specifically attached to proteins and lipids – a process called glycosylation – and thereby they tremendously increase the versatility of those molecules. Exposed to the extracellular face, they play a pivotal role in the immune response and cell–cell recognition.

7.1.3.1 Sugars, Monosaccharides, and Polysaccharides

Carbohydrates and saccharides are made of only carbon, oxygen, and hydrogen, fewer atom types than those required for nucleic acids and proteins. Yet the complexity of carbohydrate-containing molecules can be enormous.

Monosaccharides The individual building blocks of carbohydrates are sugars or monosaccharides, consisting of a chain of at least three carbon atoms with the center carbons being hydroxy alcohols (HCOH). The number of carbon atoms in the chain determines the primary names such as triose, tetrose, pentose, hexose, and heptose. The nature of the carbonyl determines a secondary name: a sugar with an aldehyde is an aldose (e.g., glucose), a sugar with a ketone is a ketose (e.g., fructose) (Figure 7.13).

There are always two mirror images of sugars, referred to as the D- and L-forms. The D-configurations are more relevant in nature, hence the prefix D- is often omitted. In addition, in the n carbon atoms in linear aldoses, $n-2$ are chiral. Thus, for glucose, there are $2^4 = 16$ possible stereoisomers – all of them having different names. Stereoisomers that vary only in the configuration of one hydroxy alcohol are called epimers. In Figure 7.13 it is illustrated that glucose and mannose are C_2 epimers of an aldohexose, whereas psicose and fructose are C_3 epimers of ketohexose.

The linear form of sugars is not very stable and therefore the carbonyl easily reacts with one of the hydroxyl moieties to form a ring structure. Six-membered rings (pyranoses) and five-membered rings (furanoses) are the most common. The

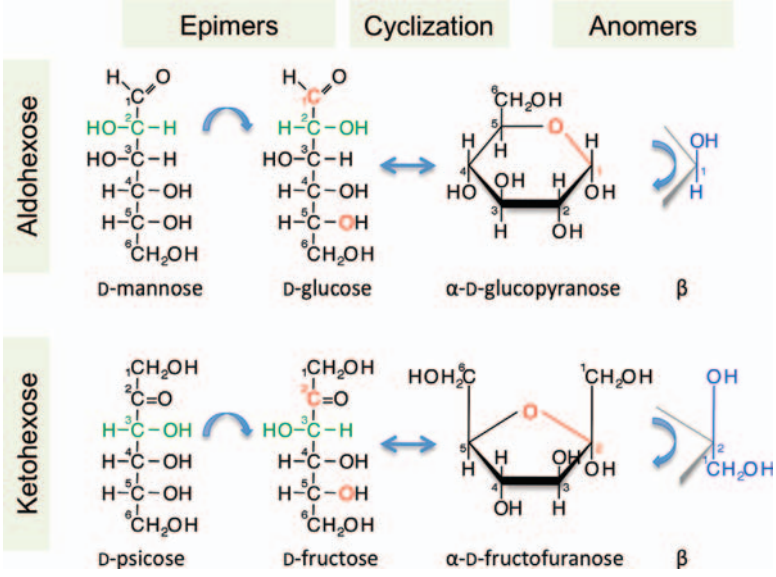

Figure 7.13 Monosaccharides. Typical examples of aldohexoses and ketohexoses. D-Mannose and D-glucose and also D-psicose and D-fructose are stereoisomers with respect to the highlighted carbon atom (green), that is, they are epimers. Cyclization of D-glucose and D-fructose leads to α-D-glucopyranose and α-D-fructofuranose, respectively. Exchanging the direction of the functional groups at the anomeric carbon leads to the β-anomers.

formation of α-D-glucopyranose from D-glucose and α-D-fructofuranose from D-fructose is illustrated in Figure 7.13. The ring closure has the consequence that the carbonyl carbon, here called the anomeric carbon, becomes a chiral center leading to α- and β-variants. The carbon atoms of the rings are not in a plane but adopt so-called chair structures that can interconvert fairly freely. In contrast, anomeric and epimeric forms are fairly stable.

The individual groups of sugar molecules are reactive and therefore many sugar derivatives exist. It is far beyond the scope of this chapter to address such modifications systematically. A couple of common examples are noteworthy. If the aldehyde group is replaced with a carboxy group (COOH), an aldonic acid results. Upon attachment of an OH group, the sugars carry the suffix "itol," such as in the important lipid component inositol. If a proton replaces one of the OH groups at the sugar backbone, the monosaccharides are called deoxy sugars. A prominent example is deoxyribose as it occurs in DNA (Figure 7.3). In amino sugars, one or more of the OH groups are replaced with an amino group (NH_2). An important variant is *N*-acetylneuraminic acid: it is a mannose moiety with an acetylated amine and a pyruvic acid group. *N*-Acetylneuraminic acid and its derivatives, referred to as sialic acids, are important components of glycoproteins and glycolipids (see Figure 7.15).

Polysaccharides Individual monosaccharides can be linked by glycosidic bonds between their hydroxyl groups, giving rise to a very wide range of possible polymeric molecules, also referred to as glycans. Since glycosylic bonds can be formed between any hydroxyl groups, such polysaccharides are not only linear chains of identical or different monosaccharides, they also can be branched to form tree-like structures (see Figure 7.15).

Linkage of two monosaccharides results in disaccharides. An important example is lactose, the component of milk formed by the coupling of galactose and glucose. Another is sucrose, also known as table sugar, in which glucose is linked to fructose as illustrated in Figure 7.14. Tri- and oligosaccharides are less common.

Higher order polysaccharides serve as structural and energy storage molecules. Linkage of several thousand glucose units yields cellulose (Figure 7.14), the primary component of plant cell walls. Cellulose strands form hydrogen-bonded fibers, which are virtually insoluble in water. They give plant cell walls and wood their mechanical strength and require specific enzymes for their degradation. Chitin, which forms the exoskeleton of insects, spiders, and crustaceans, is a polysaccharide made of *N*-acetylglucosamine units. Cellulose and chitin together are very abundant in nature – they are the major carbon storage units in the biosphere.

Glycosaminoglycans are linear polysaccharides of alternating uronic acid and hexosamine units. Together with collagen and other proteins, they form the extracellular matrix in connective tissues such as skin, tendon, and cartilage and provide viscosity and elasticity. An important example is hyaluronic acid, a glycosaminoglycan whose viscoelastic properties make it a perfect natural lubricant and shock absorber. The sulfated glycosaminoglycan heparin occurs in intracellular granules of mast cells in arterial walls. It prevents blood clotting and is therefore an indispensable clinical tool.

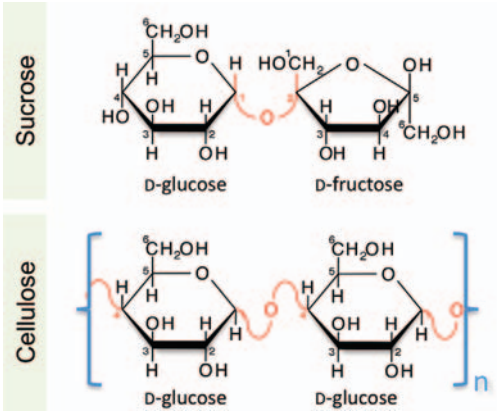

Figure 7.14 Polymerization of monosaccharides. The disaccharide sucrose is formed by linkage of the anomeric carbons of glucose and fructose via a glycosidic bond (red). Cellulose is a long chain of glucose units linked between their C-1 and C-4 carbons.

By means of covalent linkages, glycosaminoglycan can be attached to proteins. The meshwork of covalently and noncovalently aggregated glycosaminoglycans and proteins forming the extracellular matrix is called proteoglycan. Such molecules can reach gigantic sizes of several million daltons. The cell walls of bacteria are composed of a covalently linked mixture of glycosaminoglycans and peptide, the peptidoglycan. This structure is of major medical importance because it largely

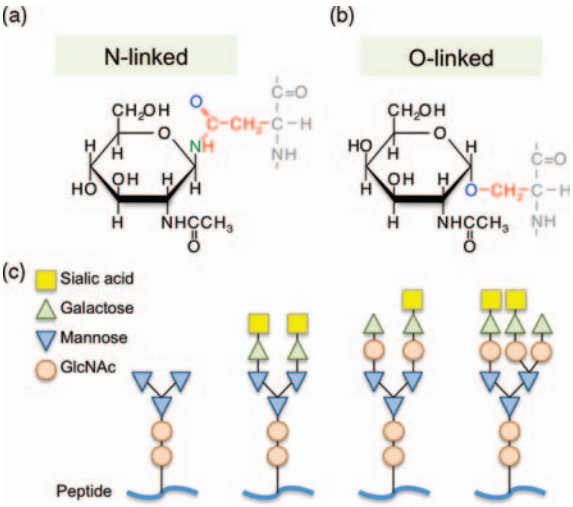

Figure 7.15 Glycosylation of proteins. (a) Formation of an *N*-glycosylic bond between *N*-acetylglucosamine (GlcNAc, black) and asparagine. (b) Formation of an *O*-glycosylic bond between *N*-acetylgalactosamine (GalNAc, black) and serine. The peptide backbones are shown in gray. (c) *N*-Linked oligosaccharides attached to a peptide. The first pentasaccharide consisting of two GlcNAc and three mannose units is an invariable component of *N*-linked protein glycosylation (adapted from Voet *et al.* [3]).

determines the virulence of bacteria and, in some cases, the cell wall alone can evoke symptoms of an infection (see Section 7.4.4).

Living organisms store energy in the form of large polysaccharide molecules. In plants, the principal form is starch, a mixture of α-amylose and amylopectin, both having long chains of glucose units. Starch is the major energy source for humans; it is degraded by digestive enzymes to a variety of disaccharides, trisaccharides, and oligosaccharides (dextrins). Animals use the polysaccharide glycogen as one of the ways to store energy, mainly in skeletal muscle cells and the liver. Glycogen is a heavily branched polymer of glucose residues. Enzymatic cleavage of such branches ensures rapid energy mobilization.

7.1.3.2 Glycosylation of Proteins and Lipids

Glycosylation is the enzymatic process that connects saccharides to produce glycans, either free or attached to proteins and lipids.

Protein Glycosylation This enzymatic process provides a co-translational and post-translational modification mechanism that modulates the structure and function of membrane and secreted proteins. The degree of glycosylation can be high such that some glycoproteins can obtain about twice the mass of the corresponding non-glycosylated proteins. Whereas the protein synthesis strictly follows the genetic blueprint provided by the DNA sequence (see Section 7.1.2.2), the polysaccharide chains are subject to greater environmental fluctuations and the carbohydrates of glycoproteins exhibit a certain degree of variability.

Glycan can be attached to proteins by either *N*- or *O*-glycosidic bonds. *N*-Linked glycosylation starts co-translationally at the rough ER by attaching a tree of 14 sugar residues to the nitrogen of the residue asparagine (Asn), when it occurs second next to serine (Ser) or threonine (Thr), Asn–xxx–Ser or Asn–xxx–Thr, where xxx denotes an arbitrary residue except proline (Pro) or aspartate (Asp). Further processing inside the ER and the Golgi apparatus results in a diversity of sugar chains with a core pentasaccharide of two *N*-acetylglycosamines and three branched mannose groups (Figure 7.15). In addition, fructose can be attached to the first *N*-acetylglycosamine.

O-Linked glycosylation is a post-translational modification, mostly taking place in the Golgi apparatus. Sugar chains starting with *N*-acetylgalactosamine (GalNAc) are attached to the OH group of the residues serine (Figure 7.15) or threonine, independently of their neighboring amino acid sequence.

The key enzymes required for the processing of polysaccharides are glycosidases that cleave off monosaccharides and glycosyl transferases that attach individual sugar groups.

Lipid Glycosylation Lipids are glycosylated by the attachment of glycans to ceramide, as discussed in Section 7.1.4.1.

Because of the immense complexity of polysaccharides attached to proteins and lipids, their specific functions are not known in detail, but they are certainly diverse. The carbohydrate shell of a glycoprotein can protect the polypeptide from proteolytic attacks, can assist in correct protein folding, and may serve as a quality check in

protein processing, that is, proteins without the appropriate glycosylation may be recognized as immature. In addition, sugar residues at proteins function as an address label such that proteins are transported to the correct location inside a cell (protein targeting). Polysaccharides exposed on the cell surface are important for cell–cell recognition; such inter-cell contacts are mediated by proteins (lectins and selectins) that bind to specific polysaccharides. Moreover, the composition of carbohydrates exposed on cell surfaces is a valuable immunological marker, forming the basis for the ABO blood group system.

7.1.4 Lipids and Membranes

Lipids are the fourth large group of biomolecules. Unlike nucleic acids, proteins, and carbohydrates, they do not polymerize. Nevertheless, owing to their hydrophobicity they aggregate to form the structural matrix of biological membranes. In this function, they not only separate the cell interior from the extracellular space, they also form intracellular organelles and are scaffolds for important biochemical reactions. In addition, lipids function as energy storage molecules and they also serve as signaling molecules, playing roles both in normal physiology and in disease states (Section 7.3.2).

7.1.4.1 Lipids: Fatty Acids and Head Groups

The structures of lipids are much more diverse than those of amino acids and nucleic acids because, strictly speaking, most biological molecules soluble in organic solvents can be considered as lipids. Here we only address a few classes that are particularly important for the formation of lipid membranes – fatty acids, triacylglycerols, glycerophospholipids, sphingolipids, and cholesterol. Membrane lipids often consist of one or more nonpolar fatty acid chains and one hydrophilic headgroup.

Fatty Acids The hydrophobic moiety of lipids is formed by fatty acids, which are carboxylic acids with hydrocarbon side chains (a series of CH_2 groups), typically with 14–20 carbons. More than half of the naturally occurring fatty acids are unsaturated; their hydrocarbon tail chain contains one or more double bonds so that the tail carbon atoms could accept additional hydrogen atoms. In addition to several commonly used names, a systematic nomenclature system exists to cope with the vast structural diversity of lipids. For example, stearic acid [octadecanoic acid, $CH_3(CH_2)_{16}COOH$)] is a fatty acid with 18 carbons and no double bond, and hence is denoted 18:0. Oleic acid [9-octadecenoci acid, $CH_3(CH_2)_7CH{=}CH(CH_2)_7COOH$] also has 18 carbons, but there is a double bond between carbons 9 and 10, hence the short form is 18:1*n*-9. In polyunsaturated fatty acids, the double bonds typically occur at every third carbon atom. Double bonds in hydrocarbon chains produce a kink in the structure (Figure 7.16a) and therefore they decrease the melting point of fatty acids. As a consequence, the fluidity of lipid membranes increases with the degree of unsaturation of the fatty acids or the number of double bonds present in the membrane lipids.

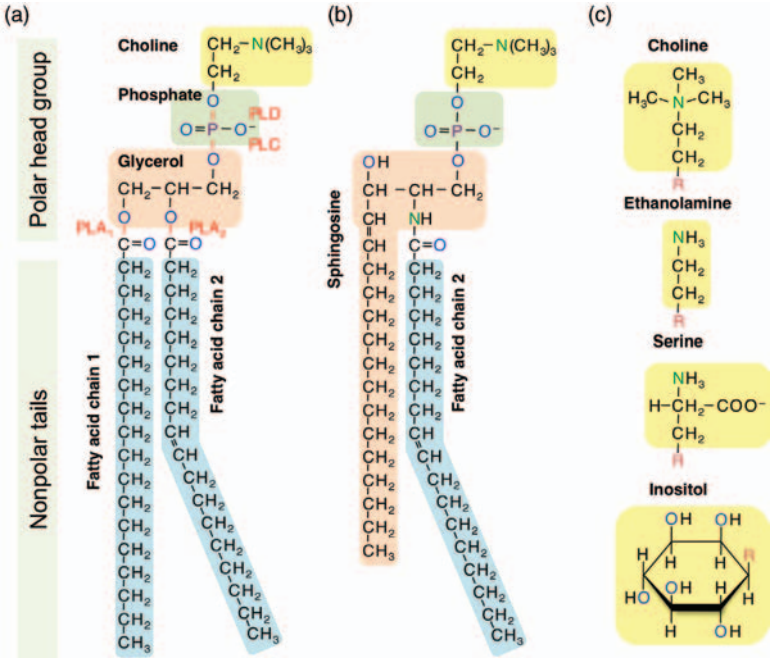

Figure 7.16 Structural elements of a lipid molecule, exemplified for phosphatidylcholine (a) and sphingomyelin (b). Cleavage sites for some phospholipases are indicated in red. (c) Chemical structures of some typical lipid headgroups. R refers to the phospholipid scaffold.

Triacylglycerols (Triglycerides) A common way to store energy is based on triacylglycerols, glycerol molecules in which fatty acid chains are attached to each of their three OH groups. In humans, about one-quarter of the body mass is fat (21% for men, 26% for women), forming an energy reserve that lasts much longer than the stored content of carbohydrates.

Glycerophospholipids The major types of membrane lipids are glycerophospholipids. These lipids are based on glycerol units with fatty acid side chains attached to the first two carbons. The third carbon holds a phosphoryl group, which is then typically linked to a hydrophilic headgroup. In phosphatidic acid this headgroup is just a proton. The structure of phosphatidylcholine is illustrated in Figure 7.16a. It has a saturated fatty acid chain at the C-1 position and an unsaturated chain at the C-2 position. The phosphoryl group together with the choline residue are hydrophilic such that the entire molecule has an amphiphilic character with a nonpolar tail and a polar headgroup. The amphiphilicity of lipids is a major requirement for their self-aggregation into larger structures such as membranes.

Common phospholipids such as occur in biological membranes are phosphatidylethanolamine, phosphatidylserine, and phosphatidylcholine (Figure 7.16).

Sphingolipids Another group of lipids important for biological membranes is based on the amino alcohol sphingosine, comprising 18 carbon atoms. Addition of a fatty acid chain to the amide group at the C-2 position in sphingosine creates a biologically important sphingolipid, ceramide, which plays a role as a messenger within in a cell (Section 7.1.4.3). A related molecule, sphingomyelin (Figure 7.16b), a sphingolipid that contains a phosphocholine as the headgroup, is a vital component of the myelin sheath surrounding and insulating nerve cell axons. In cerebrosides, the headgroup of a ceramide is a sugar residue. Gangliosides are complex lipids consisting of a ceramide with an attached oligosaccharide including at least one sialic acid. Such glycosylated lipids play an important role in cell–cell recognition.

Cholesterol Cholesterol is a slightly amphiphilic structure of three six-membered rings and one five-membered ring. Although infamous for its association with cardiovascular disease, cholesterol is essential for life. In plasma membranes, cholesterol makes up about 30–40 mol% of all lipid molecules and influences membrane fluidity. Cholesterol is also a precursor to very important steroid hormones such as cortisol, aldosterone, estrogens, testosterone, and vitamin D.

7.1.4.2 Formation of Membranes and Vesicles

Lipids do not polymerize but they can form large structures by spontaneous aggregation. The structural prerequisite for this feature is their amphiphilic nature; they are composed of a hydrophobic tail and a hydrophilic headgroup. In an aqueous phase lipid molecules are barely soluble. At fairly low concentrations they tend to form micelles (Figure 7.17b), spherical structures in which the headgroups face the water and fatty acid tails fill the interior.

Although the dimensions of the lipids limit the sizes of micelles, self-aggregation to bimolecular layers gives rise to very large molecular assemblies. The hydrophobic tails form a core region and the headgroups face the water. Depending on the ratio of headgroup surface area and the space-filling volume of the hydrocarbon chains, lipid bilayers may form concave, convex, or planar structures. Small lipid vesicles (Figure 7.17c) are used for storage of transmitter molecules, for example. Lipid membranes (Figure 7.17d) with various degrees of curvature are the basis of membranes delimiting cells (plasma membranes) and organelles.

The formation of membranes does not involve covalent bonds; they are entirely held together by various non-covalent forces, largely so as to minimize the interaction of hydrocarbon tails and to maximize the interaction of the headgroups with water. By virtue of these hydrophobic forces driving the process of self-aggregation, membranes are self-sealing; small holes are spontaneously closed, parts of the membranes can be separated off to form independent vesicles (budding), and vesicular membranes can be incorporated in a larger membrane (exocytosis, endocytosis). Thus, lipid membranes are highly dynamic.

The thickness of a lipid bilayer membrane differs somewhat depending on the lipid composition and the incorporation of membrane proteins. A thin membrane has a thickness of about 4 nm and thick membranes can be about 7 nm.

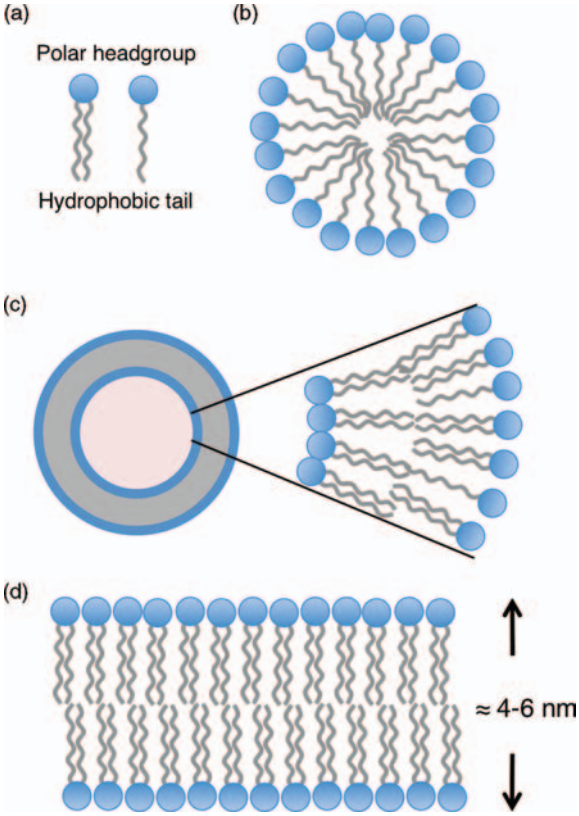

Figure 7.17 Self-aggregation of lipids. (a) Schematic presentation of lipid molecules with one or two fatty acid chains comprising a polar headgroup and a hydrophobic tail. (b) In micelles the hydrophobic tails cluster together to form a sphere with the headgroups pointing towards the aqueous phase. (c) Vesicles are spheres formed of lipid double layers; the composition of the inner and outer layers can be substantially different. (d) A planar lipid bilayer membrane.

As the layer separating the cell interior from the extracellular space, the plasma membrane is the most apparent membrane structure in cells, but it typically makes up less than 10% of the total cellular membrane. The remaining membrane is used to form organelles and small vesicular structures.

Lipid membranes are very effective barriers for polar molecules because of the hydrophobic core region. Therefore, pure lipid membranes are nearly perfect electrical insulators, providing the basis for the establishment of electrical membrane potentials. Hydrophobic substances, such as urea and glycerol, permeate readily through membranes. Water molecules also permeate across membranes. Larger molecules or charged molecules require specific transport proteins that aid them in crossing the membrane (see Section 7.3.2).

7.1.4.3 Lipids as Signaling Molecules

Lipids and lipid-derived molecules not only serve a role as the matrix for biological membranes or as an energy reserve, they also function as signaling molecules. Some phospholipids are phosphorylated and dephosphorylated and hence change their electric charge and functional properties mediated by the action of lipid kinases and phosphatases. The most prominent example is the membrane component phosphatidylinositol-4,5-bisphosphate (PIP_2). Dephosphorylation results in PIP and PI3-kinases phosphorylate PIP_2 to PIP_3.

Membrane phospholipids such as PIP_2 are hydrolyzed into smaller but important lipid-derived signaling molecules by the action of phospholipases, which cleave specific bonds in phospholipids. Phospholipase A_1 hydrolytically excises the fatty acid chain at the C-1 position whereas phospholipase A_2 does so at the C-2 position (Figure 7.16). The latter leaves a lipid with only one fatty acid chain – a so-called lysophospholipid. As the name suggests, this form of lipid destabilizes membranes. Arachidonic acid, a precursor for many local messengers, is also released with the aid of phospholipase A_2 from membrane-bound phosphatidylinositol and other phospholipids. Phospholipase D cleaves off the headgroup after the phosphorus atom, while phospholipase C (PLC) cleaves it off before the phosphorus atom. PLC thus produces the important messengers diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP_3) from PIP_2 (see also Section 7.3.2).

7.1.4.4 Interaction of Lipids with Light

Many pigments in biological materials that absorb light strongly or that display fluorescence are lipids. Aromatic structures with delocalized electrons typically are soluble in organic solvent and therefore tend to partition in the hydrophobic center of proteins or inside membranes. Vitamin D and vitamin A (retinol), the latter derived from the red pigment β-carotene, are good examples. Retinal, the oxidized form of retinol, is the pigment in the photoreceptors in the eye.

Like other biological material, lipids can be oxidatively modified and, hence, excessive irradiation with light of low wavelength will directly or indirectly cause lipid peroxidation. Since this process likely results in deleterious effects on biological membranes, Nature has devised some protective measures. One is α-tocopherol, a variant of vitamin E, which is incorporated into membranes and acts as a strong antioxidant, protecting lipids and membrane proteins from oxidative damage.

7.1.5 Special-Purpose Proteins: Cofactors and Prosthetic Groups

Protein complexes made of one or more polypeptide chains containing up to 20 amino acid types (Figure 7.6) with possible co-translational and post-translational modifications (Figure 7.12) can perform a diverse array of functions. However, in some cases, additional inorganic and organic molecules, collectively referred to as cofactors or prosthetic groups, are incorporated into proteins to confer novel functionalities, typically catalytic in nature. Some cofactors are simple metal ions, such as copper, iron, manganese, nickel, and zinc, and others are larger organic

compounds, such as flavin adenine dinucleotide (FAD), nicotinamide adenine dinucleotide (NAD^+), nicotinamide adenine dinucleotide phosphate ($NADP^+$), and heme. The degree of association between the cofactors and the parent proteins can be variable. Some cofactors are bound so tightly that the proteins are almost always found with the cofactors included, referred to as holoproteins, whereas in others the association is not as stable and fractions of the proteins may be found without the cofactors (apoproteins). The proteins with cofactors/prosthetic groups are of special interest in biophotonics because many of them exhibit light-sensitive characteristics. Selected examples are briefly discussed below.

7.1.5.1 Opsins Exemplified by Rhodopsin

Opsins are the best-known family of light-harvesting proteins and serve multiple physiological functions. For example, the sensitivity and acuity of our visual experience is enabled by opsin proteins in rod and cone photoreceptor cells in the retina.

Cylindrical rod photoreceptor cells are present throughout the retina with a couple of notable exceptions including the very center, and the rods are particularly important in dim-light monochromatic vision or scotopic/mesopic vision. The sensitivity to light is so high that a single photon can be readily detected by a rod photoreceptor cell. The first event in the high-sensitivity light transduction process is absorption of a photon by the visual pigment rhodopsin, a G protein-coupled receptor protein with seven transmembrane helical segments that contains retinal, a vitamin A aldehyde, as the chromophore cofactor (Figure 7.18). In the dark, the retinal in the kinked 11-*cis* form is covalently linked to the nitrogen atom of a lysine side chain in a transmembrane helical segment via a protonated Schiff base linkage. An incident photon with a wavelength centering 500 nm (blue–green) isomerizes the retinal around the C-11=C-12 double bond with a quantum yield of ~0.67 within 0.2 ps, forming linear all-*trans*-retinal. The opsin protein undergoes multiple conformational changes and eventually assumes a conformation known as Meta II. Metarhodopsin II activates the adjacent G protein (*transducin*), which initiates a series of biochemical reactions involving cGMP (cyclic guanosine monophosphate) to amplify the original signal, ultimately resulting in a visual experience sometime later ($\geq$100 ms). Following activation of the intracellular signaling cascade, the all-*trans*-retinal dissociates from the protein (bleaching). Eventually, through a multi-step reaction taking place in the retinal pigment epithelium, all-*trans*-retinal is recycled to an 11-*cis*-retinal precursor, which is then incorporated back into rhodopsin in rod photoreceptor cells. At different stages in the light transduction process, the chromophore has distinct spectral characteristics and this feature has allowed time-resolved biophotonics approaches, such as time-resolved variants of fluorescence microscopy, infrared microscopy, and Raman spectroscopy, to provide detailed mechanistic information.

Cone photoreceptor cells, with a more tapered appearance, are located almost exclusively near the center of the retina and mediate our high-acuity color vision under well-lit conditions or photopic vision. The biochemical reactions taking place in cone photoreceptor cells are similar to those occurring in rod photoreceptors; photons induce isomerization of the chromophore 11-*cis* retinal contained in cone opsin proteins, leading to activation of nearby G proteins. A distinct opsin with a

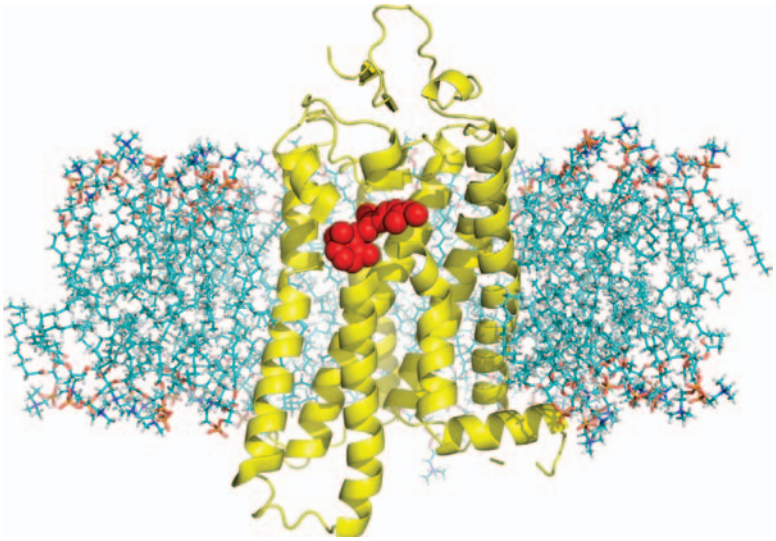

Figure 7.18 Structure of bovine rhodopsin (PDB ID: 1GZM) in its bilayer environment highlighting the retinal (red).

characteristic light absorption spectrum is present in each of three classes of cone photoreceptor cells in the human retina. Accordingly, the three human cone photoreceptor cells are often referred to as blue or S cones with a maximum absorption at ~420 nm, green or M cones with a maximum absorption at ~530 nm, and red or L cones with a maximum absorption at ~560 nm. The differential but overlapping spectral characteristics of the cone opsins are conferred by amino acid differences near the chromophore in the transmembrane segments and also those near the C terminus in the cytoplasmic compartment. The overall light sensitivity of cone photoreceptor cells is not as exquisite as that of rod photoreceptor cells, in part because the biochemical amplification gain in the cone cells is smaller. However, differential excitation of the three classes of cone photoreceptor cells by a light stimulus forms the basis of our color vision.

Opsins are also found in many prokaryotic organisms such as bacteria and algae, in which retinal-containing opsin proteins typically perform light-activated transport of ions across cell membranes. Recently, channelrhodopsins from green algae have been expressed in the brains of rodents and nonhuman primates so that their brain electrical activity and behavior can be experimentally manipulated by flashes of light.

7.1.5.2 **Porphyrin Proteins**

Heme (iron protoporphryin IX, Figure 7.19a) is a planar tetrapyrrole macrocycle synthesized through a series of reactions taking place in both the cytoplasm and mitochondria, and incorporated into numerous proteins as their prosthetic factor. Detailed mechanisms of heme binding to proteins vary but an interaction between the heme iron center and the imidazole side chain of histidine (His) is common. Functionally, the presence of the redox-sensitive iron center (Fe^{2+}/Fe^{3+}) in the heme

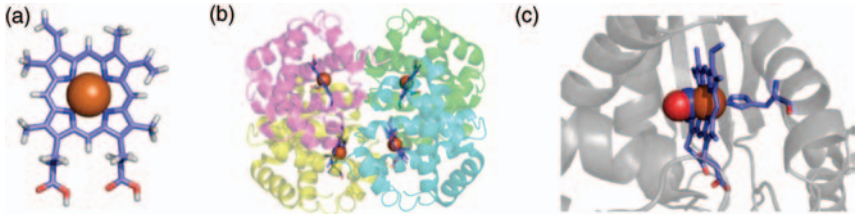

Figure 7.19 Heme, hemoglobin, and soluble guanylyl cyclase. (a) Heme. (b) Four-chain hemoglobin complex with four heme cofactors (PDB ID: 3HHB). (c) Soluble guanylyl cyclase (PDB ID: 2O0C), illustrating coordination of heme with a histidine side chain (right) and an interaction of NO with the iron center.

moiety is utilized for gas transport, gas detection, and catalysis through electron transfers. For example, the O_2 and carbon monoxide (CO) sensitivity of hemoglobin responsible for oxygen delivery is well known (Figure 7.19b) and the enzyme-soluble guanylyl cyclase (Figure 7.19c) involved in numerous processes including blood vessel dilation is an NO- and CO-sensitive heme protein.

7.1.5.3 Living Colors: Fluorescent and Phosphorescent Proteins

GFP from the bioluminescent jellyfish *Aequorea victoria* is intrinsically fluorescent without any special prosthetic group. In GFP, consisting of 238 amino acid residues, a ring is formed spontaneously among the succeeding residues Ser–Tyr–Gly. The resulting conjugated double bonds are fluorescent with an ideal excitation at 400 nm and an emission at 508 nm (green). A three-dimensional structure of an engineered form of GFP, enhanced green fluorescent protein (EGFP), is shown in Figure 7.20a, highlighting the optically active site. Numerous variants of EGFP with altered spectral properties exist; mutations in the GFP protein shift the emission to lower [cyan fluorescent protein (CFP)] or higher wavelength [yellow fluorescent protein (YFP)], for example (e.g., [9]).

Because EGFP and its variants are intrinsically fluorescent without any cofactor, these relatively small proteins have emerged as very powerful tools in cell biology. Fused to other proteins, GFP moieties are used to visualize the expression and location of engineered proteins, as illustrated in Figure 7.20b. Equipped with specific signal sequences, expressed GFP can mark organelles such as mitochondria or the nucleus. Meanwhile, an array of available GFP variants gives the experimenter the opportunity to label proteins specifically with different colors such that many more than one type of protein can be monitored at a time in single cells or whole organisms.

Since the photonic properties of GFP molecules depend on the immediate environment of the chromophore, several methods were devised to use GFP as reporter for intracellular events. For example, GFP moieties fused to a Ca^{2+}-sensing protein and genetically expressed in every cell or select cells in a living organism including mice can be utilized for *in vivo* measurements of the intracellular concentration of Ca^{2+}. GFP variants with extra cysteine residues, so-called roGFPs, change their fluorescence properties when two of such cysteines form a disulfide bridge and thereby report on the intracellular redox milieu.

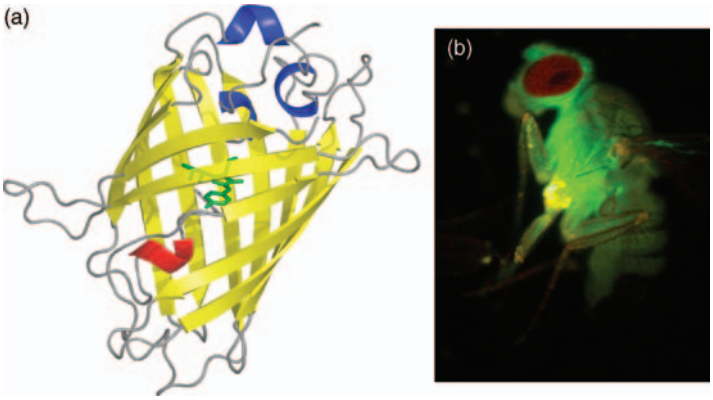

Figure 7.20 (a) Structure of GFP (PDB ID: 1EMA). On the outside, 11 antiparallel β-strands (yellow) form a very compact cylinder. Inside this β-structure there is an α-helix (red), in the middle of which is the chromophore (green). There are also short helical segments (blue) on the end of the can. The cylinder has a diameter of about 2.5 nm and a length of about 3 nm. (b) Fluorescence image of a transgenic fruit fly expressing an EGFP-tagged protein in nervous tissue.

Genetically Modified Animals: Knock-out and Transgenic Animals

Various methods exist to manipulate the genome of laboratory animals. The easiest is the destruction of a gene such that no corresponding functional protein can be generated. Such animals are then referred to as knock-out animals; a mouse having gene *ABC* deleted on both chromosomes (homozygous) would be termed $ABC^{-/-}$. To generate a knock-out mouse, embryonic stem (ES) cells are manipulated in cell culture, such that the normal gene is inactivated and a selectable marker, such as an antibiotic resistance gene, is inserted instead. Such modified ES cells are reintroduced into early-stage mouse embryos and implanted into the uterus of a female mouse. After several rounds of cross-breeding this will finally generate mice with a deficiency in just one specific gene. Using more involved strategies, gene knock-out can be designed such that it is controlled by exogenous factors (*inducible knock-out*). Gene knock-out can be combined with tissue specificity so as to affect gene expression in specific organs only. *Transgenic animals* are those that carry a new gene or a mutated gene. The time and financial resources required to produce such genetically modified animals vary greatly with the species. Whereas transgenic plants and fruit flies can be generated within a few weeks, gene knock-out in mammals often takes many months.

Variants of EGFP are also useful for fluorescence resonance energy transfer (FRET) experiments reporting on the distance between two chromophores and thereby providing insight into the dynamics of cellular proteins. The physical

proximity, typically less than 10 nm, can be inferred if excitation of one chromophore (donor) influences the status of the other chromophore (acceptor). In a related measurement method called bimolecular fluorescence complementation (BiFC), two fragments of a GFP are expressed in two proteins and, if the two proteins physically interact, functional GFPs are formed and the fluorescence is observed. The contribution of GFP-based technology was recognized with the Nobel Prize in Chemistry in 2008 awarded to Osamu Shimomura, Martin Chalfie and Roger Y. Tsien.

7.1.6
Low Molecular Weight Molecules

In addition to lipids and the polymeric macromolecules discussed thus far, the cytosol of cells contains very many different types of molecules of lower molecular weight. It would be far beyond the scope of this brief introduction to discuss those in detail and, therefore, we will consider just a few molecules important for biophotonics research.

7.1.6.1 Adenosine Phosphates

The most important molecule for short-term energy storage and exchange is adenosine-5′-triphosphate (ATP). It is a nucleotide with a molecular mass of about $507\,\mathrm{g\,mol^{-1}}$ and provides energy to cellular reactions by hydrolysis to adenosine diphosphate (ADP), yielding $-30.5\,\mathrm{kJ\,mol^{-1}}$, or adenosine monophosphate (AMP), yielding $-45.6\,\mathrm{kJ\,mol^{-1}}$. Since ATP is unstable, it is immediately used and must be recycled constantly. Therefore, humans at rest produce about 70 kg of ATP per day. The intracellular concentration of ATP is between 1 and 10 $\mathrm{mmol\,l^{-1}}$. The ATP:ADP concentration ratio provides an estimate of the energy status of a cell.

ATP is not only used as "energy currency" inside the cell, it also serves roles as extracellular and intracellular signaling molecule (see Section 7.3) and takes part in DNA replication and transcription.

7.1.6.2 Nicotinamide Adenine Dinucleotide

NAD^+ and the protonated form NADH are coenzymes functioning as a redox pair, that is, NAD^+ is the oxidizing agent accepting electrons from other molecules while the reducing agent NADH is an electron donor. NAD^+, with a molecular mass of about $663\,\mathrm{g\,mol^{-1}}$, exists in all cells and is of vital importance for various redox reactions. Therefore, the NAD^+:NADH concentration ratio is a measure of the redox state of a cell, thereby providing information on the metabolic state and the cell's health. Typical ratios are around 700. The concentration of NAD^+ and NADH in the cytosol depends on the cell type but it is on the order of 1 $\mathrm{mmol\,l^{-1}}$.

These molecules are important for photonic research because both absorb UV light strongly. NAD^+ has an absorption peak at 259 nm with an extinction coefficient of $16\,900\,\mathrm{M^{-1}\,cm^{-1}}$; NADH has an additional absorption peak at 339 nm with an extinction coefficient of $6220\,\mathrm{M^{-1}\,cm^{-1}}$. Therefore, from the absorbance at 340 nm one can easily infer the NAD^+:NADH concentration ratio and, hence, the redox

state. In addition, NADH undergoes fluorescence with an emission peak at about 460 nm, whereas NAD^+ does not fluoresce. This provides another means of monitoring the redox state via fluorescence microscopy. Around 260 nm excitation the fluorescence of NADH dominates the autofluorescence of virtually all cells.

7.1.6.3 Glutathione

The tripeptide Glu–Cys–Gly [glutathione (GSH), reduced form] forms a dimeric disulfide-linked structure, glutathione disulfide (GSSG, oxidized form) and thereby reduces other targets. GSH therefore is an antioxidant that helps to protect cells from reactive oxygen species. GSSG needs to be regenerated to GSH by means of glutathione reductase. The equilibrium between GSH and GSSG is another indicator of the cellular redox state. In a healthy cell, typically 90% of glutathione exists as GSH and only 10% as GSSG. Elevated oxidative stress manifests as an increased GSSG:GSH ratio. The cellular concentration of GSH is typically a few millimoles per liter.

Owing to the potential hazard imposed by light-generated reactive species in cells, in particular long-term photonic experiments on living material require the maintenance of a healthy cell state. Control of cytosolic ATP, NADH, and GSH can be used as a quality check and supplementation of the cytosol with these factors can help to diminish oxidative damage during a photonic experiment.

7.2 Cells

The principal unit of life is the cell. This simple statement is just as fundamental for biological science as the atomic theory is for chemistry. In the 1830s, Matthias Schleiden and Theodor Schwann proposed the cell theory, stating that all organisms are composed of one or more cells. In 1855, this was extended by Rudolf Virchow, who found that cells never arise from non-cellular material but only by division from pre-existing cells. A closer look at this basic unit is not only important for microbiologists who study unicellular bacteria, but also for others studying multicellular organisms with intricate interactions among the cells.

7.2.1 Compartments of a Human Cell

About 10^{14} individual cells form the body of an adult human, and despite an enormous degree of cellular differentiation, all of these cells have the same principal building plan. Human cells share this concept with the cells of our closer relatives, for example, all mammals including important biomedical model organisms like mice and rats. Later we will compare cellular principles in mammalian cells and those of other life forms, such as plants or the unicellular protozoa and bacteria.

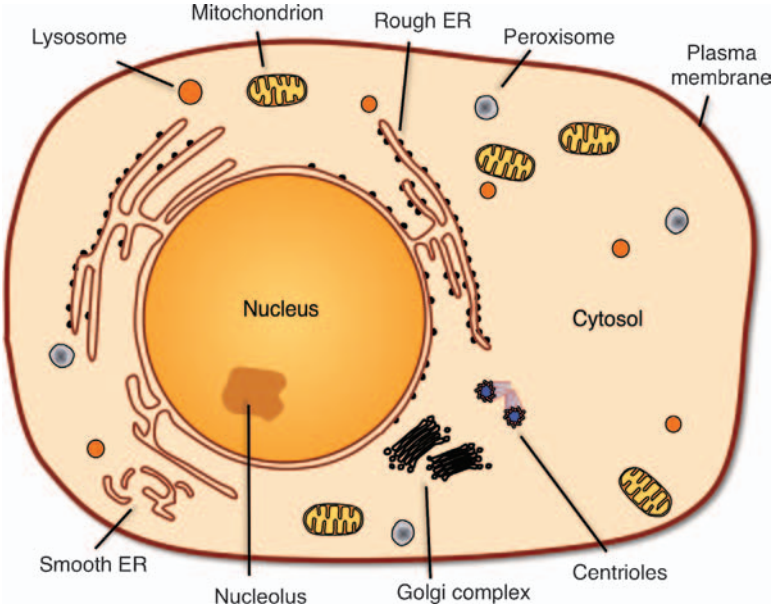

Figure 7.21 Structural organization of a prototypical human cell. The dimensions are not to scale to enhance clarity. For example, the thickness of cellular membranes is exaggerated.

Shape and size of human cells can vary substantially. Red blood cells have diameters below 10 μm, whereas a secondary oocyte, waiting to be fertilized, is about 100 μm across and visible to the naked eye. The longest cells in our body are the sensory neurons connecting the toes with the spinal cord over a distance up to 1.5 m. Despite these huge differences, the structural organization within most of the cells follows the same blueprint. Figure 7.21 is a schematic diagram of a prototypic human cell with a size of approximately 20 μm across.

The cell is separated from its external environment by the plasma membrane. This allows a complex organization of the cell interior and the accumulation of energy-rich metabolites. Inside the cell, additional membranes enclose compartments called organelles, the biggest of which is the nucleus. Typically this is a near spherical structure with a diameter of about 5–10 μm and it harbors most of the genetic information in form of the chromosomes. Within the nucleus a region of higher density, called nucleolus, is often visible by light microscopy. In contrast to other organelles, the nucleolus is poorly demarcated and not surrounded by a membrane. The volume between the nuclear membrane and the plasma membrane, the cytoplasm, comprises an aqueous phase – the cytosol –, and additional organelles.

Directly contiguous with the nucleus is the membrane of the ER, a widespread tubular system involved in synthesis, transport, and secretion of various important biomolecules. Closer examination using electron microscopy often reveals a dense decoration of the cytosolic ER surface with uniformly sized particles, the *ribosomes*. These areas are called rough ER, in contrast to the smooth ER, lacking ribosomes. The presence of ribosomes is a marker for ongoing synthesis of proteins designated

for export or for other compartments being restocked via the ER. By contrast, smooth ER is involved in the biosynthesis and modification of other biomolecules, such as lipids and carbohydrates. Most of the macromolecules from the ER are further modified and sorted in the *Golgi complex*, stacks of membrane-surrounded, flattened compartments that were first described in 1898 by Camillo Golgi. *Mitochondria*, the organelles that generate most of the cell's energy currency ATP, are surrounded by a double-membrane system. More than 1000 mitochondria are typically found in each cell. Their shapes range from filamentous tubules to almost spherical bodies resembling bacteria. In fact, according to the now undisputed "endosymbiotic theory," mitochondria were originally derived from bacteria that have been engulfed by larger cells and since then remained there to the benefit of both parties. This explains the double-membrane system and the presence of a genetic code specific for mitochondria (Sections 7.1.1 and 7.1.2.2). *Endosomes*, *lysosomes*, and *peroxisomes* are additional membrane-delimited vesicular structures of a human cell. Furthermore, several large intracellular structures exist without a membranous envelope. As the definition of the term "organelle" has never been precise, some of these structures, including the centromeres are traditionally also called organelles.

7.2.1.1 **The Plasma Membrane and Its Transport Proteins**

The plasma membrane is the interface between every cell and its environment and, just like the walls surrounding ancient cities, the membrane protects the cell from the loss of valuables and allows tight control of cargo transport into and out of the cell. The design principle of the membrane as a barrier is simple but very efficient. It builds on the fact that the hydrophobic parts of lipids and hydrophilic environments are incompatible. The cell interior, and also the extracellular space, are dominated by the omnipresence of water and the cellular content is adapted to this aqueous environment. Thus, a contiguous envelope, consisting of lipid molecules, is a perfect way to separate the hydrophilic biomolecules on the two sides.

The amphiphilic nature of phospholipids drives these molecules to form bilayers in aqueous environments with no energetic costs to the cell (see Section 7.1.4.1). Hence a lipid layer, only ~4–5 nm thick, is wrapped around every cell of our body, prohibiting efflux and influx of ions and of hydrophilic biomolecules such as sugars, proteins, and nucleotides. Biomembranes are called bilayers, because they are formed by two closely packed layers of molecules, the inner and outer leaflets. Functionally, we could also name them trilayers, as a lipid core layer is shielded from water by the headgroup layers on either side. With extensive electron microscopy studies since the late 1950s, it became clear that not only the plasma membrane but also all intracellular membranes of the organelles have the same ultrastructure.

Membrane Fluidity In contrast to the metaphor of a city wall, the plasma membrane is anything but rigid. The founders of the modern membrane concept, Jonathan Singer and Garth Nicolson, in 1972 used the term "fluid mosaic" to account for the exquisite freedom of motion for all phospholipids at body temperature. Rotational diffusion lets phospholipid molecules turn around their own lateral axis 10^8 times per second. In addition, lateral diffusion makes neighboring phospholipids change their

places in less than 1 μs. In addition, the membrane as a whole can undergo wavelike, undulating motions on a microsecond time scale, preventing any loss of membrane integrity, even under pressure. It is obvious that the actual shape of a cell cannot be constrained by a fluid membrane layer. The typical discoid shape of a red blood cell (erythrocyte) and the branching structures of neuronal dendrites require a more rigid support. Proteins of the cytoskeleton provide the structuring components that determine a cell's actual shape. Typically, a dense protein network located underneath the plasma membrane is further connected to structural proteins extending throughout the cytosol.

Membrane Proteins Having a tight, lipid-based envelope is advantageous for the cell, but gates are needed for nutrient import and for export of a variety of molecules. In fact, every cellular membrane incorporates proteins that fulfill the task of controlled transport or the propagation of signals across the membrane. As a rule of thumb, about 50% of the plasma membrane mass is formed by membrane proteins. The set of 20 natural amino acids allows the construction of proteins to accommodate both the aqueous environment and the lipid part of the membrane. Amino acids such as alanine, leucine, and isoleucine are characterized by nonpolar side chains. Polypeptide stretches made from such hydrophobic amino acids therefore tend to position away from water and to insert into membranes. On the other hand, polar amino acid residues in a membrane protein can form cavities or pores to fit hydrophilic cargo such as proteins, sugars, and ions. Despite the huge diversity in potential protein folding patterns, the architecture of proteins in the plasma membrane follows a stereotypic concept. One or multiple α-helical stretches of approximately 20 amino acid residues are the basic building block of any mammalian transmembrane protein. These helices can be formed solely from hydrophobic residues or, if several helices are contacting each other, amphipathic helices can be organized in a way that places only the lipophilic faces towards the surrounding lipid, while hydrophilic sides are facing each other. As we will discuss later, proteins of mitochondrial membranes are an exception to this construction principle. Whereas the transmembrane parts of plasma membrane proteins are fairly uniform, extracellular and intracellular loops linking the transmembrane helices can adopt very diverse folding patterns and domain structures.

Membrane Anchors Peripheral membrane proteins do not span the membrane but they are tightly associated with it, mostly by means of membrane anchors. These are lipid moieties covalently linked to residues of the respective proteins. Three major classes of such lipid modifications can be distinguished: acylation, prenylation, and linkage of so-called glycosylphosphatidylinositol (GPI) anchors. The fatty acids myristate (C_{14}) and palmitate (C_{16}) are common acyl anchors, typically attached to an N-terminal glycine residue. Farnesyl (C_{15}) or geranylgeranyl (C_{20}) moieties are anchored to one or more cysteine residues near the C terminus. Both anchor types attach proteins to the cytoplasmic surface of the plasma membrane. The typical anchor for the external surface is GPI, being attached to the cleaved C-terminal end of a protein. The protein to be modified contains a stretch of hydrophobic amino acids at

its C-terminal end, anchoring the protein initially in the membrane of the ER during biogenesis. This membrane anchor is then cleaved off and replaced by the membrane-bound GPI. In this structure, the inositol ring of a phosphatidylinositol (PI) molecule is followed by glucosamine, three mannoses, and phosphoethanolamine, which is coupled via its amino group to the new carboxyl end of the protein.

Membrane Asymmetry Membrane proteins are not only involved in transport processes across the membrane, they also help lipid molecules to move *within* the membrane. As described above, membranes in a human cell are energetically stable bilayers, assembled from various phospholipids, sphingolipids, and cholesterol (Figure 7.22). However, all living cells invest energy to establish a strong asymmetry of lipid distribution between the outer and inner leaflets. The outer leaflet of a typical plasma membrane is mainly formed of phosphatidylcholine (PC) and sphingomyelin (SM), the two membrane lipids with choline as the headgroup (Figure 7.16). By contrast, the aminophospholipids phosphatidylethanolamine (PE) and phosphatidylserine (PS) and also PI form the inner leaflet. Cholesterol, with its very small headgroup, is found in both layers as it can interchange between them. The membrane-resident proteins responsible for the strong asymmetry are commonly called flippases and floppases. These lipid translocases belong to the class of active

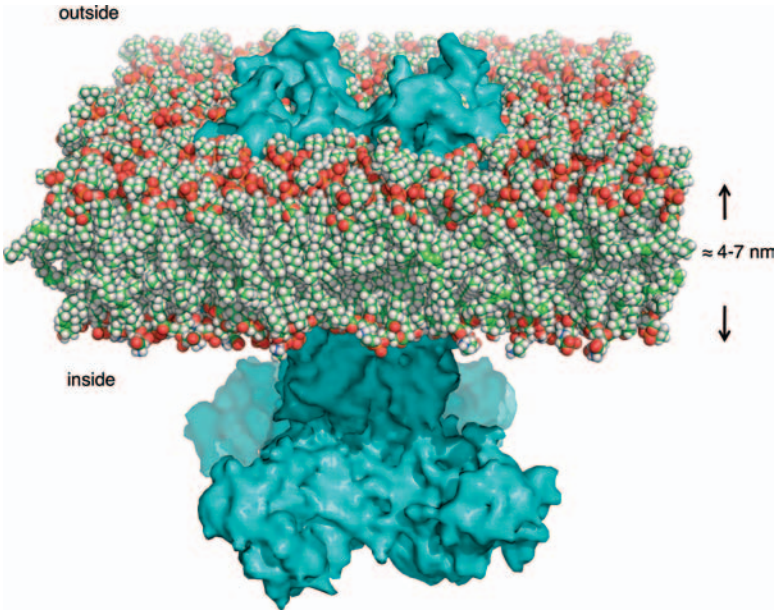

Figure 7.22 A single voltage-gated potassium channel embedded in a lipid bilayer containing phosphatidylcholine, phosphatidylserine, phosphatidylethnolamine, and cholesterol. The channel (PDB ID: 2R9R) is depicted using its molecular surface representation (cyan) and the membrane components are shown using spheres. Green, carbon; white, hydrogen; blue, nitrogen; red, oxygen; orange, phosphate. The image was rendered using MacPyMol. Ions and water molecules are not shown for simplicity.

transporters or pumps, working against a chemical gradient at the expense of ATP. Whereas flippases continually work on the inward movement of PE, PS, and PI, floppases transport PS and SM to the outer leaflet.

Membrane asymmetry has fundamental biological consequences, as we may illustrate with the specific role of PS as a signaling molecule. The flippases, responsible for keeping PS in the inner leaflet, are strongly inhibited by Ca^{2+} ions in the cytosol. Under resting conditions the cytosolic Ca^{2+} concentration is very low. Damage of a cell mostly manifests as an increase in the cytosolic Ca^{2+} concentration and hence inhibits flippase activity. At the same time, a third type of lipid translocase, scramblases, is activated by Ca^{2+}. Scramblases are passive transporters, accomplishing a rapid but unspecific phospholipid exchange between the layers, driven by the existing gradients. In consequence, PS headgroups will appear on the outer cell surface, where they indicate that the cell is in an unhealthy situation. This is a signal to the immune system to activate *phagocytes*, immune cells that are specialized to engulf other cells or cellular debris (see Section 7.2.1.7).

Lateral Mobility of Membrane Proteins According to the fluid mosaic model, not only membrane lipids but also the embedded transmembrane proteins are free to move laterally within the membrane (Figure 7.22). Now we know that lateral movements are much more restricted in biological membranes. Such limitations in fluidity occur when membrane proteins have cytosolic contacts to the cytoskeleton. Anchoring to intracellular proteins is in fact very common and holds membrane proteins in place. For example, in intestinal epithelial cells, a protein can be confined to the apical membrane area facing the gut lumen. Typical contact motifs often reside in the distal C terminus of the membrane protein. The presence of a hydrophobic residue in the very last position and a Ser or Thr in the −3 position of the C terminus provides a docking site for so-called PDZ domains. This domain was named after three proteins for which it was originally described: post-synaptic density, discs large, and zona occludens-1. PDZ domains, comprising about 90 amino acid residues, are typically found in adapter proteins, linking integral membrane proteins to actin fibers of the cytoskeleton.

Lipid Rafts Restricted lateral mobility can also be a result of heterogeneity in the membrane lipid composition. One such phenomenon of the plasma membrane is the formation of so-called *lipid rafts*. The outer leaflet can form small, dynamic zones enriched in sphingomyelin and cholesterol. The surface area of these rafts is typically below the resolution limit of light microscopy. Because of the small size, the exact dimensions and the lifetime of rafts are still a matter of intense debate. However, the protein makeup in rafts appears different from that in the rest of the membrane. For instance, GPI-anchored proteins are enriched in raft compartments. The inner leaflet area under the raft is rich in cholesterol and phospholipids carrying predominantly saturated acyl chains. Notably, typical proteins in these areas are dual-acylated kinases and small guanosine triphosphatases (GTPases). Most likely this arrangement of surface receptors and intracellular signaling proteins promotes a rapid transfer of extracellular signals into the cytoplasm.

Glycoproteins and Glycolipids In addition to lipids and proteins, the plasma membrane also contains carbohydrate, up to 10% by weight. Sugars can be covalently linked to both proteins and lipids, but glycoproteins account for ~90% of the sugar in the plasma membrane. Virtually all of the sugar moieties, regardless of the linked structures, face the extracellular space. The exact functions of glycosylation are far from being understood, but sugars are certainly involved in sorting processes, intercellular recognition, and interaction with the cell environment. Of high practical relevance in medicine are carbohydrates linked to lipids in the plasma membrane of human red blood cells, forming the basis of the ABO blood grouping system. The last moiety in a short chain of sugars determines the blood group. All members of blood group A carry *N*-acetylgalactosamine in this position whereas blood group B is determined by a galactose moiety instead. As these sugars are well exposed on the surface of the blood cells, they are recognized readily by cells of the immune system. If a blood transfusion delivers cells with the incompatible sugar, it would trigger defense reactions of the immune cells. Interestingly, the two enzymes, responsible for the linkage of either *N*-acetylglucosamine or galactose, are encoded by two variants of the same gene. As every individual has two copies of this gene, one from each parent, many individuals have a mixed genotype and both alternative enzymes are formed. They form blood group AB, characterized by the presence of both sugar types in their blood cells. As a fourth alternative, the members of blood group O did not receive a functional gene copy and neither *N*-acetylglucosamine nor galactose is coupled to their glycolipids. As a consequence, type O individuals could donate blood to any other individual; however, they cannot receive blood from other ABO groups because both sugars are "foreign" to the immune system of type O individuals.

7.2.1.2 The Nucleus

The nucleus houses the vast majority of the genetic material of the cell and separates the space where protein building plans (mRNA) are synthesized, the nucleoplasm, from the area where they are translated into protein, the cytoplasm. The nuclear envelope is formed by two adjacent lipid bilayer membranes, the inner and outer nuclear membranes. They are separated by about 10–50 nm and the volume between them is contiguous with the ER lumen. The outer nuclear membrane is in direct contact with the rough ER and shares a similar set of proteins, whereas the inner nuclear membrane has its own distinct set of proteins. Mechanical support of the envelope is provided by a protein network attached to the nucleoplasmic surface of the inner nuclear membrane, the nuclear lamina. This network is built of intermediate protein filaments, one of three categories of cytoskeletal proteins (see Section 7.2.1.8).

DNA Packing in the Nucleus In addition to stabilization of the nuclear envelope, the nuclear lamina also serves as an attachment site for chromatin fibers. Chromatin is a generic term for the complexes formed by DNA, histones, and nonhistone proteins. The well-known structures of highly condensed chromosomes exist for only a short period of time in the life of a cell. Maximum condensation of the DNA allows the

equal distribution of the chromosomes between daughter cells during cell division. When a division is completed, the DNA no longer forms visible chromosomes, but appears as rather diffuse matter, filling the nucleoplasm. Despite their disorganized appearance in light microscopy, fluorescence staining of individual chromosomes shows that these decondensed chromosomes are not randomly intermingled, but rather restricted to specific regions. Inspection of the nucleoplasm by electron microscopy does not identify individual chromosomes, but typically distinguishes compacted, denser areas in the nucleoplasm, the so-called heterochromatin, from a more dispersed euchromatin. Heterochromatin is a macroscopic reflection of gene silencing. This inactive state is constitutive for the distal ends of all chromosomes, the telomeres, and the central parts of the chromosomes, the centromeres. In contrast, any active use of DNA for transcription or replication requires the decondensation of the genetic material. For the major parts of all chromosomes, the degree of condensation is dynamic and depends on the differentiation of an individual cell. In females, a complete chromosome, one of the two X chromosomes in each cell, is typically inactivated as facultative heterochromatin, the *Barr body*. Inactivation of one of the X chromosomes ensures that male and female cells produce about the same amounts of X-encoded proteins. X chromosome inactivation in females is a random process in early embryogenesis and the condensed state of the X-chromosomes is subsequently transmitted to all descendant cells. As hair/fur pigmentation in mammals is partly determined by a gene product of the X chromosome, this can result in random patches of different coat color, as seen in the so-called calico cats. Accordingly, male cats, that do not inactivate X chromosomes, do not show calico color patches.

The Nucleolus The largest substructure in the nucleus visible in light microscopy is the nucleolus, an irregular region of higher density. Unlike other organelles, the nucleolus is not surrounded by a membrane. The higher density is due to the accumulation of rRNAs, RNA-processing enzymes, and partly assembled ribosomes as the nucleolus is the site of ribosome production. The large and small ribosomal subunits, huge complexes formed of several rRNAs and proteins, are exported from the nucleus after assembly to act as protein synthesis factories in the cytoplasm. Three of four different rRNAs are encoded by a single gene, which is located in multiple copies on five different chromosomes of the human cell. Thus, in a diploid cell, 10 chromosomes carry rRNA genes at their distal ends. During rRNA synthesis, these ends stick together closely and form the center of the ribosome production factory. The size of the nucleolus is variable and depends on the need for ribosomes in the cytosol. In active cells producing very large amounts of protein, the size of the nucleolus can reach up to 25% of the nuclear volume.

Nuclear Pores The nuclear envelope keeps the genetic material away from the sites of active metabolism, but exchange and communication between nucleoplasm and cytoplasm are vitally important. Since the sequence information for protein synthesis at cytoplasmic ribosomes is carried by mRNA, continual export of mRNA from the nucleus to the cytoplasm is required. As mentioned before, the ribosomal subunits

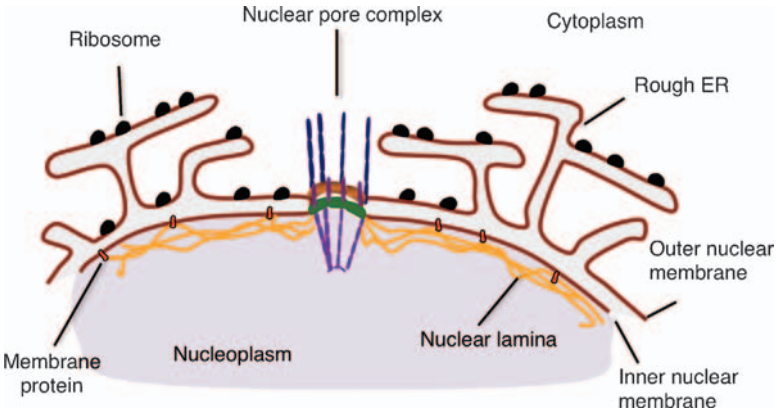

Figure 7.23 Structure of the nuclear envelope in contact with the ER.

are also formed in the nucleolus and need to be exported. For actively growing human cells in culture, it is estimated that over 10 000 ribosomal subunits leave the nucleus per minute. Ribosomal proteins themselves are synthesized by ribosomes in the cytoplasm and need to be imported into the nucleus. Other proteins with high import rates are the histones, needed to build the nucleosome structures with the DNA. Other candidates for nuclear import are RNA polymerases and regulatory proteins responsible for gene transcription. To meet all these transport demands, the nuclear envelope is perforated with several thousand pores (Figure 7.23).

Each of these pores is formed as an immense protein assembly, termed the *nuclear pore complex* (NPC). With a total mass of about 80 000 kDa, the NPC is one of the largest structures of the cell. Multiple copies of about 30 different proteins, the nucleoporins, are organized such that electron microscopy images from the cytosolic side reveal a ring-like structure with octameric symmetry. On its cytoplasmic side, eight filaments of about 800 nm length extend into the cytoplasm. Views from the nucleoplasmic side show analogous filaments, but joined at their ends to form a basket-like structure (Figure 7.23). The whole membrane-embedded ring structure connects both nuclear membranes and it is in direct contact to the nuclear lamina.

Nuclear Import and Export The inner diameter of the nuclear pores is not fixed but dynamic; the nucleoporins form a flexible aperture-like ring. This structure accommodates small proteins of 50 kDa or less, in addition to huge complexes such as small and large ribosomal subunits with 1400 and 2800 kDa mass, respectively. Ions, metabolites, and proteins below 50 kDa diffuse passively through the NPC, whereas all larger proteins need helper proteins, the so-called importins and exportins, to pass in and out through the NPC. This guided transport relies on short amino acid motifs in the cargo proteins. A classical nuclear-localization signal (NLS) is formed by seven amino acids with mostly positively charged side chains near the C-terminus of an imported protein. Transport through the NPC is not only specific but also requires energy, such that NLS-tagged proteins can be accumulated in the nucleus. Direction

of the translocation process and energy input are brought about by the small GTPase Ran. In its guanosine triphosphate (GTP)-bound state, Ran can drive the outward movement of the protein importins or exportins through the NPC. After an importin has conveyed a cargo protein into the nucleoplasm, release of the cargo is triggered by binding of Ran-GTP to the importin. The complex of importin and Ran-GTP then leaves the nucleus through an NPC. In the cytoplasm, Ran is activated to cleave its GTP and to unbind from the importin. This hydrolysis of GTP to guanosine diphosphate (GDP) and P_i provides the energy that drives the cyclic process. Now, the importin is free to bind another cargo protein and to re-enter the nucleus, while Ran-GDP independently travels back to the cytosol. To complete the cycle, in the nucleus the Ran-bound GDP is replaced by GTP. Other proteins are exported through the NPC in a similar manner, but unlike the extrusion of importin, a Ran-GTP-bound exportin will carry a third partner, a protein with a nuclear export signal.

The export of mRNA also depends on guidance by bound proteins, but does not involve the Ran protein. Importantly, the export-competent complex of binding proteins and mRNA is only formed after excision of introns from the precursor mRNA, such that mostly mature messengers come in contact with the ribosomes in the cytoplasm. Some exceptions exist; in those cases mRNA is spliced inside the cytosol.

Nucleus and Cell Division Prior to cell division, the genome has to be replicated and the nucleus must be divided into two daughter nuclei. In human cells, this is accomplished by a complete breakdown of the nucleus followed by the re-formation of two new nuclear envelopes. During mitosis, the process leading to chromosome segregation, the filament proteins of the nuclear lamina are phosphorylated and the resulting negative charges trigger disintegration of the network, followed by a retraction of the nuclear envelope into the ER. Similarly, phosphorylation of the proteins of the NPC leads to reversible dissociation of the pore complexes. At the end of mitosis, the nuclear envelope is reformed from tubular ER, a complex process that is induced by contacts between ER and the chromosomes.

7.2.1.3 Endoplasmic Reticulum (ER)

The largest membrane system in the eukaryotic cell is formed by the ER, a network of flattened tubes and sacs called cisternae. It comprises roughly 50% of the cellular membrane surface and about 10% of the total cell volume. Major ER functions include protein synthesis and modification, synthesis of lipids and steroid hormones, detoxification, and Ca^{2+} sequestration. Rough and smooth areas of the ER can be distinguished by electron microscopy. Both parts of the vesicular systems are contiguous, but the resident proteins in rough and smooth areas are specialized, reflecting different enzymatic activities. The rough endoplasmic reticulum (RER) is directly connected to the nucleus and ongoing protein synthesis in this area is morphologically visible by the presence of ribosomes on the cytoplasmic membrane surface. Proteins synthesized at these ribosomes are either transferred into the lumen of the ER or they reside in the ER membrane. However, only a small fraction of the proteins synthesized at the RER remain there as resident proteins. Most of the

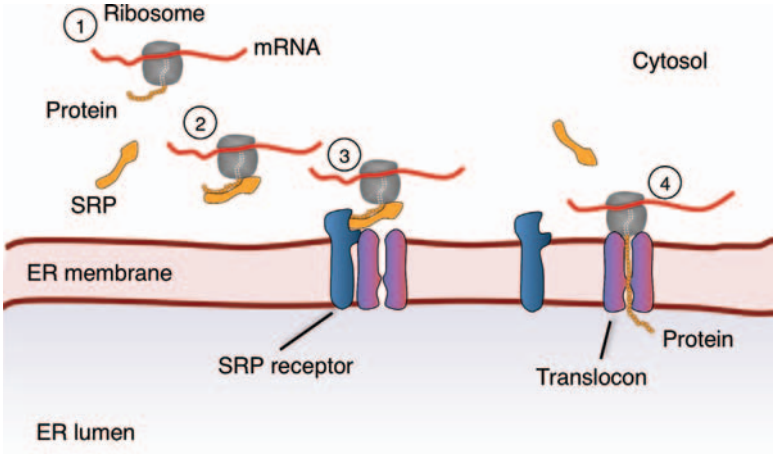

Figure 7.24 Synthesis of secreted proteins at the ER membrane. Ribosomal synthesis of all proteins starts in the cytosol (1). Binding of the signal recognition particle (SRP) to the N-terminal signal sequence of a membrane protein halts the synthesis (2). The complex of mRNA, ribosome, nascent protein, and SRP is translocated to the SRP receptor in the ER membrane (3), where it comes in close contact with the translocon complex. Following release of the SRP and tight docking of the ribosome to the translocon, protein synthesis is resumed and the growing polypeptide is threaded through the translocon pore (4).

proteins are destined for other compartments and the ER is only the first transit station on their journey.

Signal Sequences Direct Proteins to the ER The first events of protein synthesis take place in the cytoplasm, as small and large ribosomal subunits assemble around a molecule of mRNA. Initiation and elongation of the translation process need additional helper proteins, but the major translation machine is the ribosome itself. The growing polypeptide chain leaves the ribosome and globular cytoplasmic proteins will immediately start to fold into their native structure. These proteins are released into the cytoplasm when the last amino acid is attached. By contrast, a large group of proteins has a unique property: the N-terminal end of the growing polypeptide chain carries the information to stop the synthesis process until the whole complex of ribosome, mRNA, and the growing protein make contact with the ER membrane (Figure 7.24). In fact, the N-terminal residues of these proteins are used as a "sorting code" by the ER. The critical event is the binding of a *signal-recognition particle* (SRP), a large RNA–protein complex, to a stretch of about 15 residues at the N-terminus of the nascent protein. The amino acid sequences of these signals are not very conserved, but all contain at least eight hydrophobic residues in the center, often preceded by one or more basic amino acids. The mammalian SRP itself is a complex formed of one small RNA molecule and six distinct proteins. One of these proteins forms a signal-binding pocket lined by hydrophobic residues. Binding of the N-terminal signal sequence of the nascent protein in this pocket immediately stops the ongoing protein synthesis at the respective ribosome. The

complex of SRP and mRNA is then translocated to the ER, where it is recognized and bound by an ER-resident protein called SRP receptor. This membrane protein brings the SRP and the ribosome in close proximity to a gated pore complex in the ER membrane, the translocon. Upon binding of the ribosome, this pore lines up with the large ribosomal subunit such that the growing polypeptide slides directly into the aqueous translocon pore. The contact between the ribosome and the translocon complex is perfectly tight such that no ions pass through the channel during protein transfer. Ribosomes sitting in such complexes on the ER surface cause the rough texture of the RER.

Protein Folding in the ER Depending on the hydrophobicity profile of the growing protein, it will either be completely transferred into the ER lumen or, if hydrophobic helices are formed, these transmembrane-spanning helices anchor the new polypeptide in the ER membrane. The signal sequences of soluble proteins are usually cleaved after translocation by the membrane-bound signal peptidase. In transmembrane proteins, the signal can be cleaved, but it can also be preserved in the mature protein. The RER is not only an important starting point for protein sorting, but is also crucial for protein folding and glycosylation. For many soluble proteins and also membrane proteins, the formation of disulfide bridges is required to stabilize their native structure, a process called oxidative folding. This task cannot be accomplished under the reducing conditions of the cytoplasm; a set of proteins present in the lumen of the ER fulfills this task. The initial event, the *de novo* formation of a disulfide link, is accomplished by the enzyme Ero1p. It uses the oxidizing power of molecular oxygen to link two of its own cysteines. This disulfide can be transferred to protein disulfide isomerases, which then pass it on to substrate proteins.

Protein Glycosylation Another important function of the RER is protein glycosylation. Regardless of their final destination, both soluble proteins and membrane proteins are usually modified by addition of sugar moieties. In the ER the targets of modification are asparagine (Asn) residues in the newly synthesized proteins. While the exact amino acid sequence of any protein can be determined by the encoding gene, the sequence of added sugars depends on the action of gylcosyltransferases and their spatial localization. Hence genome sequencing or determination of mRNA sequences cannot fully predict the final structure of a glycosylated protein. The basal sugar structure added to proteins in the ER is a preformed assembly of 14 sugars (see Section 7.1.3.2). This invariant structure is assembled on a lipid carrier in the ER membrane and subsequently transferred to proteins by the ER enzyme oligosaccharyltransferase. Mutations blocking this basal modification system are lethal. Other enzymes subsequently modify the original 14-unit sugar structure by adding or trimming off some of the sugar moieties.

In addition to functions in the mature protein, glycosylation has an important role in quality control for virtually all proteins in the ER. The basic sugar structure contains three terminal glucose moieties that are fully removed during further processing steps in the ER. However, if a protein is not yet properly folded, a glycosidase will add a new, single glucose moiety to the structure. This glucose

tag induces the retention of the protein in the ER lumen, where it is bound by the ER-resident membrane protein calnexin. The folding process in the ER lumen is usually assisted by helper proteins, so-called chaperones. Thus longer retention periods in the ER increase the chance of complete folding. Nevertheless, disulfide formation, folding, and oligomerization of subunits are not very efficient processes. For some proteins the estimated "success rates" of folding are far below 50%. Hence the ER needs a way to clear this ballast of inefficient protein production. This is accomplished by export of misfolded proteins through the same translocon structures that are used for protein import.

Retention and Retrieval of ER Proteins For most proteins that are produced, folded, and glycosylated in the RER, these steps are just the starting point of a journey to their final destinations, such as other organelles or the plasma membrane. This transport is based on the formation of small vesicles, formed from the ER membrane, leaving with destination to the next station of protein traffic, the *cis*-side of the Golgi complex (see below). However, ER-resident proteins must be retained from this constant flow of material in order to keep the ER compartment functional. This is accomplished by retention and retrieval mechanisms. Soluble resident ER proteins are marked with a short retrieval sequence, formed by the amino acids Lys–Asp–Glu–Leu (KDEL) at the C-terminus. This short motif is recognized and bound by the *KDEL receptor*, a membrane protein that loads the protein into budding vesicles that will be sent back from the Golgi compartment to the ER (retrograde transport; see Figure 7.25). For

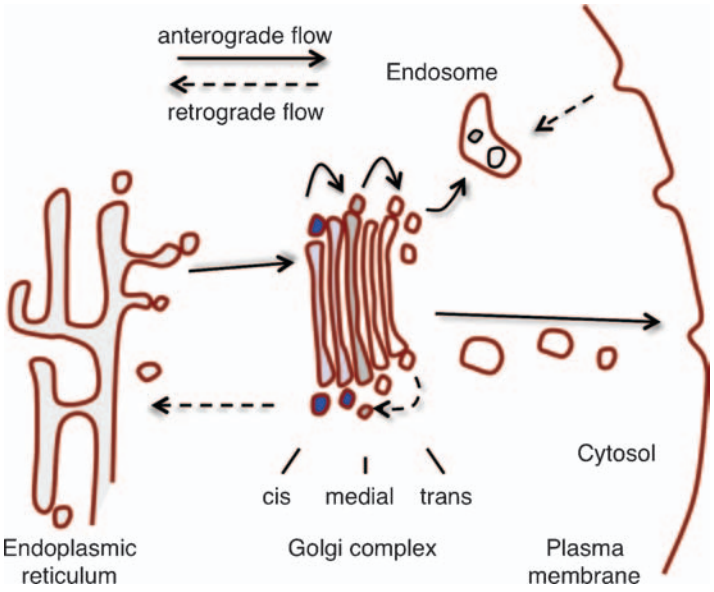

Figure 7.25 The Golgi complex as central sorting station of the cell. Solid arrows indicate the vesicle-mediated transport of proteins from the ER via the Golgi complex to endosomes or the plasma membrane. Retrograde transport between the same compartments is indicated by dashed arrows.

resident membrane proteins, analogous signals determine retrieval and retrograde transport in a similar fashion. These retrieval mechanisms capture proteins that escaped the ER, but packing of resident proteins into vesicles is *per se* less frequent than for secreted proteins. The mechanisms underlying this active retention are not well established, but it is assumed that resident proteins of ER or other compartments have the general tendency to aggregate into larger complexes that are just too big to enter vesicles.

The Smooth ER In contrast to the flattened structures of the RER, areas of smooth endoplasmic reticulum (SER) typically appear as a network of branched tubules, although this morphological distinction is not true for all cell types. The SER has metabolic functions including lipid and steroid hormone synthesis. The latter is a characteristic of endocrine cells in the gonads, usually reflected by more extended regions of SER. The synthesis of membrane lipids is of general importance in all cells and the majority of all lipids in plasma membrane and intracellular membranes originate from the SER. Interestingly, this does not mean that all membranes within a single cell have approximately the same phospholipid composition. For example, the content of phosphatidylcholine is usually much higher in the ER than in the plasma membrane, whereas phosphatidylserine has a higher concentration in the plasma membrane. Another important feature of the SER is its role in the sequestration of Ca^{2+} ions. The cytosolic concentration of free Ca^{2+} ions in the cytoplasm is typically very low (see Section 7.3.2.1), in part because it is actively pumped into the SER, which function as Ca^{2+} reservoirs. Upon specific triggers, Ca^{2+} is released back into the cytoplasm, initiating cellular responses. In skeletal muscle cells a specialized form of SER, the sarcoplasmic reticulum (SR), rapidly releases Ca^{2+} ions in response to electrical stimulation and hence initiates muscle contraction.

7.2.1.4 The Golgi Complex

Whereas the ER is a major site of protein synthesis and modification, the Golgi complex, or Golgi apparatus, can be envisioned as *central sorting station* of the cell. Proteins and also lipids coming from the ER are handled in the Golgi complex, further modified, and targeted to their final destinations. The classical morphology of the Golgi compartment resembles a stack of pancakes with frayed rims, formed of flat membrane-enclosed cisternae (Figure 7.25). Each stack comprises about 4–7 disk-like elements with a diameter up to 1 μm. Human cells typically contain many of these Golgi stacks, linked by tubular connections and thereby forming a complex located near the nucleus. This spatial organization is achieved by connecting microtubules of the cytoskeleton. The individual stacks can be morphologically and functionally divided into three distinct compartments. The *cis* face comprises the cisternal elements in proximity to the ER, followed by *medial-* and *trans-Golgi cisternae*. Thin networks of tubules and vesicles on either side of the stack are called *cis-Golgi network* and *trans-Golgi network*. The spatial organization is accompanied by a clear functional compartmentalization, such that specific enzymes of the glycosylation machinery are located in distinct cisternae of the *cis*, medial, or *trans* part of a stack.

Golgi Stacks Are Dynamic Interestingly, resident membrane proteins of the Golgi are distinguished from membrane proteins of other compartments by shorter transmembrane helices, comprising around 15 amino acids instead of the typical 20–25 amino acid helices in most other proteins. This difference provides the basis for a Golgi retention mechanism. Vesicles leaving the *trans*-Golgi are thicker than the membrane of the Golgi membranes themselves, thereby excluding transmembrane proteins with too short transmembrane segments. The precise organization of the Golgi stacks rises the question of how these structures are generated and maintained. Two alternative models are under discussion, the "vesicular transport model" and the "cisternal maturation model." The former model assumes a static position of the Golgi cisternae with a fixed set of enzymes in each part of the structure. Transit molecules would primarily move in forward-directed vesicles and retrograde vesicles would return enzymes that escaped from their major site of activity. By contrast, in the maturation model, complete cisternae would move through the Golgi stack and thereby take along proteins and lipids from the *cis* to the *trans* side. During this movement, the enzyme equipment of individual cisternae would mature. Enzymes belonging to the early *cis* face would permanently move backwards from medial disks to newly formed disks on the *cis* side and medial enzymes would travel back from disks that just reached the *trans* side. More recent studies, using spatially focused photobleaching of fluorescent proteins in distinct cisternae, favor a rather static model. However, in contrast to the classical vesicular model, transit between disks is not only mediated by vesicle transport, but may also be carried out in large part by a direct equilibration between individual disks through connecting tubules.

Protein Handling in the Golgi Stacks Newly synthesized and folded proteins from the ER typically leave the RER in vesicles and enter the *cis* face of a Golgi stack. They are then passed along through medial and *trans* discs. Transport in ER and Golgi is not necessarily unidirectional, but vesicles connecting the individual compartments can also move in a retrograde manner. This is especially important to bring ER-resident proteins back from the Golgi complex to their ER destination and to ensure a specific enzyme composition in each of the three Golgi compartments. One of the major processing steps in the Golgi complex is to continue and complete the protein modifications that have been initiated in the ER. Processing of the N-linked oligosaccharides includes further removal of mannose, addition of *N*-acetylglucosamine, galactose, and the negatively charged sialic acid. Furthermore, *O*-linked glycosylation on Ser and Thr amino acid residues only takes place in the Golgi complex. Despite a good knowledge of sugar modifications on proteins and the compartments for individual processing steps, for the majority of the glycosylated proteins the functional impact is still largely elusive. Another post-translational modification that is specifically accomplished in *trans*-Golgi cisternae is the addition of sulfate to tyrosine residues. Tyrosine sulfation of exported proteins or on extracellular epitopes of plasma membrane proteins was found to strengthen protein–protein interactions.

7.2.1.5 Mitochondria are the "Power Plants" of the Cell

Among the most complex organelles in the human cell are the mitochondria, membrane-enclosed structures in the cytoplasm that can be visualized by light microscopy. Most human cells carry several hundred to thousands of individual mitochondria. The volume typically occupied by the mitochondria makes up between 10 and 25% of the total cell volume. Depending on the cell type, the size and shape of the mitochondria can be diverse. The overall structure of a mitochondrion can resemble a cylinder with a diameter of about 1 μm and a length of 4 μm, whereas in other cells mitochondria appear as long tubules or even as branched, interconnected networks. These structures are usually dynamic because mitochondria can fuse with one another. New mitochondria are generated from existing mitochondria by a process called fission. This multiplication of mitochondria is important in dividing cells, as the organelles cannot be formed *de novo* and must be inherited to the daughter cells. About 100 years ago, Konstantin Sergejewitsch Mereschkowski proposed that mitochondria are not innate parts of the cell, but rather descended from bacteria that have been engulfed by another cell. This "endosymbiotic theory" was initially greeted with skepticism but, with the finding of DNA present in mitochondria and the analysis of mitochondrial genes in the 1980s, the idea gained strong support and is now fully accepted.

Compartments of the Mitochondria Mitochondria are more than a simple enveloped vesicle. A closer look shows the existence of two juxtaposed membranes, the *outer mitochondrial membrane* and the *inner mitochondrial membrane*. The inner membrane forms characteristic infoldings, the cristae, reaching into the inner lumen called *mitochondrial matrix*. Practically, five compartments of the mitochondrion can be distinguished: the outer membrane, the intermembrane space, the lumen of the cristae, the inner membrane, and the matrix (Figure 7.26). The outer membrane encloses the whole organelle and separates it from the cytoplasm. This membrane, with a total protein content of about 50%, is similar to other cellular membranes, but in remarkable contrast, the transmembrane segments of the resident proteins of this membrane are typically folded as β-sheets, instead of the common α-helical segments. This folding pattern resembles the structure of the porin proteins in the outer membrane of *E. coli* and other so-called Gram-negative bacteria. Because of these membrane proteins, the outer mitochondrial membrane partly allows the exchange of ions and small molecules between the cytosol and the intermembrane space.

The Inner Mitochondrial Membrane In contrast to the outer mitochondrial membrane, the inner membrane provides a tight permeation barrier that separates the matrix from the intermembrane space. This membrane is devoid of cholesterol, but contains a high concentration of cardiolipin, a "double lipid" with four fatty acids, which is otherwise found only in bacteria. The invaginated inner membrane surrounds the cristae and its surface area can make up to one-third of the total membrane area of the cell. The density of cristae in a mitochondrion is especially high in those cells with a high energy consumption such as heart muscle cells. The inner mitochondrial membrane is exceptionally rich in proteins, with at least 3:1 ratio

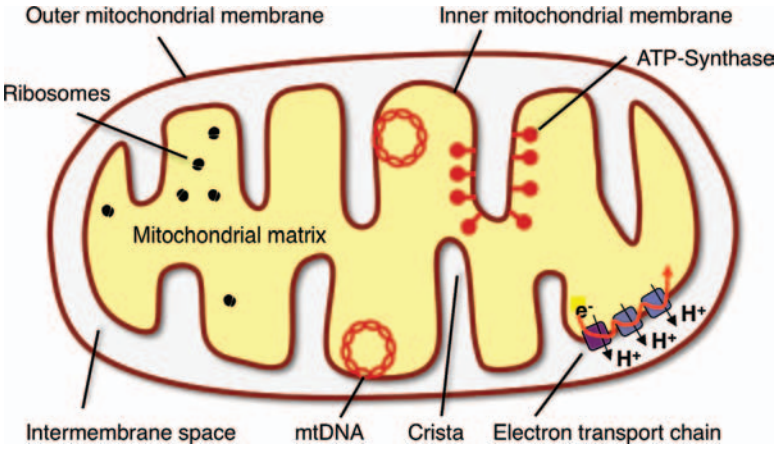

Figure 7.26 Cartoon of a mitochondrion with its compartments. Five functional compartments can be distinguished: the outer membrane, the intermembrane space, the inner membrane with the electron transport chain, the cristae, and the inner matrix. Cristae are invaginations of the inner membrane; they are in contact with the intermembrane space, but local solute concentrations can differ.

of protein to lipid. The enzymes incorporated here are essential for oxidative phosphorylation, the process that generates most of the cellular energy in the form of ATP. The electron transport chain transfers electrons from NADH to molecular oxygen and utilizes the energy difference to drive protons (H^+) from the matrix into the intermembrane space or the lumen of the cristae. The ATP–synthase complexes in the same membrane act like turbines, coupling the energy stored in the electrochemical gradient of protons to the production of ATP from ADP.

The Mitochondrial Matrix Along with the ER lumen, the mitochondrial matrix is considered an important site for the storage of Ca^{2+} ions and the triggered release of these ions acts as an intracellular signal. The matrix also contains the enzymes required for the final metabolism of pyruvate and fatty acids to gain the end product CO_2 and NADH, the energy-rich substrate for the ATP-producing electron-transport chain of the inner membrane. Additional important components of the mitochondrial matrix are DNA molecules, tRNA, ribosomes, and proteins of the transcription–translation machinery. Mitochondria were originally derived from free bacteria and, during a long process of evolution as symbiont in the nucleated cell, most of the mitochondrial genes have been translocated to the central genome in the nucleus. Nevertheless, mitochondria retained some genes and ribosomes of their own to produce proteins in the mitochondrial matrix (see below). In contrast to the chromosomes in the nucleus, mitochondrial DNA has a ring-shaped structure and is devoid of histone proteins.

Mitochondrial Protein Import The interaction of mitochondria with the rest of the cell is characterized on the one hand by busy export of the valuable energy source ATP.

On the other hand, 99% of the mitochondrial proteins must be imported from the cytosol in order to maintain ATP synthesis. This high import demand exists because most mitochondrial genes have been translocated to the nuclear genome and only 13 proteins are still encoded by the organelle's own DNA. Proteins destined for a mitochondrial compartment do not follow the main secretory pathway along the ER and Golgi and ribosomal synthesis is typically completed in the cytosol. To facilitate transport of mitochondrial proteins, chaperones bind to the nascent polypeptide chains and prevent their final folding. Supported by a transport receptor protein, the new protein is then threaded into a β-barrel protein complex of the outer mitochondrial membrane, the TOM complex. Matrix proteins typically have N-terminal signal sequences, analogous to the ER-targeting signals. The mitochondrial import signals typically form amphipathic α-helices of 20 or more amino acids with positive charges (Arg, Lys) on one side of the helix and hydrophobic residues on the opposing side. Such proteins will continue their way through TIM23, a translocator in the inner mitochondrial membrane. TIM and TOM proteins come in close proximity during transport and both membranes (Figure 7.27) appear in direct contact in electron microscopy images of active translocator sites. Once a protein has reached the matrix, a mitochondrial protease cleaves the mitochondrial signal sequence and the protein folds into its final tertiary structure and reaches the mitochondrial matrix. Proteins destined for the inner mitochondrial membrane will be processed by TIM22. This complex allows the lateral release of hydrophobic helices of the transported protein into the inner membrane. By contrast, proteins targeted to the outer mitochondrial membrane enter the intermembrane space before being retrieved back into the outer membrane. The pore formed by the β-barrel-shaped TOM complex is tightly closed all around and does not allow a lateral release of cargo proteins directly into the outer

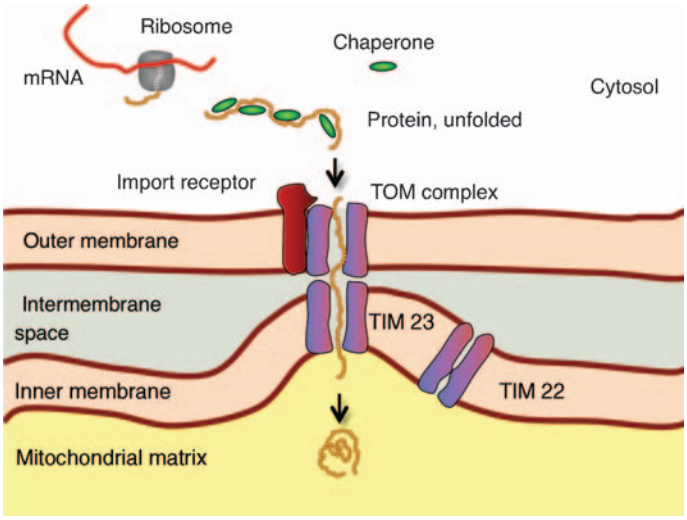

Figure 7.27 The mitochondrial import system for proteins from the cytosol.

membrane. In contrast to the co-translational transport of growing proteins into the ER, the post-translational protein import into mitochondria needs additional input of energy provided by the hydrolysis of ATP.

7.2.1.6 **Peroxisomes**

Peroxisomes are morphologically rather unobtrusive, round organelles, surrounded by a bilayer, and with diameters of about 0.1–1 μm. It was not until the middle of the twentieth century that peroxisomes, and also lysosomes, were identified and described by Christian de Duve. This relatively recent discovery may be explained by the small size and the unremarkable appearance of peroxisomes. In some mammalian cells they contain electron-dense crystals, but human peroxisomes are usually without noticeable inner structures. Several hundred peroxisomes are typically found distributed throughout the cytosol of every cell. Like mitochondria, they proliferate by fission of existing peroxisomes. This fact led to a long-lasting discussion about a potential endosymbiotic origin of the peroxisomes. However, unlike mitochondria, they contain neither DNA nor ribosomes of their own. The name of the organelle refers to the presence of enzymes involved in the handling of peroxides. Hydrogen peroxide (H_2O_2), a toxic and reactive oxidant, can arise from several sources but peroxisomes themselves also generate H_2O_2 as a common product of resident enzymes. D-Amino acid oxidase, glycolate oxidase, and other peroxisomal enzymes utilize molecular oxygen (O_2) to oxidize their substrates and generate H_2O_2 as the secondary product. The peroxisomal enzyme catalase is required for the immediate breakdown of H_2O_2, yielding water (H_2O) and O_2 as final products. Many of the oxidative reactions performed by peroxisomal enzymes resemble enzymatic activities in the mitochondria, with the notable difference that peroxisomes do not directly produce energy. A prominent example is the stepwise breakdown of fatty acid molecules, β-oxidation. In this sequential reaction, fragments comprising two carbon atoms are released and exported as acyl-CoA to the cytosol. This energy-rich compound can be reused in biosynthetic reactions or further processed to gain energy. Another important function of peroxisomes, especially in liver and kidney cells, is the detoxification of toxic compounds such as ethanol, phenol, or formaldehyde. About 25% of the ethanol consumed is oxidized to acetaldehyde in peroxisomes. Importantly, peroxisomes are also involved in functions other than degradation and detoxification processes. An essential biosynthetic function of peroxisomes is the formation of phospholipids with ether-linked fatty alcohols, instead of the standard, ester-linked fatty acid chains. These *plasmalogens* are important phospholipid components of the myelin sheets, insulating membrane layers surrounding nerve axons.

Protein Import to Peroxisomes Like mitochondria, peroxisomes are not part of the major vesicle traffic pathways emerging from ER and Golgi. Consequently, all enzymes of the peroxisomal lumen and the surrounding membrane need to be imported from the cytosol. The import machinery is not well characterized, but more than 20 proteins, the so-called peroxins, are involved in the ATP-driven uptake of proteins. In contrast to the mitochondrial import machinery, peroxisomes can take

up proteins that have already adopted their final structures. However, the enzymes catalase and peroxidase receive their prosthetic heme group only after import into the organelle is completed. The sorting codes, determining a peroxisomal protein's destination, can sometimes be found at the N termini of peroxisomal proteins, but in most cases a short amino-acid motif at the distal C terminus is responsible for uptake. Artificial transfer of the short amino-acid sequence Ser–Lys–Leu to the C terminus of a cytosolic protein is sufficient to direct the recombinant protein into peroxisomes. The importance of a functional peroxisome import system is underscored by the finding that various peroxin gene mutations, known to deactivate the uptake system, lead to relatively rare human diseases collectively termed the Zellweger syndrome. In the patient's cells, peroxisomes are still visible, but they lack their resident proteins at least in part. The Zellweger syndrome is typically characterized by severe failures of the liver, kidneys, and brain, leading to death within the first few months after birth.

7.2.1.7 **Lysosomes**

The second organelle discovered by de Duve, the lysosome, is not uniform in either shape or size, ranging from small vesicles of around 20 nm up to more irregular structures up to 1 μm in diameter. The lysosomes are equipped with a variety of hydrolytic enzymes, enabling them to act as the cell's central "recycling station." A lysosome can hold at least 50 different enzymes: proteases, glycosidases, RNases, DNases, lipases, and many others. Equipped with these enzymes, lysosomes are prepared for the destruction of practically all cellular biomolecules and even foreign molecules, as the enzyme lysozyme can degrade peptidoglycan, a major component of bacterial cell walls. All these hydrolases share a requirement for low pH between 4.5 and 5.0. This low pH is the major characteristic of the lysosomal lumen and serves as an important safeguarding system. The assembly of destructive enzymes in the lysosome is potentially dangerous for all other constituents of the cell. However, in case of their liberation into the cytosol, the acid hydrolases will be inactive in the practically neutral milieu around pH 7.2. The exceptionally low pH of the lysosome is sustained by proton ATPases in the lysosomal membrane. These transporters pump H^+ from the cytosol into the organelle lumen – a process that is driven by the hydrolysis of ATP. The resident lysosomal proteins in the acidic environment seem to be protected from destruction by an unusually high degree of glycosylation.

Transport to Lysosomes Lysosomes are equipped for the degradation of virtually all possible macromolecules, but efficient transport routes must exist to bring the material destined for degradation into the lysosomal compartment. This is established via different vesicular transport pathways. As depicted in Figure 7.28, a major degradation route starts with small vesicles, pinching off the plasma membrane, a process called endocytosis. This import pathway takes up material from the extracellular space, encapsulated in endocytic vesicles. Lipids and proteins of the plasma membrane themselves also take part in this passage to destruction. Transport to lysosomes is the classical way to remove membrane proteins and also membrane lipids. Just as in all other compartments, the lipids and proteins of the plasma membrane are subject to a continual replacement. Primary vesicles from the

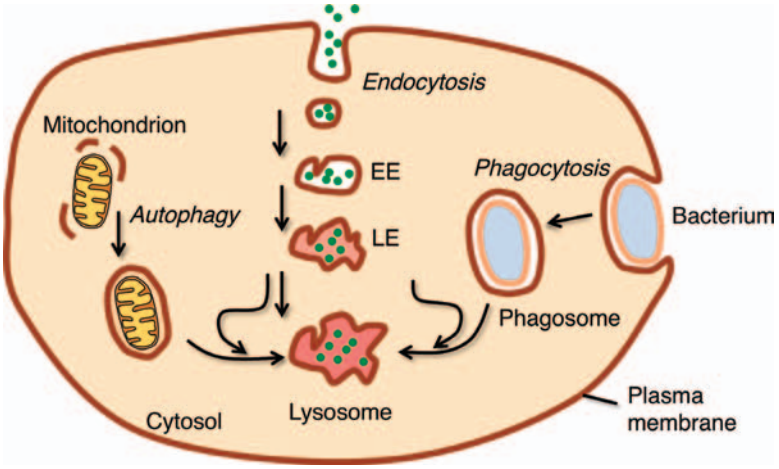

Figure 7.28 Lysosome traffic. Alternative pathways leading to degradation in lysosomes. Maturation of early endosomes (EEs) to late endosomes (LEs) and lysosomes is associated with a gradual reduction of the internal pH value.

plasma membrane will fuse with others and increase in size. In addition, vesicles coming from the Golgi complex will fuse to such *early endosomes* and bring lysosomal hydrolases. Endosomes are subject to a maturation process, during which the internal pH is decreased until the *late endosome* will finally have all characteristics of a lysosome. Another important pathway to degradation is the engulfment of bacteria or viruses at the plasma membrane. This process (*phagocytosis*) produces an internalized particle completely surrounded by a cellular membrane, the phagosome. These organelles can be fused to mature lysosomes and the content of the phagosome will be degraded. An analogous pathway starts at the ER membrane that eventually envelopes inner organelles, such as complete mitochondria or peroxisomes. This process (*autophagy*) allows for the complete renewal of cellular organelles over time. It is also a mechanism to gain new material for the cellular synthesis machinery in times of nutrition deprivation.

Transport of Hydrolases to Lysosomes The central role of lysosomes as the recycling site for all classes of molecules requires a continual replenishment of acid hydrolases to the lysosomal compartment. In contrast to peroxisomes and mitochondria, lysosomes do not possess a proprietary protein import machinery. Instead, lysosomes make use of the main protein traffic route, starting in the ER and proceeding through the Golgi complex (Figure 7.25). In the Golgi compartment, the fate of lysosomal proteins must differ from exported proteins or from resident proteins of the plasma membrane. In fact, so-called signal patches, short amino acid motifs on the protein surface, are recognized by the glycosylation machinery of the Golgi complex. As a result, *N*-linked oligosaccharides will be modified such that a mannose 6-phosphate (M6P) group is formed on the oligosaccharide tree. In the late stacks of the *trans*-Golgi network, membrane-resident receptor proteins bind this modified sugar with high affinity and thereby anchor the labeled hydrolases to the membrane.

In the *trans*-Golgi network, distinct types of vesicles are continually formed, one class of which is explicitly enriched in M6P receptor proteins. Hence the vesicles are loaded with various hydrolases marked with the M6P tag. After fusion to endosomes, the inner side of the vesicles becomes part of the endosomal lumen. Just like lysosomes, the endosomes are more acidic than the surrounding cytosol. Acidification is caused by the activity of proton ATPases in the endosomal membrane. As a result, the maturation process of vesicles to early and late endosomes is accompanied by a decrease in the internal pH. Interestingly, the affinity of M6P receptors to M6P is strictly regulated by pH. With lowered pH, this binding affinity decreases and the captured hydrolases are released to the lumen of late endosomes or lysosomes. Vesicles rich in M6P receptors are formed at the endosomal membrane. They bud off from the endosome to be relocated to the *trans*-Golgi stacks, ready to bind new target proteins at neutral pH.

7.2.1.8 **The Cytoskeleton**

The membrane bilayers surrounding the cell and its internal compartments are highly flexible and the actual shape of the cell and its compartments is not determined by the membrane but stabilized by a network of proteins. Underneath the plasma membrane, a dense protein meshwork defines the overall structure of the cell. Similarly, structural support of the nuclear membrane is provided by the underlying lamin network inside the nucleus. Cytoskeletal structures not only align with membranes, but also traverse the cytoplasm in all directions, thereby providing a scaffold to mount intracellular organelles such as mitochondria and peroxisomes. The contacts between organelles and the cytoskeleton are not static attachments, but motor proteins can drive a busy traffic along the cytoskeletal routes inside cells. Three major types of cytoskeletal protein structures can be recognized: *actin filaments*, *intermediate filaments*, and *microtubules*, in part distinguished by their characteristic diameters of 7, 10, and 25 nm, respectively. All three cytoskeletal components are aggregates of smaller subunits collectively forming extended, filamentous structures. In the case of actin filaments and microtubules, the basic structures have a globular shape, whereas intermediate filaments are formed as assemblies of extended, helical proteins. The cytoskeletal protein assemblies are stabilized without covalent bonds between the subunits, allowing the rapid association and dissociation of cytoskeletal structures. Three major functions can be attributed to the cytoskeleton:

1) structural stabilization of the cell
2) movements within the cell such as vesicle transport or the segregation of chromosomes during cell division
3) cell movements such as muscle contraction and cell migration.

Such diverse activities are possible because the cytoskeletal proteins provide binding platforms for a variety of more specific, associated proteins, including the molecular motor proteins.

Actin Filaments The actin filament is a two-stranded helical polymer with a diameter alternating between 5 and 9 nm (Figure 7.29). The basic subunit is the globular actin

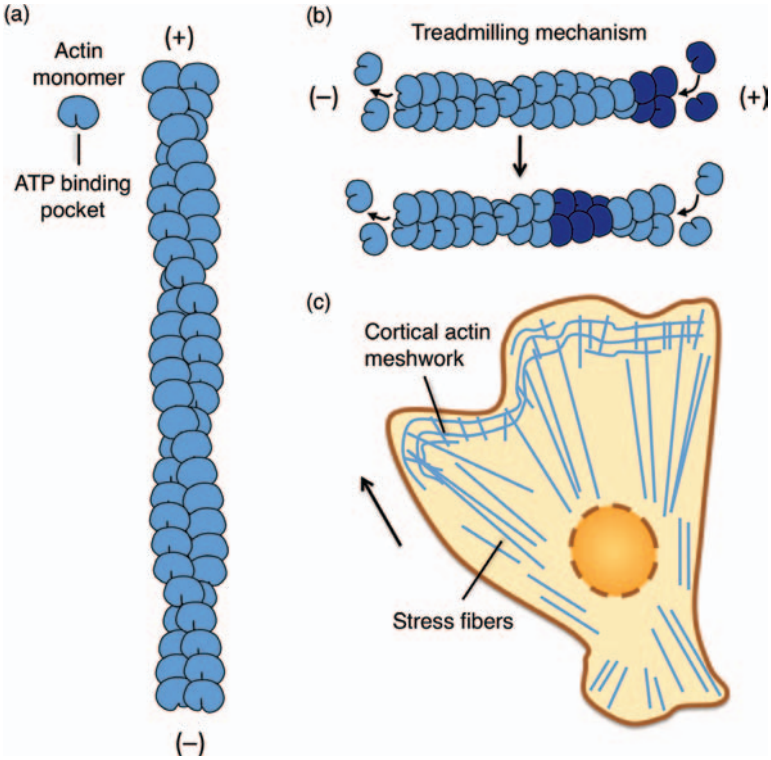

Figure 7.29 The actin cytoskeleton. (a) The two-stranded helical structure of actin microfilaments. (b) The actin filament turnover follows a treadmilling mechanism. (c) Typical subcellular localization of actin filaments in a migrating cell. The arrow indicates the direction of cell movement.

monomer (G-actin) that binds the energy-rich nucleotide ATP in a cleft on one side of the protein. Upon assembly of actin monomers into filaments (F-actin), all subunits align such that the ATP-binding cleft is directed to one side, the minus end of the filament. This gives polarity to the overall structure of the filament. After entry into the polymer, the bound ATP is hydrolyzed to ADP that stays bound in its binding pocket. As a consequence, a small conformational change in the actin molecule lowers its affinity for other actin subunits. Typically, ATP-carrying actins are added to the filament whereas ADP-bound actins have a tendency to leave the polymer structure. Assembly and disassembly can occur at both ends of the filament but the ratio of assembly to disassembly is higher at the plus end of the filaments such that actin filaments with two free ends will grow at their plus ends and shrink at the minus end. When both processes are in a steady state, the filament undergoes *treadmilling*, a mechanism that keeps the overall length of the polymer constant, while new subunits are constantly added at the plus end, move through the entire filament, and finally leave it at the minus end. Thus, existing actin filaments in the cell are not static but undergo constant reconstruction. When ADP-bound actin has left the

polymer, its nucleotide can be exchanged for ATP, and the subunit is ready for a new round through a filament.

The overall organization of actin filaments can vary with their localization in the cell and is determined by accessory cross-linking proteins. One group of such cross-linking proteins, including filamin, joins the actin filaments such that loose three-dimensional networks of gel-like consistency are formed. This is the typical appearance of the actin cytoskeleton in the cell cortex, the cytosolic region beneath the plasma membrane. Another group of actin-bundling proteins couples actin filaments in parallel arrangements. The so-called *stress fibers* are contractile actin bundles with antiparallel organization of the filaments. Stress fibers typically extend from the center of a cell towards the periphery and α-actinin is one of the major cross-linkers in these fibers. As determined by the dimensions of α-actinin, the lateral distances between the bundled actin filaments are about 30 nm. The ability of the stress fibers to contract is provided by myosin molecules, the typical motor proteins of actin filaments, which can bind between the loosely arranged α-actinin molecules. By contrast, parallel actin bundles formed by the cross-linking protein fimbrin are more densely packed with distances around 15 nm and they are not contractile. Such parallel bundles are typically found in a thin projection at the leading edge of a migrating cell, the so-called *filopodia*. Very regular parallel assemblies of 20–30 actin fibers can be formed by villin, another small bundling protein. These villin-linked bundles form the core of the microvilli, finger-like extensions of the plasma membrane with a length of about 1 μm and diameters around 80 nm. These very regular cell structures can largely expand the surface area of a cell. Microvilli are found on the apical side of many epithelial cells, for example, in the intestine, where the uptake of nutrients through the plasma membrane takes place.

Microtubules In contrast to actin, the building blocks forming microtubules are not homomeric, but heteromeric dimers of α-tubulin and β-tubulin (Figure 7.30). The polymeric structure formed from the tubulin dimers is a stiff, hollow cylinder formed from 13 protofilaments that are aligned in parallel. This cylinder with an outer diameter of 25 nm is stabilized by noncovalent contacts between heads and tails of the tubulin dimers in the longitudinal axis and by lateral contacts between tubulins in neighboring filament strings. These lateral bonds connecting the protofilaments are homotypic contacts between two α-tubulins or between two β-tubulins. Like actin filaments, the microtubule has a polarity defined by the orientation of its subunits. β-tubulins are exposed to the plus end of the tube, whereas α-tubulins mark the minus end. In principle, both ends of the microtubule can grow or shrink, but in the living cell all microtubules are fixed with their minus ends to the *microtubule-organizing center* (MTOC), an amorphous protein-rich structure in the vicinity of the nucleus. In animal cells the MTOC also harbors the centrioles, two barrel-shaped structures formed by nine triplets of microtubules. During cell division, the centrioles are involved in the formation of a microtubule spindle apparatus that separates the chromosomes between the two daughter cells. At the plus end of a microtubule, the type of nucleotide bound to β-tubulin determines growth or disassembly. Just like actin, both tubulins have a nucleotide binding site, but they bind GTP instead of ATP.

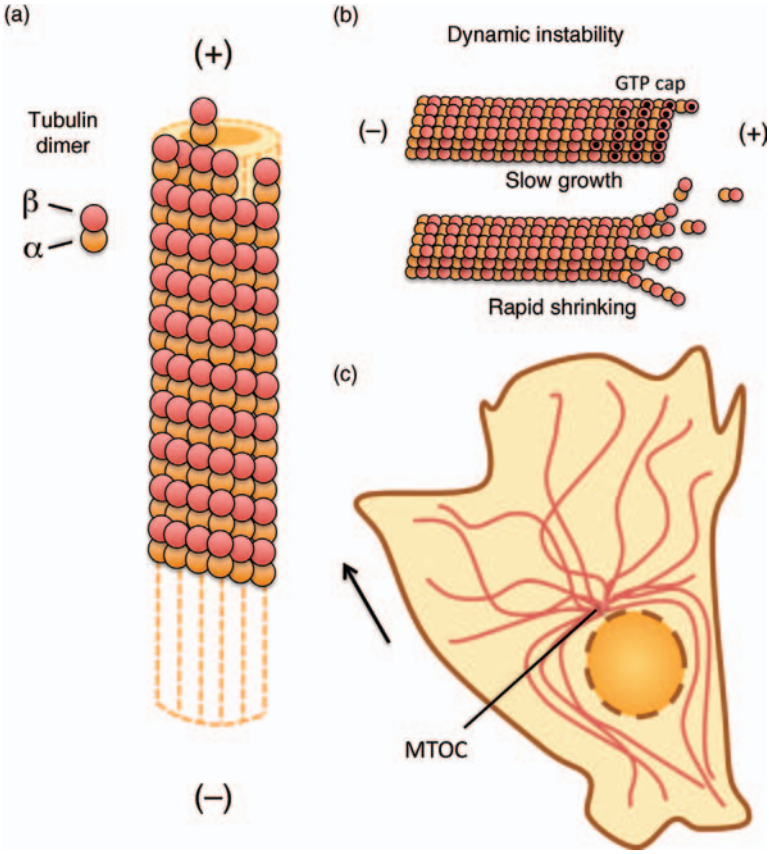

Figure 7.30 Microtubules. (a) Microtubules are long, hollow cylinders composed of 13 parallel protofilaments. The protofilaments are strings of tubulin dimers, each consisting of α-tubulin and β-tubulin. (b) Microtubule turnover is governed by dynamic instability of the plus end. GTP–tubulin dimers (with black dot on β-tubulin) stabilize the plus end of the microtubule. (c) Subcellular localization of microtubules in a migrating cell. All microtubules arise from the microtubule-organizing center (MTOC) near the front of the nucleus. The arrow indicates the direction of cell movement.

In the dimeric subunits, both tubulins are tightly connected such that the GTP bound to α-tubulin is trapped by the coupled β-tubulin and the nucleotide is neither released nor hydrolyzed. In contrast, GTP in the β-tubulin can be hydrolyzed to GDP. Similarly to actin filaments, this conversion of bound GTP to GDP is associated with a lowered binding affinity of the respective tubulin dimer. The turnover of microtubules is characterized by periods of slow growth typically alternating with shorter periods of very rapid disassembly, a mechanism called *dynamic instability*. During the growth periods, the addition of tubulin dimers with GTP-loaded β-tubulin exceeds the rate of GTP hydrolysis in the incorporated tubulin dimers. This results in the formation of a so-called GTP cap at the plus end, stabilizing the

overall structure. However, when the rate of dimer incorporation falls below the rate of GTP hydrolysis, the GTP cap is lost and rapid disassembly occurs. This abrupt shrinking process is enforced by the inherent tendency of GDP-containing filaments to assume a curved shape. Only upon more rapid association of new GTP-containing subunits is the microtubule rescued and the protofilaments are forced into a linear conformation.

Intermediate Filaments The third kind of cytoskeletal polymers are the intermediate filaments, a more heterogeneous group of polymer-forming proteins. Several families of filament proteins are known, but all share a similar central domain with a long α-helical secondary structure. These domains contain a series of 40 or more heptad repeat amino-acid motifs that stabilize the lateral assembly of coiled-coil dimers. These parallel-oriented coiled-coiled protein aggregates are the underlying building blocks of all intermediate filaments, which are formed as rope-like lateral assemblies of the long dimers. In a typical intermediate filament, the cross-section has a diameter of 10 nm and consists of 16 dimers, eight of them oriented in each direction. As already described, *lamins* are the typical components of the nuclear lamina that stabilizes the nuclear envelope beneath the inner nuclear membrane. The keratins are a large intermediate filament family of proteins found in epithelial cells and also in hair and nails. *Vimentin* and vimentin-like proteins are the typical intermediate filament proteins in all types of muscle cells. Three different *neurofilaments* are the main cytoskeletal intermediate filament component in neuronal axons. The neuronal intermediate filaments grow with the outgrowing axon and the thickness of the filament bundles determines the diameter of the axon.

7.2.1.9 Transport Vesicles, Exocytosis and Endocytosis

Transport Vesicles The membrane-enclosed organelles of a living cell are in constant communication with each other and soluble molecules and also lipids must be exchanged among the different compartments. Much of this transport is accomplished by vesicles, budding off one membrane and fusing with another membrane. Such vesicles can be diverse in diameter and shape; some are small and spherical whereas other vesicles have more irregular or tubular shapes. Despite this variability, transport vesicles can be grouped according to the coat proteins that form a cage-like structure when the vesicle buds off from the donor membrane. Coat proteins are required to shape the donor membrane such that a basket-like deformation of the membrane appears, which is finally pinched off as a closed vesicle (Figure 7.31). In addition to this mechanical function, the coat proteins help to assemble those membrane proteins in the deforming membrane patch that are to be incorporated into the vesicle. In turn, these membrane proteins can bind soluble proteins to pack them into the transport vesicle.

The assembly of coat proteins is not constitutive, but requires the binding of a GTPase with bound GTP. As already described for the Ran GTPase, the small GTPases exist in two conformations, the GTP-bound and the GDP-bound state. Thereby, the state of GTPases required for coat assembly provides a control

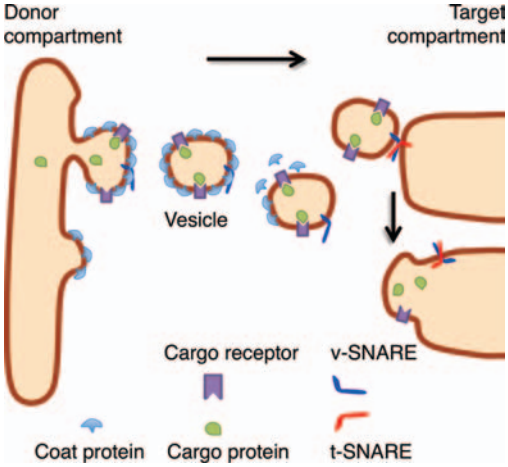

Figure 7.31 Intracellular vesicle transport. Vesicles budding from a donor have characteristic coat complexes. Cargo receptor proteins assemble proteins to be loaded into a budding vesicle. Specific binding and vesicle fusion to a target membrane depend on the matching interaction of vSNAREs and tSNARES on vesicle and target membrane, respectively.

mechanism to keep the membrane traffic balanced. Three major types of vesicles can be distinguished based on their coat protein complexes: the COP I-coated, COP II-coated, and clathrin-coated vesicles. COP II is the typical coat complex of vesicles in the anterograde transport from ER to the *cis*-Golgi network, whereas retrograde transport, for example, in the retrieval pathway from Golgi to ER, uses vesicles with COP I coats. The best-defined and most regular structure is found in clathrin-coated vesicles. Clathrin subunits are formed by three large and three small subunits assembled in a three-legged structure. These stable structures assemble with each other to form coated pits, and finally geometrically spherical structures consisting of hexagons and pentagons. This assembly shapes the donor membrane to form uniform vesicles. The final release of such vesicles requires the GTPase dynamin. Dynamin assembles around the neck of the budding vesicle and triggers its final release. Regardless of the type of vesicles, all have in common that the coats are removed after detachment from the donor membrane. Coat disassembly is triggered by the hydrolysis of GTP bound to the GTPase that previously had induced the assembly process. Loss of the vesicle coat is prerequisite for the later fusion of the vesicle with a target membrane.

Traffic Along Microtubules The movement of a vesicle between donor and target membrane is not random diffusion through the cytosol. This would be too slow for long-distance traffic, for example, along the axon of a peripheral nerve cell. The solution to this problem is a close connection of all vesicles to microtubules of the cytoskeleton, which are oriented with plus ends in the cell periphery and minus ends being attached to the MTOC in the vicinity of the nucleus. Docking of a vesicle to a microtubule not only provides direction but also, more importantly, allows active and

rapid transport. Two types of motor proteins link vesicles to a microtubule: kinesins, moving to the plus end of a microtubule, and dyneins, moving to the minus end. Thus, vesicles from the *trans*-Golgi network that are bound for the cell periphery will be linked to kinesin motor proteins. Each single step of such molecular motors is driven by the hydrolysis of one ATP molecule. The speed of this transport depends on the ATP concentration and on the presence of additional microtubule-associated proteins or other vesicles on the same microtubule. Under ideal conditions in a test tube, dyneins move at rates around 10 $\mu m\, s^{-1}$, whereas kinesins are somewhat slower with rates about 3 $\mu m\, s^{-1}$. In a cell with a diameter of 20–50 μm, this means that budding, transport, and fusion of a vesicle can be accomplished in just a few seconds. By contrast, transport along a neuronal axon can take a few days from a cell soma in the spinal cord to the periphery of the same neuron in a leg or arm.

Vesicle Fusion, SNARE Proteins, and Exocytosis Just like the formation of vesicles, the fusion of vesicles to their target membranes must also be controlled with respect to specificity and timing. Specificity is brought about by anchor proteins in the vesicle and in the target membrane, the SNAREs (soluble *N*-ethylmaleimide-sensitive-factor attachment receptors). This is a protein family with more than 20 members, sharing extended helical domains that can form intertwining complexes with the helix of another SNARE. The tSNAREs are anchored in a target membrane and vSNAREs are linked to the vesicle membrane. A vesicle carrying a certain type of vSNARE will only dock to a membrane equipped with a compatible type of tSNARE. If liposomes with matching SNAREs are mixed they will start to fuse. As SNAREs spontaneously form close complexes, the separation of two SNAREs requires energy input. In fact, the specialized ATPase NSF (*N*-ethylmaleimide-sensitive factor) can bind to SNARE complexes and unravel the intertwined helical domains at the expense of ATP hydrolysis. This mechanism allows SNAREs to be recycled and used for another fusion event. At the same time the activity of NSF defines the susceptibility of the target membrane for further vesicles. In a living cell, docking and fusion are distinct processes and in many cases a signal is required to initiate the final fusion of vesicles that are already docked by SNARE complexes. The classical signal to initiate the final tight contact between SNAREs is a sudden increase in the intracellular Ca^{2+} concentration in the close vicinity of the vesicles.

In the case of vesicle fusion to the plasma membrane, the consequence of the fusion event is that the vesicle content is secreted or released to the extracellular space. The specific term *exocytosis* is used to describe this type of fusion. One of the best-studied examples of exocytosis is the secretion of synaptic vesicles. Synapses are the contact sites between two nerve cells or between a nerve cell and a muscle cell. Importantly, the secretion of transmitters must follow the high frequency of electrical signals reaching the synapse (see Section 7.3.1.4). This could not be accomplished if vesicle transport along the microtubules were a rate-limiting step. To achieve extremely fast secretion, a pool of transmitter-loaded vesicles is usually docked to the presynaptic membrane, waiting for Ca^{2+} ions as a trigger for final membrane fusion and rapid transmitter release.

Endocytosis The term endocytosis describes the uptake of material from the extracellular space into the cell by vesicle formation at the plasma membrane. Three uptake mechanisms can be distinguished: *phagocytosis* describes the inclusion of particles into endocytic vesicles, *pinocytosis* is the uptake of fluids, and *receptor-mediated endocytosis* describes the uptake of specific molecules that are bound by receptor proteins in the plasma membrane. All three processes typically start with a small invagination of the plasma membrane extending to a deeper infolding that is finally released as vesicle into the cytosol. Depending on the size of the engulfed particle, phagocytosis vesicles can be large. Typically, the endocytosed vesicles, or *endosomes*, will be gradually converted to lysosomes through fusion with acidic vesicles, filled with lysosomal hydrolases (Figure 7.28). Similarly to phagocytosis, vesicles formed during pinocytosis can be variable in size. By contrast, receptor-mediated endocytosis is typically accomplished with vesicles of defined diameter. In the best-studied case, clathrin-dependent endocytosis, this vesicle diameter is about 100 nm. Clathrin is the typical coat protein of vesicles arising from the plasma membrane. Vesicles arising from clathrin-coated pits are enriched in transmembrane proteins with highly selective extracellular receptor domains. Ligand binding to the receptor proteins promotes their closer assembly and a deeper infolding of the pit. The exact shape of the vesicle formed is determined by the geometry of the surrounding clathrin structure. An important clathrin-*independent* endocytosis pathway is associated with lipid rafts, specialized cholesterol-rich areas, in the plasma membrane. In this case, vesicle formation requires incorporation of the protein caveolin into the vesicle membrane.

7.2.2 The Differentiated Cell

7.2.2.1 Cell Lineage and Tissue Types

In multicellular organisms, all individual cells have specific functions and, despite their largely identical genetic resources, mature cells differ in morphology and functionality according to their specific roles in the organism. A general principle of cell differentiation is that only a subset of the available genes is used in any given cell. In extreme cases such as red blood cells, the nucleus with the chromosomes is lost completely; the cell lives for a limited time without any further flow of information from the genome. However, specialization alone is not sufficient to form a viable organism. Importantly, the differentiated cells must act in a coordinated fashion and structural and/or functional contacts between cells are required to build up higher order structures, the tissues. Tissues are functional units of cells that interact closely and they typically contain more than one cell type. In higher organisms, different tissues can be organized together to form the individual organs. Despite a huge variability of tissues, three major classes can be distinguished according to the cell types and cell–cell contacts: *epithelial tissue*, *muscle tissue*, and *nervous tissue*. A fourth class of tissue is the "*connective tissue*," a commonly used term for all remaining types of cell clusters including bone cells, cartilage, and the various blood cells.

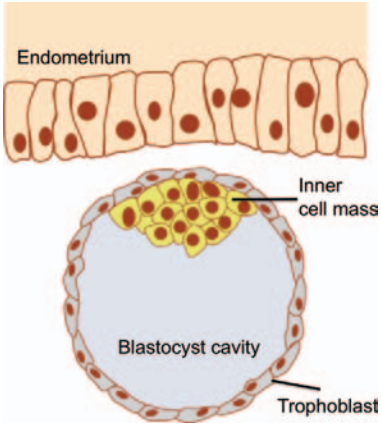

Figure 7.32 The blastocyst has two cell types. Schematic drawing of a mammalian blastocyst at an early stage of embryogenesis before nidation. The cells of the inner cell mass will later develop the embryo, whereas trophoblast cells are responsible for nutrition and contact with the endometrium.

Cell Lineage As multicellular organisms grow from a single cell – the fertilized egg or zygote – that cell must have the capacity to develop into all other cell types of the adult organism. This initial *totipotency* is lost when cells differentiate. For example, a normal keratinocyte of the skin does not retain the potential to form a muscle cell although the genetic information for the required proteins is still present in its chromosomes. The program of differentiation starts shortly after fertilization. During the first cell divisions, all cells have the same appearance and function but already at day five of the human embryogenesis two different cell types exist. In the blastocyst, a single layer of *trophoblast* cells surrounds a fluid-filled cavity and the inner cell mass (Figure 7.32).

This inner cell mass, or embryoblast, develops into the embryo, while the trophoblast provides nutrients to the embryo and will later form the placenta. The decision whether a cell becomes part of the inner cell mass or the trophoblast is the first differentiation step, and many more are to follow throughout the organism's life. At this stage, before implantation in the endometrium of the uterus, the blastocyst consists of about 150 cells. Figure 7.33 depicts the principle of serial decisions on the way from a totipotent cell to numerous terminally differentiated cells.

The full pattern of cell divisions that lead to a certain cell type is called *cell lineage*. To study the mechanisms underlying the decisions that drive a cell in one or another direction, scientists can isolate cells from the inner cell mass and apply different signals, such as hormones or growth factors, to these *embryonic stem cells*. The term stem cell indicates that a cell has on the one hand the potency for numerous divisions in an undifferentiated state (self-renewal), and on the other it is able to generate more differentiated cells. This differentiation is typically an asymmetric process: a stem cell divides into one new stem cell and one further differentiated cell. As a general principle, with every decision on the pathway of cell lineage the degree of potency is reduced. At an intermediate stage, *committed progenitor cells* still have the potential to

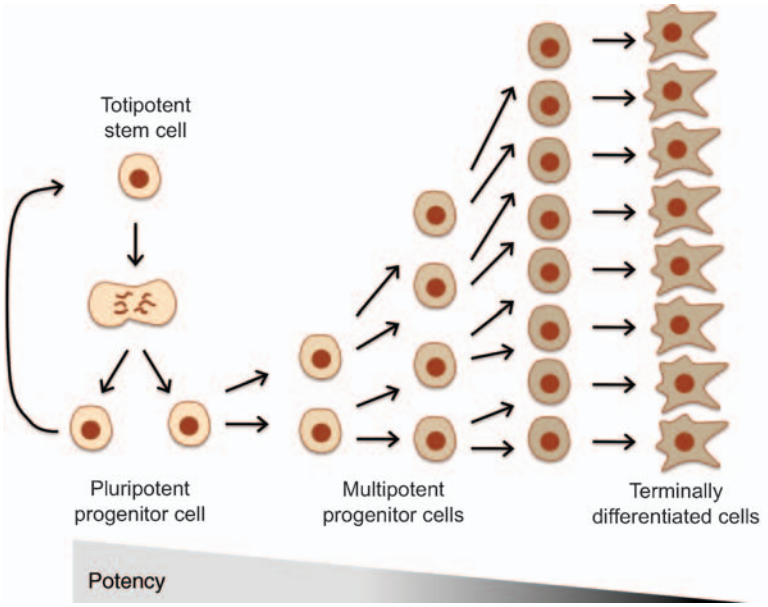

Figure 7.33 Cell differentiation. Progressive cell differentiation and loss of potency on cell lineage pathways from totipotent stem cells to terminally differentiated cells.

develop into more than one cell type, but they cannot generate cells of a completely different lineage that separated off at an earlier stage in the pathway of divisions.

Given this concept, adult organisms would have no potential to regenerate defect tissues, to heal wounds, or to create new cells, such as blood cells. It is now clear that *adult stem cells* with some residual potency of differentiation reside throughout life in specific niches of the adult organism. These cells are less potent than embryonic stem cells, but they can be progenitors for more than one type of terminally differentiated cell types. Adult stem cells are only a minor fraction of cells in a given tissue and they usually undergo very slow rounds of self-renewal during the lifetime of the organism. One of the challenges in regenerative medicine today is to develop a safe method to coerce terminally differentiated adult somatic cells into pluripotent stem cells, induced pluripotent stem (iPS) cells.

7.2.2.2 **Blood Cells**

The concept of stem cells and cell lineage was largely developed based on studies of blood cells and their continuous renewal. All cells in the blood have a limited lifetime, hence stem cells must exist to ensure the supply of new blood cells. Despite the clear differences in shape and function, all blood cells are derived from the same progenitors, the *hematopoietic stem cells*. Together with other types of stem cells, they are found in the bone marrow of large hollow bones. A simplified scheme of hematopoiesis is given in Figure 7.34. The multipotent hematopoietic stem cells divide at very low rates. The daughter cells can either be new self-renewing stem cells or committed hematopoietic progenitors. The latter cell type is still multipotent, but it

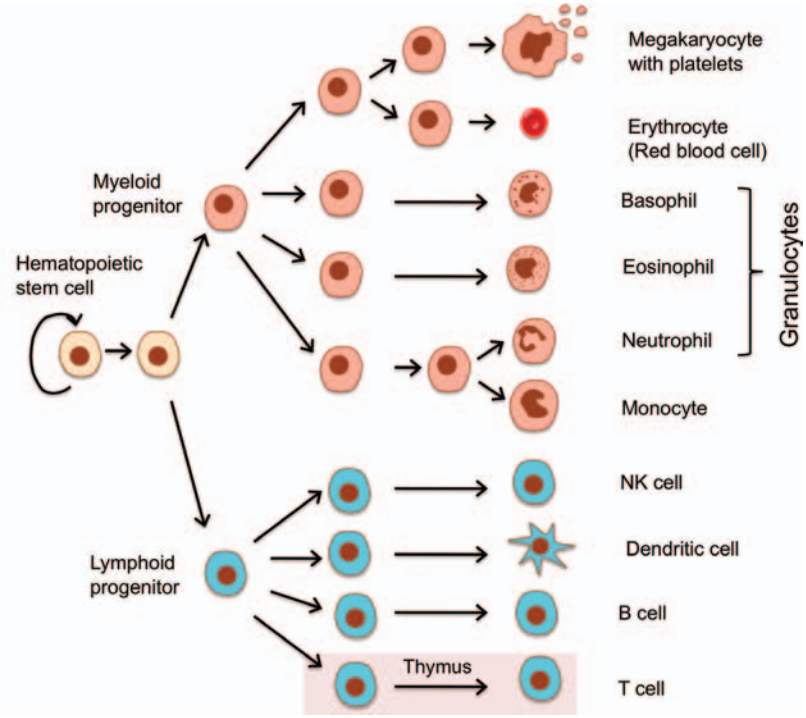

Figure 7.34 Hematopoiesis – development of blood cells. Simplified scheme of the lineage pathways leading from hematopoietic stem cells in the bone marrow to differentiated blood cells. Not all cell types circulating in the blood are represented.

has lost the self-renewing potency. At this point, descendants are committed to undergo either lymphoid or myeloid differentiation. The lymphoid line leads to four types of immune cells: natural killer (NK) cells, dendritic cells, B cells, and T cells. The myeloid line gives rise to erythrocytes (red blood cells), which are the most common blood cells, and among others, granulocytes, monocytes, and platelets. All blood cells other than erythrocytes and platelets are commonly termed white blood cells or leukocytes.

Erythrocytes With about $2–3 \times 10^{13}$ cells in the human adult, the erythrocytes comprise about one-quarter of the total body cell number and they are by far the most common cells in the blood. Corresponding to their role as oxygen transporters for all body organs, erythrocytes are packed with hemoglobin, making up more than 90% of the total protein content. This high concentration and the huge number of erythrocytes in all parts of the body make hemoglobin one of the major obstacles for biophotonic *in vivo* experiments or optical analysis of tissue samples. The mature erythrocyte is practically devoid of all of the normal cellular organelles such as a nucleus, ER, and mitochondria. A human erythrocyte is much smaller than most other cells, with a diameter of about 7 μm and a thickness of 2 μm. With the typical discoid shape, red blood cells can be squeezed through small capillaries of less than

half of their own diameter. The red blood cell is highly flexible and easily deformed but, due to a dense network of proteins lining the inner face of the plasma membrane, they immediately recover their discoid shape when the compression is relieved.

The average lifetime of human erythrocytes is 120 days, after which they are removed by macrophages in the spleen, liver, or bone marrow. The production of new erythrocytes in the bone marrow (erythropoiesis) is stimulated by erythropoietin (EPO), a glycoprotein hormone. EPO is produced by endothelial cells in the kidney and liver, a process that is regulated by the relative oxygen concentration. In the circulating blood, part of the EPO is always bound to erythrocytes, such that a reduced number of cells lead to more free EPO. This mechanism ensures tight coupling of erythropoiesis and removal of red blood cells. The process of erythropoiesis in the bone marrow takes about 8 days and follows the myeloid pathway of differentiation (Figure 7.34). During the first 5 days, the progenitor cells start to differentiate, but they also divide several times to increase the number of cells. After day five, the cells differentiate without further cell divisions. The last group of cells before reaching the mature erythrocyte is the reticulocyte, a cell without a nucleus derived from an erythroblast. Reticulocytes leave the bone marrow and circulate for one more day before maturation to an erythrocyte is complete. In the blood, these immature cells make up about 1% of the total red blood cells.

Leukocytes The white blood cells, or leukocytes, are part of the immune system. Leukocytes can be derived from both myeloid and lymphoid progenitor cells. *B cells* are the producers of antibodies, the primary weapon of the humoral immune response, whereas *T cells* have a central role in cell-mediated immunity. Notably, T cells do not mature in the bone marrow, but progenitor cells travel through the bloodstream to reach the thymus gland, where they expand to large populations of immature cells, the thymocytes. The mature T cells express distinct, individual T-cell receptors on their surface. T cells and B cells are part of the specific, *adaptive immune response*. By contrast, the NK cell, another descendant of the lymphoid lineage, is an important player of the *innate immune response* that provides the first line of defense against pathogens, before the slower adaptive system can react. Immune cells from the myeloid lineage comprise *monocytes* and *granulocytes*, the latter showing characteristic granules in their cytoplasm. Like NK cells, the neutrophil granulocytes are part of the innate immune system. Due to their segmented nuclei, they are also called polymorphnuclear cells. Neutrophils are distinguished from *eosinophil* and *basophil granulocytes* by a different staining behavior in cytological preparations. Monocytes are moving in the bloodstream, but they are still progenitor cells, responsible for the continuous supply of the antigen-presenting dendritic cells and macrophages, specialized phagocytic cells that engulf cellular debris and pathogens. At sites of infection, monocytes can also leave the bloodstream into the infected tissue, where they differentiate to resident macrophages or dendritic cells.

In contrast to the blood cells of the immune system, *platelets* (thrombocytes) have their unique function in the control of bleeding. When blood vessels are injured, collagen of the basement membrane becomes exposed to the blood and serves as a signal to activate platelets, which in turn secrete proinflammatory cytokines and the

platelet-derived growth factor (PDGF) that triggers new blood vessel formation. The platelets are also directly involved in wound closure, as they can form insoluble clots upon activation. With diameters around 3 μm, the platelets, without a nucleus, are the smallest cell type in blood. In fact, they are only small anucleated cell fragments of a much larger progenitor cell, the *megakaryocyte*. A constitutive release of platelets is important, as the average lifetime of the mature platelet in blood is only about 10 days. Megakaryocytes, from which platelets are derived, are huge cells with a diameter of up to 100 μm. During growth, they replicate their DNA several times without division of the cell.

7.2.2.3 Cell Contacts and Extracellular Matrix

Cellular contacts are crucial for the three-dimensional organization and integrity of tissues. The contacts involved in tissue formation follow common principles of architecture that are found throughout the human body. According to morphology and function, three major classes of such cell contacts can be distinguished: *communicating contacts*, *barrier contacts*, and *anchoring contacts*.

Gap Junctions Communicating contacts of mammalian cells are formed as symmetric assemblies of *connexin* proteins. The members of this multigene family share a uniform structure comprising four transmembrane segments. Six connexin proteins form the *connexon*, a hemichannel in the plasma membrane. Two hemichannels in membranes of neighboring cells can assemble to form a functional gap junction, bridging the cytoplasm of both cells. In this configuration, the two adjacent plasma membranes are separated by a distance of about 3 nm. This characteristic "gap" between the two cells is reflected in the name of this junction type (Figure 7.35).

Typically, gap junctions are clustered in regions up to 300 nm in diameter, the plaques. The hydrophilic pore in the center of each gap junction allows free diffusion of molecules with molecular weight up to 1000 Da. Hence both ions and small regulatory substances such as cyclic nucleotides can equilibrate between the

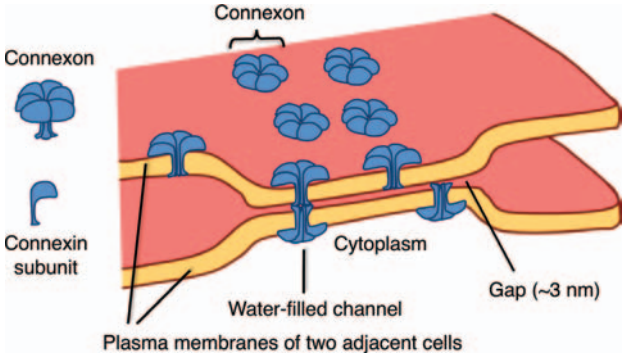

Figure 7.35 Gap junctions. Two adjacent plasma membranes connected by gap junctions. Connexons are hemichannels composed of six connexin proteins. Functional intercellular channels are formed by the connection of two adjacent hemichannels.

connected cells. Proteins and other large molecules are generally precluded from passage through gap junctions. However, gap junction channels are not simply size-exclusion filters. Individual differences in the selectivities of specific gap junctions are determined by the composition of the connexin proteins. A hemichannel can exist as a homomer formed of identical subunits, but heteromeric connexons are also widespread. Gap junctions can switch between open and closed configurations, but the exact gating mechanisms are not well understood. Apart from disassembly of both hemichannels, closure can also be triggered in the joined configuration, for example, by phosphorylation of critical amino acids in connexin subunits. Channel closure is also induced by high concentrations of intracellular Ca^{2+}, a signal that can eventually induce cell death and therefore must be prevented from spreading across the cell cluster. The exchange of small messenger molecules between cells has important physiological consequences. Groups of cells in a tissue can act as a synchronized functional unit. If only a few cells in a connected cluster are stimulated by a hormone, the whole cell cluster can respond in a coordinated fashion. In the same way, the flux of ions allows the electrical synchronization of cell clusters. In the heart, such electrical contacts between neighboring cells are of vital importance. Electrical impulses from the pacemaker region can spread rapidly from cell to cell as ions flow through the gap junctions, a prerequisite for the synchronous contraction of heart muscle cells (also see Section 7.3.1.4). Abnormal coupling of heart muscles can lead to a potentially deadly irregular heartbeat.

Tight Junctions In many epithelial tissues, a tightly sealed cell layer functions as a barrier precluding solutes from uncontrolled access to the underlying tissue. Classical examples are epithelial cells of the gut and the lung. In both cases, a space being in contact with the body's outer environment, for example, the intestinal lumen, is separated from inner tissues. Epithelial cells are organized like a well-laid mosaic with only small interstices between the individual cells. Nevertheless, the tiny space between neighboring plasma membranes would be sufficient to allow free access of small water-soluble molecules. The body would lose these molecules and, on the other hand, potentially harmful molecules, for example from the gut lumen, could enter the intercellular space of a tissue. Such an uncontrolled exchange is prevented by tight junctions that function as seals running all around the epithelial cells. In contrast to gap junctions, there is no space between the opposing membranes of two adjacent cells (Figure 7.36a).

The occluding tight-junction contacts typically contain two types of transmembrane proteins, claudins and occludins, both forming homomeric complexes with each other. These protein interactions bring the plasma membranes of two cells in close contact and seal the space between them. Whereas in some tissues the tight junction permeability is extremely low, in other tissue types the sealing property of the contact is less pronounced. These differences depend on the type of claudin proteins involved in the structure. Claudins form a family of closely related proteins with more than 20 members. Tight junctions not only serve as a diffusion barrier, but also define an important border between the upper (apical) and lower (basolateral) parts of epithelial cells.

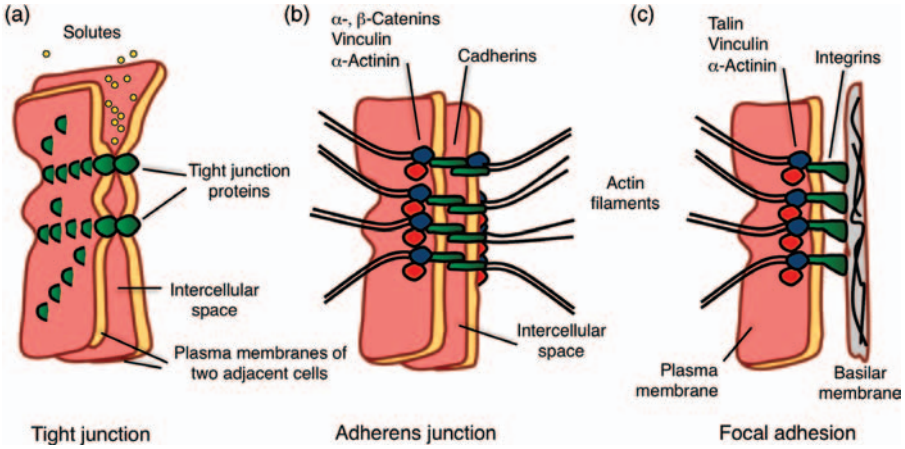

Figure 7.36 Tight junctions, adherens junctions, and focal adhesions. (a) Tight junctions seal the cell–cell contacts in epithelia. (b) Adherens junctions are based on homophilic interactions between cadherins in neighboring cells. In the cytosol, cadherins are linked via adapter proteins to the actin cytoskeleton. (c) Focal adhesions are integrin-mediated contacts of the cell membrane to proteins of the extracellular matrix, for example, the basilar membrane.

Anchoring Junctions Anchoring junctions can make contacts between two cells, and also contacts between a cell and proteins outside the cell, the *extracellular matrix*. In both cases the principle is the same, as contacts are made by a transmembrane protein that is itself connected to either actin filaments or intermediate filaments of the cytoskeleton. Figure 7.36 shows two junctions that are both connected to intracellular actin filaments, the *adherens junction* with cadherins as the binding component (b), and *focal adherens junction* with integrins as the binding transmembrane protein (c). Classical cadherins are single-pass transmembrane proteins, forming lateral dimers in the plasma membrane. The extracellular ends of such dimers make strong homophilic contacts with an identical cadherin dimer of a neighboring cell. These contacts depend on the presence of Ca^{2+}, keeping the extracellular cadherin domains in a rigid and extended conformation. Most classical cadherins are associated with catenins as cytosolic adapter proteins that link the complex to actin filaments. In epithelial cells, adherens junctions often form a belt-like ring around the cells, localized below the tight-junction ring. By contrast, the focal adhesions in epithelial cells are concentrated on the basal part of the membrane, where the extracellular domains of integrins bind to the underlying basilar membrane. In this way, the whole cell layer has a firm hold on the extracellular matrix. Similarly, muscle cells use focal adhesions to attach to their tendons. The muscle-specific integrin α7 is important for the attachment of muscle cells to laminins in the extracellular matrix. Genetic loss of this integrin is the molecular basis for a severe form of congenital muscle dystrophy. Integrins and cadherins can also couple to intermediate filaments instead of the actin cytoskeleton. The corresponding junc-

tions are called *desmosomes* for cadherin-mediated contacts between neighboring cells and *hemidesmosomes* for integrin contacts to extracellular matrix proteins.

Nonjunctional Adhesion Contacts Cell adhesions can manifest in microscopically distinct structures, but they can also occur without visible structures around the connected sites. Such "nonjunctional" adhesions are often involved in weaker, transient contacts between cells or between cells and matrix. Just like in junctional contacts, cadherins and integrins act as major binding proteins. Other transmembrane proteins forming nonjunctional adhesions are *selectins* and Ig-CAMs (*immunoglobulin-like cell adhesion molecules*). Selectins are single-pass transmembrane proteins with a "lectin" domain at the distal, extracellular end. Lectins are sugar-binding entities that can make specific contacts with oligosaccharides on other cells. Heterophilic contacts of this type are especially important for making initial contacts between blood cells and endothelial cells. L-selectins, found on leukocytes, mediate contacts with glycoproteins on endothelial cells and thereby facilitate the entry of blood cells into secondary lymphoid organs. On the other hand, endothelial cells can also express E-selectins in response to an inflammation and slow the movement of passing leukocytes. Supported by subsequent stronger contacts, the leukocytes finally come to a stop and squeeze between the endothelial cells to migrate into the infected tissue. The Ig-CAMs mediate Ca^{2+}-independent cell–cell contacts. A common feature of this protein class is the presence of one or more immunoglobulin domains in the extracellular part. Such domains, stabilized by disulfide bridges, are also characteristic of antibody molecules. In neurons, the expression of so-called N-CAMs is important for initial contacts with other neurons, especially during embryonic neural development. Interestingly, N-CAMs can also have opposing effects, preventing the contact with other cells. This is accomplished by modification of the N-CAM protein with long polysialic acid chains that hinder attachments between other adhesion molecules. Whereas N-CAMs typically form homophilic contacts, the *intercellular adhesion molecules* (ICAMs) use a heterophilic mechanism, for example, by binding to integrins on adjacent cells.

The Extracellular Matrix In higher multicellular organisms, the space between the cells is not just filled with liquid. In order to provide a tear-resistant structure, cells actively secrete a matrix that allows the cells to adhere and that provides orientation for the cellular assembly. The major constituents of the extracellular matrix (ECM) can be divided in two classes of molecules: (a) polysaccharides that can be covalently linked to proteins and (b) fibrous proteins, including collagen, fibronectin, and laminin. The ECM contributes significantly to the autofluorescence of human tissues because collagen and elastin are natural fluorophores with a high quantum yield.

Glycans of the ECM The typical glycans are highly hydrated and form a gel-like structure that resists compression but allows free diffusion of nutrients or hormones. The polysaccharide macromolecules are mostly formed as unbranched chains of 50 or more disaccharide repeats. As one of the sugars in the disaccharide units is always an amino sugar (e.g., *N*-acetylgalactosamine), these macromolecules are termed

glycosaminoglycans (GAGs) (see Section 7.1.3.1). The amino sugar moieties are in most cases sulfated, resulting in a highly negative charge of the long chains. *Hyaluronan* is a simple type of GAG that lacks sulfation. With a length of up to 25 000 disaccharides per chain, it is one of the largest molecules in the body. Hyaluronan is found in most body fluids and serves as a lubricant in the joints. Most other GAGs are proteoglycans, with covalently linked core proteins. These GAGs are assembled in the Golgi apparatus, where a tetrasaccharide is first linked to a serine residue of the protein. The sugar chain is then extended with the typical disaccharides by serial activities of glycosyltransferases in the Golgi compartment and later secreted through exocytosis. In contrast to secreted glycoproteins, the carbohydrate content of the end product can exceed the molecular weight of the core protein by up to 20-fold. Once a proteoglycan is secreted, it can associate with other GAGs to form huge polymeric complexes with dimensions of several micrometers.

Proteins of the ECM The most abundant proteins in the human body are the collagens, members of a family of fibrous molecules. They can assemble to form stiff, rope-like structures that further polymerize to extended fibrils, for example, in skin, cartilage, or blood vessels. Collagen fibrils are typically grouped in bundles of 2 μm or more in diameter. In the tissue, such bundles are arranged as banded patterns with high periodicity. This has an important consequence for the analysis of skin and other collagen-rich tissues with optical methods because the periodic fluctuation of the refractive index in collagen aggregates causes intense Rayleigh scattering in mammalian tissue. Collagen is also a major source of autofluorescence, with an emission maximum of about 380 nm. Collagen proteins are secreted via the secretory pathway involving ER and Golgi complexes (Figure 7.37). In the Golgi lumen, proline and lysine residues in the protein chains are hydroxylated to form hydroxyproline and hydroxylysine. These modified polypeptides assemble to form triple-stranded helical molecules that are stabilized by interchain hydrogen bonds between the hydroxylated amino acids. Following secretion of the procollagen, the triple helices are further modified. Residues at the N- and C-terminal ends of each polypeptide chain are cleaved off by exoproteases and procollagen modules assemble to larger fibrils. The stability of the fibrils is greatly increased by covalent cross-links between lysine residues. Unlike the collagens, fibronectin, another major protein of the ECM, does not self-assemble into fibrils. On the surface of a cell, however, fibril formation can be induced by contacts to integrins in the plasma membrane. The salient structure of fibronectin is a dimer built of two glycoprotein chains that are linked by disulfide bonds at one end of the dimer.

Elastin, another ECM protein, is the main component of elastic fibers in connective tissues. In contrast with collagens and fibronectin, elastin is not glycosylated. The polypeptide chain comprises hydrophobic segments that are interspersed with alanine- and lysine-rich α-helical segments. The hydrophobic elements are important for the elastic properties, whereas the α-helical segments are required to cross-link elastin monomers into larger networks. Elastin is also an important endogenous fluorophore in tissue with an emission peak around 410 nm.

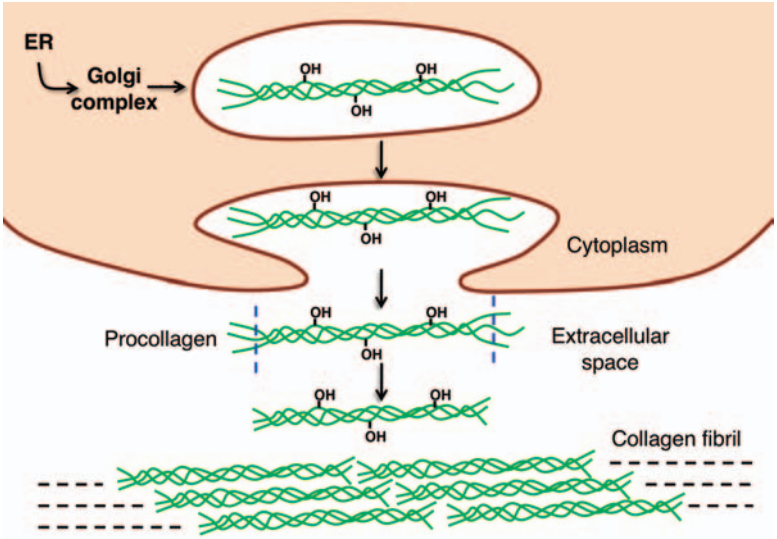

Figure 7.37 Synthesis of collagen fibrils of the extracellular matrix. Triple helices of collagen are formed in the Golgi complex and secreted through vesicles. Proline and lysine residues are hydroxylated and form hydrogen bonds that help to stabilize the triple-stranded helix. Following export, the propeptides are proteolytically shortened on both ends and triple helices assemble into large fibrils. Hydroxylation of polypeptide chains in the final fibril is not shown for simplicity.

7.2.2.4 **Epithelial Cells**

The cells lining the inner or outer surfaces of the body form *epithelial tissues*. The common characteristics of this tissue type are the presence of a lumen-exposed surface on one side and of a basement membrane on the other side. The functions of epithelia can differ markedly, but they always act as barriers, separating underlying tissues from the environment or from an internal lumen. Hence epithelial cells are functionally contiguous with one another and the intercellular space between them is very limited.

All glandular organs such as the salivary gland, sweat glands, and liver contain epithelial cells and all ducts and tubes of the body are lined by epithelia. The epithelium forming the inner surface of the blood vessels is usually called the *endothelium*. With a total number of about 10^{13}, endothelial cells are one of the most abundant cell types in the human body. Tight junctions are important connections between epithelia cells, but additional contacts, such as adherens junctions or gap junctions, are also established. Depending on the density of the tight junctions and the exact protein composition therein, some epithelia are completely impermeable whereas others may not act as a tight barrier.

Some epithelia are responsible for the uptake of material from the environment, such as the intestinal epithelium. Other epithelia, especially those in glands, function to secrete their own products such as hormones, sweat, or breast milk.

The overall structure of an epithelium differs depending on the number of layers that it contains. In the *simple epithelium*, all cells are arranged in a single layer. If two or

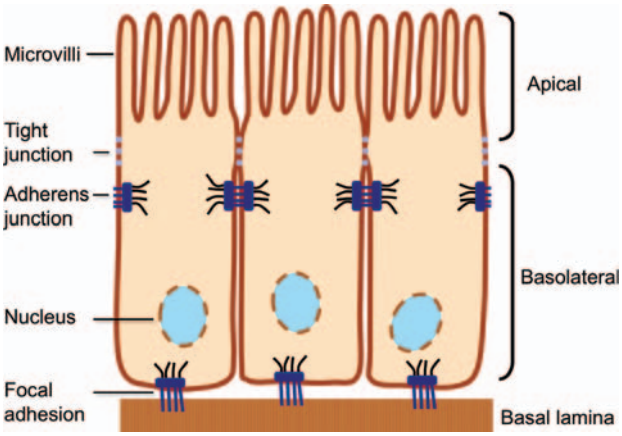

Figure 7.38 A simple columnar epithelium. The cells have a clear polarity, with an apical side and a basolateral side, being separated by tight junctions. An epithelium of this type covers the surface of the small intestine, where the apical surface area of the cells is increased by microvilli, reaching into the intestinal lumen. On the basal side, the cells are anchored to the upper layer of the basement membrane, the basal lamina.

more cellular layers are formed, the epithelium is called *stratified*. A *squamous* simple epithelium consists of a single layer of flat-shaped cells. Typical examples are the lung alveolar epithelium or the blood vessel endothelium. An epithelium is *cuboidal* if the cells are nearly equal in width and height, as found in many kidney tubules. Figure 7.38 shows a *simple columnar epithelium*, characterized by single-layered epithelial cells with a cell height clearly exceeding the width. The densely packed microvilli on the apical surface are typical of the epithelia of the small and large intestine. The enlarged cell surface allows the mass transport of nutrients across the barrier. The structure of these cell extensions is determined by parallel bundles of about 25 actin filaments. The densely packed microvilli have very regular diameters of around 100 nm, hence they are not optically resolved by conventional light microscopy. Owing to a fuzzy appearance in the light microscope, the zone of the microvilli has been termed the brush border.

Stratified epithelia are formed by more than one cellular layer. In many glands, such as mammary glands or salivary glands, the basal layer is formed by actin-rich contractile cells, the myoepithelial cells. Other cells that produce the specific secretory product are arranged in layers on top of these cells. Contraction of the myoepithelial cells then allows the active secretion of the glandular products. The terminology for epithelia comprising more than one cell type in different layers follows the pattern of the outermost layer. Accordingly, the epidermis of the skin is called a stratified squamous epithelium because the outermost cells have squamous shape, whereas cells in the basal layer are cuboidal.

The epidermis is a good example of the continuous renewal processes in many tissues, involving cell differentiation, morphology changes, and terminal cell death. A simplified cartoon of the epidermal cell layers is shown in Figure 7.39. The

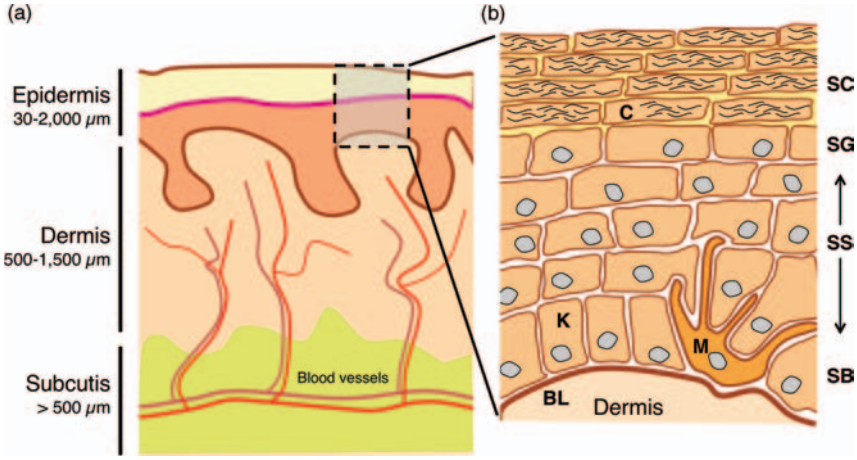

Figure 7.39 Schematic drawing of the epidermis (b) and its location in the skin (a). The epidermis forms the outermost layer of the human body. It is separated from the underlying dermis and by a basal lamina (BL). Keratinocytes (K) are organized in the layers *stratum basale* (SB), *stratum spinosum* (SS), and *stratum granulosum* (SG). The *stratum corneum* (SG) is made of terminally differentiated keratinocytes. These corneocytes (C) are dead cells without a nucleus. They are filled with keratin and embedded in a lipid-rich matrix. Melanocytes (M) are interspersed in the *stratum basale*, where they produce the pigment melanin that is transferred to keratinocytes.

dominant cell type of this epithelium is the keratinocyte. The cuboidal keratinocytes in the lowest layer are in contact with the basal lamina and they continually divide to renew the cell layers above. One of the two daughter cells will remain in the basal layer, whereas the other descendant moves upwards into the stratum spinosum. On their migration through this layer, the cells begin to flatten and to produce keratin, an insoluble intermediate filament protein. In the thin granular layer, or stratum granulosum, the keratinocytes contain visible granules filled with the intermediate filament protein keratohyalin. In the outermost layer, the keratinocytes become corneocytes, anucleated flattened cells surrounded by a dense layer of lipids. This is the final differentiation stage that a keratinocyte reaches about 5 weeks after its "birth" in the basal layer. The highly enriched keratin in the interior of these cells gives the epidermis mechanical stability. The secreted "cement" around the cells is made of lipids such as ceramides, cholesterol, and fatty acids. With these substances the stratum corneum makes an effective barrier against water and all soluble substances. In the outermost cell layers of the horny part of the epidermis, the stratum corneum, the cells start to weaken their cell–cell contacts, so that they are continually lost during washing and rubbing.

There are additional cell types residing in the skin. A dense layer of bacteria lives between the loosely connected outermost cells and feeds on the cell debris and the lipids. About 1000 bacteria per square millimeter find their natural habitat here. In the deeper layers of the epidermis, immune cells (*Langerhans cells*) patrol between the keratinocytes. Merkel cells are mechanoreceptor cells in the basal layer that are

connected to sensory nerve endings. Together with the nerve cell, they function as touch sensors of the skin, responsible for the sensation of gentle touch and the discrimination of shapes and textures. Another prominent cell of the basal layer is the pigment-producing *melanocyte*. The skin pigment melanin is stored and transported in the melanosomes, specialized vesicular organelles similar to the ubiquitous lysosomes. The melanosomes are transported along dendritic processes of the melanocyte from which they are finally released to be taken up by connected keratinocytes. The melanocytes comprise less than 10% of the cells in the basal layer of the epidermis. The skin color is not determined by the number of melanocytes in the skin, but rather by the amount of melanin they produce and transfer to the neighboring keratinocytes.

The Basal Lamina All epithelia are separated from underlying stroma by a dense network structure with a thickness between 30 and 120 nm, the *basal lamina*. A similar extracellular matrix structure is wrapped around muscle cells, separating them from connective tissue. The major protein components of the basal laminae are type IV collagen and laminins. Laminins are glycoproteins with the inherent ability to self-assemble as trimeric complexes with a cross-like structure. The long arm of the cross can be used to anchor cells, whereas the three shorter arms are connected to other components of the basal lamina. Ultrastructurally, the basal lamina can be divided into a lighter upper zone (*lamina lucida*) and an electron-dense lower layer, called the *lamina densa*. The latter is tethered to an underlying thick layer of collagen fibrils. This whole arrangement is usually called the *basement membrane*. Basal laminae are more than a structural foundation that anchors epithelia or muscle tissue. They also influence the connected cells, induce polarity, and promote cell survival and proliferation.

7.2.2.5 Nerve Cells and Glial Cells

The nervous tissue is built of two very different cell types: *neurons* and *glial cells*. Neurons, or nerve cells, are the electrically excitable cells of the nervous tissue, responsible for the propagation of electrical signals through the body. The major functions of glial cells are to accompany neurons, provide physical support, buffer ions, and supply nutrients and oxygen. In the human brain, both cell types are found in an approximate 1:1 ratio.

The human body contains nervous tissue in three functional entities: the brain, the spinal chord, and the *peripheral nervous system* (PNS). The first two are also called the *central nervous system* (CNS). They have in common that nerve cells are concentrated at high densities and that a bone structure provides mechanical protection, whereas the *blood–brain barrier* shields the nerve cells from chemical threats. This barrier is constituted by the endothelial cells in the CNS vessels tightly controlling the exchange of soluble molecules between the cerebrospinal fluid surrounding the nerve cells and blood. Endothelial cells in the CNS are connected by tight junctions that almost completely restrict the passage of solutes, whereas hydrophobic hormones and also O_2 and CO_2 can pass. Entry of soluble molecules, including glucose as the major source of energy, depends closely on transmembrane

transporters in the plasma membrane of endothelial cells. The blood–brain barrier represents an important factor in the design of therapeutic agents; those designed to treat the brain must pass the blood–brain barrier easily whereas those destined for other tissues should not pass the barrier.

The PNS resides mainly outside this protected area because it connects the CNS with all inner organs, the limbs, and the skin. Two types of directional nerves accomplish this connection. Neurons of the *afferent* nerves relay information from the periphery to the CNS, and *efferent* neurons deliver signals from the CNS to effector organs, glands, and muscles. The PNS can be further divided into the *autonomic nervous system* and *somatic nervous system*. The former controls all functions of the body that are not under deliberate, conscious control, such as heart rate, respiration rate, digestion, and many others. The tissues controlled by the autonomic nervous system are smooth muscles, cardiac muscle, and glandular tissues. By contrast, skeletal muscles are controlled by the somatic nervous system. The efferent fibers of this system transmit signals from the CNS to the skeletal muscles and allow the voluntary control of muscle activity. Afferent fibers of the somatic nervous system deliver signals from peripheral sensory neurons to the CNS.

Nerve Cells Neurons come in very different sizes and shapes, but a unifying morphological feature, applicable to most of them, is a composition of three functional units, namely cell body (soma), axon, and the dendrites. This basic structure is depicted in Figure 7.40. The soma contains the nucleus and most of

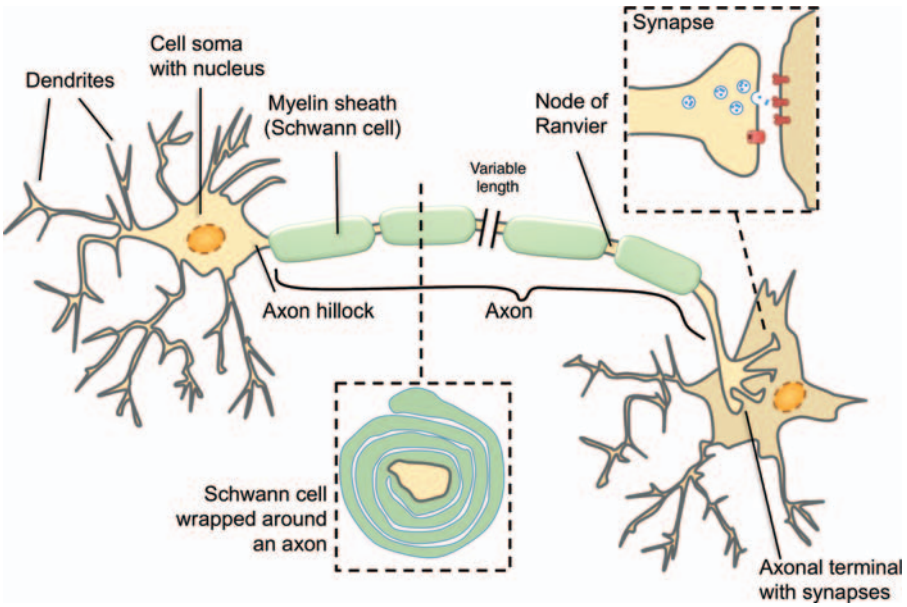

Figure 7.40 Basic structure of a neuron with a myelinated axon. The magnified sections show cross-sections through the axon with the myelin sheath and a synaptic contact.

the cellular synthesis takes place here. Hence proteins or neurotransmitters produced in the soma need to be transported into dendrites and into the axon. This long-distance traffic is accomplished as active transport of vesicles along microtubules.

The dendrites are cellular extensions that often resemble the branching pattern of a tree. For most neurons, the dendrites are the major entrance sites for incoming electrical signals. They are docking platforms for the synapses from other neurons and deliver the signal further down to the soma. In addition, incoming synapses can also be connected to the plasma membrane of the soma itself.

The axon is a long extension of the nerve cell that transmits the electrical signals, often over long distances. The axon hillock, an area at the beginning of an axon, is densely packed with voltage-gated sodium channels enabling the cell to generate action potentials or nerve impulses, the electric information unit of a neuron (see Section 7.3.1). Two main types of axons can be distinguished, the fast-conducting myelinated axons and slow-conducting non-myelinated axons. The myelin sheath is wrapped around the axon, except at the nodes of Ranvier. The myelin layer is formed by closely attached glial cells; in the PNS these are Schwann cells and in the CNS oligodendrocytes. At contact sites to the axon, the membrane of the glial cell grows continuously until several layers of plasma membrane are concentrically wrapped around the axon. In the final state, these membrane layers are tightly packed with no cytoplasmic content lying in between. In contrast to most plasma membranes, the bilayers in myelin sheaths are enriched in lipids, with a lipid-to-protein ratio of about four. The main function of the myelin layer is to provide electrical insulation for the axon, analogous to the plastic insulation of a power cable. It increases the electrical resistance across the axon membrane more than 1000-fold and strongly reduces the electrical capacitance. As a consequence, myelinated axons can conduct electrical impulses about 50 times faster than non-myelinated axons of the same diameter. Slowly conducting nerve fibers without myelin sheath are typically found in the autonomic nervous system. For the continuous control of functions such as heart rate and digestion, the speed of electrical signal transmission is not critical and myelination is dispensable. By contrast, skeletal muscles are innervated by myelinated axons of the somatic nervous system to allow fast responses.

Glial Cells Schwann cells and oligodendrocytes forming the myelin sheath in the PNS and CNS, respectively, belong to the *macroglial cells*. The largest fraction of macroglia in the CNS are the star-shaped *astrocytes*. Cells of this type have a direct role in the formation of the blood–brain barrier as they form tight complexes with endothelial cells of the capillaries. Importantly, the functions of astrocytes are not restricted to the passive support of neurons. More recently, it became evident that astrocytes may participate directly in neurotransmission by releasing neurotransmitters such as glutamate. Linked by gap junctions, astrocytes can form large syncytial complexes and Ca^{2+} flux along these connected cells can trigger the release of neurotransmitters. Additionally, astrocytes are also involved in the reuptake and clearance of neurotransmitters. In the PNS, satellite cells play a similar role. Like astrocytes, they can form complexes that are interconnected by gap junctions and Ca^{2+} waves can travel along such cell complexes. Various functions are adopted by

microglia cells, in both the PNS and CNS. This cell type comprises mobile cells that are capable of phagocytosis and they provide the main immune defense of the CNS. Microglia cells do not descend from neural progenitor cells like neurons and other glial cells, but they are derived from precursor cells in the bone marrow and travel into the CNS.

7.2.2.6 **Muscle Cells**

Muscles convert chemical energy from ATP into mechanical energy, causing the movement of organs within the organism or motion of the whole organism. The fundamental unit of a muscle is the muscle cell with a contractile machinery formed by actin and myosin filaments. This section is focused on morphology and specific properties of these cells. Regardless of the type of muscle cell, repeated conformational changes of myosin proteins cause the myosin filaments to slide along actin filaments, such that the overall protein assembly and the muscle cell itself are shortened. In contrast, the relaxation and stretching of muscle cells are passive processes. Three types of muscle cells can be distinguished based on tissue organization and function: *smooth muscle* cells, *skeletal muscle* cells, and *cardiac muscle* cells (Figure 7.41). Like neurons, many muscle cells have excitable plasma membranes to generate and propagate action potentials. The plasma membrane of the muscle cells is commonly termed *sarcolemma*.

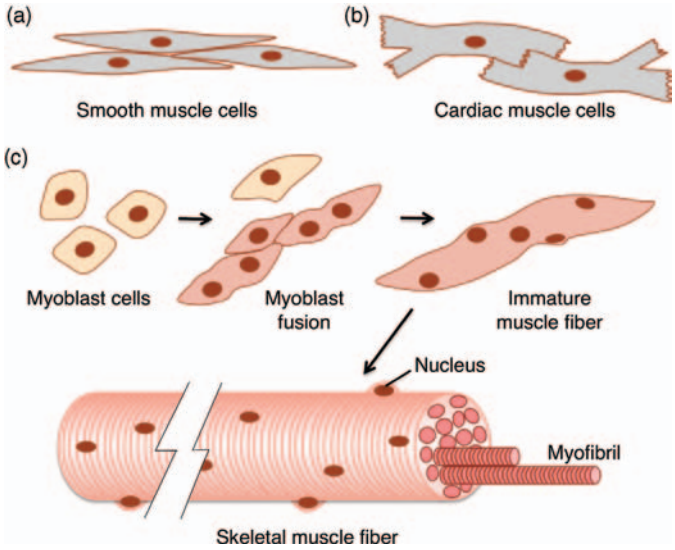

Figure 7.41 Three types of muscle cells. (a) Smooth muscle and (b) cardiac muscle tissues consist of single contractile cells. Cardiac cells can be branched; they are tightly connected to neighboring cells at the undulated blunt ends. (c) Skeletal muscles consist of large polynucleated cells (muscle fibers) generated by fusion of progenitor cells (myoblasts). The assembly of myosin and actin filaments in myofibrils causes a striped (striated) appearance of skeletal muscle fibers.

Smooth Muscle Cells Smooth muscles consist of spindle-shaped cells (Figure 7.41a) with a length ranging from 10 μm in artery walls to 600 μm in the uterus during pregnancy. Consistent with their involvement in involuntary contraction, smooth muscles are innervated through the autonomous nervous system. In multi-unit muscles, innervation is directed to individual, functionally independent muscle cells. In single-unit smooth muscle, for example in the intestinal walls, the cells are connected by gap junctions. This allows electrical contact and concerted contractions of a larger cluster. Such muscle cell clusters contract spontaneously if stretched. In the cytoplasm of smooth muscle cells, bundles of actin filament are arranged such that one end of the bundle is fixed to *dense bodies* in the cytoplasm, while the other end is connected to a second actin bundle via intercalating myosin filaments. Repeated sets of this structure are coupled in long chains (*myofibrils*) through the whole cytoplasm of the cells. On the surface of the plasma membrane, these myofibrils are fixed to *attachment plaques*. As the repeating structures in the myofibrils are not aligned between neighboring cells, the overall appearance of the tissue is smooth and not striped as in skeletal muscle cells. The contraction of smooth muscle cells is slower than in skeletal muscle, but the contracted state can be much more sustained.

Skeletal Muscle Cells Skeletal muscles consist of cylindrical-shaped muscle fibers with an average length of 1–3 cm and diameters ranging from 10 to 100 μm. The longest fibers of about 30 cm are found in the sartorius muscle that runs down the thigh. Each muscle fiber is a huge cell with many nuclei, originating from the fusion of committed progenitor cells, the myoblasts (Figure 7.41c). In the mature muscle fiber, the individual nuclei are located underneath the sarcolemma. The outer surface of the sarcolemma is covered with a thin and flexible layer of collagens and polyglycans. Importantly, the cytoplasmic protein dystrophin is a central part of a protein complex that connects the cytoskeleton through the membrane to the surrounding extracellular matrix. Mutation or loss of dystrophin causes Duchenne muscular dystrophy, a severe and eventually lethal disease. The fusion of myoblasts occurs both during development and throughout adulthood when muscles grow or need regeneration. In the adult muscle, small *satellite* cells are closely attached to the muscle fibers. They represent persistent myoblasts that are needed to regenerate the multinucleated muscle fibers after damage. The innervation of skeletal muscle cells comes from the somatic nervous system and allows voluntary control of muscle contractions.

As in smooth muscle, the basic unit of skeletal muscle contraction is the myofibril. In the cytoplasm of skeletal muscle cells, these long bundles of actin and myosin filaments are organized in parallel, such that the muscle fiber has a striped or *striated* appearance. Each stripe is formed from two sets of actin filaments and an intercalated set of myosin filaments. The outer ends of the actin proteins are fixed at the Z-discs. Contraction is brought about by a sliding filament mechanism in which the myosin filaments move deeper between the actin filaments. In the relaxed muscle, each sarcomere has a length of approximately 3 μm, whereas contracted sarcomeres are on average 1.5 μm long. As an important specialization of the skeletal muscle cell, the ER, here called SR, is organized as an envelope around each of the myofibrils. The SR

structure does not form a tight seal around the filaments, but rather looks like a curtain with many holes. The purpose of the SR is to store and quickly release Ca^{2+} ions in response to excitation and Ca^{2+} ions are the trigger for the sliding movement of myosin filaments.

Cardiac Muscle Cells Cardiac muscle cells (*cardiomyocytes*) are not fused (Figure 7.41b), but with close end-to-end connections each cell acts like a block in a tightly assembled pavement. The mature tissue has no prominent progenitor cell population like the satellite cells of skeletal muscle and cardiac muscle tissue hardly regenerates after injuries and cell death. However, more recent evidence suggests that some cardiac progenitor cells exist even in adult tissue. Given the high mortality rates caused by myocardial infarction, there is a strong research interest in cardiac stem cells, but the therapeutic potential awaits further clarification. The contractile machinery of cardiomyocytes follows a similar building plan as in skeletal muscle, although the cells are not fused. The myofibrils are also striated with repeated modules of actin and myosin filaments between Z-discs. At the cell membrane the filaments end in *intercalated discs* instead of a Z-disc. At these blunt ends, each cardiomyocyte is closely connected to the next cardiomyocyte, forming a system of functionally coordinated cells. The inner cell architecture and the SR also resemble the skeletal muscle, but only one set of T-tubules is found per sarcomere. The cardiac muscle is not under voluntary control as it is innervated by the autonomous nervous system.

7.2.3 The Biological Diversity of Cells

7.2.3.1 Biological Diversity and Taxonomy

All living cells share principal structures such as DNA, proteins, or lipid bilayers; the life of all cells involves common principles such as the universal genetic code or the use of energy-rich ATP to drive enzyme reactions. However, based on this common ground, over some billions of years evolution has generated an enormous diversity of cells and organisms and it is obvious that bacteria, single-celled algae, and mammalian cells differ significantly in many of their cellular structures and biochemical properties. In consequence, experiments with biological samples from different organisms require at least some knowledge of the specific properties of the object under study and of the phylogenetic relations between different species.

It is a common practice to employ model organisms for the investigation of biological principles that can be extrapolated to other organisms of interest. This can have practical or ethical reasons, for example, the genome of a mouse can be specifically altered to study gene function with relevance for other mammals including humans. However, every model has its limitations and transfer of knowledge from one organism to another requires great caution. For example, the bacterium *E. coli* is routinely used to propagate and manipulate human DNA, but it is important to remember that bacterial cells have no nucleus and, hence, human gene regulation cannot be studied easily in this model organism.

This section cannot provide a comprehensive introduction to biological diversity, rather it is aimed at giving a first insight into the major classes of organisms and at highlighting phylogenetic relationships between them.

Taxonomy Taxonomy is the science of classification of living beings. The modern system of scientific classification aims for an unbiased representation of the phylogenetic relatedness between species, regardless of superficial analogies in the outer appearance. Based on its position in the classification system, every species then derives its unambiguous scientific name. The so-called *binomial nomenclature* system for organisms dates back to Carl Linnaeus who published a systematic overview of life forms in the eighteenth century. According to his system, all species are named such that the two lowest scientific ranks, genus and species, form the name of an organism. For instance, in the name *Homo sapiens*, "*Homo*" is the more generic term, which includes many extinct relatives such as *Homo neanderthalensis* and *Homo erectus*. The specific name "sapiens" refers to the species. By definition, this is a group of organisms capable of interbreeding and separated from other groups with which no interbreeding occurs. According to scientific standards, *italic* letters are used to highlight scientific species names in the literature. If there are no ambiguities possible, the genus name is often abbreviated, for example, *E. coli*. A scheme depicting the current hierarchical rank system is shown in Figure 7.42.

Three Domains of Life Linnaeus divided all organisms into two kingdoms: animals and plants. The modern taxonomy system now distinguishes six kingdoms: bacteria, archaea, animals, plants, fungi, and protists. On top of this, a new category, the *domain*, was installed when the microbiologist Carl Woese had analyzed and

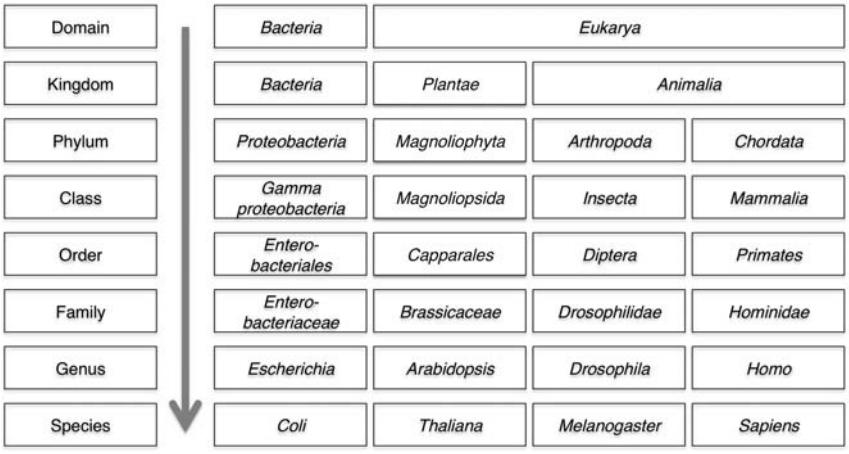

Figure 7.42 Hierarchy of biological classification ranks. The two lowest levels, genus and species, are used to build the unambiguous scientific names for all organisms. In addition to ourselves (*Homo sapiens*), typical model organisms are shown: the bacterium *Escherichia coli*, the mouse-ear cress *Arabidopsis thaliana*, and the fruit fly *Drosophila melanogaster*.

compared ribosomal RNA sequences between species. Ribosomes are common to all known organisms and the vital function of this protein-producing machine caused a stable conservation of rRNA sequences over extremely long periods of evolution. Molecular phylogeny assumes that the degree of divergence between the gene sequences in two given species correlates with the evolutionary distance between them. The most conserved sequences, such as rRNA, can be used to judge the evolutionary distance between non-related species, whereas more specialized genes, undergoing more rapid changes, allow closer relatives to be differentiated. Based on Woese's comparisons, it became evident that the evolutionary distance between certain bacterial species is just as large as the distances of both kinds of bacteria to animals or plants. There is now general agreement to divide all life forms into three major categories or "domains": archaea, eukarya, and bacteria (Figure 7.43).

Despite the superficial morphological resemblance of archaea (or archaebacteria) and "normal" bacteria (eubacteria), sequence similarities imply that archaea and eukarya separated later during evolution. The three-domain system replaced the formerly used differentiation between *eukaryotes* and *prokaryotes*. Nevertheless, both categories are still commonly used to distinguish cells with a membrane-surrounded nucleus (eukaryotes) from bacterial cells without nucleus (prokaryotes). For archaea and bacteria, the domain category is equivalent to the "kingdom." The domain eukarya is further divided into four kingdoms: animals, plants, fungi, and protists.

It is obvious today that the kingdom "protists" does not reflect a homogenous, monophyletic category, but rather comprises several more or less unrelated groups. The *slime molds* resemble fungi, as they typically use spores to reproduce. In contrast, plant-like photoautotrophic protists, called protophyta, are able to gain energy from

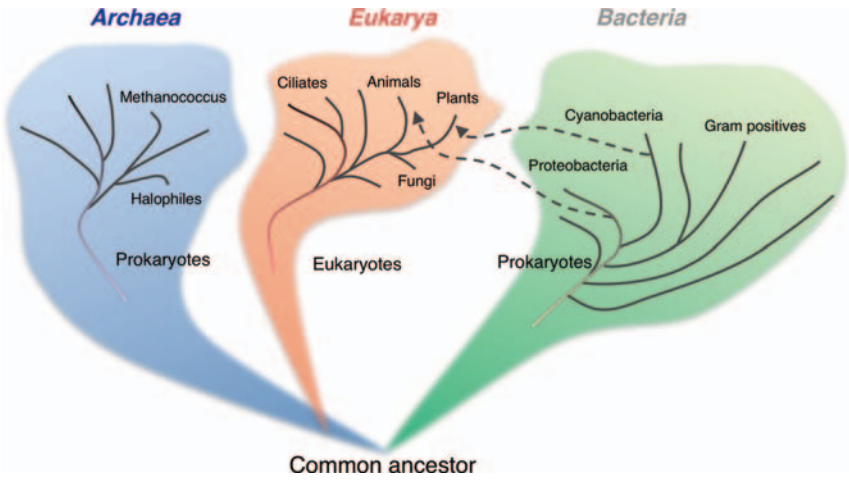

Figure 7.43 Three domains of life. The represented phylogenetic relationship tree is based on the comparison of ribosomal RNA sequences. It assumes that all organisms descended from a common type of progenitor cell. Irrespective of the phylogenetic distance, archaea and bacteria are often grouped together as "prokaryotes" to distinguish them from organisms with nucleated cells, the "eukaryotes."

sunlight. Other protists, called protozoa, have animal-like characteristics, such as a dependence on the uptake of other organisms or at least of energy-rich parts of other organisms. This group includes, for example, the genus *Paramecium* and also the malaria parasites of the genus *Plasmodium*.

The kingdom *animals* appears most familiar, as the colloquial term animal is often associated with the closer relatives of humans, the vertebrates. It is important to know that these animals with a vertebral column and spinal chord, including fish, amphibians, reptiles, birds, and mammals, form only one of many groups in the animal kingdom. The larger diversity within this kingdom may be illustrated by a single example of a more distant relative, the jellyfish. This organism is now prominent in biophotonics, as the green fluorescent protein (GFP) was isolated from the species *Aequoria victoria*, living in the Pacific Ocean. Jellyfish are unrelated to vertebrate fish and the commonly known umbrella-shaped type of jellyfish represents only one step in a two-stage life cycle. In the first stage of the cycle, jellyfish form sessile stalks with feeding tentacles. These polyps can asexually produce the free-floating, umbrella-shaped medusae, which are either male or female. Upon sexual reproduction between them, the life cycle starts again with a polyp. The bioluminescent medusa can generate flashes of blue–green light. The emission is triggered by calcium ions that induce conformational changes in the photoprotein aequorin, a 22 kDa molecule carrying coelenterazine as a prosthetic group. Upon oxidation, this cyclic organic molecule is converted into an excited state from which it relaxes with the emission of blue light. Part of the energy is transmitted by FRET (Förster resonance energy transfer) to the GFP, finally resulting in green fluorescence emission. Surprisingly, it is still unknown what the benefit of this sophisticated bioluminescence system is for the animal.

7.2.3.2 **Plant Cells**

Plants are one of the kingdoms already introduced by Linnaeus, but since then several refinements in the definition have occurred. Fungi and some groups of algae were separated to form their own branches of eukarya. Plants can be divided into four major groups: *seed plants*, *green algae*, *ferns* and their relatives, and the *bryophytes*, a group including the mosses. Among all plant species that have been identified thus far, the seed plants are by far the largest group with over 250 000 species. *Gymnosperms* are seed plants with unenclosed "naked" seeds, a group that includes the conifers and the Gingko tree. The colloquial term "plant" is most often used for the largest group of seed plants, the *angiosperms* or *flowering plants*. A typical cell of a flowering plant is shown as a cartoon in Figure 7.44.

As an important difference from animal cells (Figure 7.21), the flowering plant cell is surrounded by a stable *cell wall* composed of cellulose and hemicellulose fibrils embedded in a matrix of pectin. This wall around the plasma membrane provides physical rigidity and prevents the plant cell from swelling by water influx. Cellulose is built of glucose, the same compound as in starch but with a reverse orientation of the bonds between the glucose molecules. The pectins are more complex heterosaccharides containing galacturonic acid residues. With increasing age, the cell walls gain higher mechanical stability and hydrophobicity through incorporation of lignin, a

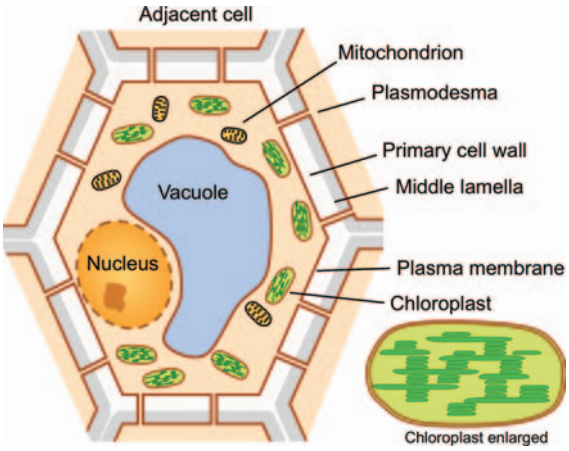

Figure 7.44 A typical cell of a flowering plant. The plant cell is surrounded by a stable primary cell wall. When the cell stops growing, a secondary wall can be formed between plasma membrane and primary wall. Plasmodesmata are cytosol bridges that connect neighboring cells. The vacuole, surrounded by the tonoplast membrane, is functionally related to lysosomes in animal cells. Chloroplasts are the sites of photosynthesis in plant cells. They are endosymbiotic organelles derived from cyanobacteria.

huge phenol-containing macromolecule that cross-links to the polysaccharides of the cell wall. The wooden parts of a plant are usually rich in lignin. Enclosed in the corset of their cell walls, plant cells still have direct contacts to their neighboring cells via the plasmodesmata. These small tunnels with diameters around 50 nm are surrounded by the plasma membrane. Between 1000 and 10 000 plasmodesmata connect the cytoplasm of a single cell with its neighboring cells. Small water-soluble molecules and even small proteins can pass through the plasmodesmata, such that all cells of the plant form an interconnected system, the so-called symplast.

A striking peculiarity within the cytoplasm of most plant cells is the vacuole, a water-filled organelle surrounded by a membrane, the tonoplast. Vacuoles have an acidic pH and in many respects they fulfill the role of the lysosomes in animal cells, as they contain hydrolytic enzymes and they are involved in autophagy, the breakdown of other organelles. In addition, the vacuole with its large content of small, osmotically-active molecules is important for the hydrostatic pressure of the plant cell. In plants without rigid cell walls this pressure, or turgor, is responsible for keeping the whole plant erect. Another difference from animal cells is the lack of centrioles in the centrosomes of the plant cell. Nevertheless, plant centrosomes have similar functions to their animal counterparts, serving as anchor sites for the minus ends of microtubules. Apart from microtubules, the cytoskeleton of a plant cell also contains actin filaments, but intermediate filaments are usually rare or even absent in plant cells.

Chloroplasts Maybe the most important achievement of the plant cell is *chloroplasts*. It can be assumed that cyanobacteria, as progenitors of the modern chloroplast, were taken up by eukaryotic cells as a second endosymbiotic organelle besides mitochondria. Chloroplasts still have their own genome and bacterial-type ribosomes, but like

mitochondria, many of the genes required to build the functional chloroplast were translocated into the nucleus of the host cell during evolution. Thus, chloroplasts cannot live outside the host cell and plant cells depleted of their chloroplasts are unable to regenerate the organelles *de novo*. Due to the endosymbiotic origin of the chloroplasts, the stroma of the chloroplast is surrounded by two membranes, the inner one originally belonging to the cyanobacterium and an outer membrane derived from the eukaryotic host cell plasma membrane.

Sequence analysis of the chloroplast genomes from many different plants implies that the uptake of cyanobacteria by a eukaryotic cell was no unique event, but may have occurred several times during evolution. Interestingly, not only were cyanobacteria integrated into nucleated cells, but also eukaryotic algae with chloroplasts can be engulfed by another eukaryotic cell. An example is the marine alga *Guillardia theta* that contains four different genomes: in its own nucleus, in the mitochondria, in the vestige of the co-opted nucleus (the nucleomorph), and in the chloroplasts of the engulfed cell.

The great benefit of cyanobacteria uptake by the host is that the organism can switch from a heterotrophic lifestyle with the dependence on energy-rich nutrition to an autotrophic way of life. A cell with chloroplasts is able to use the energy from sunlight to build up organic material from CO_2 and water. During evolution, multicellular plants gradually developed from simple unicellular algae, but chloroplasts remain vital for the whole organism. In a seed plant, not all cells are exposed to sunlight and consequently not all cells have green chloroplasts. In the developing plant, chloroplasts are derived from undifferentiated precursors, the proplastids. In light-exposed cells, the proplastids differentiate to mature chloroplasts, but in other tissues, such as the roots, they can also give rise to other plastids, for example, the starch-storing amyloplasts. When a proplastid develops into a mature chloroplast, a prominent structural change is the formation of disk-like membrane-surrounded suborganelles, the thylakoids. The thylakoid membranes harbor the light-harvesting pigments: the porphyrin chlorophyll and different carotinoids, which are isoprenoid molecules with 40 carbon atoms. Several thylakoids are typically assembled as stacks, the so-called grana. In the mature stage, the chloroplast lumen, or stroma, is densely filled with these grana. The pigments in the thylakoid membranes form light-harvesting complexes in which the energy of absorbed photons is funneled to central chlorophyll molecules by resonance energy transfer. From these central chlorophylls, excited electrons are transferred to neighboring acceptors and at the end of a chain reaction NADPH is formed in the chloroplast stroma. The reducing power of this molecule can be used in light-independent reactions to generate sugar molecules from CO_2. The ATP required for this synthesis is also generated at the thylakoid membrane. In the thylakoid lumen, protons are set free through the light-dependent lysis of water molecules. The accumulation of protons in the thylakoids generates a steep concentration gradient towards the chloroplast lumen and the flux of protons through a membrane-spanning ATPase drives the formation of ATP on the stroma side. Oxygen, produced as a byproduct of water photolysis, leaves the plant as a gas. This is of vital importance for the life of humans and many other organisms on Earth that need oxygen to gain energy from their food.

Plant Cell Differentiation and Tissues Just like animal cells, most cells in a plant are differentiated to take on a specific task in a tissue. In a flowering plant, different cell types are found in roots, stem, and leaves. Importantly, the stem forms two types of vascular systems to mediate transport from root to leaves and vice versa. The *xylem* system is responsible for the transport of water and inorganic solutes, whereas transport of organic molecules is performed in the *phloem* system. The source for the growth and regeneration of all plant tissues is undifferentiated meristematic cells. Just like animal stem cells, these cells undergo asymmetric cell divisions, producing a new stem cell and a more differentiated cell. Primary *meristem* zones are found at the tip of the roots and at apical shoot tips in specific growth zones. To allow secondary growth of a plant, lateral, secondary meristems surrounding the stem promote the formation of secondary xylem and phloem such that the plant can grow in diameter. In a tree, xylem forms the central wooden part, whereas only the inner part of the bark is phloem.

7.2.3.3 Bacterial Cells

Bacteria were neglected for a long time because they are too small to be identified with the naked eye. Bacterial cells are about 10 times smaller than most animal cells with dimensions between 0.5 and 5 μm. It was in 1676 when the Dutch tradesman Antoni van Leeuwenhoek reported that he had seen little "animalcules" in pond water and in saliva through his home-made one-lens microscope. At that time the relevance of his observation was not realized and it was only in the second half of the nineteenth century when Louis Pasteur and Robert Koch found that bacteria can be causative agents of diseases.

Today it is clear that bacteria colonize almost every place on the planet and that pathogenic germs are only a small minority among the prokaryotes. In contrast to eukaryote cells, the outer shape of bacterial cells is not characterized by wide variability. Most prokaryotic cells fall in the categories of either round cells (cocci), elongated rod-like cells (bacilli), or spiral cells (spirochetes). More complex shapes such as comma forms and cells with long appendages exist, but the degree of morphological diversity by no means compares with the differences between, for example, neurons, retinal sensory cells, and blood cells. The variability of bacteria becomes more obvious when the metabolic properties of these cells are inspected. Bacteria can be classified according to their relation to oxygen. *Aerobic* bacteria require the presence of oxygen, whereas *anaerobes* can only live in the total absence of gaseous oxygen, such as in deep-sea sediments. A third group of bacteria, the facultative anaerobes, prefer to live with oxygen, but can also grow without. Alternatively, bacteria can be classified according to their preferred source of energy. *Photoautotrophic* bacteria make use of the energy from light to fix carbon from carbon dioxide, whereas chemoautotrophs gain their energy by the oxidation of sulfur, nitrogen, or other elements. By contrast, the *heterotrophs* must take up energy-rich molecules from their surroundings. The breakdown of these nutrients can occur either in the presence of oxygen (respiration) or in the absence of oxygen (fermentation). Traditionally, these and other metabolic properties were used to classify bacteria, but DNA sequence comparisons indicate that the criteria do not reflect the underlying phylogenetic relationships.

As outlined above, the most extensive reorganization of bacterial classification was introduced to distinguish between archaebacteria and eubacteria. Regardless of the relatively large phylogenetic distance between the two groups, a common characteristic of both is the lack of a membrane-surrounded nucleus. Prokaryotic chromosomal DNA is usually a single ring structure that is localized in a confined area of the cytosol, the nucleoid. In contrast to eukaryotic chromosomes, the DNA is optimized as a compact, space-saving array of genes that usually lack introns. However, introns in principle could have existed in bacteria and archaebacteria in the past and whether the lack of intron sequences in prokaryotic genes now is just due to a secondary loss during evolution is unclear. Another similarity between the prokaryotes of both domains concerns the translation machinery. Whereas archaea and eubacteria have ribosomes of 70S (according to their Svedberg sedimentation coefficient), eukaryotes harbor 80S ribosomes.

Eubacteria The relations between the major eubacterial groups or *phyla* are too complex to be discussed in brief and a large number of bacterial organisms have not even been grouped yet. Importantly, a major distinction in the eubacterial domain can still be made on the basis a simple staining technique that Hans Christian Gram empirically invented and published in 1884. Using his method, typical *Gram-positive* cells are stained purple, whereas *Gram-negative* bacteria remain unstained or pink. The reason for this difference is a 20–80 nm thick mesh-like cell wall of Gram-positives that retains the applied dye (Figure 7.45). This cell wall is formed of peptidoglycan (murein) – a polymer of sugars and amino acids. Gram-negatives also have a peptidoglycan layer, but at about 7 nm it is just as thick as lipid bilayer. It should be noted that Gram-positive staining behavior is not exclusive to eubacteria, as some archaebacteria with complex-polymer cell walls are also positive for the Gram staining procedure.

The eubacterial Gram-positives form a rather homogeneous phylogenetic group with well-known genera such as the round-shaped *Streptococcus* and *Staphylococcus*, or rod-like members of the genera *Bacillus* or *Clostridium*. Some Gram-positives have a flagellum, a whip-like filament built of the protein flagellin. Flagella are anchored with ring-like structures in the peptidoglycan layer and in the plasma membrane. A proton gradient across the plasma membrane can be used by the bacterium to rotate the flagellum and thereby to drive a forward movement of the entire cell. In some species of Gram-positives the thick peptidoglycan is not the outermost boundary of the cell, but an extensive layer of polysaccharides, the capsule, can be found on top of the cell wall. In pathogenic bacteria such as *Streptococcus pneumoniae* and *Staphylococcus aureus*, the capsule can be an important virulence factor that protects the bacteria from the host immune cells. The water-rich polysaccharide layer also forms a barrier for hydrophobic molecules. In combination with the hydrophobic plasma membrane, this results in protection of the bacterium against potentially harmful small molecules, including antibiotics.

Gram-negatives The Gram-negative eubacteria form several distinct phylogenetic groups. Apart from the thinner peptidoglycan, another important characteristic is

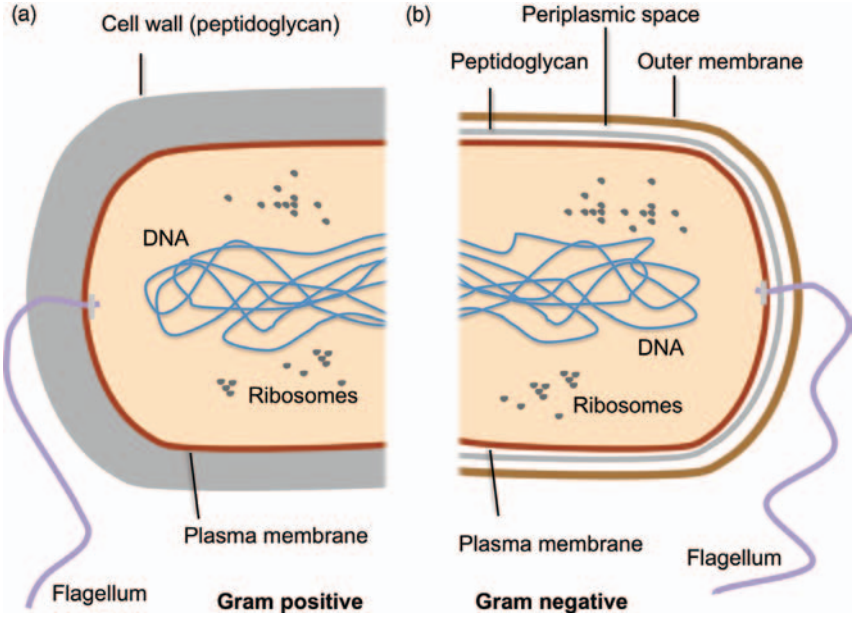

Figure 7.45 Comparison of Gram-positive and Gram-negative bacterial cells. Gram staining is determined by the thickness of the peptidoglycan cell wall. (a) Gram-positive cells have a thick, multilayered peptidoglycan but no outer membrane. (b) In Gram-negative cells, a thin peptidoglycan layer is found between the plasma membrane and outer membrane. The compartment between the two membranes is the periplasmic space. Both bacterial cell types can have rotating flagella for cell motility.

the *outer membrane*. As depicted in Figures 7.45 and 7.46, a second bilayer surrounds the peptidoglycan layer and, due to a constant distance between them, an additional cellular compartment is formed, the *periplasmic space*. Importantly, there is no ATP in the periplasm and no proton gradient is established across the outer membrane. The outer membrane is firmly anchored to the peptidoglycan by lipoproteins. A lysine residue at the C-terminal end of this protein is covalently bound to residues of the peptidoglycan layer, whereas at the opposite side of the lipoprotein cysteine-linked lipids are embedded in the inner leaflet of the outer membrane.

The outer membrane bilayer has a very specific and asymmetric composition. Whereas the inner leaflet resembles a normal, phospholipid-dominated membrane layer, the outer leaflet mainly contains lipopolysaccharides (LPS) or endotoxin. These molecules comprise three parts, the *lipid A* structure in the membrane, a conserved core domain of a polysaccharide chain, and a variable outer part of the polysaccharide. The polysaccharides exposed as the outermost layer serve a similar function to hydrophilic capsules, forming a hydrophilic barrier for hydrophobic molecules. An additional layer of free capsule polysaccharides can also be assembled on top of the LPS. For pathogens, such as *Salmonella typhi* and disease-causing strains of *E. coli*, the variable outer parts of the polysaccharides constitute an important strategy for

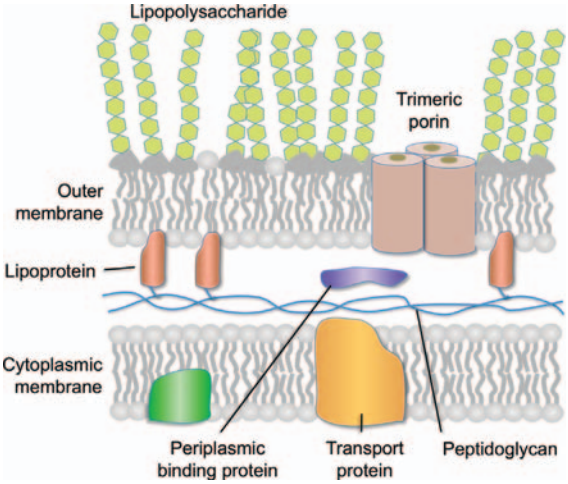

Figure 7.46 Membrane structure of Gram-negative bacteria. In addition to a normal cytoplasmic membrane, Gram-negative eubacteria are enveloped by an outer membrane. This bilayer is highly asymmetric, with lipopolysaccharides (LPS) dominating the outer leaflet. In pathogenic Gram-negatives, variability of the outer sugar chain ends of LPS serve as an immune-escape mechanism. The outer membrane is covalently attached to a thin layer of peptidoglycan via lipoproteins. The periplasmic space between the two membranes is in direct contact with the extracellular medium; small solutes pass freely through porins in the outer membrane.

escaping the host's immune system. Immune cells that could remove the bacteria identify the enemy by its outer layer. Owing to the variability in the sugar patterns of bacterial LPS, the resistance of a host organism can never be perfect. During the long co-evolution of humans and pathogenic germs, the immune system developed a sophisticated early warning system: whenever the hydrophobic membrane anchor of an LPS molecule, the *lipid A* moiety, is recognized in the bloodstream, this is a first indicator of a bacteremia and triggers a generalized activation of the immune system and fever. LPS is first bound by a soluble lipid-binding protein (LBP) and this complex in turn activates membrane-standing receptor proteins of the immune cells. Via internal signaling cascades, this will finally trigger the release of proinflammatory cytokines to stimulate other immune cells. This is beneficial for the infected individual, but an overshooting reaction is dangerous as it can cause septic shock, a major cause of death in intensive care units.

The outer membrane provides a protective layer for the bacterium, but it also necessitates additional transport functions to ensure the uptake of nutrients. The outer membrane is typically rich in *porins*, β-barrel-type transmembrane proteins with a water-filled pore that allow the free diffusional exchange of small hydrophilic molecules between the exterior and the periplasmic space. In addition, more specific porins act as gated pores for the uptake of amino acids, sugars, and iron complexes. For pathogenic bacteria, the extremely low availability of free iron in the body fluids is a growth-limiting factor and several independent iron-uptake receptors can exist in

the outer membrane of a Gram-negative bacterium. The subsequent translocation of cargo from the outer membrane into the cytosol involves soluble periplasmic binding proteins and transporter proteins in the cytoplasmic membrane.

Archaebacteria The domain archaea is divided into four phyla, but further groups might exist. The classification is difficult, as the majority of archaebacterial species cannot be studied in the laboratory. The name archaea was inspired by many archaebacterial species living in ecological niches resembling the geological conditions of the early Earth. This includes hot springs, salt lakes, and even hydrothermal vents in the deep sea. Being adapted to such habitats, many species can live at temperatures around 100 °C. However, not all archaebacteria are extremophiles, for example, methanogenic archaebacteria live as commensals in the guts of humans and cattle. In contrast to eubacteria, no pathogenic archaea are known although humans have always had contact with archaeal species.

The adaptation of many archaea to extreme temperatures makes them an important source of thermostable enzymes for biotechnology. Life at high temperatures not only requires proteins with higher thermal stability, but also the cell membranes must be adapted. Normal phospholipid membranes become more fluid with increasing temperature and at 100 °C the integrity of human or eubacterial membranes would be completely lost. In archaebacterial membranes, the phospholipids carry isoprenoid side chains instead of fatty acids. Methyl side groups in these structures reduce the rotational mobility and make the membranes more compact. In extreme cases, archaebacterial membranes are composed of phospholipids with isoprenoid chains that are fused in the middle, such that a very stable monolayer is built from molecules with hydrophilic headgroups on both sides.

7.3 Cell Signaling

Cells of multicellular organisms are not self-sufficient and isolated – they need to communicate with one another to exchange material and information and to ensure proper coordination of vital functions. Complex molecular languages have evolved to accomplish these tasks. To tackle the problem, collectively termed "cell signaling," we will define a *signal* in terms of cellular communication and discuss according to the medium (carrier, *mediator*) of the signal, how signals travel (*signal transmission*), and how they are converted to signals of other kinds (*signal transduction*).

A cellular signal can be any molecular or cellular state characterized by well-defined parameters. It becomes a meaningful signal when a state or a set of states has some functional interpretation. Signals (or states) therefore can be extremely diverse and can only be interpreted in a context-dependent manner. In Figure 7.47, typical signaling mechanisms are illustrated. In (a) the mediator of the signal may be a molecule that first needs to travel through the plasma membrane; it then enters the nucleus, and finally alters the gene transcription program in a specific manner, here indicated by a change in nucleus color from blue to yellow. This is a typical example of

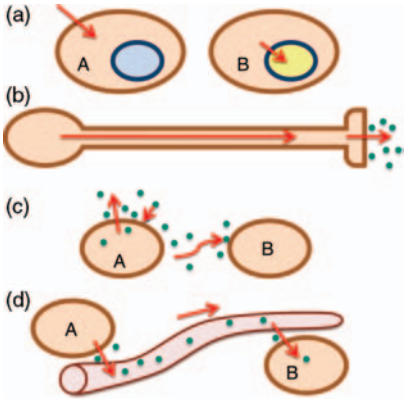

Figure 7.47 Types of cell signaling. (a) Signal transduction mediated by an extracellular signaling molecule that crosses the plasma membrane and subsequently enters the nucleus to affect gene transcription and, hence, renders the cell in an altered state. (b) Transmission of signals along neurons and the subsequent release of synaptic signaling molecules. (c) Release of signaling molecules from a cell can affect itself (A to A: autocrine) or a cell within the diffusion distance (A to B: paracrine). (d) Endocrine signaling: hormones released from cell A are circulated with the blood and affect cell B at some distance away.

hormone signaling in which the active gene transcription pattern is considered a state. In (b) is illustrated a case in which an electrical signal is sent along a neuronal axon. At the nerve ending, the synapse, the electrical signal triggers the release of a chemical messenger – a case of signal transduction. Part (c) illustrates two cases of chemical signal transmission. A chemical mediator released from cell A feeds back to the same cell, a process called autocrine signaling. When the mediator travels to a cell nearby (cell B), that represents a case of paracrine signaling. Classical hormone signaling is shown in (d), where a chemical mediator is released from cell A, distributed via the bloodstream in the body to exert its effect at a far distance at the target cell (B), a process termed endocrine signaling.

In the following section we first address electrical and rapid chemical signaling as it occurs in neurons, muscle, and endocrine cells. Then chemical signaling, in particular involving secondary intracellular mediators, is discussed, followed by some examples of hormone signaling with long-term consequences for the gene transcription profile. "Signaling pathways" provide a brief insight into contemporary thinking of how intracellular signals are processed in a parallel manner.

7.3.1 Electrical and Rapid Chemical Signaling

7.3.1.1 Ions and Membrane Potential

One parameter characterizing the state of a cell is the electrical membrane potential or the voltage between the cytosol and the extracellular space. By convention, the bulk extracellular space is set to zero potential. The membrane potentials of cells in a resting state, the resting membrane potentials, typically are between −40

and −90 mV. Excitable cells such as neurons and skeletal muscle cells can generate action potentials, that is, paradigmatic changes in the membrane potential. These action potentials are sometimes called nerve/muscle impulses or spikes. Also in nonexcitable cells the membrane potential is of vital importance because it largely determines the gradient for the import and export of molecules.

Alteration of the membrane voltage, for example action potentials of a neuron, on the one hand can be considered a signal. On the other hand, changes in membrane potential will change the equilibrium concentrations of ions and other molecules. The signaling aspect is always coupled to a transport of material and vice versa.

The physical reason for that coupling is expressed by the definition of electrochemical gradients. If an ion species is distributed in an unequal manner between the inside and the outside of the cell, and when the membrane is only permeable to that ion species, then the diffusion of ions along their concentration gradient can be exactly compensated by an electrical potential difference, called the Nernst potential or the equilibrium potential:

$$E_{\text{ion}} = \frac{RT}{zF} \ln\left(\frac{[\text{M}]_{\text{out}}}{[\text{M}]_{\text{in}}}\right) \tag{7.1}$$

where R is the gas constant, T the absolute temperature, z the valence of the ion under consideration, F the Faraday constant, and [M] the ion concentrations on either side of the plasma membrane. In Figure 7.48a, typical distribution of the most relevant ions is illustrated for a human skeletal muscle cell with the arrows indicating the direction of the concentration gradients. The extracellular solutions are usually rich in Na^+ and Cl^-, whereas in the cytosol K^+ ions are most abundant.

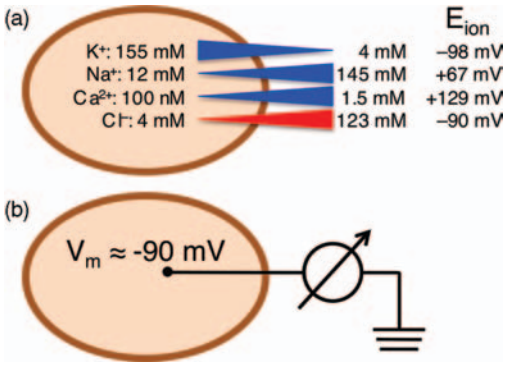

Figure 7.48 Ion distributions and membrane potential. (a) Distributions of the major small ions in a typical human skeletal muscle cell. The arrows indicate the chemical gradients to the extracellular space. Also indicated are the Nernst potentials (E_{ion}) predicted for the given gradients at 37 °C. Note that in some other cell types the intracellular Cl^- concentration can be substantially higher. Bulk electroneutrality is established by a high concentration of intracellular organic anions (note depicted). (b) The membrane potential is defined as the electrical voltage of the cell interior with respect to a ground electrode in the extracellular space. A typical resting membrane potential of a skeletal muscle cell is −90 mV.

In real cells, the ion flux through membranes is never governed by one ion species only. Therefore, to estimate the net ion flux for a given membrane voltage, other contributing ion species, weighted by their permeabilities, must be considered – typically using a formalism referred to as the Goldman–Hodgkin–Katz equation. The membrane voltage at which the net electric current vanishes is called the reversal potential, E_{rev}.

The reversal potential of typical Na^+ conductance is positive ($> +40$ mV), whereas the reversal potentials of K^+ and Cl^- conductances are typically negative (-70 to -90 mV). Hence in excitable cells, resting membrane potentials are largely determined by the gradient of K^+ and Cl^-; the asymmetric distributions of these ions work to hyperpolarize the membrane. Any Na^+ conductance will counteract this process and, hence, it will *depolarize* the membrane.

Free Ca^{2+} ions are a special case because their bulk cytosolic concentration typically is very low, about 100 nM. The Ca^{2+} concentration in the extracellular space is between 1 and 2 mM. Therefore, the equilibrium potential for Ca^{2+} is very high (>100 mV) and Ca^{2+} influx also depolarizes the membrane.

The fluxes of the mentioned ions manifest themselves as a transport of electric charge through ion-selective channel proteins (see below), measurable as electric current. For the example shown in Figure 7.48 and a membrane potential of 0 mV, the flux of Ca^{2+} and Na^+ ions will result in an inward flux of cations, that is, a negative electric current. K^+ ions would leave the cell and Cl^- ions would enter the cell; because of their opposite electrical charges, both would give rise to a positive electric current. Net negative currents promote depolarization whereas net positive currents promote hyperpolarization of the membrane.

7.3.1.2 Action Potentials – Coding of Information

Excitable Cells Excitable cells have the ability to develop temporal changes in the membrane potential in a relatively stereotypical manner, referred to as action potentials. Depending on the cell type, these waveforms of membrane potential can be rather brief (less than 1 ms in neurons), intermediate (a few hundred milliseconds in cardiac muscle cells), or very slow (several seconds in some smooth muscle cells). The maximum amplitude of an action potential largely depends on the type of ion responsible for the depolarization of the membrane. Most commonly in mammals that is Na^+; according to Figure 7.48a, the Nernst potential for Na^+ is about $+50$ mV and, hence, the peak amplitude of an action potential driven by Na^+ influx cannot be greater than that value. Other types of action potentials are driven by Ca^{2+} influx; they are typically slower than those driven by Na^+. The action potential of cardiac cells is triggered by Na^+ current but then sustained by Ca^{2+} influx.

Although the shapes and durations of action potentials can vary substantially, all have in common that they work essentially according to an all-or-none principle, that is, typically an action potential only develops when the membrane potential crosses a certain threshold value. Within the limit of this simplification, the action potential itself does not contain much more information than a single bit, that is, "on" or "off."

The information transmitted by neurons is then provided not by the quality of action potentials but largely by their frequency of occurrence.

This situation is illustrated in Figure 7.49, showing a schematic sensory neuron. Let us suppose that the ending of this neuron resides in a fingertip and extends via its long axon to the spinal cord where it makes contact with another neuron, ultimately sending signals to the brain. The cell body, the soma, of this neuron is not directly in line with the axon. The task of this sensory neuron is to transmit electrical signals reporting on an external stimulus. In this example, this stimulus is a mechanical agitation of the nerve ending, and thus it is a mechano-sensitive neuron. If the nerve ending is stimulated by a brief and weak pressure, the membrane of the nerve ending is depolarized in a graded manner causing a *receptor potential*. This receptor potential then spreads passively along the axon while decreasing in size. It reaches a trigger zone close to the first myelinated section, that is, the electrically insulated area of the axon formed by wrapped-around Schwann cells. If the receptor potential at the trigger

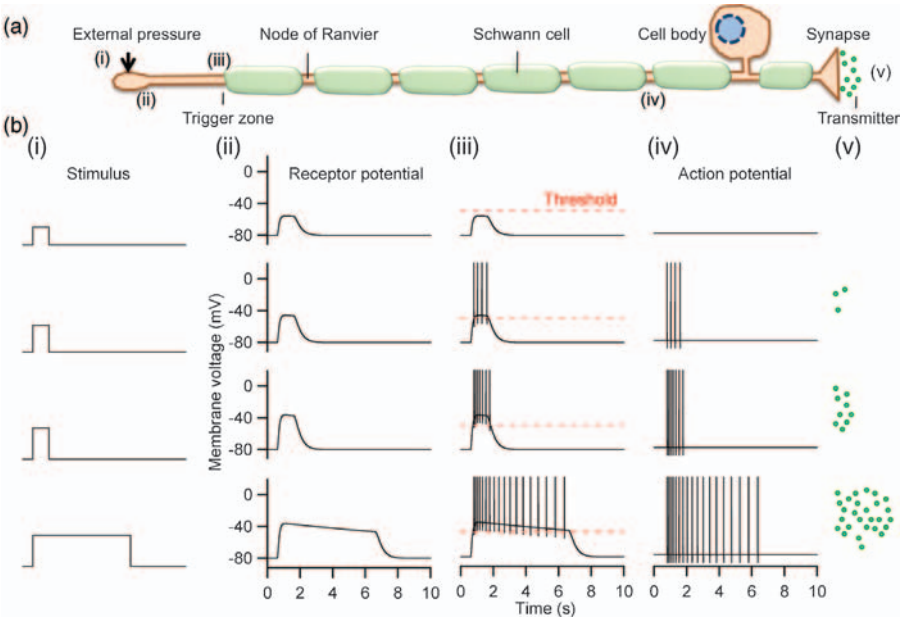

Figure 7.49 Schematic presentation of electrical signal coding by a sensory neuron. (a) Cartoon of a sensory neuron with the nerve ending acting as transduction site, the myelinated axon, the cell body, and a synapse. (b) Four scenarios of how a mechanical agitation of the transduction site generates a receptor potential, how this triggers action potentials, and finally how the transmitted action potentials result in transmitter release at the synapse: (i) mechanical stimulus, (ii) receptor potential at transduction site, (iii) membrane potential at trigger zone, (iv) membrane potential at the synapse, (v) released transmitter molecules. The sensory neuron acts as complex DA/AD converter with integrating and differentiating capacity. Small Roman numerals in (a) indicate where signals shown in (b) were measured (adapted from Kandel *et al.* [10]).

zone exceeds a certain threshold, an action potential is generated – on top of the receptor potential. Generation of an action potential is said to be an active process.

Stronger and more extended receptor potentials generate more and more frequent action potentials. This electrical activity is then transmitted passively through the axonal cable to the next node of Ranvier where it is actively amplified. In this way, the signal travels section by section, that is, from one node of Ranvier to the next. This process of saltatory conduction results in very rapid signaling of up to $100\,\mathrm{m\,s^{-1}}$ in humans, ensuring that the brain receives the sensory information within $\sim$10 ms.

Owing to the combination of passive signal transport under the myelin sheath and active action potential generation at the nodes, the DC component of the initial signal, that is, the receptor potential, is filtered such that only a sequence of action potentials arrives at the synapse (DC filtering). Since at this point the entire information of the mechanical stimulus is encoded as a sequence of action potentials, the signal underwent an analog-to-digital conversion. At the synapse the opposite process takes place. The more action potentials arrive at the synapse, the more Ca^{2+} can enter the cytoplasm from the extracellular space during the brief depolarization episodes. Since Ca^{2+} is constantly cleared from the synapse by active mechanisms (see below), the intracellular Ca^{2+} concentration in the synapse is a measure of a transient integral (or running average) of the incoming action potentials. The local Ca^{2+} concentration in turn determines how much neurotransmitter (Section 7.3.1.4) is released from the synapse to stimulate the receiving cell.

This simple example shows that already a single nerve cell – consider that there are about 100 000 000 000 (10^{11}) neurons in a human brain – can perform complex tasks, e.g., it can transduce an external signal (here mechanical) into an analog electrical signal (receptor potential), reject sub-threshold input, encode the analog signal by a series of action potentials, remove DC values by differentiation, integrate digital electrical input to produce an analog chemical signal (Ca^{2+} concentration) in the synapse, and finally send a chemical message (neurotransmitter) to the next neuron.

Nonexcitable Cells Even in nonexcitable cells, those which do not generate action potentials, the electrical membrane potential serves an important functional role. Here, excursions in membrane potential do not occur with a stereotypical time course but vary with the cellular state and quality and also with the degree of external stimulation. Often one end result of depolarization is, as in excitable cells, an increase in the intracellular Ca^{2+} concentration and, hence, a trigger for the release of chemicals such as liberating hormones in gland cells. In addition, the membrane voltage regulates the transport of ions across the plasma membrane – an important task in all epithelial cells. Therefore, in a simplified manner, we can state that excursions of the electrical membrane voltage are either a "signal" to be transmitted or a "driving force" for the transport of material. While both aspects are always coupled, the signal aspect is more relevant in excitable cells and the transport is the important feature in nonexcitable cells.

Measurement of Electrical Cell Signals Electrical membrane potentials are typically recorded with electrophysiological methods. They require an electrical contact with

the cell interior for measuring the voltage difference between "inside" and "outside" of the cell. Various methods exist to insert fine-tipped electrodes, either electrolyte-filled glass capillaries or metal electrodes, into individual cells and sensitive amplification electronics permits the registration of electrical signals of individual cells. Depending on the mode of operation, one even can record the membrane potential while maintaining a desired current flow (*current clamp*) or record the current through the plasma membrane at a given voltage (*voltage clamp*). Although such methods are extremely powerful and indispensable for physiological research, they are very tedious, expensive, and time consuming. In addition, they are typically only suited for recording signals from individual cells – or just a few cells. Moreover, impalement of cells with electrodes requires direct access and often is not feasible in a noninvasive manner.

Voltage-Sensitive Dyes Therefore, great effort has gone into the development of optical methods for monitoring the electrical cell potential. Several amphiphilic dyes are available that partition into the plasma membrane and undergo conformational changes depending on the membrane voltage. Such changes then result in an alteration the dye's spectral properties. Some voltage-sensitive dye systems rely on fluorescent resonance energy transfer between two dyes (e.g., dibutylbarbituric acid–trimethine oxonol and coumarin). Further, a great variety of such dyes are available according to their speed (i.e., how quickly they respond to changes in the membrane potential), their spectral properties, or the signal intensity. Commonly used fast voltage-sensitive dyes are substituted aminonaphthylethenylpyridinium (ANEP) dyes, such as di-4-ANEPPS and di-8-ANEPPS. ANNINE-6plus is a voltage-sensitive dye with a very fast response time in the nanosecond range and high voltage sensitivity. Recent years have seen development and deployment of genetically encoded voltage-sensitive fluorescent proteins. Although the field may still be in its early stages, the approach holds great promise.

7.3.1.3 Ion Channels, Transporters and Pumps

Electrical signals, as discussed above, are changes in the transmembrane voltage necessarily accompanied by the transport of charges, typically ions, across the membrane. Thus, for generating an electrical signal, cells need to be equipped with very specific mechanisms regulating the transport of ions through the membrane. As discussed in Section 7.2.1.1, an artificial lipid bilayer is a nearly perfect electrical insulator. Only lipophilic or small uncharged molecules can easily traverse the bilayer in a passive manner (Figure 7.50a). Charged molecules, such as the physiologically most relevant ions H^+, Na^+, K^+, Ca^{2+}, and Cl^-, require specialized membrane proteins – *ion channels* (Figure 7.50b) or *carriers* – to cross the membrane according to their respective electrochemical gradients.

However, ions and other molecules are also transported against their electrochemical gradients at the expense of energy from other sources. One distinguishes between *primary active* and *secondary active* transporters. Primary active transporters are so-called *ion pumps*. These proteins transport one or more types of ions against their electrochemical gradients often at the expense of ATP, which is hydrolyzed to

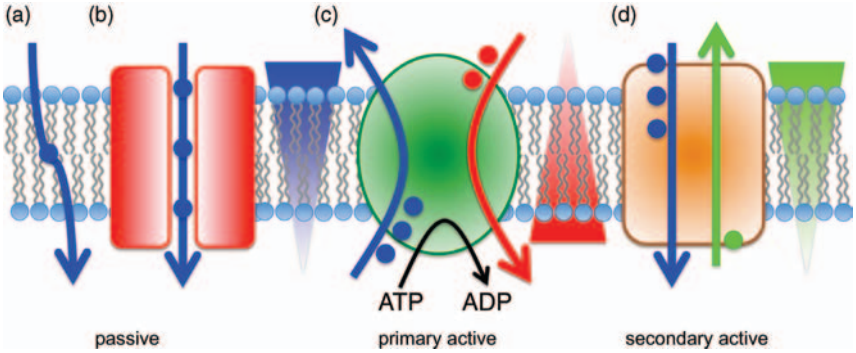

Figure 7.50 Membrane transport – illustration of pathways by which molecules can cross biological membranes. (a) Passive diffusion. (b) Ion channels. (c) Active transporter or pump. At the expense of ATP these proteins pump molecules against their electrochemical gradient into or out of the cell. (d) Secondary active transporters. The example shows an antiport, that is, a transport protein that exchanges two molecule species. Typically the gradient for the one species is used to transport the other species against its gradient. The examples indicate an Na^+/K^+ pump (c) and an Na^+/Ca^{2+} exchanger (d). Large arrow heads indicate electrochemical driving forces.

ADP for each transport cycle (Figure 7.50c). The electrochemical gradients thus established are in turn the energy sources for secondary active transport systems. One of these cases is illustrated in Figure 7.50d, showing a so-called *antiport* or *exchanger*, that is, a transport protein that transports one type of molecule in one direction while transporting another one in the opposite direction. If one molecule follows its electrochemical gradient, say the one indicated by the blue arrow, the other can be transported against its gradient provided that the overall energy balance permits that process. In *symports*, two types of molecules are simultaneously transported in the same direction using the gradient of one type. One example in mammals is the secondary transport of glucose, driven by the primary gradient of Na^+ ions.

Ion Pumps Some ion pumps, in particular those transporting protons (H^+), obtain their energy from absorbed photons or redox processes. In mammals, however, the most common forms are powered by hydrolysis of ATP, and therefore they are often referred to as ATPases. Na^+/K^+-ATPase is a fundamentally important transporter in animals. For every molecule of ATP hydrolyzed, this protein complex physiologically transports three Na^+ ions out of the cell while importing two K^+ ions. Because the net transport of charge is $+1$, this pump is electrogenic. By means of Na^+/K^+-ATPase, the intracellular concentration of Na^+ is kept low (about 5–15 mmol l^{-1}) and the concentration of K^+ high (120–150 mmol l^{-1}). The net export of ions is important for an osmotic balance; a failure of Na^+/K^+-ATPase, such as when an individual suffers an ischemic stroke, ultimately would lead to cell swelling. Whereas the gradient of K^+ is used in most cells to establish or to maintain the resting membrane voltage (see below), the Na^+ gradient serves as an energy source for the secondary transport of other types of molecules.

An example of a secondary transport, coupled to the Na^+ gradient, is the extrusion of Ca^{2+} ions from the cytosol of cardiac muscle cells via the Na^+/Ca^{2+} exchanger (antiport, Figure 7.50d). Along with the action of a plasma membrane Ca^{2+} pump, the Na^+/Ca^{2+} exchanger keeps the intracellular Ca^{2+} concentration at a low level such that the cardiac muscle cells contract at a submaximal force level. Once the Na^+/K^+-ATPase has been blocked by specific inhibitors such as digoxin (or digitalis), a cardiac glycoside extracted from the foxglove plant, the Na^+ gradient is diminished. As a consequence, Ca^{2+} cannot be cleared efficiently from the cytosol via the Na^+/Ca^{2+} exchanger, resulting in stronger cardiac muscle contractions. High doses of digoxin, however, can be fatal.

Ion Channels Ion channel proteins mediate the passive flow of ions across cell and organelle membranes down their respective electrochemical gradients. Typically, ion channels are complexes formed from several protein units. In humans, a very large number of genes, close to 1000, code for ion channel proteins or proteins that take part in directly forming ion channel complexes; hence here we can only concentrate on some of the fundamental features and functional principles.

The most remarkable feature that distinguishes ion channels from other ion transport mechanisms, such as transporters and pumps, is their typically large transport rate, on the order of up to 10^7 ions s^{-1}. For a monovalent ion, say Na^+, this transport is equivalent to an electric current of $10^7\ s^{-1}$ times the elementary charge e_0, that is, $\sim 1.6 \times 10^{-12}$ A (1.6 pA). Although this is an incredibly small current, it can be measured when a very small area of cell membrane containing one channel (sometimes more) is sealed on to the tip of a fine glass capillary tube connected to amplification electronics. The development of this so-called *patch-clamp method* permits the direct real-time observation of how individual proteins, down to a single protein, operate; the discovery earned Erwin Neher and Bert Sakmann the Nobel Prize in Physiology or Medicine in 1991. Although nowadays proteins are typically classified according to the respective genes based on homology and phylogenetic relationships, classification of ion channel proteins according to (a) the ion selectivity, that is, the types of ions that can pass a channel, and (b) the mode of operation, that is, by which means an ion channel is triggered to open or close, is very practical.

Some channel types are very specific for a certain type of ion, some do not distinguish much among the monovalent cations and only exclude anions and multivalent cations, others only discriminate between anions and cations, and yet others are also completely nonselective channels passing both ions and larger molecules.

Because the physiologically most relevant ions are H^+, Na^+, K^+, Ca^{2+}, and Cl^-, it does not come as a surprise that there are ion channels specialized to conduct exactly these ions only – or at least preferentially. For example, K^+ channels are typically very selective, that is, K^+ permeates through them >100 times better than Na^+. Na^+ channels and Ca^{2+} channels are slightly less selective. Cl^- channels do not need to be very selective because Cl^- is virtually the only small anion available. Therefore, under physiological conditions, an open Cl^- channel only conducts Cl^- ions. The effectively high selectivity of K^+ and Cl^- channels is an important

prerequisite for them acting as channels to determine the resting membrane voltage, which is then largely defined by the gradient of K^+ or Cl^- ions. For the generation of an action potential, the membrane needs to be depolarized – a task that is typically accomplished by Na^+ and/or Ca^{2+} channels. Termination of an action potential and its exact shape and repetition frequency depend on many factors such as the spontaneous closure of Na^+ and Ca^{2+} channels once the action potential starts, and the activity of K^+ channels that open only under depolarized conditions – to counteract the influx of Na^+ and/or Ca^{2+}.

What becomes clear in this scenario is that at least those ion channels being involved in the rapid electrical signaling need to be controlled by the membrane voltage itself. Such voltage-gated ion channels form a large superfamily of proteins, most of them being selective for K^+, Na^+, or Ca^{2+}. These channels are typically closed at resting membrane voltage. Moderate depolarizations, induced by receptor potentials (Figure 7.50) or by the activity of so-called pacemaker channels, may increase the probability that voltage-gated Na^+ or Ca^{2+} channels open. In particular Na^+ channels can then open their gates very quickly ($\sim$100 µs) in a very steeply voltage-dependent manner to depolarize the membrane further in an all-or-none fashion. The activity of Na^+ channels is self-limiting because the Na^+ influx diminishes when the potential comes close to the Nernst potential for Na^+. In addition, the channels undergo very rapid inactivation; they spontaneously close within about 1 ms after opening. Moreover, the delayed opening of voltage-gated K^+ channels helps to terminate the action potential by bringing the membrane potential back to the resting voltage. Among others, depending on the Na^+ channels' recovery from inactivation and the closure of K^+ channels, the next action potential can be fired, resulting in a train of electrical activity. This fundamental basic principle of nerve and muscle electrical excitability (illustrated in Figure 7.51) was reported in 1952 by Alan L. Hodgkin and Andrew F. Huxley, who received the Nobel Prize in Physiology or Medicine in 1963 together with John C. Eccles.

As we will see below, alteration in the membrane voltage is not the only stimulus by which ion channels are gated. In the example shown in Figure 7.49, the development of a receptor potential by mechanical agitation of a nerve ending is brought about by the activation of mechano-sensitive ion channels. Likewise, there are ion channel types being activated by chemicals (extracellular or intracellular), heat/cold, the absorption of photons, or intracellular chemical reactions; some channel types do not appear to be "gated" at all – they are open throughout their lifetime and are only regulated by means of protein synthesis and degradation.

7.3.1.4 **Synapses and Chemical Signaling**

For the transmission of electrical signals from one cell to another, they need to make physical contacts. In a simple case, two cells are in close proximity and the adjacent membranes are physically coupled by so-called cell–cell channels or gap junctions (Figure 7.35). Such channel complexes consisting of two six-subunit proteins, one from each cell, form large channels with little ion selectivity and they establish electrical contacts between the cells; a change in membrane potential in one cell is also experienced by the neighboring cell, attenuated by the electrical impedance

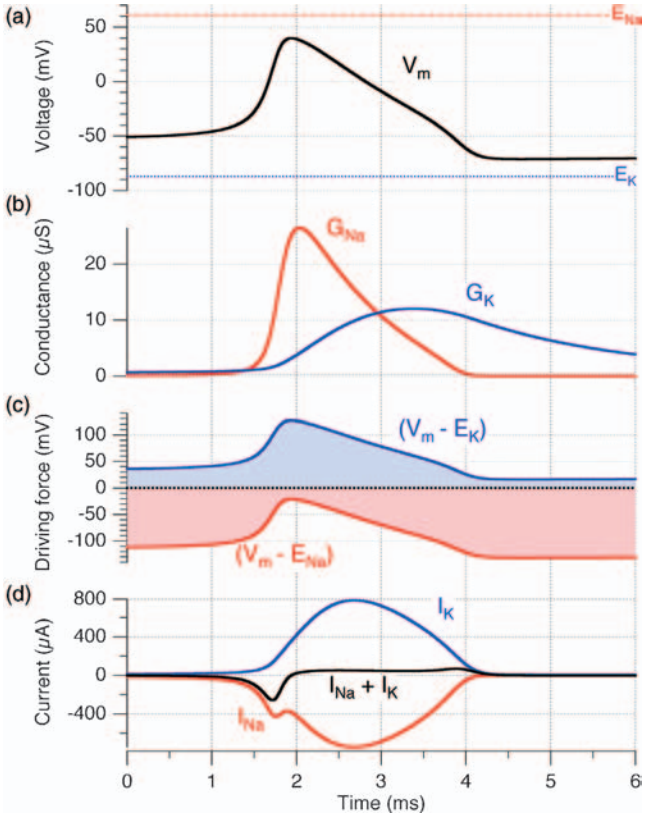

Figure 7.51 Components underlying a neuronal action potential. (a) Time course of an action potential with an indication of the equilibrium potentials for Na^+ and K^+. (b) Membrane conductance during the action potential, separated in those of Na^+ and K^+. (c) Driving forces. (d) Net ion current flowing across the membrane (black) and the underlying Na^+ and K^+ currents flowing in opposite directions. The results depicted schematically represent a large invertebrate nerve action potential.

formed by the resistance of the gap junctions and the membrane capacitance. These *electrical synapses* play an important role when cells in an organ are to be synchronized, as is required, for example, for the concerted contraction of muscle cells in the heart. If cells in a tissue are electrically coupled in such a manner, they are said to form a *syncytium*.

The great advantage of an electrical synapse is its coupling speed; however, it is largely bidirectional and does not provide much specificity. More complex rapid cell–cell communication therefore happens via *chemical synapses*, which means a "sending" presynaptic cell liberates a chemical, termed a transmitter, which then diffuses to the "receiving" postsynaptic cell to elicit a response. The speed of this signaling largely depends on the diffusion of the transmitter from the sending to the receiving cell and, therefore, the synaptic cleft usually is very narrow (20–100 nm).

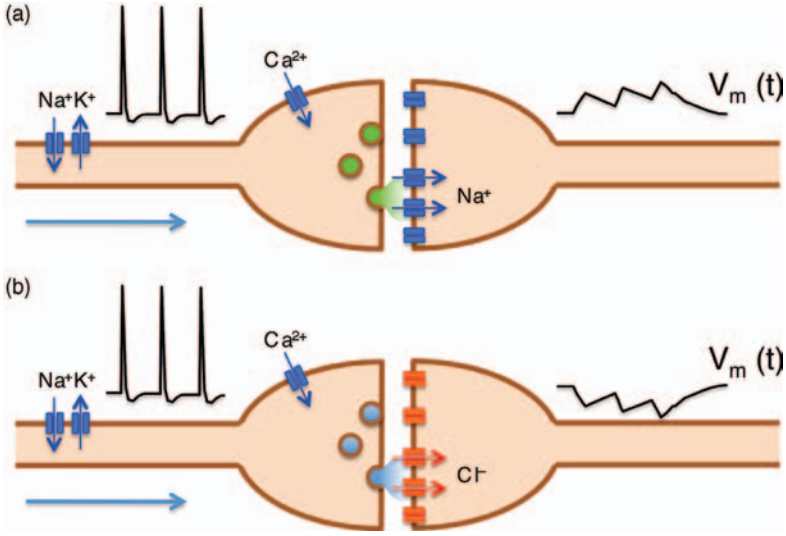

Figure 7.52 Chemical signaling via synapses. Synaptic cell contacts formed by a presynaptic (left) and a postsynaptic (right) terminal separated by the synaptic cleft. Incoming action potentials generated by Na^+ and K^+ channels depolarize the synapse to open Ca^{2+} channels. The Ca^{2+} influx triggers the release of neurotransmitter, stored in vesicles. Upon diffusion to the postsynaptic membrane, the neurotransmitter opens ligand-gated ion channels and changes the postsynaptic potential, $V_m(t)$. (a) Excitatory synaptic contact: an excitatory neurotransmitter, for example, acetylcholine or glutamate, is released. This opens cation-selective ligand-gated ion channels in the postsynaptic membrane to generate an EPSP (excitatory postsynaptic potential). (b) Inhibitory synaptic contact: an inhibitory neurotransmitter, for example, glycine, activates Cl^--selective ion channels to generate an IPSP (inhibitory postsynaptic potential).

The size and shape of synapses can vary substantially depending on the cell type, but usually they are confined cellular areas forming so-called nerve terminals (Figure 7.52). Since these terminals (both presynaptic and postsynaptic) are small and topologically confined, they are specialized sites with local properties regarding membrane potential and intracellular milieu (e.g., Ca^{2+} concentration). Local membrane potentials of synaptic terminals in presynaptic and postsynaptic cells are referred to as pre- and postsynaptic potentials, respectively.

Action potentials, mostly created by the activity of voltage-gated Na^+ and K^+ channels, arrive at the presynaptic terminal where they activate voltage-gated Ca^{2+} channels. The resulting increase in the local intracellular Ca^{2+} concentration is the trigger for a reservoir of transmitter-filled vesicles to fuse with the synaptic membrane (see Section 7.2.1.9), and to liberate their content into the synaptic cleft. This process is also very rapid because the vesicles are already in place, closely attached to sites of fusion, the active zone.

At the postsynaptic membrane, the transmitter molecules bind to their specific receptors, many of which are also ion channels. They subsequently open and permit an ion flow that contributes to an alteration of the postsynaptic potential.

The specificity of synaptic transmission resides in both the type of transmitter released and the type of receiving receptor, which together determine whether a synaptic contact is *excitatory* or *inhibitory*. As illustrated in Figure 7.52a, the transmitter of an excitatory synapse activates ion channels in the postsynaptic cell that depolarize the membrane, that is, they excite the cell and potentially generate a new action potential. In mammals, typical excitatory transmitters are acetylcholine and glutamate; they open postsynaptic ligand-gated cation channels, in the first place resulting in a postsynaptic influx of Na^+ and (in some cases) Ca^{2+} and causing an excitatory postsynaptic potential (EPSP). A single action potential arriving at the presynaptic terminal may not be sufficient to elicit a postsynaptic action potential. Only when the frequency of action potentials is high enough will many EPSPs integrate in the postsynaptic cell finally to trigger firing and propagation of an action potential.

Figure 7.52b shows the scenario for an inhibitory synapse. Here the typical transmitters are glycine and γ-aminobutyric acid (GABA); they activate Cl^--permeable ligand-gated channels in the postsynaptic membrane, thus typically (but not necessarily) causing a hyperpolarization [inhibitory postsynaptic potential (IPSP)] and damping electrical activity.

Some neurons utilize more than one transmitter type, which often operate on different time scales (e.g., milliseconds versus seconds). Typically, however, neurons are classified according to their principal neurotransmitter type that they release. For example, glutaminergic neurons release glutamate and GABAergic neurons release GABA. The receiving postsynaptic cell receives inputs from a variety of presynaptic neurons and possesses the appropriate receptors to detect the neurotransmitters. As a consequence, the electrical activity of a neuron in the brain is determined by the temporal and local superposition of many excitatory and inhibitory inputs.

Ligand-Gated Ion Channels The examples above showed that there are several types of ion channels activated by extracellular ligands or neurotransmitters. These channels typically are formed from up to five protein subunits and are classified according to their ion selectivity (cation or anion selective) or their specific activating ligand. Typical examples of ligand-gated cation channels are those activated by acetylcholine (nicotinic acetylcholine receptor channel) and glutamate. Whereas acetylcholine is a transmitter often mediating signal transmission in peripheral cells, for example, at the interface between neurons and muscle cells (neuromuscular junction), glutamate is a transmitter primarily found in the CNS. Both acetylcholine receptor channels and glutamate receptor channels exist as various isoforms and some are able to conduct Ca^{2+} in addition to monovalent cations. Typical examples of Cl^--permeable ligand-gated ion channels are those activated by the amino acid glycine and by GABA. Both glycine receptor channels and $GABA_A$ receptor channels play an important role in inhibitory signal transduction in the CNS, including the brain stem and spinal cord.

Learning and Memory A human brain consists of about 10^{11} neurons in addition to about the same number of glial cells that are increasingly recognized to participate in

information processing. Each of the neurons has on average 7000 synaptic connections to other neurons. Although this impressive number of about 10^{15} synapses per brain decays in the adult by about one order of magnitude, the remaining 10^{14} synapses form the basis of the gigantic cognitive power of a human brain. Given that a synapse can either be excitatory or inhibitory, a tremendously complex meshwork of electrical wiring can be achieved. However, a chemical synapse is by no means a static element like a connection in an electronic circuit. Synapses exhibit a high degree of plasticity, that is, their transmission efficiency is subject to activity-dependent regulation. The *use* of a synapse, that is, the frequency of action potentials arriving, will change the synaptic strength on various time scales. Some of the long-term changes in synaptic strength studied by neurobiologists include long-term potentiation (LTP) and long-term depression (LTD). The strengthening or weakening of synaptic contacts is a cellular basis for such complex phenomena as learning and memory. For more insight, the interested reader may refer to textbooks on neurobiology.

7.3.2
Ligands, Receptors and Second Messengers

In the previous sections we have already made use of the terms *ligand* and *receptor*. Here we will consider how to distinguish various types of ligands and receptors and how signals, encoded by ligands, are processed.

In Figure 7.53, several terms used in this context are illustrated. A ligand is a diffusible molecule (chemical signaling) that binds to a specific receiving molecular complex – a receptor. Ligands can have various names depending on their specification; we have already discussed hormones and transmitters (e.g., neurotransmitters). Since ligands usually mediate a specific response, they are often referred to as mediators. If mediators are not responsible for a major cellular response but only alter this response in a graded manner, they may be called modulators. When "activating" a receptor they are referred to as *agonists*, but if they inhibit a receptor often the name *antagonist* is used.

The chemical structures of ligands range from large peptide structures (e.g., the hormone insulin and the immune system signal interferon), amino acids (e.g., glycine) and low molecular weight compounds such as acetylcholine, ATP and steroids, to ions such as H^+, Ca^{2+} and Zn^{2+}. The size and physicochemical properties of a ligand largely determine how quickly and where it reaches its target. Large or permanently charged ligands will not be able to enter a cell and therefore can only bind to receptors situated on the plasma membrane. Others, such as steroid hormones, are readily membrane permeable and can bind to receptors in the cytosol or even directly in organelles such as the nucleus.

Receptors typically are proteins with binding sites for their specific ligands. Depending on the receptor type, they transmit the received signal in various ways. The processes involved in the reception of a signal by a receptor and the generation of subsequent signals are collectively referred to as *signal transduction*, to be detailed in the following sections. As illustrated in Figure 7.53, receptors delimited to the

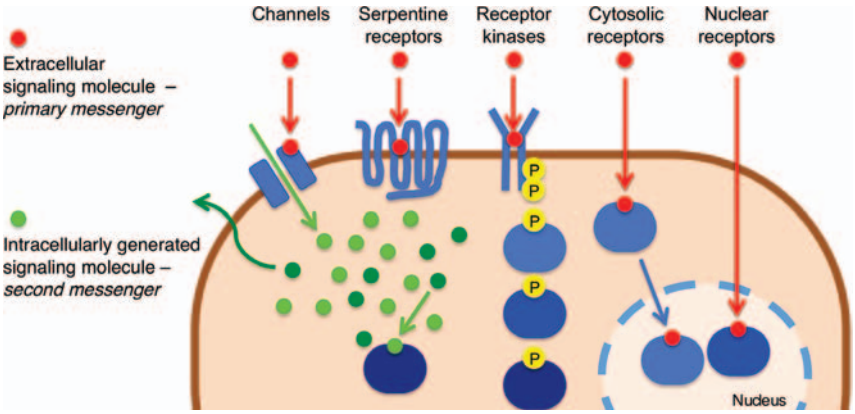

Figure 7.53 Signal transduction. Schematic illustration of how diffusible extracellular signaling molecules (red), so-called primary messengers, are received by various membrane-delimited and intracellular receptors (blue). Recognition of the initial signal either directly initiates a cellular response or it is only the first step in a signaling cascade. Small intracellular signaling molecules, second messengers, play an important role; most of them bind to intracellular constituents and thus relay the "message," others can even leave the cell to initiate retrograde signaling. Many receptors can activate further signaling proteins by direct association or by post-translational modification such as protein phosphorylation.

plasma membrane can largely be grouped into those acting as ion channels, receptors that in effect produce or release another ligand, a so-called second messenger, receptors that "activate" other cellular proteins, and receptors that acquire enzymatic activity when stimulated. This list is by no means complete or exclusive; some receptors have multiple functions and depend strongly on the cellular state itself. Only some ligands directly produce a cellular response by binding to membrane receptors. In many cases the initial binding to a receptor – either in the plasma membrane or somewhere intracellularly – is only the first step in a so-called *signaling cascade* (see Section 7.3.4), often involving intracellular second messengers, formation and breakage of protein complexes, and post-translational protein modifications.

7.3.2.1 **Second Messengers**

A second messenger is a chemical substance whose concentration is altered in response to a primary signal mediated by a primary messenger (ligand). It can be synthesized by enzymes or released by ion channels. Removal of second messengers from the cytosol involves chemical breakdown by specific reactions or active export. The principal purpose of second messengers is to relay extracellular signals, which cannot cross the cell membrane, to intracellular sites. Here they trigger signal cascades and finally result in a cellular response to the primary stimulus.

In addition to accomplishing the mere signal transduction, second messenger systems fulfill more complex tasks (Figure 7.54). In most cases they strongly amplify the chemical signal. For example, a single neurotransmitter molecule bound to a plasma membrane ion channel may open that channel to permit the influx of many

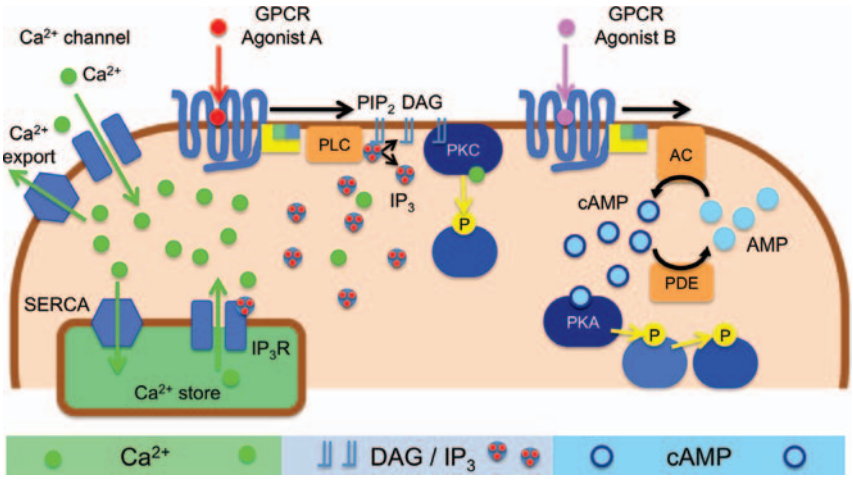

Figure 7.54 Second messenger systems. Schematic presentation of three selected second messenger systems coexisting in a cell. *Left*, Ca^{2+} system. Ca^{2+} ions enter the cytosol via Ca^{2+} channels in the plasma membrane or in intracellular Ca^{2+} stores; this influx is antagonized by Ca^{2+} export systems such as SERCA. *Center*, inositol–lipid system. Activation of a G protein-coupled receptor (GPCR) by an extracellular agonist liberates the heterotrimeric G protein that subsequently activates phospholipase C (PLC). PLC cleaves the membrane lipid PIP_2 into the second messengers DAG (diacylglycerol) and IP_3 (inositol triphosphate). DAG is an activator of the Ca^{2+}-dependent kinase PKC, whereas IP_3 liberates Ca^{2+} from internal stores by binding to IP_3-receptor channels. *Right*, cAMP system. Agonist binding to a GPCR activates adenylate cyclase (AC) mediated by a G protein. AC produces cAMP from AMP and is antagonized by phosphodiesterases (PDE). cAMP is an activator of protein kinase A (PKA), which then phosphorylates target proteins at specific serine and/or threonine residues.

millions of Ca^{2+} ions, which act as second messenger molecules. Various different types of extracellular stimuli may affect the same second messenger and, hence, may induce signal integration. Another important feature is that the production and breakdown of second messengers can be local such that a cell is capable of simultaneously performing multiple spatially separated signaling tasks.

There are three basic types of secondary messenger molecules. Hydrophilic messengers are water soluble, relatively free to diffuse in the cytosol or stored in organelles (Ca^{2+}, cAMP, cGMP, IP_3). Hydrophobic messengers typically are derived from membrane lipids; they are poorly soluble in water and therefore remain preferentially in the lipid phase where they can reach and regulate effector proteins in or at the membrane [diacylglycerol (DAG), phosphatidylinositols, arachidonic acid]. Finally, there are gaseous second messenger molecules that readily diffuse through the cytosol and across membranes so as to reach neighboring cells [nitric oxide (NO), carbon monoxide (CO), hydrogen sulfide (H_2S)].

In the following we will briefly discuss the most important second messengers, their generation and some of their secondary effectors.

Calcium Free Ca^{2+} ions are a special case of second messengers because they are not synthesized and degraded by enzymatic activity but enter the cytosol via Ca^{2+}-permeable channels in the plasma membrane and they are released from Ca^{2+}-loaded intracellular stores such as the ER (or SR in muscle cells) and the mitochondria. Ca^{2+} is by far the most important and versatile intracellular messenger as numerous molecular processes taking place in the cytosol depend on the intracellular free Ca^{2+} concentration, $[Ca^{2+}]_i$. In resting cells $[Ca^{2+}]_i$ is very low (about 100 nM), whereas the Ca^{2+} concentration is typically high (>1 mM) in the extracellular space and in the Ca^{2+} stores.

Ca^{2+} influx into the cytosol mainly is mediated by specific Ca^{2+}-permeable ion channels. In the plasma membrane these are typically voltage-gated Ca^{2+} channels (CaV), which open when the membrane is depolarized such as when an action potential reaches the respective site. In addition, there are several other types of ion channels that are selective to cations and, hence, upon activation contribute to an increase in $[Ca^{2+}]_i$. To name a few, there are transient receptor potential (TRP) channels and specific forms of ligand-gated channels responding to the transmitters glutamate [NMDA (*N*-methyl D-aspartate) receptors] or acetylcholine (nicotinic acetylcholine receptors). Intracellular Ca^{2+} stores release their Ca^{2+} into the cytosol by means of ligand-gated Ca^{2+} channels such as ryanodine receptors (RyRs) and IP_3 receptors. Some RyRs are specialized to permit very rapid Ca^{2+} release from the SR in skeletal muscle cells by directly coupling to select CaVs in the plasma membrane. In contrast, release of Ca^{2+} via IP_3 receptors is typically a slower process. In addition, there are so-called store-operated Ca^{2+} channels in the plasma membrane that permit Ca^{2+} influx from the extracellular space once the intracellular stores send an "empty" signal.

An increase in $[Ca^{2+}]_i$ typically is a transient event as Ca^{2+} is constantly removed from the cytosol. In the plasma membrane there are two important Ca^{2+} export systems: the plasma membrane Ca^{2+}-ATPase and Na^+/Ca^{2+} exchangers (see Section 7.3.1.3). The major system for refilling the intracellular Ca^{2+} stores is the ion pump SERCA (sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase). SERCA itself is under the control of phospholamban, a protein whose activity is regulated by phosphorylation by protein kinase A (PKA).

Because very many cellular constituents bind Ca^{2+}, there is a great difference between the free and total (bound plus free) concentrations of intracellular Ca^{2+}. For example, inside the SR the protein calsequestrin strongly binds Ca^{2+} and thereby reduces the concentration of free Ca^{2+}. The gradient of free Ca^{2+} against which SERCA must pump is thus diminished, although the total Ca^{2+} concentration inside the SR can be 10 000 times higher than in the cytosol. Another consequence of the presence of cytoplasmic mobile and stationary Ca^{2+}-binding molecules (Ca^{2+} buffers) is that the distribution of free Ca^{2+} inside the cytosol is not determined solely by the diffusion of Ca^{2+} in solution and that $[Ca^{2+}]_i$ is by no means homogenous inside a cell. At the sites of Ca^{2+} influx, local $[Ca^{2+}]_i$ can be much higher (>>1 μM) than $[Ca^{2+}]_i$ averaged over the entire cytosol, allowing for local and temporally limited Ca^{2+} signaling inside a cell. Typical phenomena observed in this

context are Ca^{2+} sparks (local transients in $[Ca^{2+}]_i$) and Ca^{2+} waves (spatial and temporal oscillations in $[Ca^{2+}]_i$).

We have briefly mentioned prominent examples of Ca^{2+}-triggered processes such as muscle contraction and the release of transmitters (exocytosis). However, many other cellular functions, in one way or the other, depend on Ca^{2+} ions and therefore the effector proteins of the second messenger Ca^{2+} are extremely diverse. Some proteins possess specific Ca^{2+}-binding moieties such that Ca^{2+} binding exerts a conformational change, leading to a change in function of the respective protein. For example, Ca^{2+} entering the cell during an action potential may bind directly to the cytosolic domain of a Ca^{2+}- and voltage-activated K^+ channel. This channel then opens and the resulting efflux of K^+ hyperpolarizes the cell. In many cases, however, the effector protein itself does not have an intrinsic capacity to bind Ca^{2+} directly. Instead, specific Ca^{2+}-binding proteins are utilized to "sense" the intracellular Ca^{2+} concentration and relay that information to the effector protein. Among the very many Ca^{2+}-binding proteins, the most ubiquitous is calmodulin (CaM); it harbors four so-called EF-hand structures and undergoes a substantial conformational change when Ca^{2+} is bound to them. When associated with an effector protein, CaM thus transmits the "Ca^{2+} signal" to the target protein. Owing to the different Ca^{2+} sensitivities of the EF-hand motifs, such signaling can occur at low and high $[Ca^{2+}]_i$ levels. Other Ca^{2+} signaling steps involve chemical reactions such as protein phosphorylation. Specific Ca^{2+}-dependent kinases (e.g., CDPK) or Ca^{2+}/calmodulin-dependent kinases (CaMKs) phosphorylate the effector protein in response to an increase in $[Ca^{2+}]_i$. Ultimately, Ca^{2+}-dependent molecular processes may affect gene transcription, thus exerting long-term changes to the cell.

Cyclic Nucleotides *Cyclic adenosine monophosphate* (cAMP) is a second messenger controlled by enzymatic reactions for its generation and removal. The precursor of cAMP is ATP (see Section 7.1.6), which is dephosphorylated and cyclized to cAMP by the enzyme adenylate cyclase [synonymous with adenylyl cyclase (AC)]. In turn, AC itself is activated by receptor stimulation and stimulatory G proteins (see below). The lifespan of cAMP is limited by phosphodiesterases (PDEs), a large class of enzymes that hydrolyze cAMP to yield AMP.

The primary effector proteins of the second messenger cAMP are cAMP-dependent protein kinases (PKA)s. Once activated, the enzymes phosphorylate a multitude of target proteins such as phospholamban, as mentioned above. Another prominent example of a PKA-mediated process is the liberation of glucose in muscle cells upon stimulation by the stress hormone adrenaline (synonymous with epinephrine). As for Ca^{2+}-dependent kinases, the activation of PKAs can lead to long-lasting alterations of cellular states by modulating gene transcription.

Cyclic guanosine monophosphate (cGMP) is chemically very similar to cAMP. It is produced from GTP by the action of guanylate cyclase [synonymous with guanylyl cyclase (GC)]. GCs are either membrane receptors, activated by ligands, or soluble in the cytosol (sGC), activated by nitric oxide. As for cAMP, breakdown of cGMP is mediated by PDEs.

In addition to the effects mediated by kinases, both cAMP and cGMP also have direct impacts on proteins such as cyclic nucleotide-gated ion channels (cNGCs). These channels play an important role in the sensing of odorants (cAMP) and light (cGMP) (see Section 7.3.2.2).

The balance between the concentrations of free AMP versus cAMP and that between GMP versus cGMP, respectively, are tightly controlled by the activity of PDE. The action of caffeine, for example, is partly mediated by an inhibition of PDE, thus slowing the decay of cAMP. On the other hand, the hormone insulin activates PDE, thus lowering the concentration of cAMP and limiting the liberation of glucose. One of the major effects of cGMP is relaxation of smooth muscle cells. Since penile erection relies on the relaxation of vascular smooth muscles in the *corpus cavernosum*, inhibition of the cGMP-specific PDE-5 by sildenafil is a way to treat erectile dysfunction by maintaining an elevated cGMP concentration.

Lipid-Derived Second Messengers Two second messengers belonging to the phosphoinositol system are released upon enzymatic cleavage of a membrane lipid molecule. When stimulated by a receptor (see below), the membrane-delimited enzyme PLC cleaves PIP_2 (see Section 7.1.4.3), to yield DAG and IP_3.

DAG largely remains in the membrane compartment and is a potent activator of the Ca^{2+}-dependent protein kinase C (PKC), thus initiating a cascade of phosphorylation events. IP_3 is a water-soluble molecule that diffuses inside the cytosol to activate IP_3 receptor channels to liberate Ca^{2+} from intracellular stores. This is an example where Ca^{2+} could be considered a third messenger, because it is "activated" by the second messenger IP_3. As we shall see below, the concept of third- and higher order messengers has limited usefulness because all second messenger systems are highly coupled and interdependent.

By the action of the enzyme phospholipase A_2 (PLA_2), the polyunsaturated fatty acid arachidonic acid is cleaved from membrane phospholipids. Alternatively, it is derived from DAG. It acts as a lipid second messenger and stimulates secretion. In addition, it is a precursor of a large family of tissue hormones – the prostaglandins. Because arachidonic acid is lipid soluble, it can pass the plasma membrane and can affect neighboring cells.

Gaseous Messengers – NO and CO Gaseous messengers such as nitric oxide (NO) and carbon monoxide (CO) can diffuse freely beyond cell borders and therefore are both *second* messengers within the parent cell and *primary* messengers for the neighboring cells. NO is generated from the amino acid arginine by specific enzymes, the nitric oxide synthases (NOSs). As mentioned above, a prime target of NO is the soluble guanylate cyclase containing heme as the prosthetic group. By means of cGMP production, NO therefore plays an important role as a vasodilator by relaxing vascular smooth muscle cells. In specialized glutamatergic synapses, NO acts as so-called retrograde messenger; produced by activation of the postsynaptic cell (via increased Ca^{2+} levels), NO diffuses back to the presynaptic cell to close ion channels. This feedback system is an important element in the priming of synaptic contacts and it is probably one key component in learning and memory.

CO is increasingly recognized as a second messenger. It is largely generated during the breakdown of the blood pigment heme by heme oxygenase (HMOX) and contributes to the relaxation of smooth muscle cells.

Photonic Detection and Manipulation of Second Messengers Owing to the central role of second messengers in controlling cellular functions, there is tremendous interest in measuring their concentrations in living cells at high temporal and spatial resolution and to manipulate their concentrations in the cytosol. Biophotonic experimental approaches are well suited for these tasks. A variety of Ca^{2+}-selective dyes are available to measure $[Ca^{2+}]_i$. The selection depends on the range of Ca^{2+} concentrations to be observed, the speed of response, and the instrumentational availability of excitation and emission wavelengths. One dye frequently used is FURA-2; excited with about 340 and 380 nm light, it can provide relatively accurate measurements of $[Ca^{2+}]_i$ in a ratiometric manner. Likewise, there are systems for the visualization of cAMP and cGMP, based on either engineered proteins or low molecular weight compounds. Quantitative measurement of other second messengers – remember that we have addressed a few prominent examples only – is still an active field of research.

So-called caged compounds are used to liberate second messengers inside a cell upon stimulation by light. Typically these are light-sensitive substances that bind a messenger and release it once the compound is photochemically cleaved or has undergone a photoinduced conformational change. For the liberation of Ca^{2+} with near-UV light, substances such as DM-nitrophen [1-(2-nitro-4,5-dimethoxyphenyl)-1,2-diaminoethane-*N*,*N*,*N*′,*N*′-tetraacetic acid] and NP-EGTA (nitrophenyl ethylene glycol tetraacetic acid) are often used.

7.3.2.2 G Protein-Coupled Receptors

The physiological generation of most second messengers typically requires the activation of a membrane receptor by an extracellular stimulus. The information about receptor activation must be relayed to other downstream components in the cytosol through a second messenger. The coupling interface between the numerous types of transmitters or agonists that carry a chemical signal to the cell on the one hand and the second messenger systems and effector proteins on the other is a double-layered system of (very many) receptor proteins and (much fewer) heterotrimeric GTP-binding proteins, so-called G proteins (Figure 7.55a).

The receptor proteins that belong to that system are referred to as G protein-coupled receptors (GPCRs). They all have in common a topology with seven transmembrane helical elements (therefore they are also called serpentine receptors or 7-helix receptors) with a central binding site for a specific agonist. The agonists vary in size and structure; they include light-sensitive compounds, odor molecules, pheromones, hormones, and neutrotransmitters. GPCRs are by far the largest family of membrane receptor proteins (>1000 in humans). Typically they are classified according to their functional properties and agonists. In the neurobiological literature, GPCRs are often called *metabotropic* receptors in order to distinguish them from *ionotropic* receptors, that is, ligand-gated ion channels. For

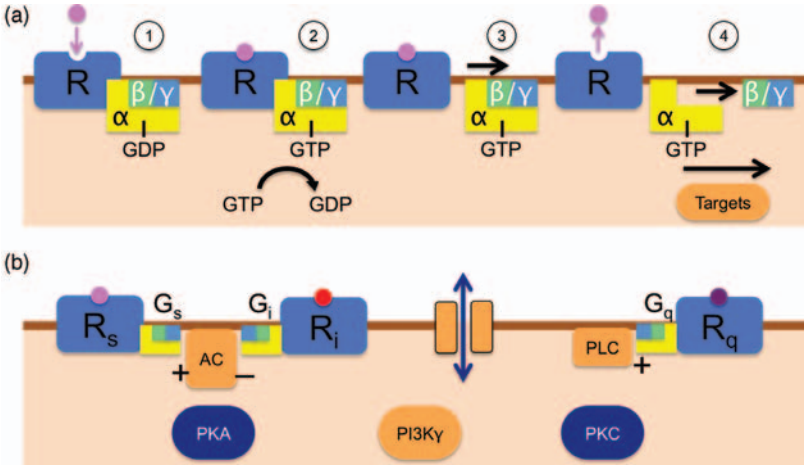

Figure 7.55 G protein-coupled receptors. (a) Sequence of G protein activation. (1) The receptor (R) is associated with the GDP-bound G protein complex consisting of α and β/γ subunits. (2) Upon agonist binding to the receptor, GTP is exchanged for GDP at the α subunit. (3) The G protein complex dissociates from the receptor. (4) The GTP-bound α subunit dissociates from β/γ. Both are now free to interact with downstream targets. (b) GPCRs selectively couple to different types of G proteins: stimulatory G_s and inhibitory G_i proteins regulating the activity of adenylate cyclase (AC), and also G_q proteins leading to phospholipase C (PLC) activation. While the generated second messengers subsequently regulate kinases (e.g., PKA, PKC) and ion channels, G proteins also directly interact with targets such as the protein and lipid kinase (PI3K γ) and ion channels.

example, whereas the nicotinic acetylcholine receptor (nAChR) is an ion channel, the metabotropic acetylcholine receptor (mAChR) is a GPCR. Likewise, there are metabotropic glutamate and serotonin receptors.

Activation of a GPCR is terminated by dissociation of the agonist. In addition, the sustained presence of an agonist in many cases results in receptor desensitization; the receptor progressively loses its sensitivity towards the respective agonist. This feedback process is an important mechanism by which the sensitivity of a receptor is adjusted, effectively increasing the dynamic range of detection.

GPCRs play key roles in modern medicine; about 30% of all prescribed drugs act on GPCRs and some are prescribed fairly frequently, such as β-blockers, neuroleptics, antihistamines, opiates, and sympathomimetics. For example, β-blockers are used for multiple forms of cardiovascular disease, including high blood pressure.

Heterotrimeric G Proteins The activity of GPCRs is signaled to the cell interior by means of heterotrimeric G proteins. These are membrane-associated proteins consisting of three distinct subunits, α, β, and γ. In an inactive form, GDP is bound to the α subunit in the complex. The GPCR, in close contact with the G protein, undergoes a conformation change upon ligand binding and thereby acquires a function as a guanine nucleotide exchange factor (GEF). This activity facilitates the exchange of GDP for a GTP molecule at the G protein and the GTP-bound G protein

is released from the GPCR. The GTP-bound α subunit then separates from the β/γ complex (Figure 7.55a). Depending on the exact situation, an activated G protein, the liberated α subunit, or the β/γ subunits can then interact with target proteins. With time, the α subunit hydrolyzes the bound GTP to GDP and reassociates with the β/γ complex, terminating the signal.

Typically, G proteins are classified according to the functional impact of their activated α subunit. Stimulatory G_s proteins activate whereas inhibitory G_i proteins inactivate the cAMP pathway. G proteins of the G_q subfamily activate the phosphoinositol messenger system (Figure 7.55b). In addition, both G-α and G-β/γ can directly affect other proteins such as ion channels. For example, activation of a G protein cascade may hyperpolarize a cell by opening of K^+ channels by the G-α subunit. On the other hand, the β/γ complex can increase the open probability of Ca^{2+} channels, hence leading to cell depolarization. Some ion channels are controlled by GPCRs in a twofold manner: rapid activation by direct G protein binding is followed by a delayed modulation via a second messenger.

For studying G protein-mediated cell signaling, two molecules are of particular interest. The GTP analog GTP-γ-S is not easily hydrolyzed by the G-α subunit under physiological conditions. When applied to a cell it binds to G proteins in an irreversible manner, causing sustained G protein activation. GDP-β-S is a GDP analog; when bound to a G protein it cannot be exchanged for GTP and, hence, causes G protein inhibition. Both analogs exist in labeled forms (radioactive or fluorescent) and provide experimental insight into the complex processes underlying G protein signaling.

Photoreception As discussed in Section 7.1.5.1, rhodopsins (see Figure 7.18), the photoreceptor proteins in the rods of the eye retina, are a special group of GPCRs. Here the "agonist" is the prebound retinal that becomes active upon photon absorption. The activated rhodopsin then activates the associated G protein, here called transducin, which in turn directly activates a class of cGMP phosphodiesterase. The latter catalyzes the breakdown of the second messenger cGMP to 5′-GMP. In the plasma membrane of rod cells, there are cation-selective cGMP-activated ion channels creating an influx of Na^+ and some Ca^{2+} when the cGMP concentration is high – the dark current. A decrease in the cGMP concentration as a result of photon absorption closes the ion channels and hyperpolarizes the rod cell, providing a signal that is relayed to the synapse of the photoreceptor cell. This process is very efficient: by means of G protein coupling, the absorption of one photon by the retinal in rhodopsin can lead to the hydrolysis of about 100 000 cGMP molecules. This is a good illustration of how the second messenger system is used to amplify the primary signal, one photon in this example.

7.3.3
Receptor Kinases, Hormones, and Transcription Regulation

Whereas ion channels have an immediate impact on cell function by permitting ions to cross the cell membrane, GPCRs also affect cell functions via G proteins and

second messengers. The latter then often activate kinases that phosphorylate (and thereby activate or inactivate) a wide range of target proteins. In many cases, however, the initial activation of a kinase is only the beginning of a phosphorylation cascade, that is, a sequence of phosphorylation events in which the initial "signal" is relayed from one kinase to the next and so forth. Moreover, the primary receptor can be a kinase itself – a so-called receptor kinase.

By means of a sequence of molecular events, the initial chemical signal eventually leads to an alteration of gene transcription, thus modifying the "state" of a cell. The latter often is classified according to rather coarse cellular phenotypes such as "proliferation" (cells divide), "migration" (cells move), "differentiation" (cells change morphology and adopt a more specialized function), or "apoptosis" (cells undergo a programmed cell death). In the following we discuss a few steps in this "signaling cascade."

7.3.3.1 **Receptor Tyrosine Kinases**

Tyrosine kinases are enzymes that phosphorylate proteins at tyrosine side chains. In humans there are 90 genes coding for tyrosine kinases, and 58 encode those that are also capable of receiving chemical signals – the receptor tyrosine kinases (RTKs). RTKs are localized at the cell surface and they typically respond to the binding of peptide signaling molecules such as growth factors, cytokines, and hormones. We discuss RTKs in more detail because of their pivotal role in regular cell functions and also their implication in the development and progression of various types of cancer (see Section 7.4.1).

Although diverse in structure, RTKs have in common a single transmembrane segment anchoring them in the plasma membrane, a variable extracellular structure with specific binding motifs for their ligands, and a more conserved intracellular catalytic domain harboring kinase activity (Figure 7.56). Ligand binding to the receptor triggers a sequence of molecular events, here exemplified for the epidermal growth factor receptor (EGFR); activation of the EGFR can lead to cell proliferation and migration, hence this receptor plays an important role in some forms of cancer. Once the agonist, epidermal growth factor (EGF), is bound to the extracellular binding site, two receptor monomers form an active dimer, stabilized by a disulfide bridge. The conformational change is transmitted to the catalytic domains, which then phosphorylate themselves. The catalytic domain, phosphorylated at tyrosine residues, then forms the target of a class of proteins that bind via their SH2 (Src Homology 2) domain. One such adapter protein is Grb-2 (growth factor receptor-bound protein 2). Grb-2 attracts the guanosine nucleotide exchange factor protein SOS (Son of Sevenless), which transiently interacts with and activates a small G protein (see Section 7.3.2.2), finally triggering an avalanche of further signaling event (see below).

RTKs are diverse in both structure and function, and can deviate markedly from the example above. RTKs are grouped into about 20 different classes; a few prominent examples are the following:

- the ErbB family, of which EGFR is a member
- insulin receptors

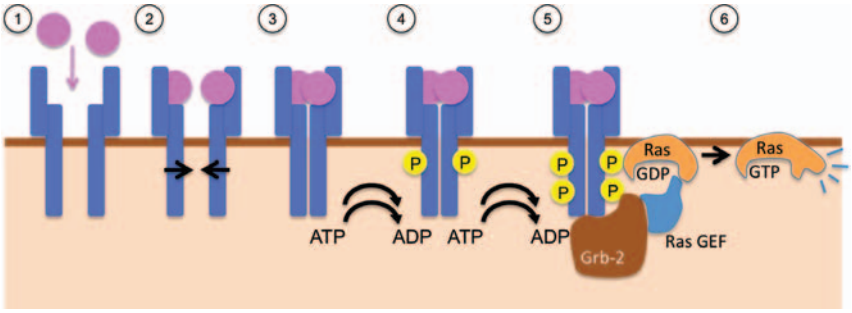

Figure 7.56 Receptor tyrosine kinase (RTK). Sequence of events during the activation of an RTK, for example the epidermal growth factor receptor (EGFR). (1) An agonist, here the small signal protein epidermal growth factor (EGF), binds to the receptor, which is anchored in the plasma membrane with only one transmembrane α-helix. (2) Upon binding, two activated receptors associate to form a dimer (3). (4) Their intrinsic tyrosine kinase activity results in autophosphorylation of their intracellular catalytic domains. (5) Once phosphorylated, the receptor becomes a binding target for adapter proteins, such as Grb-2 (growth factor receptor-bound protein 2). (6) Further association of guanosine nucleotide exchange factor proteins (GEF), such as SOS, activate the small G protein Ras by exchange of GTP for GDP. Activated Ras then starts a signaling cascade involving a series of phosphorylation events (see Figure 7.57).

- receptors for various growth factors such as PDGF (platelet-derived growth factor receptor), FGR (fibroblast growth factor receptor), and VEGF (vascular endothelial growth factor).

They all have in common that the binding of the specific agonist activates the receptor, which then stimulates subsequent intracellular events, in many cases manifesting itself as an alteration of the gene transcription pattern.

RTK signaling is terminated by dephosphorylation of the receptor. This is achieved by protein tyrosine phosphatases (PTPs). Since PTPs are the natural counterparts of RTKs, they are important elements regulating the "level of activation." Therefore, like RTKs, PTPs are involved in cellular processes such as cell growth, differentiation, mitosis, and oncogenic transformation, that is, a dysfunction of PTPs may cause cancer and can have fatal consequences.

7.3.3.2 Small G Proteins – Intracellular Bimodal Switches

Extracellular signals relayed into the cell by membrane receptors are frequently "translated" into second messengers or the activation of membrane-bound heterotrimeric G proteins (large G proteins). Receptor tyrosine kinases also follow the general paradigm with the exception that, rather than activating a heterotrimeric G protein, they are coupled to a class of so-called small G proteins (20–25 kDa). The latter are similar to the α subunits of heterotrimeric G proteins and they belong to the Ras superfamily of small GTPases.

Small G proteins to a certain extent can be considered as second messengers, because they carry a message depending on their association with guanosine

nucleotide. When bound to GDP, small G proteins are in an inactive form; they are activated when GDP is exchanged for GTP. This reaction is facilitated by GEF proteins, such as SOS (Figure 7.56). GEF actually helps GDP to dissociate from the G protein and, because of the cytosolic excess of GTP, separation of GEF will most likely result in a reassociation of GTP, thus completing the exchange cycle. The G protein is inactivated by hydrolysis of GTP, and this reaction is catalyzed by *GTPase-activating proteins* (GAPs). *Guanosine nucleotide dissociation inhibitors* (GDI) keep the G protein in its GDP-bound inactive form. The balance between GEF, GAP, and GDI activity determines the guanine nucleotide status of Ras proteins. The small G proteins therefore are bimodal "on/off switches". Because they are small and often soluble in the cytosol, small G proteins can carry the information stored in their activation state to various sites inside a cell.

There are more than 100 members in the superfamily of Ras proteins, including Rho, Ran, Rab, Arf, and many more. The Ras family is generally responsible for cell proliferation, Rho for cell morphology, Ran for nuclear transport, and Rab and Arf for vesicle transport. Owing to their involvement in elementary cell functions such as proliferation and migration, Ras proteins are so-called proto-oncogens, that is, excess Ras activity can lead to uncontrolled cell growth and tumor formation.

Ras proteins have various effector proteins such as lipid kinases (PI3K). A very well studied signal cascade triggered by Ras is the mitogen-activated protein kinase pathway, which starts with the Ras-mediated activation of Raf (rapidly growing fibrosarcoma) proteins.

7.3.3.3 **Mitogen-Activated Protein Kinase**

Ras initiates a phosphorylation cascade, culminating in the activation of MAPK, which enters the nucleus and phosphorylates various nuclear transcription factors (such as Elk1). This general complex of signal transduction is presented in a simplified manner in Figure 7.57a. An extracellular ligand binds to a receptor. Upon binding, the receptor becomes a target for adapter proteins – intracellular proteins that bind to the receptor at cytosolic moieties. This complex formation is an important aspect in cell signaling and it strongly determines cellular states. It not only happens at membrane-spanning receptor proteins but is practically relevant for all signaling proteins found throughout the cell. The adapter proteins may then "recruit" further proteins into the complex. In our example in Figure 7.57 these are GEFs that activate nearby small G proteins. This is the starting point of a so-called phosphorylation cascade. This means that a protein becomes phosphorylated with the aid of the activated G protein. The target protein, however, is a kinase itself, such that it can now – in its activated form – phosphorylate additional proteins, which can be kinases again. In the example discussed here, the final kinase is the mitogen-activated protein kinase MAPK. Therefore, kinases phosphorylating MAPK are referred to as mitogen-activated protein kinase kinases (MAPKKs), and so forth. From a signaling point of view, the "information" now resides in the phosphorylation status of a sequence of proteins. Depending on the final target, that is, the regulation of a transcription factor in the nucleus, signal transduction results in a long-lasting cellular response such as "proliferation." It is

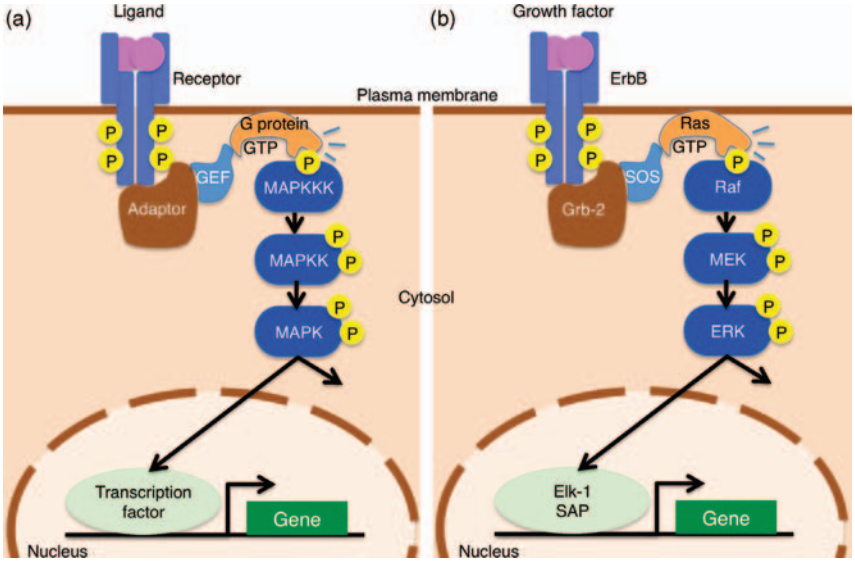

Figure 7.57 Mitogen-activated protein kinase pathway. (a) Signal transduction via the MAPK pathway, starting with the activation of a membrane receptor and subsequently of a G protein. The latter activates a kinase that phosphorylates further kinases, finally the MAP kinase. MAPK then affects transcription factors in the nucleus, that is, proteins that regulate how a gene is transcribed into mRNA. (b) The same pathway as in (a) showing a specific example (for details, see text).

very obvious that complex processes such as "proliferation" cannot be elicited by only turning one knob inside a cell. Therefore, to understand the final cellular outcome of an extracellular chemical signal one must consider all possible reactions (for clarity we show only one here) and, instead of setting individual switches by activated MAPK, rather a complex program of altered gene transcription is typically launched.

In Figure 7.57b, a specific example of MAKP signaling is illustrated. The membrane receptor is here the RTK ErbB. Autophosphorylated RTK recruits the adapter protein Grb-2 and the guanine nucleotide exchange factor SOS. Membrane-delimited Ras is activated, starting a phosphorylation sequence involving the serine/threonine kinases Raf, MEK (mitogen-activated kinase kinase), and ERK (extracellular signal-regulated kinase). ERK is the actual MAP kinase and can, among other reactions, affect the transcription factors Elk-1 and SAP in the nucleus.

7.3.3.4 **Nuclear Receptors**

The extracellular chemical signals discussed thus far are received by the cell via receptor proteins residing in the plasma membrane. Such signals can then be relayed into the nucleus to alter transcription using second messengers, MAPK, or related pathways. However, some ligands, such as steroids, thyroid hormones, vitamin A, and vitamin D, are hydrophobic enough to pass through the plasma membrane.

Hence these ligands can directly reach their receptors within the interior of the cell or even inside the nucleus. In the first place, such *nuclear receptors* regulate gene expression and thereby control complex cellular functions such as development and metabolism. In contrast to the signaling proteins discussed thus far, nuclear receptors have the ability to bind to DNA and function as transcription factors. Owing to the profound importance of nuclear receptors for development, these proteins are promising therapeutic drug targets. However, lipophilic xenobiotics binding to nuclear receptors can cause severe intoxication and developmental disorders.

Two major groups of nuclear receptors are recognized according to their localization and the mechanism of activation. Nuclear receptors of type I reside in the cytosol as a component of multimeric protein complexes; when bound to a ligand, type I receptors are liberated from the protein complexes and are transported into the nucleus (nuclear translocation). In the nucleus they bind to genomic DNA at specific sequences, the hormone response elements (HREs). Binding of the receptor to DNA then triggers the association of additional proteins that finally regulate the transcription of a gene downstream of the HRE. Examples of hormones binding to type I nuclear receptors are androgens, estrogen, progesterone, and glucocorticoids.

Nuclear receptors of type II are always inside the nucleus, associated with DNA. Ligand binding initiates a conformational change of the receptor, enabling it to change its interaction with other proteins (e.g., corepressor and coactivator proteins) that actually regulate gene transcription. Type II receptors include the retinoic acid receptor and the thyroid hormone receptor.

7.3.3.5 Gene Regulation

The term *gene regulation* comprises all molecular steps necessary to transcribe specific genes into mRNA and, finally, to generate the corresponding proteins. These include the regulation of the chromosomal structure, that is, the arrangements of chromatin domains, the transcription, post-transcriptional modification (e.g., mRNA splicing and editing, regulatory RNAs), transport of mRNA, the translation, and finally the termination of translation regulated by mRNA degradation.

All these steps are tightly regulated by numerous proteins. External signaling input to cells often cumulates in an effect on gene regulation, thus enabling the cell to change its state within a few minutes. Such altered "states" can be transient but they can also be stabilized to last for very long time – as for example during the differentiation of stem cells to specialized neurons (see Section 7.2.2.1). Although discussed here as the final result of a signaling cascade, gene regulation can also be considered the birth of a new signal (or multiple signals), thus being part of a gigantic meshwork of mutual dependences continuously changing with time.

Site-Specific Labeling of Proteins

When a protein is to be monitored in living cells, its intrinsic photonic properties may not be sufficient for efficient detection. One may employ fluorescently labeled antibodies that bind to specific epitopes at the protein. However, antibodies have several disadvantages, such as limited accessibility and localization of the epitope

(see the Box "Antibodies" in Section 7.1.2.5) and time and costs required for antibody production. An alternative is to perform a direct covalent coupling of a fluorescent dye to a specific site on the protein. Although such couplings are in principle possible at any amino acid, the easiest and most relevant side chain used cysteine. By means of a disulfide formation bond, dyes with a free thiol group can be coupled to proteins efficiently. Although native cysteines are sometimes used for labeling, a more frequently used approach is to introduce cysteines at specific sites of the protein by mutating the coding DNA and by heterologously expressing the protein in a host cell system. Such methods are often applied to extracellularly accessible domains of membrane proteins. Typical examples of cysteine-specific labeling compounds are methanethiosulfonate (MTS) reagents.

One of the major challenges in biophotonics research is to shed light on this puzzling complexity, for example, to provide tools allowing for the spatially and temporally resolved visualization of gene activity. A combinatorial approach utilizing multiple fluorescent markers, such as enhanced blue/cyan/green/yellow fluorescent proteins, may allow such visualization in the future.

7.3.4
Signaling Pathways

The examples discussed above give us a simplified view of how cellular signals are processed inside a cell. Signals thereby are manifested as "states," that is, a specific structural property of the cells such as the local concentration of second messengers, the status of proteins being activated by phosphorylation or by binding of nucleotides, or by the formation or dissociation of protein complexes, to name just a few. Such "states" then often propagate inside a cell, giving rise to terms such as "signaling cascade" or "signaling pathway." Hence we may talk about a cAMP pathway or a MAPK pathway, for example. When characterizing such pathways, the direction is indicated, referring to *upstream* and *downstream* events, where the start of a pathway usually is the initial binding of an extracellular ligand to a receptor in the plasma membrane or inside a cell.

Among the obvious reasons for having such signaling pathways in cellular systems is their potential for signal amplification: a single transmitter molecule can trigger an avalanche of cellular reactions. In addition, multi-step signaling enables a cell to generate responses with different time courses: while the intracellular Ca^{2+} concentration rises locally within a few 100 μs upon an activation of a Ca^{2+} channel in the plasma membrane, subsequent Ca^{2+}-mediated alterations of the gene transcription program may take minutes or hours. The cell hence has capabilities of effectively processing initial signals such as to perform temporal and spatial differentiation and/or integration.

Cellular signaling pathways are enormously complex; there are numerous pathways and there are alternative routes in the downstream and upstream directions. As a consequence, the physiological outcome of activated signaling pathways can only be understood when all other pathways are properly controlled. Activation of pathway A,

for example, may cause the inhibition or activation of pathway B, leading to concepts such as *signal*, *crosstalk*, and *transactivation*.

The only way to deal with this bewildering complexity is a systematic approach of pathway analysis. On the one hand complete experimental data sets are needed to describe the activity of genes, the existence of proteins (maybe even including their state of modification), and the existence and concentration of all other metabolites inside cells. Such data sets are now compiled using modern microarray technologies to detect mRNA (genomics) and proteins (proteomics) of the entire genome under consideration (pangenomic arrays). In addition, high-end mass spectrometric methods provide detailed and quantitative insight into the cellular content of proteins and metabolites (metabolomics). This very rich source of experimental results needs to be processed so as to gain manageable information reflecting a biologically relevant meaning. This urgent need has triggered the development of *systems biology* as a new branch of science that tries to describe biological systems (e.g., microorganisms, cells, or even higher organisms) as one unit composed of very many interacting elements.

Information from highly parallel "omics" experiments is then analyzed with systems biological methods to isolate individual pathways and to detect their coupling to other pathways. An example illustrating several pathways in one cell is shown in Figure 7.58. Meanwhile there are many databases available providing

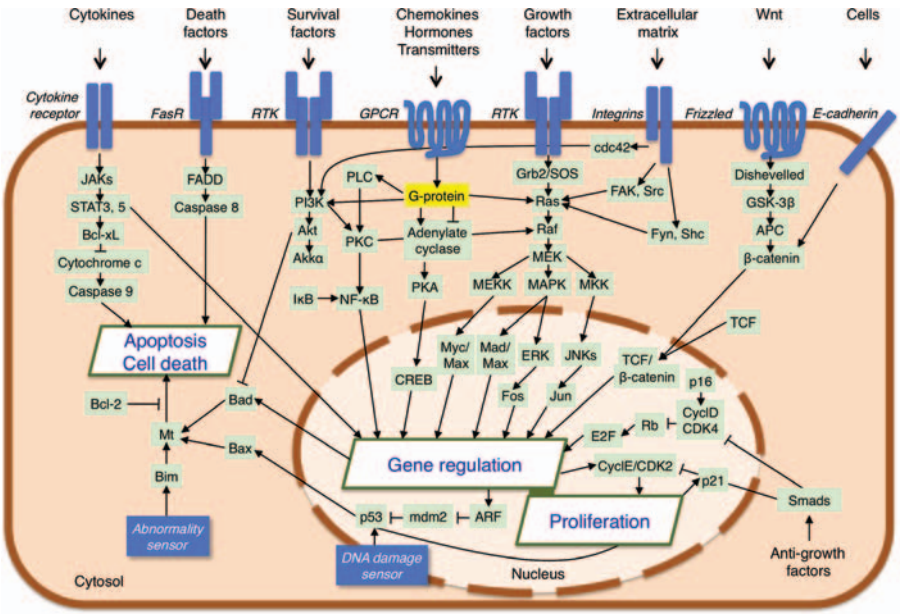

Figure 7.58 Pathway analysis and crosstalk. Schematic description of a few pathways important in cellular signaling. This illustration, although showing only a very small subset of cellular signaling components, already indicates that there are very many more types of receptors, adaptors, mediators, and effectors than discussed in this brief overview of cell signaling. Not illustrated are diffusible second messengers, such as Ca^{2+} and cAMP, which also strongly modulate the individual intracellular reactions.

information on pathways in cellular signaling. Owing to the complexity, these are often specialized to certain scientific subtopics such as a disease or a specific drug or protein. The reader may try to localize such information on the Internet by searching for "cancer signaling pathway" or may look at the Kyoto Encyclopedia of Genes and Genomes (KEGG) database.

Although of impressive complexity and completeness, the currently available data that form the basis of contemporary pathway analysis often lack sufficient temporal and spatial resolution. In addition, in many cases only rough estimates regarding the concentrations of interaction partners and activated elements are available. Therefore, future research will aim at the analysis of cell signaling in living cells in real time with subcellular resolution. The development and use of methods from biophotonics are a logical approach because of the advantage of the minimal invasiveness of light–matter applications.

7.4 Some Examples of Diseases

A disease is any condition in which the normal body function is impaired. The cause of the condition (*etiology*) and the disease progression (*pathogenesis*) vary widely. Many diseases remain *idiopathic*; their causes are unknown. Selected examples are presented below to illustrate the disease diversity.

7.4.1 Cancer – Loss of Proliferation Control

Cancer is a group of frequently fatal diseases characterized by uncontrolled cell growth. *Cancer* is a general term referring to a disease state with dysregulated cell growth, whereas a *tumor* is a solid accumulation of cancer cells. Primary cancer manifested as a tumor in one organ may spread via lymph or blood, and invade other organs, forming metastatic cancer elsewhere. The risk of cancer development is markedly influenced by both genetic factors and environmental factors, including exposures to toxins and viruses. Mechanistically, cancer is a dysfunction of cell growth; as such, a primer of cell division and cell cycle is presented below before our discussion of select cancer cases and potential therapy options.

7.4.1.1 Cell Division

All cells of an adult human are the result of serial cell divisions starting with the fertilized oocyte, as the founder cell of the whole organism. The process by which a cell is split in two, *cytokinesis*, involves the equatorial assembly of a contractile ring made from actin and myosin filaments. This ring of motor proteins constricts the cell membrane to form a deepening cleavage furrow that eventually splits the cell into two daughter cells. Tightly linked to cytokinesis is a process called *mitosis*, during which

all chromosomes are symmetrically arranged and evenly distributed between the two cell halves. This separation of chromosomes follows a strictly organized program that involves the transient halt of RNA synthesis, maximum condensation of all chromosomes, disassembly of the nuclear envelope, and the fixation of the chromosomal centromeres to microtubules arising from microtubule-organizing centers (see Section 7.2.1.8) in both hemispheres of the cell. These microtubules are responsible for the mechanical work that drives two sets of chromosomes into each half of the dividing cell. At the end of mitosis, nuclear envelopes are re-formed in both daughter cells, chromosomal packaging is loosened, and normal transcriptional activity resumes. Mitosis and cytokinesis are precisely coordinated and the whole process takes about an hour in most animal cells. Importantly, cell division and the mechanical separation of chromosomes are only the final steps of a more complex series of events, the *cell cycle*.

Cell Cycle Phases and Checkpoint Control Animal cell growth is not a simple continuous process of macromolecule accumulation and increase in cell volume, but can be divided into four discrete functional phases (G_1, S, G_2, and M) (Figure 7.59). Cell cycle progression is also by no means automatic, but requires the cell to make decisions at several checkpoints. Immediately after a new cell results from division, it starts to produce mRNA and proteins and the overall production of macromolecules proceeds until the next mitosis starts. However, DNA replication, the duplication of chromosomes, is delayed for at least several hours. This first cell cycle period with no replication activity is called G_1 (first gap) phase, as it separates mitosis and the DNA synthesis (S) phase. The duration of G_1 is not only dependent on the availability of nutrients and thereby the speed of cell growth, but is also

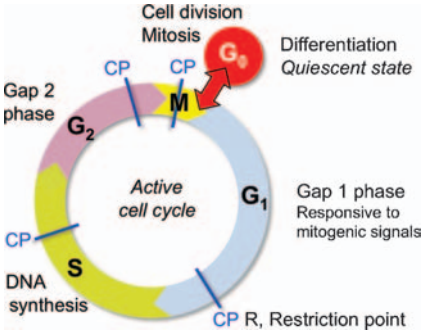

Figure 7.59 The cell cycle of a mammalian cell. Dividing cells pass through four distinct phases with checkpoints (CP) to ensure that progression is linked to specific conditions. Major prerequisites for S, G_2, and M phase progression are genome integrity, completed replication, and proper chromatid assembly, respectively. In G_1, the cell is primarily controlled by extracellular signals that decide if progression to DNA synthesis occurs or if the cell enters the quiescent state G_0. The molecular basis of the control system is provided by cyclins, which are present at oscillating concentrations, and cyclin-dependent protein kinases (CDKs).

characterized as a period of pronounced responsiveness to extracellular signals. As outlined in Section 7.3, mitogenic signals that can stimulate cell proliferation via membrane receptors and downstream signaling pathways are normally required to drive cell proliferation. The G_1 phase is the time period during which a cell is responsive towards this kind of extracellular signals and, even if nutrients are available in abundance, it will not proceed to the S phase without such a signal.

However, extracellular signals not only trigger cell *proliferation* but also control cell *differentiation*. If a cell in G_1 experiences an excess of differentiation signals over proliferative signals, it will not proceed to DNA replication, but rather remain in a stable, differentiated state called the G_0 phase. By contrast, if sufficient proliferative signals were received, the cell will proceed past the so-called restriction point ("R point") (Figure 7.59) and from there on behave largely independently of extracellular signals. Shortly after passing the R point, during the S phase the cell duplicates all chromosomes, a mandatory requirement for the next cell division. The S phase also includes a checkpoint and replication will be halted if any DNA damage is detected at this stage. Only if repair enzymes successfully restore genome integrity can a halted cell proceed past this point. The S phase is complete when all chromosomes have been replicated. The cell will not directly enter mitosis, but remain in a second gap phase (G_2) for at least some hours. Another checkpoint at the entrance of the M phase blocks the cycle again if the genome duplication is not fully completed. Once the cell has passed this point, the mitosis proceeds according to a predetermined program, unless at the "spindle attachment checkpoint" chromatids are not properly assembled on the mitotic microtubule spindle. Overall, the mammalian cell cycle is a process with four clearly distinct phases and multiple checkpoints at which a clear decision is required before the cell is allowed to proceed.

Cyclins and Cyclin-Dependent Kinases When the cell cycle works much like a precision clock, what controls speed, direction, and potential halts at the checkpoints? A first insight came from studies on mitosis in frog embryos, which revealed very precise and synchronous oscillations of concentration of a protein termed *cyclin B*. A gradual increase in cyclin B concentration is followed by a rapid degradation of the protein that is triggered by polyubiquitin chains added by a specific ubiquitin ligase. Later it was found that other cyclins show very similar fluctuations but with peaks at other points of the cell cycle. The complete absence of cyclin B after mitosis prevents any cell from direct re-entry into mitosis, as this would be fatal before DNA replication. Whereas cyclins B, E, and A are regulated by rapid protein degradation, cyclin D1 and other D cyclins that peak during G_1 are not degraded, but exported from the nucleus into the cytosol and thereby rendered inactive. This mobile characteristic of the D cyclins is important for the role of conveying extracellular signals to the cell cycle. Incoming mitogenic signals can cause D cyclins to migrate back into the nucleus and thereby promote cell cycle progression. The two described mechanisms underlying cyclin fluctuations explain the timing of the different phases and unidirectional progression, but the actual effectors of checkpoint decisions are protein kinases that must form heterodimers with individual cyclins to become active, the *cyclin-dependent kinases* (CDKs). One activity of the cyclin B–CDK1 complex

is to phosphorylate nuclear lamins, thereby triggering nuclear lamina breakdown during mitosis. Another prominent example of CDK activity is phosphorylation of the retinoblastoma protein (pRb) by cyclin D–CDK4/6 complexes and by cyclin E–CDK2 during G_1. The tumor suppressor protein pRb with no or only a few phosphorylated sites can bind and inactivate transcription factors required for the progression beyond the restriction point. In contrast, hyperphosphorylation of pRb by the cumulative activities of both cyclin–CDK complexes prevents this inhibiting function of pRb and, hence, drives cell progression beyond the G_1 phase into the S phase.

7.4.1.2 **Cell Death**

Cell death is not necessarily a misadventure in multicellular organisms, but rather a normal process occurring throughout the organism's life, during both development and adulthood. For instance, normal sculpting of the fingers requires that cells in the areas of the hand that are supposed to become the intervening spaces die during development. This controlled interdigital cell death follows a stereotypical signaling program called *apoptosis*, a form of programmed cell death (PCD). Apoptotic cells not only stop their metabolism and destroy their own DNA, but they also signal phagocytic cells to engulf the dead cells or their resulting fragments in membrane vesicles called apoptotic bodies. This apoptosis program is needed during development but it also provides an important safety mechanism throughout adult life. Whenever cells experience unusual challenges, such as DNA damage, viral infection, or severe dysregulation of signaling pathways, induction of apoptosis is a common way to avert damage to the surrounding tissue and the whole organism. However, apoptotic cell death is not the only way to end the life of a cell. In many surface epithelia such as the intestine or the epidermis of the skin, old and inactive cells are continuously shed to the exterior (Section 7.2.2.4). Epidermal keratinocytes in their terminal differentiation state in the outermost cell layers of the skin are dead and without a nucleus; the cells are not actively removed by other cells but simply lost upon washing or rubbing. Loss of selected cells such as exfoliation of the skin cells does not pose a problem for the organism. However, if metabolically active cells are damaged and cannot be cleared, the leakage of cell contents might severely damage neighboring cells of the tissue. This uncontrolled cell death or *necrosis* is a common consequence of burns and frostbite. In contrast to apoptosis, the cell remnants are not trapped in membrane-sorrounded vesicles, but cytosol and even the content of lysosomes packed digestive enzymes can be released. Necrotic wounds are therefore dangerous for the organism and they often impair wound healing.

Apoptosis Signaling The program of apoptotic cell death is inherent to all cells of the body and the signaling system effecting this event must be tightly controlled to avoid unwanted loss of cells. The last steps and the terminal result of apoptosis are always similar, but with respect to the initiating steps, *intrinsic* and *extrinsic* pathways need to be distinguished (see Figure 7.60). Intracellular (intrinsic) apoptosis signals can be triggered by DNA damage through UV radiation, by cytotoxic drugs, or by oxidative stress. The intracellular signals typically lead to the same critical event, namely the

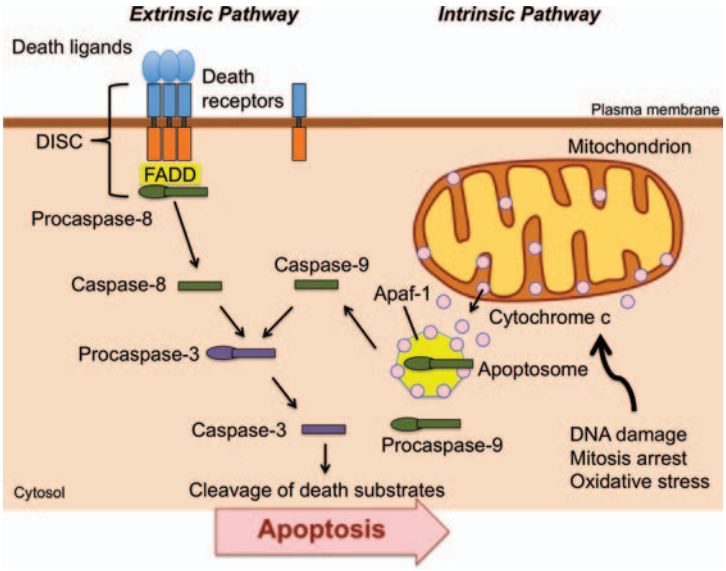

Figure 7.60 Apoptosis – programmed cell death. Controlled cell death enables the organism to remove individual cells during development or in response to cell stress and damage. Cell death commands are conveyed by caspases, proteinases that are primed by proteolytic cleavage of procaspases. Initiation of a caspase cascade can be triggered either by the activation of death receptors or by cytochrome *c* release from mitochondria. Caspase 3 and other effector caspases at the end of the signaling cascade cleave various protein targets in the cell and thereby cause apoptotic cell death.

release of the small heme protein cytochrome *c* from the mitochondrial intermembrane space into the cytosol. Here, cytochrome *c* binds to the protein Apaf-1 and together they form a wheel-like structure with sevenfold symmetry, the apoptosome. This complex then binds and activates the protein procaspase-9. *Caspases* are a family of cysteine-dependent aspartate-directed proteases. They are produced as inactive precursor proteins that can be activated by cleavage of the inhibiting prodomain. Two functional classes of caspases are known: *initiator caspases* that cleave and activate other caspases, and *effector caspases* that cleave other substrates. Caspase-9 acts as an initiator and activates procaspase-3. The active caspase-3 in turn cleaves a broad variety of substrates including actin, tubulin, and pRb, with the inevitable consequence of apoptotic cell death.

Whereas many internal signals finally affect the mitochondrial membrane and its permeability to cytochrome *c*, extrinsic signals use a separate pathway to activate the caspase cascade. The membrane receptors responsible for conveying extracellular apoptosis signals are called *death receptors*. Activating ligands can be soluble proteins but also membrane-bound proteins on the surface of immune cells. Thus, monocytes or other immune cells can instruct a suspicious cell to undergo apoptosis as a suicide program. This is particularly important for the control and removal of tumor cells or virus-infected cells. Death ligand binding causes death receptor trimerization and in turn triggers the binding of cytosolic proteins to the receptor. The Fas-associated

death domain (FADD) protein is such a cytosolic adapter protein and together with the death receptor and procaspase-8, it forms the death-inducing signaling complex (DISC). Active caspase-8 formed by this complex can directly cleave the effector caspases such as caspase-3. Thus, extrinsic and intrinsic pathways converge and result in very similar final stages of apoptosis. One typical hallmark of apoptosis is the fragmentation of chromosomal DNA such that pieces 130–180 bp in length are generated. Another important step is the activation of scramblases in the plasma membrane due to increased cytosolic Ca^{2+} levels. As a consequence, the phospholipid phosphatidylserine, which is normally localized to the inner leaf of the plasma membrane, will appear on the outer surface of the cell membrane as a signal for macrophages to remove the apoptotic cell.

7.4.1.3 Cancer – Diagnosis and Therapy

Cancer is a general term for a diverse and large group of diseases that can affect all parts of the body. A common feature in cancer is the uncontrolled growth of abnormal cells that grow beyond their normal tissue boundaries, often forming a tumor or a neoplasm, and eventually invade other parts of the body. This process, termed metastasis, is the major cause of cancer mortality. With nearly 8 million deaths, cancer accounted for ~13% of all deaths worldwide in 2007. Cancer has long been recognized as a severe health issue throughout the history of medicine, but it was not until the twentieth century that the molecular mechanisms underlying this group of diseases began to emerge. A major breakthrough came in the 1970s, when Varmus and Bishop provided evidence for genetic mechanisms underlying the uncontrolled growth of cancer cells. We now know that tumors can arise from normal cells if mutations in otherwise normal genes occur or if the expression level of a group of genes is strongly altered.

Cancer Types and Cancer Risk Cancers are typically grouped according to the tissue from which they arise and approximately 110 different cancerous diseases have been categorized in this way. Although almost any tissue type can become cancerous, the incident is not uniform across different tissue types. In those tissues with highly differentiated cells that do not appreciably undergo cell divisions, such as nerve tissue, tumor formation is relatively uncommon. By contrast, the epithelium of the colon, with a high rate of cell division, is a very common site of cancer emergence. The leading causes of worldwide cancer deaths are tumors arising in the lung, followed by the stomach, colon, liver, and breast. The first morphological evidence for a cancer is enhanced cell growth or the occurrence of less mature cells in a tissue. Such *dysplasias* are classified as *benign* as long as they do not invade nearby tissues. As soon as such cells grow beyond the normal tissue borders, the tumor is called *malignant*. Malignant cell growth in epithelia, termed *carcinoma*, is responsible for over 80% of cancer deaths, including carcinomas of the mammary gland, stomach, intestine, lung, and liver. Nonepithelial cancers arising from connective tissues or from myocytes are commonly termed *sarcomas*. Another major group of cancers are the *leukemias* and *lymphomas*, both arising from cells of the hematopoietic lineage. The *neuroectodermal* tumors are a group of cancers arising from the outer cell layer

of the early embryo. They include different kinds of glioma, neuroblastoma, and malignant melanoma. The distribution of cancer entities in the body can vary markedly in different populations. For example, the risk of malignant melanoma of the skin is about 150-fold higher in Australia than in Japan, and the incidence rate for cancer of the nasopharynx is 100-fold higher in Hong Kong than in the United Kingdom. Such extreme differences are in part due to genetic differences between the populations, but individual lifestyle and environmental factors are even more important risk determinants. In the United States and Northern Europe, the majority of lung cancers can be attributed to active smoking and the lung cancer incidence rates strictly follows the habit of cigarette smoking. Other risk factors with proven association with cancer incidences comprise diets with high fat, high nitrate, or low fiber and exposure to specific carcinogenic agents such as radium, arsenic, benzene, and asbestos.

Oncogenes and Tumor Suppressor Genes Many human diseases are caused by pathogens such as bacteria and viruses. In 1910, Peyton Rous showed that cancer can be an infectious disease spread by viruses. He found that a sarcoma in the muscle of a chicken is transferred to other chickens by the Rous sarcoma virus (RSV). Similarly, human cancers can be caused by viral infection. Examples are cervical cancer caused by the human papilloma virus (HPV) and adult T cell lymphoma caused by the human T cell leukemia/lymphotropic virus type 1 (HTLV-I). However, for the majority of all cancers no infectious agents could be identified, and it became clear that alterations in the human genome can have similar effects as viral infections, leading to a *transformed* phenotype of individual cells. Detailed analysis of the viral life cycle within host cells eventually identified molecular mechanisms of tumor formation that apply to both virally spread and nonviral forms of cancer. In the genome of RSV, a single gene termed *src* for sarcoma is responsible for the transforming activity but is not required for normal viral replication. Bishop and Varmus showed that *src* is not restricted to viral genomes, but that a gene closely related to *src* is found in the chicken genome itself and also in humans. With this observation, the first cellular *oncogene* was discovered, establishing the concept that normal genes can have the potential to drive cancerous cell growth. More precisely, the intact gene is called a *proto-oncogene*, and mutations can render it hyperactive and induce its oncogenic activity. In the case of *src*, it became evident that ~12% of advanced human colon carcinomas carry mutations in this gene. Thus, *src* can induce cell transformation independent of any viral activity. Today, a large number of proto-oncogenes are known in the human genome and they have in common that the encoded proteins are in one way or another involved in cell cycle control, such that hyperactivity causes increased cell proliferation. The mutations that activate proto-oncogenes are not always simple single-point mutations. In more than 90% of all patients with chronic myeloid leukemia (CML), a translocation of genetic material between chromosomes 9 and 22 is present in bone marrow stem cells. At the breakpoint of this rearrangement on chromosome 22, the "Philadelphia chromosome," part of the *bcr* gene is fused to the tyrosine kinase gene *abl*, with the consequence that the fusion protein BCR/ABL has increased tyrosine kinase activity.

The Src protein is also a tyrosine kinase and one of its target proteins is the growth factor ErbB (Figure 7.57), which initiates signaling along the MAPK pathway. Thus, a signaling pathway that normally drives cell proliferation in response to extracellular mitogenic signals can be dysregulated such that growth factor-independent cell proliferation occurs. Following this rationale, it is no surprise that the receptor ErbB itself was also found to have significant oncogenic activity. In over 30% of all human breast cancers, multiple copies of the *erbB-2* gene (also called HER-2/*neu*) are found. This gene amplification leads to higher densities of the receptor on the cell surface and thereby enhanced mitogenic signaling at normal growth factor concentrations. Even more direct activation of cell proliferation programs can be triggered if the machinery driving gene transcription is hyperactive, irrespective of the signaling cascades. This is the case in juvenile neuroblastoma, where the transcription factor gene N-*myc* is often found in 10 or more copies in the genome. This amplification leads to increased levels of the transcription factor protein and correlates with a poor prognosis. Irrespective of the cellular role of an oncogene, increased activity often leads to faster proliferation. Alternatively, oncogenic proteins can increase the cell's potential to migrate and to invade into foreign tissues, and even the formation of new blood vessels, angiogenesis, can ultimately be triggered by oncogenic factors (Figure 7.61).

In the normal cell, proliferation is not simply controlled by activating signals, but rather determined by the balance between activating and inhibitory signals. Hence any failure of an inhibitory protein can have similar consequences as the increased activity of a proto-oncogene. The class of genes encoding such inhibitory proteins is called *tumor suppressor genes*. Like oncogenes, they can affect all levels of cell signaling, from membrane receptors down to transcription factors (Figure 7.61). A prominent example is the *p53* gene, encoding a master regulator protein of cellular apoptosis. Cell-cycle abnormalities and DNA damage, as they often occur in fast-growing tumors, would normally lead to cell cycle arrest and induction of controlled cell death. However, in a large fraction of tumors, the transcription factor protein p53 is not present in normal amounts, leading to survival of the tumor cells. The lack of a tumor suppressor protein, such as p53, can be caused by mutations that affect the protein function. Alternatively, reduced expression of the otherwise normal gene can be caused by hypermethylation of the promoter or other genetic events.

Tumorigenesis The risk of developing cancer increases appreciably with age. This characteristic is consistent with the notion that tumor formation is not induced by a single oncogenic event but it is the consequence of multiple genetic alterations. Accordingly, identical twins with an inherited oncogenic alteration will not necessarily both develop cancer. As soon as a second, rate-limiting genetic event occurs, a tumor may become clinically apparent. This multiplicity of genetic alterations is required because cellular signaling is governed by multidimensional networks (Figure 7.58), in which dysregulation of a single switch is normally not sufficient to reprogram the whole system. Furthermore, tumor formation is a multi-step and multi-dimensional process that depends on more than just enhanced and uncontrolled cell growth. Most cancers develop in discrete steps, such as dysplastic tissue

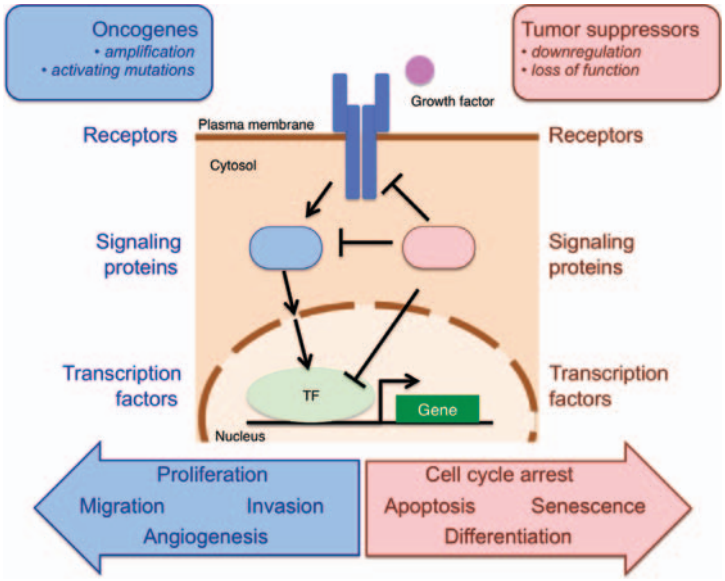

Figure 7.61 Oncogenic signaling. Signaling in tumor cells is characterized by an unbalance between proliferative signals by oncogenic factors (left) and inhibitory signals from tumor suppressors (right). Oncogenes and tumor suppressors can be found on all levels of cell signaling, from membrane receptors down to nuclear transcription factors. Cellular events that either increase the activity of oncogenes or decrease tumor suppressor functions can promote uncontrolled cell division, metastasis, and the formation of tumor blood vessels (angiogenesis).

growth, neoplastic growth into neighboring tissues, spreading along the lymphatic system, or the dissemination through blood vessels that eventually leads to distant metastases. During these phases, the requirements for the tumor cells may vary and a selective advantage at one stage may be irrelevant or even a disadvantage in a different stage.

A long-standing concept in cancer biology hypothesized that accumulation of mutations allows the tumor cell population to acquire new properties, finally leading to a highly malignant and aggressive cell type. This sequential model was challenged by the later finding that not all cells in a tumor are functionally equivalent. Just like stem cells in normal tissues, small subpopulations of slowly dividing cells with self-renewing capacity have been identified in otherwise rapidly dividing leukemias and also in breast cancer and other solid tumors. Such *cancer stem cells* are thought to initiate new tumors and to give rise to the more aggressive, fast-dividing cell type. Whether or not cancer stem cells have common functions and importance in all types of cancer must be clarified in the future. In any case, tumors are heterogeneous assemblies of different cell populations.

Cancer Treatment The standard treatment for most solid tumors is surgical resection in combination with follow-up radiotherapy and/or chemotherapy. The surgical

removal of cancer cells is of limited success if dissemination has occurred. By contrast, chemotherapy reaches wider areas of the body, including any distant metastases. The major obstacle in this approach is the lack of selectivity and consequently often severe side effects. Most commonly administered drugs are designed to interfere with DNA replication and thus cell division – cytostatic agents. As a consequence, cancer cells with high proliferation rates are more susceptible than slowly dividing cells. As many tissues including intestinal epithelia or bone marrow also need rapid cell division of normal progenitor cells, chemotherapy with cytostatics has serious limitations. The finding that slowly dividing cancer stem cells can reside within the tumor cell mass provides a mechanistic explanation for the frequent observation that a life-threatening cancer relapse can follow an initial reduction of the cancer cell mass. These cells with stem cell-like properties are often more resistant to standard therapeutic treatments than the majority of the tumor cells. If they survive the therapeutic intervention, this cell population is the seed for new tumors.

Rational Tumor Therapy The identification of cellular oncogenes and a growing knowledge of intracellular signaling networks in cancer cells have created new opportunities. Given the importance of individual oncogene products, it appeared reasonable to search for drugs that specifically target those signaling proteins instead of using classical cytostatic drugs made to interfere with the process of DNA replication. To be "druggable," an oncoprotein should have a substrate binding pocket that allows the high-affinity binding of small molecules. One of the first prominent successes of rational drug design targeting an oncoprotein was imatinib, a small multi-ring compound now marketed as Gleevec® or Glivec®. This small molecule binds to the active site of the hyperactive tyrosine kinase BCR-ABL responsible for over 90% of all cases of CML. The drug was approved for the treatment of CML and found to be more effective than previous standard treatments, leading to complete remissions in a majority of the treated patients. Imatinib is well tolerated, but long-term side effects remain to be evaluated fully. The success story of imatinib is not without a down side, as it has become evident that long-term treatment with the drug can induce a selective pressure for BCR-ABL point mutations that interfere with drug binding. Modified imatinib variants were introduced as second-generation drugs to overcome this problem. Interestingly, imatinib is not selective for BCR-ABL but c-kit and the platelet-derived growth factor (PDGF) receptor are also inhibited by the drug. This finding makes imatinib an important new drug to treat gastrointestinal stromal tumors (GIST). In up to 90% of the GIST patients, a mutation of the *c-kit* gene, important for tumor progression, is present and those GIST patients with normal copies of *c-kit* often possess mutations in the PDGF receptor gene. Consequently, imatinib is now frequently and successfully used to treat patients after surgical removal of the tumor. Imatinib is only one of many examples of *targeted therapy* approaches, and many other drugs are currently in clinical trials or even approved for cancer treatment. Such drugs are not in all cases small molecules but larger monoclonal antibodies can be valuable tools for the specific intervention with oncoproteins. For example, cetuximab, marketed under

the brand name Erbitux®, is a monoclonal antibody against the external domain of the EGF receptor. This antibody is approved for the treatment of squamous cell carcinoma of head and neck and for colorectal cancer. Trastuzumab (Herceptin®), a monoclonal antibody against the receptor HER-2, is approved for the treatment of HER-2-positive breast cancer.

Given the large number of oncogenes and the heterogeneous pattern of mutations in most tumor types, it is unlikely that we will find drugs that cure all patients suffering from a given tumor or create a "magic bullet" drug for all cancer types. However, if the diagnosis of an individual patient allows identification of the specific oncogenes involved in the pathogenesis of each patient's tumor, it may be possible to replace the non-selective chemotherapy with an individually tailored targeted therapy approach. This way to combine refined diagnosis techniques with very specific drugs is called *personalized therapy/personalized medicine* (see Section 7.4.7).

7.4.2 Cardiovascular Disease

The cardiovascular system, consisting of the heart and blood vessels, supplies blood carrying oxygen and nutrients to organs and tissues throughout the body, including the heart and vessels themselves. The cardiovascular system is a large multi-component system and prone to dysfunction. In fact, cardiovascular disease (CVD), a collection of numerous different pathologies often interacting with the immune system, is the leading mortality cause worldwide, accounting for more than 25% of all deaths in recent years, and the figure is likely to increase. Heart attack, stroke, heart failure, and high blood pressure are some of the CVD forms well known to the public. Mechanistically, CVD involves a variety of underlying mechanisms including arteriosclerosis or hardening of the arteries, ischemia or diminished blood flow, infection by bacteria or viruses that often affect the heart valves, and/or abnormal prenatal development. Various genetic factors contribute to the pathogenesis, making some individuals more predisposed to develop certain forms of CVD and modulating the severity of the disease. Certain lifestyle factors, such as cigarette smoking and a diet rich in saturated fats, are also well-recognized risk factors. A few examples of CVD are briefly summarized below.

Atherosclerosis One of the most important and extensively studied contributing factors in many different forms of CVD is atherosclerosis, a chronic inflammatory vascular condition under which atheromas or cholesterol-containing plaques form immediately beneath the inner blood-facing surface (the endothelium) of medium- and large-sized arteries. The vascular endothelium ("intima") is a one-cell layer lining blood vessels located on top of the smooth muscle cell layer ("media") and produces a large number of vasoactive signaling molecules including endothelin, bradykinin, and nitric oxide. What triggers development of atherosclerotic plaques in the first place is not entirely clear, but it is believed that an injury to the endothelium caused by a mechanical or a shear stress typically initiates a vicious cycle of atheroma formation. Injured endothelial cells exhibit enhanced vascular permeability, allowing various

molecules to traverse the vascular wall. The dysfunctional endothelial cells also alter their gene expression pattern. As a result, the endothelial cells start to express cell-adhesion molecules that facilitate attachment of circulating white blood immune cells to the injured area, creating a local inflammation and oxidative stress. The presence of low-density lipoprotein (LDL), which is often referred to as "bad cholesterol," is also an important contributing factor. The immune cells infiltrate and migrate beneath the endothelium and facilitate the formation of an atheroma just outside the normal smooth muscle layer boundary ("internal elastic lamina"). During plaque formation, infiltrated immune cells generate reactive species capable of oxidizing cell components, including LDL. Oxidized LDL is taken up by infiltrated macrophages, which then transform themselves into foam cells that store oxidized LDL in their cytoplasm. Furthermore, the infiltrated immune cells release a variety of autocrine and paracrine signals (see Section 7.4.3.1) and accelerate the development of atheroma. A collagen fibrous cap eventually surrounds the plaque, which, at the end, contains cholesterol deposits, ectopic migrated smooth muscle cells, and newly formed small blood vessels (Figure 7.62). The formation of a mature atheroma protruding the endothelium to the artery lumen interferes with the laminar flow of blood, potentially seeding additional plaques nearby.

Heart Attack and Stroke Large atherosclerotic plaques decrease the inner diameter of the afflicted arteries and compromise supplies of oxygen and nutrients to the organs and tissues. If this occurs in coronary arteries, ischemic heart disease results, which in turn may cause other secondary changes in the heart. Stenosis or narrowing of coronary arteries by atherosclerotic plaques itself is a serious medical issue, often manifesting as a form of angina or chest pain called stable angina. The situation becomes much more urgent if the plaques rupture, exposing the plaque core to the bloodstream. Plaque rupture can lead to the formation of thrombi or blood clots

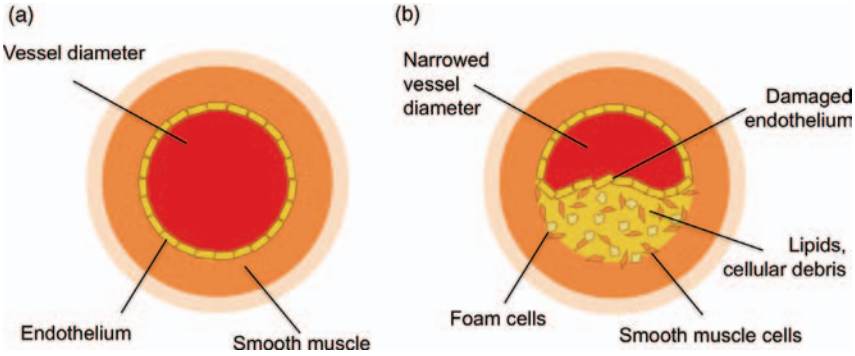

Figure 7.62 Atherosclerosis in artery. (a) Section through a blood vessel. A medium to large artery is illustrated here. The layer containing the endothelium is known as the tunica intima or simply the intima. The layer containing smooth muscle cells is called the tunica media or the media. The outermost layer is called the tunica adventitia. (b) Mature atherosclerotic plaque causing arterial stenosis (narrowing cross-section).

capable of obstructing blood flow, potentially leading to acute coronary syndrome (ACS) and to myocardial infarction (heart attack). Without adequate blood supply, the cells in the affected area die and are eventually replaced with collagen if the patient survives. The diagnosis of myocardial infarction is aided by measurements of serum biomarkers, such as troponin released from the cytoplasm of dying cardiac muscle cells. An ischemic stroke results when a similar plaque rupture occurs in an artery supplying blood to the brain. In some cases, a thrombus may break loose from the vascular wall and becomes an embolus, which may clog blood flow elsewhere – a case of embolism.

Hypertension Hypertension is a definitive risk factor for many forms of CVD and also for other diseases, such as renal disease. Today, normal blood pressure is a systolic pressure of less than 120 mmHg and a diastolic pressure of less than 80 mmHg (120/80). Those individuals with pressure levels of 120/80 to 139/89 mmHg are said to be prehypertensive and those with levels $\geq$140/90 mmHg are considered to be hypertensive. The majority of hypertension cases ($\sim$95%) are essential or primary; no specific cause can be attributed. Undoubtedly, both genetic and lifestyle factors are at play. Some of the known risk factors include family history, age, cigarette smoking, diet as such excessive sodium intake, low physical activity level, and high body weight. Physiologically, blood pressure is a function of two major variables: the cardiac function and the vascular resistance. Each of the two variables in turn depends on numerous factors, making the overall process of blood pressure regulation extraordinarily complex and the majority of the hypertension cases essential. Many prehypertensive and hypertensive patients are typically treated with medications designed to affect the contractility of blood vessels and/or the fluid handling in the kidney.

Heart Failure When the heart is beating but is not performing well enough to supply sufficient blood to organs and tissues, the condition is called heart failure. Heart failure can be caused by insufficient filling of the heart with blood, known as diastolic heart failure, and/or by ineffective ejection of blood by the heart, termed systolic heart failure. Normally, as the heart is filled with a greater volume of blood (diastolic volume), the heart output (stroke volume) increases, as described by the Frank–Starling law. In systolic heart failure, the slope of the curve relating the cardiac output and the diastolic volume is noticeably less than that in healthy hearts so that, for a given diastolic volume, the stroke volume is less. Heart failure often leads to serious secondary pathologies in end organs, such as the lungs, liver, and kidneys. The underlying etiology of heart failure is diverse, but therapeutic strategies typically involve lowering blood pressure by manipulating the fluid handling by the kidney and modulation of vascular and cardiac muscle contractility.

Cardiac Arrhythmia The rhythmic activity of the heart originates as a spontaneous action potential in the primary pacemaker cells in a small area in the right atrium called the sinoatrial (SA) node, which then spreads to the atria. The atrial electrical excitation is transmitted, through the atrioventricular (AV) node, to the ventricles. Within the ventricles, the action potential spreads through the bundle of His and

Purkinje fibers, which are essentially modified neuronal cells, and initiate coordinated ventricular muscle contraction. Cardiac arrhythmia or irregular heartbeat may result when any of the above processes is impaired and this is clinically confirmed using electrocardiography (ECG/EKG). Arrhythmias are frequently observed following myocardial infarction because the normal electrical pathway described above is disturbed by the nonfunctional cardiac cells. One example of arrhythmia is ventricular fibrillation, observed frequently in patients with ischemic heart disease; the electrical activity in the ventricle becomes unsynchronized and interferes with effective blood ejection, potentially leading to sudden cardiac death. Genetic mutations, often in those genes coding for the cardiac ion channel proteins responsible for generating and shaping the cardiac action potential, predispose the afflicted individuals to arrhythmia.

Biophotonics in CVD Technological advances, including those utilizing biophotonic approaches, have made significant contributions to our understanding of the normal heart function and also to CVD. Using optical methods, it is now feasible to visualize the spread of electrical activity and changes in intracellular Ca^{2+} (see Section 7.3.2.1) in a beating heart. The beating heart of a patient can be now visualized noninvasively using an echocardiogram. Biophotonics methods, such as Raman microscopy and fluorescent microscopy, have been utilized to analyze atheromas. Some commercial instruments use optical methods, such as measurements of optical density, to detect blood clots. It is anticipated that biophotonics will continue to play an important role in the cardiovascular physiology and pathophysiology.

7.4.3
Malfunction of the Immune System

Failures of the immune system can fall in one of three main categories: immunodeficiency, autoimmune disease, and hypersensitivity (allergy). Before discussing selected examples for each category, the following sections give an introduction to general aspects of the human immune system.

As multicellular eukaryotic organisms evolved, not only did they compete with single-celled bacteria for nutrition resources but the organisms themselves happened to be ideal, energy-rich habitats where bacteria could thrive. Successful evolution therefore required effective defense strategies to keep bacteria out or at least to restrict their growth and to prevent their attack of the host's cells. The human immune system is much more than a class of defensive blood cells; it involves a collection of multiple defense systems, employing both passive and active safeguard strategies. In general, two types of immune responses are recognized, the *innate* and the *adaptive*. The innate immune response is already active at birth and it is nonspecific; it acts rapidly against a wide variety of pathogens in a relatively generalized and stereotypical manner. In contrast, the adaptive immune system responds to specific pathogens and improves through multiple exposures to pathogens. The memory of adaptive immune cells allows faster and stronger reactions against previously encountered pathogens.

7.4.3.1 Immune Cells and Their Functions

The innate immune system can be divided into two parts: the *first-line defense* is provided by multiple barriers of different types to prevent pathogens from entering body tissues and the *second-line defense* involves all other mechanisms that kill those pathogens that crossed the first-line barriers. The skin provides a physical barrier surrounding the whole body. Tightly packed dead cells of the outer epidermal layers are embedded in secreted ceramides and other lipids; this barrier is nearly waterproof and difficult to penetrate. Importantly, the epidermis is not traversed by blood vessels such that invading bacteria cannot spread but remain localized. At body orifices, additional barrier mechanisms come into play, such as the lacrimal apparatus of the eyes and the saliva in the mouth. The constant secretion of tears from the lacrimal glands flushes potential pathogens and particulate matter out of the eye. This fluid also contains the antibacterial enzyme lysozyme and IgA immunoglobulins. Both protective molecules are also found in saliva. Other parts of the body with a continual inrush of pathogens are covered with mucous membranes. Such major portals of entry are the respiratory and the genitourinary tracts. Mucus layers on the outer epithelia help to trap microorganisms that can be removed by the rhythmic movements of cilia, the hair-like outer appendages of many epithelial cells. An important chemical barrier is provided by the extreme acidic environment of the gastric juice. In the genitourinary tract, lactic acid in the urine and frequent flushing reduce bacterial growth.

Second-line Defense of Innate Immunity Despite the barrier mechanisms in place described above, numerous bacterial cells and viruses manage to enter the human body every day. The second line of the protective mechanisms against these invaders includes cellular responses and chemical activities. A prominent component of the chemical response is the *complement system*, a set of about 30 circulating serum proteins that becomes activated in a cascading manner, leading to multiple consequences including inflammation, recruitment of phagocytes that engulf the foreign bodies, and lysis of invading cells such as bacteria. As the terminal reaction of the complement cascade, a membrane attack complex forms on bacterial surfaces that punches holes into the membrane. The complement cascade can be triggered in multiple ways, one of which involves the presence of antibody–antigen complexes. Hole formation in the bacterial plasma membrane causes a breakdown of the vital proton gradient across this membrane and kills the microbe. The same complement complex can also form holes in viral coats. This does not remove the virus, but with a perforated envelope it can no longer infect host cells. Other key reactions of the second-line response are inflammation and fever, the first being a mainly localized reaction, whereas fever is a systemic increase of the body temperature. Inflammation includes the release of histamine, leukotrienes, and prostaglandins. Together, these mediators cause vasodilation and the migration of phagocytes. Vasodilation increases the diameter of blood vessels in the affected areas and thereby delivers more immune cells. These cells, attracted by local chemical signals, leave the bloodstream and migrate into the tissue, a process termed extravasation. The general increase in body temperature during fever is triggered by breakdown products of bacteria such as

lipopolysaccharide (LPS) from the outer membranes of Gram-negative bacteria. Up to a point, fever is beneficial for the organism as the elevated temperature inhibits bacterial growth and bacterial toxins become less active.

Blood Cells Involved in Innate Immunity Several types of white blood cells (see Figure 7.34) contribute to the nonspecific immune response. Normal *monocytes* in the blood stream are nonphagocytic, but when they reach sites of infection, chemical signals released from other local cells trigger their maturation to become macrophages. This immune cell type has very high phagocytic activity and is responsible for removing bacteria, fungi, or even virus-infected cells. Macrophages not only appear on acute infections, but also persist in many different tissues as resident macrophages. In some tissues, they were given specific names, such as microglia in the brain and Kupffer cells in the liver. Other cells contributing to innate immunity are neutrophil, basophil, and eosinophil granulocytes. Neutrophils are also phagocytes and they are important in guarding mucous membranes and the skin. An important task for all immune cells is to distinguish between *self* and *nonself*, otherwise also cells of the own body could become targets of their attack. For immune cells of the innate response, the identification of nonself largely depends on *toll-like receptors* (TLRs). This family of membrane receptors is specialized to bind molecules that are common to many potential pathogens. The list of such molecules includes LPS from Gram-negative bacteria, lipoteichoic acid from Gram-positive bacteria, and double-stranded or single-stranded RNA found in many viruses. Activation of TLRs triggers intracellular signaling pathways that lead to activation of the immune cell.

7.4.3.2 Adaptive Immune Response

In contrast to innate immunity, the acquired immunity changes with every exposure to pathogens and the set of cells involved in the immune response changes and adapts to specific challenges. Central elements of acquired immunity are immunoglobulins with very specific antigen-binding sites. Antigens can be virtually any foreign molecules that enter the body. A given immunoglobulin does not recognize the whole antigen structure, but instead binds to very delimited surface areas, so-called *epitopes*. Figure 7.63 illustrates the overall structure of the IgG immunoglobulin. These proteins can either be secreted as antibodies or they can reside on the surface of B lymphocytes. IgG antibodies are composed of two heavy and two light chains linked by disulfide bonds. A constant region is common to all antibodies, but the variable region of the antibody forms a highly specific antigen-binding site. The stupendous antibody repertoire is made possible because the antibody proteins are coded by multiple genes that are assembled in a highly complex mix-and-match manner, often referred to as V(D)J recombination (see below). The term *adaptive* does not mean that antibodies adapt to fit to their targets but that selection of the best-fitting antibodies from a huge repertoire adapts the system to recognize all antigens that have been encountered over time. Five different isotypes of immunoglobulins exist: IgG, IgA, IgD, IgE, and IgM, with IgG being the predominant antibody in blood and IgA being secreted into the mucous layers of the intestine and the respiratory tract. IgM molecules are structurally different as they form large pentameric structures.

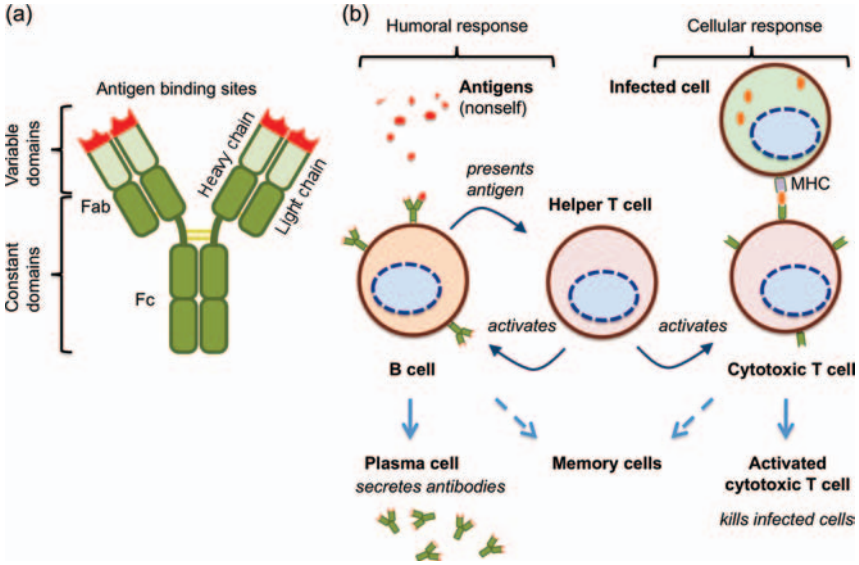

Figure 7.63 Antibodies and immune cells. (a) An IgG antibody comprising two light chains and two heavy chains. The chains are connected via disulfide bonds (yellow). The variable domains harbor the antigen binding sites. (b) Interplay of humoral (antibody) and cellular immune response. Antigen binding and activation by helper T cells induce B cells to become antibody-secreting plasma cells. A smaller fraction of the activated B cells remains as memory cells to allow a faster and stronger response upon subsequent encounters of the same antigen. Cytotoxic T cells become activated when virus-infected cells or tumor cells present an antigen on the major histocompatibility complex (MHC). Also activation of cytotoxic T cells needs support from helper T cells. Most activated T cells will attack and kill infected cells, but a smaller population remains as memory cells.

The binding of antibodies to a virus particle or to a bacterium has three important effects: (i) a pathogen is coated with a layer of antibodies so that it cannot adhere to body cells any longer; (ii) antibodies cause opsonization of the pathogen, that is, they mark it for phagocytosis; (iii) antigen–antibody complexes activate the complement cascade of the innate immune system.

B and T Lymphocytes The cellular carriers of adaptive immunity are B cells and T cells. B cells are responsible for antibody production, the *humoral* response, whereas T cells carry the *cellular* response. A common feature of the two cell types is their ability to produce antigen-binding proteins. In contrast to the Y-shaped antibodies, the membrane-bound T-cell receptors comprise only one antigen-binding site. The names of the lymphocytes refer to their site of maturation: the bone marrow for B cells and the thymus for T cells. Before maturation is completed, the immunoglobulin genes of the precursor cells are irreversibly rearranged, such that millions of different B and T cells arise, each being able to produce just one specific type of immunoglobulin. In a process called *clonal selection*, all cells that bind self antigens are later deleted to prevent their reaction with the own body cells. The remaining B and T lymphocytes are so-called naive cells. They become

activated upon binding of an antigen to their surface immunoglobulin. Activation is a complex process that can involve the mutual interaction of two lymphocytes.

If surface immunoglobulins on a B cell bind an antigen, both receptor and antigen are taken up by endocytosis. The antigen is degraded into small fragments and the epitope is returned to the surface, where it is presented to T cells. Binding of a T cell in turn activates the B cell, which will start to proliferate and differentiate into plasma cells. A plasma cell secretes large amounts of its specific antibody into the blood. Plasma cells can have lifetimes between days and months, but typically their blood concentration drops when the pathogen is cleared. Importantly, a small fraction of activated B cells becomes *memory cells*. These memory B cells persist and, if they ever encounter their antigen again, they allow much faster proliferation of the appropriate B cell population.

The T lymphocytes involved in B cell activation belong to the *T helper cell* population. Another group of T helper cells exists to activate macrophages specifically. Both helper T cells can be identified by a common cell surface protein, termed CD4. Another cell surface protein, CD8, is prominently found in a second group of T cells called *cytotoxic T cells*. These killer T cells biochemically induce death in virus-infected cells, cells that carry intracellular pathogenic bacteria, and tumor cells. The T cell can successfully identify its targets even in tissues with mainly healthy cells because it recognizes pathogen-specific antigens present on the surface of a target cell. Unlike phagocytes, a T cell does not engulf its target cell, but releases a mixture of cytotoxic proteins that damage the other cell and induce cell death by apoptosis. As with B cells, a small population of activated T cells differentiates into memory T cells, which allow a more rapid immune response upon any secondary contact with the same antigen on target cells.

Vaccination The ability of lymphocytes to generate memory cells is an efficient protection against subsequent infections, provided that the patient survived the first encounter. However, the same protective benefit can be induced not only with the whole pathogen itself but also with a characteristic antigen thereof. Such an antigen may exist on related but less virulent pathogen species, on attenuated or dead pathogens, or even as isolated proteins or protein fragments. The first reported successful vaccination was performed in 1796 by Edward Jenner. Jenner realized that milkmaids who were often exposed to cowpox were insensitive to the otherwise highly fatal smallpox infection. Jenner used material from cowpox blisters to immunize healthy individuals effectively against smallpox. Today, vaccination is a powerful way to prevent many serious diseases and it is particularly important for viral diseases, for which treatment options are limited (see Section 7.4.4.2). Modern vaccines are in most cases attenuated virus strains or purified virus proteins administered via many routes, including oral and injection.

7.4.3.3 Failure of the Immune System

Primary Immunodeficiency Diseases Proper function of the human immune system requires the activity of a large set of genetically encoded components, including antibodies, receptors, cytokines, and enzymes. As a consequence, any defect in one of

the underlying genes could severely compromise the immune system function. In general, immunodeficient patients are more susceptible to infectious diseases but the actual symptoms differ significantly. Some inherited immunodeficiencies are so mild that they may remain unnoticed for many years whereas others are severe and afflicted newborns may require immediate treatment.

The defects in inherited immunodeficiencies primarily affect B cells and T cells; however, a loss of phagocyte functions or a loss of individual complement components may have similar phenotypic effects. *Severe combined immunodeficiency* (SCID) is characterized by a lack of functional T cells. As helper T cells are required to activate B cells properly to produce specific antibodies in large quantities, both arms of the adaptive immune response, cellular and humoral, are severely debilitated. Most cases of SCID are due to a defect in the gene encoding an interleukin-2 receptor subunit, known as X chromosome-linked SCID. With the lack of functional interleukin receptors, T cell progenitors cannot respond to interleukin signals and proper T cell maturation is impaired. A second common cause of SCID is a mutation in the gene encoding adenosine deaminase, leading to accumulated ATP breakdown products, which are toxic to B and T lymphocytes. Other defects concern factors of the complement cascade or the function of phagocytic cells. In chronic *granulomatous disease*, the phagocytic cells are unable to produce hydrogen peroxide, required to kill ingested bacteria. Consequently, patients suffer from infections by opportunistic pathogens, which are unable to infect healthy individuals. Prominent examples are bacteria of the genera *Serratia*, *Klebsiella*, and *Salmonella* and fungi of the genera *Aspergillus* and *Candida*.

Acquired Immunodeficiency Disease (AIDS) Suppression of immune functions is not necessarily the result of genetic defects. The most important and best-studied case of a life-threatening immunosuppression caused by a pathogen is acquired immunodeficiency disease (AIDS), a disease caused by the human immunodeficiency virus (HIV). The World Health Organization (WHO) estimates that about 33 million HIV-infected people lived worldwide in 2008 and that about 2 million died of the disease in the same year. The target cells for HIV are helper T cells expressing the membrane protein CD4, as the viral infection relies on binding to this receptor protein. Cytotoxic T cells also can clear such infected helper T cells; however, a small population of infected helper T cells typically remains during an asymptomatic phase that can last for several years. Following a slow increase in the number of infected cells, patients eventually enter an acute phase of the disease, during which also the number of cytotoxic T cells drops. Without treatment, the death of the infected individual is usually caused by opportunistic infections, such as pulmonary bacterial diseases or infections with oncogenic viruses. Treatment for HIV infections consists of the combined application of three drugs, known as *highly active antiretroviral therapy* (HAART). This medication targets the viral enzymes reverse transcriptase and protease. The drug regimen is effective but does not cure the disease because the virus cannot be completely cleared from the body. Hence lifelong treatment is required, a demand that cannot be achieved for most patients worldwide because of the high drug cost.

Autoimmune Diseases The immune system is powerful enough to protect the organism against most invading pathogens. However, the immune cells occasionally become overactive and turn against any normal substance or tissue in the own body, causing serious problems – autoimmune diseases. While the prevalence of autoimmune diseases seems to be increasing, most prominently in more economically developed countries, the underlying disease causes are not understood and therapies are often limited to symptom management and palliative care. In *multiple sclerosis* (MS), the immune system attacks the myelin sheaths around nerve axons in the brain and in the spinal chord, and demyelination impairs the conduction of voltage signals in the affected nerves. MS is not considered a hereditary disease, but some genetic alterations may increase the susceptibility to develop the disease. Multiple subtypes of MS are recognized. In progressive MS cases, the immune system steadily attacks and damages the nerves and the patients experience increasing disability. The relapsing-remitting subtype of MS is characterized by relatively discrete periods of increased disability followed by periods with no noticeable change in the disease severity. Myelinated axons coordinate a large number of functions in the body, and MS patients can therefore experience a broad range of neurological symptoms, including cognitive impairment and depression, pain, muscle weakness, and urinary incontinence. The fundamental cause of MS is yet to be elucidated but several immunomodulators and immunosuppressants have been approved to reduce the frequency and severity of MS attacks.

Other autoimmune diseases include myasthenia gravis (MG), rheumatoid arthritis (RA), and diabetes mellitus type I (discussed in Section 7.4.6), to name just a few. MG is an autoimmune channelopathy with antibodies directed against *nicotinic acetylcholine* (ACh) receptors located on the skeletal muscle fiber, a transmitter-gated ion channel. MG is characterized by progressive skeletal muscle weakness during periods of activity that improves with periods of rest. First signs are often weaknesses of the eye muscles or of muscles involved in facial expression or chewing. Typical treatment mainly involves cholinesterase inhibitors to increase the concentration of ACh to improve muscle excitation or immunosuppressant drugs to reduce the autoimmune reaction against the channel protein. RA is a systemic inflammatory disorder that mainly attacks synovial joints of the hands and feet but sometimes also larger joints such as the knees. Symptoms include painful swelling of the joints, stiffness, and destructive erosion of the joint surfaces. Although it is widely accepted that autoimmunity plays an important role in RA, the molecular pathogenesis is only poorly understood. Apparently, abnormal interactions between B cells and T cells result in the excessive production and release of inflammatory cytokines; treatment with anti-inflammatory drugs can be used to suppress the symptoms.

Hypersensitivity *Allergy* is the most common type of immune dysfunction, characterized by an exaggerated inflammatory response to otherwise normal environmental substances, known as allergens. Allergic reactions may be elicited by a huge palette of stimuli, including airborne particles such as pollen and fungal spores, food, antibiotics, and latex. In the acute phase of the disorder, a subset of helper T cells stimulates B cells to produce and release IgE-type antibodies against the allergen.

Circulating IgE antibodies then bind to the surface of mast cells and basophil granulocytes. With the bound antibodies, both immune cells are sensitized to the allergen and upon exposure they will release potent inflammatory chemical mediators, such as histamine, leukotrienes, and prostaglandins. The symptoms such as tissue swelling and itchiness can either be localized to the sites of allergen exposure or systemic, affecting the whole body. Treatment can include drugs that interfere with the inflammatory mediators, such as antihistamines or anti-leukotrienes. If specific allergens could be determined by allergy tests, avoidance of the allergen often solves the problem. If that is not practical, desensitization is a gradual vaccination procedure against specific allergens. This can be achieved by subcutaneous injections or sublingual administration of progressive allergen doses with the aim of inducing the production of IgG antibodies against it. These antibodies are supposed to neutralize and clear the allergen, thereby preventing it from interactions with IgE antibodies.

7.4.4 Infectious Diseases

All infections, whether caused by bacteria, viruses, or parasites, follow similar general principles: (i) the pathogen must find a way to get into the host; (ii) the pathogen must be able to deal with the immune responses to remain inside the host; (iii) the pathogen must find ways to exit the host and to be transmitted to another host. These three requirements are sufficient for a successful life cycle of the pathogen. To make the whole process a disease, the pathogen must cause damage to the host in some form. If the relationship has no obvious disadvantage for the host, the intruder would rather be called a commensal. This is the case for many of the bacteria in the human mouth flora or in the intestine.

As outlined before, major entry sites into the human body are the mucous membranes of the respiratory tract, the gastrointestinal tract, and the genitourinary tract. Together, these surfaces make about 400 m^2 of mucous membrane in a human adult and, despite the defense mechanisms of innate immunity, numerous bacteria and viruses have evolved to use the aforementioned entry sites. By contrast, the intact skin is a near-perfect protective barrier, but the so-called parenteral route of infection usually depends on breaks in this barrier. Apart from injuries, parenteral infection can also occur very efficiently if an invader uses biting insects as transmission vector. This is a common entryway for many parasites, including *Plasmodium*, the malaria agent.

Following the entry, the second task of the invading pathogen is to establish a pathogen colony. Bacteria physically attach themselves to the host cells using their filamentous fimbriae or sticky glycolipids (adhesins). Viruses attempt to gain entry into the cell cytosol to avoid being flushed out or cleared by macrophages (Figure 7.64). Some pathogens, such as *Vibrio cholerae*, responsible for cholera, and *Neisseria meningitidis*, responsible for bacterial meningitis, grow rapidly within the host whereas others, such as herpes simplex viruses and Epstein–Barr virus, can remain in a latent state that allows them to stay life long with one host organism.

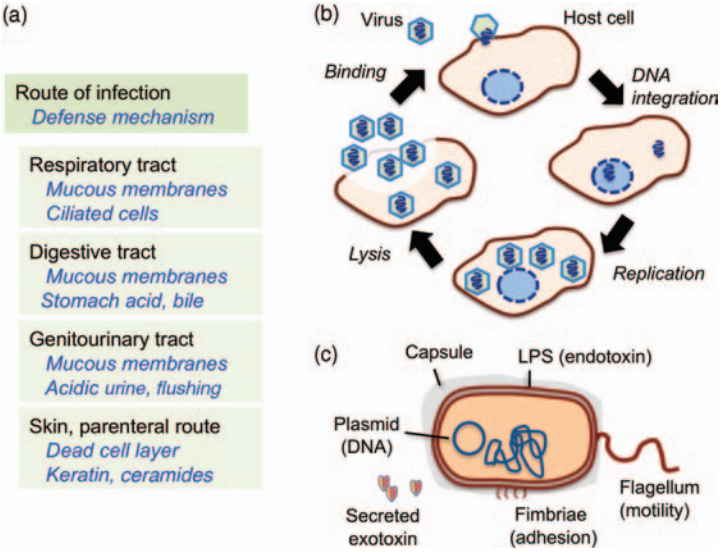

Figure 7.64 Principles of infection. (a) Typical routes of entry of bacterial and viral pathogens and defense strategies of the host (blue). (b) Scheme of a viral lytic cycle. (c) Gram-negative bacterium and virulence factors.

Finally, to ensure survival of the pathogen as a species, mechanisms of transmission to a new host must exist. The major transmission routes are contact transmission, vehicle transmission, and vector transmission. A typical example of contact transmission is the transfer of common cold-causing viruses via direct contact of the hands. Vehicle transport means that the pathogen takes a "piggyback ride" on something else, for example, contaminated food, dust particles, or water. If the carrier itself is an organism, the transfer is called vector transmission. Such vectors can be insects that sting or bite humans, but the carryover of pathogens on human food is also a vector transmission. A common example is the spread of bacteria on houseflies that are often found to shuttle between feces and food products.

In the following sections, bacterial and viral infections are briefly discussed. Although both agents account for the majority of infectious diseases in humans, one should keep in mind that fungi and parasitic protozoans can be extremely potent human pathogens. Parasite-mediated diseases such as malaria, the African sleeping sickness, and the American Chagas disease (trypanosomiasis) cause enormous medical and economic problems.

7.4.4.1 **Bacterial Infection**

Pathogenic strains are found among both Gram-positive and Gram-negative eubacteria but not among archaebacteria (Figure 7.43). Closely related strains from one species can behave either as harmless commensals or as causative agents of severe diseases. The distinguishing factor between such strains is their ability to produce *virulence factors* (Figure 7.64). Passive virulence factors protecting the bacterium

include slimy capsules composed of polysaccharides, the variable O-antigens of the outer membrane LPS in Gram-negatives, and a waxy coating on the outer surface, as produced by *Mycobacterium tuberculosis*. Active factors can be pore-forming cytolytic toxins (hemolysin) or toxins that disturb signaling pathways in the host cells. Importantly, the genes encoding bacterial virulence factors are often found on large plasmids, circular DNA molecules that are inherited in parallel to the bacterial chromosome. Such collections of virulence genes can be easily transferred between bacterial strains, such that nonpathogens can become virulent in very short time.

The Gram-negative pathogen *E. coli* belongs to the Enterobacteriaceae. Other important pathogens of this group are found in the species *Salmonella* and *Shigella*. Common to all three species is their typical fecal-to-oral transmission. Most species that are transferred on this route cause, among other symptoms, severe forms of diarrhea, a factor that supports their rapid and sometimes epidemic spread. Another prominent example is the Gram-negative bacterium *V. cholerae*. The cholera toxin can induce such severe water loss that untreated patients can die within hours. Even more potent toxins are made by some Gram-positive bacteria. The *anthrax toxin* produced by *Bacillus anthracis* is like a tripartite weapon consisting of the proteins edema factor, lethal factor, and protective antigen. Once in the acidic conditions of an endosome, edema factor and lethal toxin are converted to their active conformations. Together with the protective antigen, these toxic proteins inactivate macrophages and neutrophils of the immune system, cause tissue swelling (edema), and finally kill the host.

B. anthracis is a good example of another dangerous property of many pathogens: the ability to persist for long time as a dormant spore. When such spores are inhaled or ingested, they are reactivated and begin to proliferate inside the host. This toxic potency of the dry spores makes anthrax a deadly biological weapon. Another deadly spore-forming toxin is *Clostridum botulinum*, a Gram-positive bacterium that is sometime found in improperly prepared food items and produces neurotoxic botulinum toxins.

The toxins contain a complex of several proteins that become dissociated and activated in the host cells. Deadly paralysis is caused as the toxins bind and cleave t-SNAREs and v-SNAREs in neurons that innervate muscle cells. As described in Section 7.2, SNAREs are indispensable facilitators of synaptic exocytosis and the release of neurotransmitters. The toxin causes death as soon as muscles required for respiration are inhibited. Although this toxin can be deadly, one component in the toxin mixture has found therapeutic applications for excessive sweating and skin wrinkles. When the facial muscles that contract to form wrinkles are paralyzed by the toxin, wrinkle formation is prevented.

Antibiotics The most important finding for the treatment of bacterial diseases was that microbes produce substances to protect themselves against other microbes. In 1928, Alexander Fleming incidentally found that the fungus *Penicillium* produces a substance that kills the bacterium *S. aureus*. Later, it became evident that other bacterial species, most prominently of the genus *Streptomyces*, also produce antibacterial toxins. These newly identified and purified substances became powerful weapons for medicine to defeat bacterial infection.

Later, the active compounds could also be produced as synthetic or semi-synthetic molecules. Importantly, antibiotics directed at bacteria-specific targets were identified, allowing for a thorough antibacterial treatment without severe side effects for the human host. For example, the target of penicillin and many other antibiotics is peptidoglycan of the bacterial cell wall, a molecule that is not found in mammalian cells. Other antibiotics such as erythromycin or tetracyclin inhibit translation in bacteria; the drugs interfere with bacterial ribosomes but have no activity against eukaryotic ribosomes. Other antibiotics inhibit common prokaryotic enzymes involved in transcription and DNA replication.

Unfortunately, with the rising use of antibiotics, it has become evident that bacteria can acquire antibiotic resistance. For instance, the bacterial enzyme β-lactamase cleaves the important β-lactam ring of penicillin. Other resistance mechanisms include small mutations in the antibiotic target molecules, such that the antibiotic no longer binds to the original target and the activity of the target is preserved. The intensive use of antibiotics in hospitals puts strong selective pressure on bacteria and resistant strains have become more and more common in this sensitive environment. Pathogenic *S. aureus* strains with penicillin resistance were found shortly after the introduction of the antibiotic. Some decades later, new strains emerged that were also insensitive to the approved treatment with the β-lactamase-stable antibiotic methicillin/meticillin. These dangerous strains were named methicillin-resistant (or multidrug-resistant) *Staphylococcus aureus* (MRSA). Vancomycin has become the last line of defense against strains, but more recently even vancomycin-resistant strains (VRSAs) have been discovered, necessitating the use of even newer antibiotics.

7.4.4.2 **Viral Infection**

The most important difference between viruses and bacteria is that a virus is not an independent organism but a parasite of a host cell; a virus needs energy and the enzyme machinery of the host to multiply. Reflecting this infectious arrangement, it has been challenging to design specific and effective anti-viral drugs. The salient structure of a virus is a protein coat or shell (capsid) that covers genetic material, either DNA or RNA. Both types of nucleic acids can be packed as either double strands or single strands. In complex viruses, a phospholipid membrane with glycoproteins serves as an additional outer envelope surrounding the capsid.

Two basic capsid structures can be distinguished: icosahedral shapes and helical shapes. Icosahedral viruses have a capsid with 20 triangular surfaces whereas helical capsids can be filamentous or rod shaped. Although viruses do not have an independent life of their own, their *infection cycle* in many respects resembles the life of a real organism. During this cycle, the genetic material is duplicated and a new generation of virus particles is released. Mutations during the replication process allow the evolution of new traits and new strains evolve from existent strains.

Virus infection of a host cell does not necessarily mean that new virus particles are made in large numbers immediately. In a *lysogenic cycle*, viral DNA becomes integrated into the chromosomal DNA of the host. This ensures that the viral genetic

material is replicated by the host and transferred to the daughter cells upon mitosis. Only if such a "sleeper" virus is activated by unusual stress to the host cell or other triggers does it resume the lytic cycle and capsid protein is made to pack viral nucleic acid. With the release of virus particles, a new lytic cycle begins. As long as they are inside the host somewhere, virus particles can attack previously uninfected cells. The first step is attachment to the membrane or to specific receptor proteins followed by endocytosis. The endocytosis pathways used by viruses include clathrin-mediated uptake, caveolar endocytosis, and other mechanisms. To make use of its genetic material, the viral genetic material must be released from its capsid and envelope. This can occur at the cell membrane in some cases, but in many cases it happens in the endosome or even later in the process. For RNA viruses, replication of the genome includes a transient conversion into DNA by means of a viral reverse transcriptase. Following genome multiplication, new viral proteins are made to form new capsids and package nucleic acids. Specific packaging signals on viral nucleic acids identify them to the capsids to ensure that no host nuclei acid is packed. The final release of the new virus particles relies either on death and lysis of the host cell or budding from the plasma membrane. The former is typical for viruses with nonenveloped capsids, whereas the latter is more frequently used with enveloped viruses.

Viral dissemination and transmission occur via multiple pathways, just like bacterial infections. The most common entry site is the respiratory tract, as virus-containing aerosols are easily inhaled. The digestive tract is another common entry site; however, viruses using this route must be resistant to acid, bile, and proteolytic enzymes. The urogenital tract is the entry pathway for sexually transmitted viruses, including HIV, the causative agent of AIDS. As many of the steps in a viral life cycle involve enzymatic activities of the host, the development of selective antiviral agents is appreciably more challenging than that of antibiotics. Nevertheless, viruses often have Achilles' heels and some drugs are in fact available to make use of them. Acyclovir is a nontoxic nucleoside analog of guanine, a building block of DNA. In the cells infected with herpes simplex virus, this analog is activated by the viral enzyme thymidine kinase. Acyclovir is then incorporated into DNA, leading to death of the infected cell. Zanamavir is an inhibitor of the neuraminidase enzyme of the influenza virus and specific protease inhibitors such as indinavir are used to treat HIV infections. These antiviral agents offer some hope, but prevention of viral infection by vaccination remains the most powerful way to combat viral diseases.

7.4.5
Degenerative Diseases Exemplified by Neurodegenerative Diseases

In degenerative diseases, select body functions become progressively impaired over time. Numerous degenerative human diseases are known, afflicting different organs and tissues. Some believe that aging in itself is a degenerative disease that could be treated. Although the exact nature of aging is a matter of debate, aging is associated with many degenerative conditions. Among them are neurodegenerative diseases of the CNS, exemplified by Huntington's disease, transmissible spongiform encephalopathies, Parkinson's disease, and Alzheimer's disease, which illustrate the

diversity in etiology and pathogenesis while causing progressive loss of neurons in different areas of the brain. Because the regenerative capability of the brain is very limited, the impairment is not currently reversible and there is no cure for any of the aforementioned conditions today. It is hoped that the ongoing intensive multidisciplinary investigations, including those utilizing biophotonics, will soon lead to improvements in treatment and care, and eventually to cure and prevention.

Huntington's Disease Huntington's disease is an inherited neurodegenerative disease characterized by progressive impairments in movement and emotional and cognitive abilities. The initial symptoms, such as abnormal jerky and involuntary movements, are frequently recognized at age $\sim$40 years followed by death typically 10–20 years later from a variety of causes. The disease is autosomal dominant and caused by mutation in the huntingtin gene on chromosome 4. The gene codes for a large protein called huntingtin expressed in many tissues, especially in the brain. The huntingtin protein in Huntington's disease patients contains an abnormally greater and variable number of glutamine residues in a row, referred to as polyglutamine (polyQ) repeats, coded by CAG repeats (trinucleotide repeats) in the huntingtin gene. The number of CAG repeats in the gene can be used to predict whether an individual develops Huntington's disease, and genetic testing for the disease is available. The functions of normal huntingtin are not yet clear but recent evidence suggests that the protein has a critical role in the neuronal metabolism of cholesterol, which regulates the cell membrane fluidity. Mutant huntingtin proteins with polyglutamine repeats are suspected to accumulate in nerve cells and interfere with proper cholesterol metabolism, eventually causing cell death. Huntington's disease is only one of so-called trinucleotide/polyQ diseases and other notable examples include spinocerebellar ataxias and dentatorubral-pallidoluysian atrophy.

Creutzfeldt–Jakob Disease In inherited diseases such as Huntington's disease, the transmission agent is nuclear DNA. In contrast, other neurodegenerative diseases may involve genetic and nongenetic factors. Such a multicausal characteristic is well evident in Creutzfeldt–Jakob disease, a relatively rare but fatal neurodegenerative disease that causes dementia. Creutzfeldt–Jakob disease has three forms, depending on the etiology: sporadic, familial (inherited), and acquired. The sporadic and familial forms account for the vast majority, $>$99%, but the acquired form has been well publicized in part because of its similarity to bovine spongiform encephalopathy (BSE) or mad cow disease. The initial symptoms of Creutzfeldt–Jakob disease may include emotional and cognitive changes. Following the symptom onset, patients deteriorate very rapidly and usually die within 12 months. Postmortem examination of the brain typically reveals numerous characteristic "holes," thus giving rise to the name spongiform encephalopathy.

Creutzfeldt–Jakob disease involves conversion of normal prion proteins into abnormal pathogenic conformations. The misshaped prion proteins accumulate, leading to neuronal death. The normal prion protein is a glycosylated membrane-anchored protein with a large α-helical content. The normal functions of prion proteins are yet to be established thoroughly but its participation in proper formation

of insulation around nerve axons (myelination) is likely. One notable characteristic of prion diseases, including Creutzfeldt–Jakob disease, is that abnormal prion proteins drive other surrounding normal prion proteins to assume abnormal pathogenic conformations, which in turn coerce additional prion proteins to be pathogenic. This vicious cycle may contribute to the rapid progression of the disease. In the familial form of the disease, a genetic mutation facilitates the conformational conversion of prion. In the acquired form, it is the abnormal prion proteins themselves that transmit the disease. "Prion infection," although rare, does occur by exposure to tissues containing pathogenic prion proteins isolated from Creutzfeldt–Jakob disease patients. Decontamination of prion poses a serious challenge because abnormal pathogenic prion proteins are notoriously difficult to destroy.

Parkinson's Disease Parkinson's disease is a relatively common degenerative disease, disproportionately afflicting older individuals. Parkinson's disease patients slowly lose their motor coordination, typically exhibiting bradykinesia, impaired posture control, and muscle rigidity. Additional nonmotor symptoms may be observed and, during end stages, different degrees of dementia may be present. Multiple causal and contributing factors for Parkinson's disease are known. A small fraction of Parkinson's disease cases are inherited and genetic mutations in several genes are linked with Parkinson's disease, including those in α-synuclein, parkin, UCH-L1, DJ-1, PINK-1, ATP13A2, OMI/HTRA2, and LRRK2. Functions of the proteins coded by these genes are not yet clearly known, but they may have diverse cellular functions, including a role in synaptic transmission, protein degradation, and protein phosphorylation. Environmental factors may also contribute to the development of the disease. Although inconclusive, chemicals contained in drugs of abuse, insecticides/pesticides/herbicides, exposure to metals that cause oxidative stress, viruses, and head trauma have been implicated. The aforementioned diverse factors eventually destroy the melanin/dopamine-containing neurons in the substantia nigra in the basal ganglia of the midbrain. The surviving neurons in the brain of a typical Parkinson's disease patient contain intracellular inclusions called Lewy bodies filled with α-synuclein fibrils. Whether the α-synuclein-containing inclusions represent a causal factor for the disease or a cellular defense mechanism against the disease is uncertain. The presence of Lewy bodies is not a unique characteristic of Parkinson's disease; similar intracellular inclusions are also found in other dementia-causing neurodegenerative diseases, including Lewy body disease (LBD).

Because Parkinson's disease involves destruction of the substantia nigra neurons that release dopamine as the neurotransmitter, one of the common treatments is to administer exogenous dopamine precursors, such as levodopa, which are then converted into dopamine in the surviving neurons. The levodopa treatment is not entirely satisfactory and new therapeutic options are being actively explored. One such method is deep brain stimulation, which involves surgical implantation of an electrical stimulator into the brain. The exact mechanism of the action of deep brain stimulation is only beginning to be elucidated and a new experimental approach using genetically engineered light-sensitive ion channels coupled with optical fibers is providing promising information.

Alzheimer's Disease The most common cause of dementia in the older population today is Alzheimer's disease, which afflicts >50% of the individuals over the age of 85 years. Because this age group is projected to increase steadily in number in many countries, Alzheimer's disease is a significant health and social concern. Alzheimer's disease patients show progressive impairment of cognitive skills, especially short-term memory, and subsequent autopsies typically show marked brain atrophy and secondary expansion of fluid-filled ventricles. Such postmortem examination of the brain of a typical Alzheimer's disease patient using silver stain reveals two microscopic characteristics of the disease, amyloid plaques and neurofibrillary tangles. The plaques are extracellular deposits outside neuronal cell bodies and dendrites made of multiple proteins. The plaques are found in all individuals as they age but they are much more prominent in Alzheimer's disease patients. The primary component of the plaques in the Alzheimer's disease brain is amyloid β42 (Aβ42), with the number indicating the number of amino acid residues present. Aβ42 is one of the several peptides formed from the larger single-transmembrane protein amyloid precursor protein (APP). Proteolytic cleavage of the extracellular domain of APP by the sequential actions of the proteases α- and γ-secretase produce nonamyloid peptide fragments, but the processing by β- and γ-secretases forms amyloid peptides of two different lengths, 40 and 42 residues. Of the two forms, Aβ42 is more intimately implicated for Alzheimer's disease; aggregation or oligomerization of Aβ42 is suspected to impair normal neuronal communication, eventually leading to cell death and brain atrophy. In addition to the extracellular plaques, intracellular insoluble aggregates consisting of hyperphosphorylated tau proteins, referred to as neurofibrillary tangles, are readily observed in the Alzheimer's disease brain.

Both genetic and nongenetic factors are clearly involved in Alzheimer's disease. Rare early onset forms of the disease are familial or inherited; mutations in multiple genes, including those coding for amyloid precursor protein and presenilin, a component in γ-secretase, are known to be associated with Alzheimer's disease. However, most Alzheimer's disease cases are sporadic. Although the etiology remains to be elucidated, it is believed that certain genetic and environmental factors may modulate the disease onset and pathogenesis. As is the case for Parkinson's disease, exposure to certain metals, pesticides, and brain trauma are suspected to increase the disease risk. In contrast, changes in diet and lifestyle may offer some protection. However, once Alzheimer's disease has been diagnosed, the only therapeutic options widely available are to preserve the remaining brain function by reinforcing the endogenous cholinergic synaptic pathway with inhibitors of cholinesterase that hydrolyzes the neurotransmitter acetylcholine and to minimize neuronal death caused by overexcitation by blocking glutaminergic synaptic pathways.

7.4.6
Diabetes: Malfunction of Blood Sugar Regulation

Diabetes mellitus is a group of diseases affecting glucose metabolism. Glucose, a primary cellular energy source, is transported from the extracellular medium to the

cell interior across the cell membrane by the action of specific glucose transport proteins. The glucose uptake facilitated by selected glucose transporters in the liver, muscle, and fat cells is enhanced by the peptide hormone insulin released from the β cells in the islets of Langerhans in the pancreas. The insulin release into the blood occurs in a fluctuating and pulsatory manner from the β cells in response to many stimuli, including the blood glucose level. The mechanism of glucose utilization is disrupted in type 1 and type 2 diabetes mellitus in different ways, both resulting in hyperglycemia, an increase in blood glucose level. Among the initial symptoms useful for diagnosis of diabetes are the presence of glucose in the urine (glycosuria), frequent urination (osmotic diuresis), and subsequent dehydration.

Type 1 diabetes, sometimes referred to as juvenile diabetes as its symptoms typically but not exclusively develop relatively early in life, is accompanied by hypoinsulinemia caused by the destruction of insulin-secreting β cells. Without insulin to stimulate glucose transport into cells, the blood glucose level remains elevated and cells are forced to utilize an alternative energy source. In particular, the liver cells breakdown stored fat into fatty acids and ketone bodies, the latter of which in turn cause acidification of the blood known as diabetic ketoacidosis. The underlying cause or etiology of destruction of the insulin-secreting β cell observed in type 1 diabetes is not well understood, but it is clearly autoimmune in nature with the pathogenesis process taking place over days to weeks, possibly precipitated by viral infection. The hyperglycemia in type 1 diabetes can be managed by exogenous insulin by injections of insulin or through an insulin pump; however, a cure itself is not currently available but cell replacement therapy using stem cells holds promise.

In type 2 diabetes patients, β cells typically remain intact and insulin is released at least initially but cells in the body fail to respond to insulin: insulin resistance. Without the uptake of glucose normally observed, hyperglycemia results even in the presence of normal or sometimes greater than normal levels of insulin. Many type 2 diabetic patients are obese and may also suffer from metabolic syndrome. Epidemiologically, the incidence of type 2 diabetes, by far the most common form of diabetes (>90%), has increased noticeably in recent years. It is speculated that some lifestyle habits increase whereas others lower the disease risk. The molecular etiology of type 2 diabetes remains elusive; however, several classes of therapeutic agents targeting different aspects of the glucose regulatory pathway have been developed. For example, sulfonylureas facilitate insulin secretion from the β cells by inhibiting their plasma membrane ATP-dependent K^+ channels that otherwise keep the cells electrically inactive. Thiazolidinediones, in contrast, enter the insulin-target cell nucleus and alter gene expression to increase the insulin sensitivity.

Long-term consequences of hyperglycemia in untreated diabetes are numerous and serious, often leading to kidney failure, atherosclerosis, neuropathy, limb amputation, and blindness. Many of the complications are consequences of the vascular abnormalities caused by excess nonenzymatic glycosylation of serum proteins. Accordingly, measurement of glycosylated hemoglobin (HgA1c) is frequently used to monitor the disease progression in diabetic patients. Our understanding of the physiology and pathophysiology of blood glucose regulation has been

aided by several biophotonic approaches. Time- and spatially resolved fluorescence microscopy has been used successfully to monitor the exocytotic release of insulin from β cells. Clinically, portable devices based on near-infrared diffuse reflectance spectroscopy may allow noninvasive monitoring of blood glucose levels.

7.4.7
Personalized Medicine and Outlook

Each and every one of us is different: no two individuals are exactly alike in their genomic makeup, epigenetic makeup, and environmental experience. The effectiveness of a given medical intervention, whether preventive or curative, could vary from one individual to the next and an ideal therapeutic plan should be tailored to each person – *personalized medicine*. The premise of personalized medicine based on the molecular genetic mechanistic knowledge and its promise are obvious. Some genetic variations may increase the risk of developing a disease; establishment of proper genetic markers may permit earlier screening and detection. Other genetic variations may influence how well patients respond to different drugs – *pharmacogenomics*. Ineffective drugs with adverse off-target effects could be avoided and only the most effective drugs could be administered. Although the potential of personalized medicine is vast, its implementation, with notable exceptions in the field of oncology noted earlier, will require additional effort. The reasons for this challenge are manifold. One of the cornerstones in the implementation of personalized medicine is to develop reliable disease and therapeutic biomarkers, and this is not an easy task. Many genes may contribute to the overall risk of developing a disease and each of the single nucleotide variations may make only a minor contribution to the risk. The development of epigenetic biomarkers, such as DNA methylation and histone acetylation, is still in its infancy. Undoubtedly, personalized medicine based on the molecular genetic information will be complemented with other promising therapeutic approaches, including stem cell-based regenerative medicine. In many of these new therapeutic paradigms, biophotonics is expected to play a leading role – mostly with respect to diagnosis but likely also in some therapeutic strategies.

1
Microscopic and Spectroscopic Methods

Brent D. Cameron

Microscopy is a term used to refer to methods that allow for the visual examination of the physical properties of a sample on a micron-level scale. Although there are a wide variety of microscopic methods ranging from optical to electron microscopy, the focus of this chapter will concentrate on light-based methods. Although microscopy by itself sheds insight into the physical structure of a sample, optical spectroscopic methods, which concentrate on how photons of light interact with a sample (e.g., absorbed or scattered), can be used to examine a sample's chemical structure. Spectroscopic methods can be performed using single-point measurements or integrated with microscopic methods to allow for chemical imaging; also known as microspectroscopy.

1.1
Bright Field Microscopy

One of the most basic microscopy techniques is known as bright field microscopy. In this approach, sample illumination occurs in transmission mode through the bottom of the sample under investigation. Visual observation of the sample occurs from the top through standard microscope optics to allow for image magnification up to 1000×. Although this is one of the most common microscopy methods, bright field microscopy suffers from contrast limitations and often has difficulty with thick samples [1], as a considerable amount of the sample under investigation will be out of focus, which hinders the image resolution. Bright field microscopy often requires samples to be stained or have sufficient natural pigmentation to allow for proper viewing [1, 2]. This approach is also well suited for visualization of living preparations, such as single-cell organisms.

1.2
Dark Field Microscopy

To deal with some of the contrast issues associated with bright field imaging, especially when dealing with unstained samples, dark field microscopy is commonly

Handbook of Biophotonics. Vol.2: Photonics for Health Care, First Edition. Edited by Jürgen Popp, Valery V. Tuchin, Arthur Chiou, and Stefan Heinemann.

employed. For this approach, the configuration uses an opaque disc placed in front of the light source and behind the condenser lens [1, 2]. At this point, the light interacts with the sample and only the scattered light is collected due to a direct light block. This method can significantly improve image contrast and does not require sample staining [1]. This technique, however, is limited in terms of the intensity of the image and therefore often requires very intense illumination, which may degrade or damage the sample. Dark field configurations are commonly used as low-cost alternatives to phase contrast approaches.

1.3 Phase Contrast Microscopy

When working with biological specimens, a significant amount of the detail is undetectable when using bright field microscopy due to contrast limitations, especially for microstructures with similar pigmentation or transparencies. In 1934, a Dutch physicist, Frits Zernike, described a technique known as phase contrast microscopy. This approach can greatly enhance the contrast of transparent samples, such as microstructures contained in living cells, microorganisms, and thin tissues [3]. The phase contrast method translates minute variations in a specimen's refractive indices, which alters the phase relationships within the electric field of light into corresponding changes in amplitude [1–4]. These changes can then be visualized as differences in image contrast, and therefore details that would normally be transparent or invisible in bright field imaging can now be easily observed. Furthermore, living cells can be examined in their natural state without being fixed and/or stained. Such ability allows the dynamics of various biological processes to be observed and recorded in significant detail.

In terms of implementation, light is focused on to a specialized annulus positioned in the condenser prior to the sample (i.e., front focal plane) [1]. The light then illuminates the sample, at which point it will either pass straight through (i.e., unaltered) or will be diffracted and/or retarded in phase by structures in the specimen. Both the undeviated and diffracted light collected by the objective is then segregated at the back focal plane by a phase plate and focused on to an intermediate image plane to form the final phase contrast image. It should be noted that without the phase plate, there would be no destructive interference and therefore no significant improvement in contrast. The phase plate allows for the slight phase variations to be converted into visible amplitude changes, which provide for the contrast enhancement.

1.4 Differential Interference Contrast Microscopy

Differential interference contrast (DIC) microscopy is another technique used to improve the contrast of highly transparent or unstained samples. DIC microscopy is

somewhat similar to phase contrast microscopy in that it converts changes in the phase shift of the electric field of light, due to variations in refractive index, into detectable intensity or amplitude changes. The resulting image is similar; however, it is not plagued by the sometimes distracting bright diffraction halo [3, 5]. DIC microscopy also depicts differences in optical density as something like a three-dimensional relief image, although this sometimes may not entirely correctly represent actuality, as the occurrence is due to an optical effect instead of physical geometry.

With regard to implementation, the illumination source is initially linearly polarized at an angle of 45° and enters an optical component known as a Nomarski-modified Wollaston prism [5]. This component separates the light into its two orthogonal polarization components. One ray will be used as the sampling ray and the other as a reference. The microscope condenser focuses the rays through the sample; however, they will be slightly spatially offset to each other. Therefore, the rays may experience slightly different refractive indices and/or sample thicknesses, resulting in different optical pathlengths. The resulting rays are then focused by an objective lens and travel through a second Nomarski–Wollaston prism, which recombines the beams. At this point, the rays will interfere with each other, either constructively or destructively, leading to either bright or dark enhancements, respectively, depending on the corresponding optical path difference.

1.5
Confocal Microscopy

One of the most significant advances in the field of optical microscopy was the development of confocal microscopy. The popularity of this approach lies in its ability to examine the three-dimensional structure of thick biological samples. Confocal microscopy produces an optical image using an alternative approach to the traditional wide-field microscope. This method relies on the use of a scanning point approach instead of full sample illumination, which provides slightly higher resolution and considerable enhancement in the optical sectioning of the sample by eliminating the influence of out-of-focus light that would otherwise distort the image [6, 7]. In applications where it is desired to investigate the three-dimensional structure of a sample, confocal microscopy is commonly employed. Lastly, in terms of implementation, confocal microscopy may be combined with fluorescence spectroscopy, which allows for further exploration of biological samples.

1.6
Fluorescence Spectroscopy

Fluorescence spectroscopy is a popular research method used in biomedical research and clinical pathology. Applications include organic compound analysis,

DNA sequencing, the study of protein conformational changes, medical diagnostics, and so on. Although fluorescence measurements can be performed using single-point detectors, image-based analysis is very commonplace today. Fluorescence imaging/microscopy can provide for localization of intracellular compounds and in certain implementations detection at the level of single molecules.

Fluorescence is related to the luminescence family of processes in which certain molecules have the ability to emit light when they are in an excited state. The two categories of luminescence include fluorescence and phosphorescence, which specifically depend on the electronic configuration of the excited state and the emission pathway [8, 9]. Specifically, fluorescence is a property of certain molecules (e.g., aromatic molecules) that absorb light at a given wavelength which excites the species from its ground state to one of the various vibrational levels in an excited electronic state [8]. When the molecule falls back to a specific vibrational level of the ground state, a photon of light will be emitted in the process. Depending on the energy level in the drop, this will determine the frequency or wavelength of light emitted. Therefore, by measuring the emitted wavelengths (i.e., emission spectra) along with their respective intensities, significant information about the molecule under investigation can be determined.

In fluorescence microscopy, the fluorescence emission can be characterized not only by intensity and spatial position, but also by lifetime [10], polarization, and wavelength. Therefore, fluorescence microscopy is commonly performed using a variety of configurations. Some of these configurations include epifluorescence or incident light fluorescence [8], laser scanning fluorescence [6], confocal fluorescence [6], fluorescence lifetime imaging [10], and two-photon excitation fluorescence microscopy [11].

1.7 Infrared Spectroscopy

Infrared (IR) spectroscopy is a well-established technique for the identification of organic molecules. Specifically, it is a subcategory of spectroscopy which employs the IR region of the electromagnetic spectrum, which is normally broken up into the near-infrared (NIR) (0.78–2.5 μm), mid-infrared (MIR) (2.5–50 μm), and far-infrared (FIR) (50–1000 μm) spectral regions [12]. The method is based on vibrations of atoms within a molecule. For analysis, an IR spectrum is normally obtained by passing IR radiation through a sample and then determining which wavelengths are absorbed and to what extent. From this analysis, considerable information on the molecular and bonding structure of the sample can be determined. For biological analysis, IR spectroscopy allows for detailed examination of complex biomolecules, including proteins, lipids, carbohydrates, and nucleic acids [13].

In terms of implementation, the two main methods include a dispersive approach and the more common Fourier transform infrared (FTIR) spectrometer configuration, which is based on optical interference [12]. Detection can be made as

single-point, line, or image-based measurements. MIR spectroscopy can distinguish very subtle changes in chemical structure and therefore often this range is used in the identification of unknown substances. However, since this region of the electromagnetic spectrum is highly subject to water absorption, analysis of aqueous samples can prove extremely difficult and often requires alternative sample preparation (e.g., desiccation) or alternative sampling methods such as attenuated total reflectance (ATR). NIR spectroscopy is better suited to handle aqueous samples and is more commonly employed for applications in medical diagnostics, pharmaceutical analysis, and biological investigations [13–15]. NIR spectra consist of molecular overtones and combination bands of the fundamental molecular absorptions found in the MIR region. Therefore, NIR spectra generally consist of overlapping vibrational bands that may appear nonspecific and/or difficult to resolve. However, through the use of chemometric multivariate processing techniques, both qualitative and quantitative analyses have proven fairly successful [16, 17].

1.8 Raman Spectroscopy

Raman spectroscopy has become an important analytical tool in a multitude of research disciplines. It can be used for applications ranging through pharmaceuticals, forensics, DNA analysis, and medical diagnostics [18, 19]. The technique can provide significant information that may be used for chemical identification, bonding effect analysis, and characterization of molecular structures. Raman spectroscopy is a powerful light-scattering technique, which in simple terms can be thought of as a process in which a photon of light at a specific wavelength interacts with a sample and scattered light at different wavelengths result. This scattered light can then be analyzed to characterize the internal structure of molecules.

More specifically, Raman emissions are generated based on the concept of inelastic scattering of monochromatic light. The source excitation is usually provided by a laser source in the visible to NIR region of the electromagnetic spectrum [20]. In the case of inelastic scattering, depending on the molecular and bonding structure of the sample, a small amount of the light will experience a change in energy. In the case of reduced energy, longer wavelengths will be emitted that are unique to the sample. These are referred to as the Stokes bands and are more commonly used for analysis. In the case of higher energy (due to the molecule already being in an excited vibrational state), shorter wavelengths will be emitted, also unique to the sample. These are commonly referred to as the anti-Stokes bands. Inelastic scatter is very uncommon and accounts for only about 0.001% of the scattered light coming from the sample; most of the light is elastically scattered at the same wavelength of the excitation source.

As with IR spectroscopy, in terms of implementation, the two main methods include a dispersive approach and a Fourier transform (FT) spectrometer configu-

ration [20]. The information contained in Raman spectra is commonly complementary to MIR absorption spectroscopy and both organic and inorganic materials possess Raman spectra. These normally include sharp bands that are representative of the chemical structure of the sample under investigation. It should be noted, however, that since Raman measurements are commonly collected in the visible range of the electromagnetic spectrum, sample autofluorescence can sometimes mask the weak Raman signature, especially for biological samples [21]. Moving the excitation source out to the NIR region can normally help minimize this effect. A main benefit of Raman measurements compared with MIR spectroscopy is that the sample requires little to no preparation and water absorption is not a problem (i.e., sample desiccation is not required), hence the approach is well suited to biological samples.

It should be noted that several variations of Raman spectroscopy are used in practice. These variants are usually implemented to improve sensitivity or spatial resolution, or to acquire specific types of information. Some of these techniques include surface-enhanced Raman spectroscopy (SERS), Raman optical activity (ROA), coherent anti-Stokes Raman spectroscopy (CARS), and resonance Raman spectroscopy [21].

Glucose Sensing and Glucose Determination Using Fluorescent Probes

Mark-Steven Steiner, Axel Duerkop, and Otto S. Wolfbeis

2.1
Why Glucose Sensing?

The measurement of glucose is among the most important analytical tasks. It has been estimated that about 40% of all blood tests are related to it. In addition, there are numerous other situations where glucose is to be determined, for example, in biotechnology, the production and processing of all kinds of food, in biochemistry in general, and in numerous other areas. The continuing interest in sensing glucose, mainly in blood, is one result of the increasing age and (alarming) size of the world's population, and the fact that about 4% of its (Caucasian) population suffers from diabetes. Normal blood glucose levels range from 3 to 10 mM (54–180 mg dl^{-1}).

The market for glucose sensors is probably the biggest single one in the diagnostic field, its size being about US$40 billion per year at present. Given this size, it does not come as a surprise that any true improvement in sensing glucose represents a major step forward. The greatest need at present is, however, for continuous sensors.

Both optical and electrochemical sensors can be manufactured at costs that are so low that they can also be of the disposable type. Clinical multiparametric instrumentation (e.g., for sensing glucose and blood parameters such as pO_2, pH, Na^+, K^+, Cl^-, lactate, and urea) relies on reusable sensors. In this case, a blood sample is inserted into the instrument, a reading is made, the surface of the sensor is washed, and the sensor is recalibrated before the next sample is introduced. Electrochemical methods are mainly used in stand-alone instruments in clinical laboratories and in near-patient testing. Millions of disposable electrochemical (mediator-based) blood glucose meters are used in homecare devices that enable glucose to be determined within less than 1 min in blood samples as small as 0.3 µl [1]. Electrical wiring of enzymes [2] has led to smaller quantities of blood being taken, thus leading to almost painless sampling in a new generation of glucose sensors that have had tremendous commercial success.

Optical methods are based on the measurement of photons rather than of electrons. The absence of electrodes can be advantageous in the case of patients with heart pacemakers. Although optical schemes for sensing glucose have not had

Handbook of Biophotonics. Vol.2: Photonics for Health Care, First Edition. Edited by Jürgen Popp, Valery V. Tuchin, Arthur Chiou, and Stefan Heinemann.

the success of electrochemical schemes, they still are a topic of highly active research. In addition to color test strips, a couple of reversible optical sensors rely on the measurement of the consumption of oxygen. Among the optical methods, photometry (and reflectometry), fluorescence, and surface plasmon resonance (SPR) have had the greatest success. Almost all optical sensors for continuous monitoring rely on either fluorescence or SPR. Not a single reflectometric method is known for use in continuous sensing. This chapter is restricted to luminescence-based methods.

2.2 Classification of Sensors According to the Recognition Scheme

This review is subdivided into sections according to the method for recognition of glucose. Once selective recognition of glucose has occurred, it has to be transduced into (optical) information. The first fundamental type of glucose sensor is based on the recognition of glucose by certain enzymes (or coenzymes) that subsequently undergo changes in their intrinsic absorption and/or fluorescence, or carry a label placed near the site of interaction and capable of reporting the interaction with glucose. The second class of sensors measure (kinetically) the formation/consumption of metabolites of enzyme activity, mainly of glucose oxidase (GOx). One scheme is based on the measurement of the quantity of oxygen consumed according to Eq. (2.1). Alternatively, the hydrogen peroxide (HP) formed according to Eq. (2.1) may be determined by electrochemical or optical means. A third option consists in the determination of the quantity of protons formed (i.e., the decrease in pH) [Eq. (2.2)].

$$\beta\text{-D-glucose} + O_2 \rightarrow \text{D-glucono-1, 5-lactone} + H_2O_2 \tag{2.1}$$

$$\text{D-glucono-1, 5-lactone} + H_2O \rightarrow \text{gluconate} + H^+ \tag{2.2}$$

The enzyme glucose dehydrogenase has also been used. It catalyzes the conversion of glucose to form NADH according to

$$\beta\text{-D-glucose} + NAD^+ \rightarrow \text{D-glucono-1, 5-lactone} + NADH \tag{2.3}$$

The amount of NADH formed according to Eq. (2.3) may be measured, for example, by photometry at 345 nm or by measuring its fluorescence peaking at 455 nm, but this reaction is not reversible and comes to an end once all the NAD^+ has been consumed. Hence it is less suited (and less elegant) in terms of continuous sensing.

The third large group of sensors relies on organic boronic acids that act as molecular receptors for 1,2-diols and saccharides. The high affinity of boronic acids towards saccharides facilitates recognition of glucose levels in blood samples (3–50 mM). When coupled to a conjugated π-system (a dye), these show a change in the optical properties as a result of binding glucose [3, 4]. The fourth large group of receptors exploits the capability of glucose-binding proteins (GBPs) to bind glucose with high specificity. This includes concanavalin A (ConA) based sensor schemes and apo-GOx, a glucose oxidase whose coenzyme has been removed. On binding glucose,

some proteins undergo changes in their intrinsic optical properties in the ultraviolet (UV) region. In order to shift analytical wavelengths into the (longwave) visible region, they have been labeled with fluorophores. Methods based on labeled proteins are preferred because the choice of a proper label enables the optical properties of the system to be fine-tuned.

2.3 Glucose Sensing via the Optical Properties of Oxidative or Reductive Enzymes

2.3.1 Nonlabeled Enzymes

The first group of recognition schemes comprises enzymes and coenzymes that undergo optical changes in their spectral properties (e.g., GOx [5, 6], glucose dehydrogenase, glucokinase [7], and apo-GOx). The optical changes usually occur in the UV region (based on the intrinsic tryptophan fluorescence of GOx) and in the visible region [the coenzyme flavin adenine dinucleotide (FAD) [8] of GOx]. These respective enzymes have also been labeled with fluorophores in order to shift the analytical wavelength into the visible region. Longwave sensing is highly desirable in view of the reduced absorbance and fluorescence of blood and serum at >600 nm. Labeling usually does not strongly affect the binding constants of the enzymes.

$$\beta\text{-D-glucose} + \text{FAD} \rightarrow \text{D-glucono-1, 5-lactone} + \text{FADH}_2 \tag{2.4}$$

$$\text{FADH}_2 + \text{O}_2 \rightarrow \text{FAD} + \text{H}_2\text{O}_2 \tag{2.5}$$

$$\text{D-glucono-1, 5-lactone} + \text{H}_2\text{O} \rightarrow \text{gluconate} + \text{H}^+ \tag{2.6}$$

Changes of the intrinsic fluorescence may involve (a) the UV fluorescence of tryptophan groups [excitation/emission maxima ($\lambda_{ex}/\lambda_{em}$) at 295/330 nm] in the protein [5], (b) the fluorescence of FAD (Figure 2.1) ($\lambda_{ex}/\lambda_{em}$ 450/520 nm) [8], or (c) NAD^+ ($\lambda_{ex}/\lambda_{em}$ 340/460 nm) [9]. An interesting competitive FRET (Förster resonance energy transfer) assay was presented by D'Auria *et al.* [10]. They used the intrinsic tryptophan fluorescence of glucose kinase as donor whereas glucose derivatized with *o*-nitrophenyl-β-D-glucose-co-pyranoside is the acceptor. Addition of glucose increases donor emission and decreases FRET. The analytical range of these sensors is typically from 0.5 to 20 mM, and rarely up to 200 mM [7].

2.3.2 Labeled Enzymes

In addition to the intrinsic optical properties of glucose-specific enzymes, the optical properties of labels of the enzyme may be exploited. Fluorescein [11, 12] and coumarin [13] are among the most commonly used labels. Excitation at above 400 nm

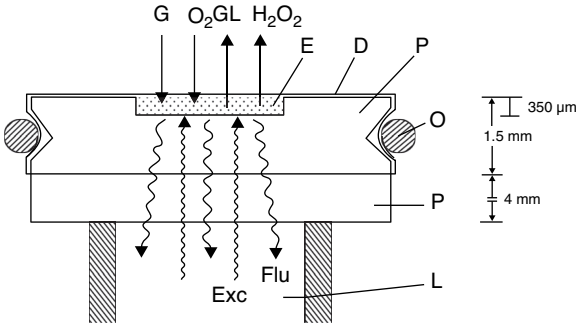

Figure 2.1 Cross-section through the sensing platelet of a fiber-optic glucose sensor. P, Plexiglas; D, dialyzing membrane; E, enzyme solution; O, O-ring; L, light guide. The arrows indicate the diffusion processes involved (G, glucose; GL, gluconolactone). The directions of the exciting light (Exc) and fluorescence (Flu) are also shown. The platelet has o.d. 20 mm; diameter of cavity, 4 mm [8]. Reprinted from W. Trettnak and O.S. Wolfbeis, Fully reversible fiber-optic glucose biosensor based on the intrinsic fluorescence of glucose oxidase, *Anal. Chim. Acta*, 1989, **221**, 195–203, with permission from Elsevier.

is more adequate for determination of glucose in real samples because of the ubiquitous UV absorption of proteins and other compounds in these samples.

2.4
Fluorescent Sensing of Glucose via Measurement of the Consumption of Oxygen Caused by the Action of GOx

The measurement of the consumption of oxygen [Eq. (2.1)] via quenchable probes (luminescent complexes of ruthenium, platinum, or palladium) immobilized in a sensor layer together with the enzyme is a fairly successful approach. The sensors described in the literature differ from each other mainly in the kind of fluorescent probe and the type of polymer matrix [hydrogels, sol–gels, polystyrene (PS)]. Among the technical layouts, optodes (optical fibers with the sensor layer fixed at the tip) and planar sensors in microwells or in a microfluidic flow cell have been reported. Continuous sensing using such enzymes and reversible oxygen sensors became available in the 1980s.

2.4.1
Planar and Fiber-Optic Sensors

The luminescence of probes such as decacyclene [14], complexes of Pt(II) [15, 16] or Pd(II) with porphyrins, Ru(phen) [17], Ru(bpy) [18] and Ru(dpp) [19], and Al-Ferron [20] have been reported to be quenched by molecular oxygen. The metal complexes can be excited in the visible spectrum, show large Stokes shifts, and have comparatively long decay times and good photostability. The signal increases strongly

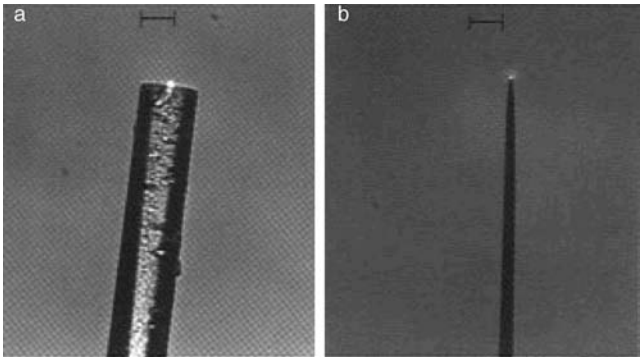

Figure 2.2 Photographs of fiber-optic glucose biosensors. (a) Sensor prepared from an unpulled, single-mode, 3–5 μm core optical fiber. The scale bar represents 50 μm. (b) Sensor prepared from a pulled, micrometer-sized optical fiber tip. The scale bar represents 10 μm [17]. Reprinted with permission from Z. Rosenzweig and R. Kopelman, Analytical properties and sensor size effects of a micrometer-sized optical fiber glucose biosensor, *Anal. Chem.*, 1996, **68**, 1408–1413. Copyright 1996 American Chemical Society.

on addition of glucose (because of the consumption of oxygen). Both fluorescence intensity and lifetime increase. Most common GOx–O_2 sensors consist of the enzyme immobilized on, or in a polymer film (2–5 μm), mostly a hydrogel or polyacrylamide (PAA) [17]. The oxygen-sensitive indicator dye is immobilized in a second polymer, preferably absorbed on silica gel beads, and incorporated in a silicone film [21]. This type of sensor with Ru(dpp) as the probe for oxygen is the only optical sensor produced commercially in very large numbers. Sensors are also known where the enzyme and dye are embedded in the same layer. The sensing layers are then attached to a support such as PS, controlled-pore glass (CPG) [15], or an optical fiber (Figure 2.2), and are often shielded by a diffusion barrier layer [22].

A fiber-optic dual sensor for the continuous and simultaneous determination of glucose and oxygen with $Ru(bpy)_3$ as O_2 transducer was described in 1995 [18]. The sensor comprises two sensing sites in defined positions on the distal end of an imaging fiber (Figure 2.3). Each sensing site contains an individual polymer cone covalently attached to the activated fiber surface using localized photopolymerization. The fluorescence images of both sensing sites are captured with a charge-coupled device (CCD) camera and oxygen quenching data for both sensing sites are fitted by a two-site Stern–Volmer quenching model. Within response times from 9 to 28 s, glucose can be detected in the range 0–20 mM with this self-referenced scheme.

Further glucose biosensors have used unusual supports (eggshell membranes or swim bladder membranes) on which GOx was immobilized [23, 24]. The glucose biosensor has a long shelf-life and was successfully applied to the determination of glucose in a beverage sample in a flow cell.

A limitation of oxygen-based detection schemes in general and oxygen-depleting detection schemes in particular is based on the varying background of oxygen in samples. This may be overcome by using a large excess of air-saturated buffer

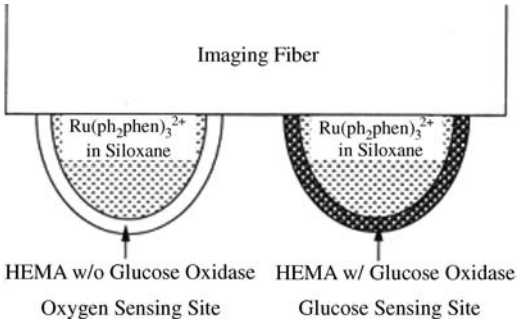

Figure 2.3 Schematic showing a cross-sectional view of the glucose and oxygen sensing sites of a fiber-optic dual sensor for the continuous and simultaneous determination of glucose [18]. Reprinted with permission from L. Li and D.R. Walt, Dual-analyte fiber-optic sensor for the simultaneous and continuous measurement of glucose and oxygen, *Anal. Chem.*, 1995, **67**, 3746–3752. Copyright 1995 American Chemical Society.

solution, or by compensating the variable oxygen background by determining it independently, for example, with a second sensor. This kind of dual sensor was reported first by Li and Walt [18], subsequently by Wolfbeis *et al.* [22], and more recently by Klimant's group [25, 26]. They used a dual sensor, consisting of two commercially available oxygen optodes in close proximity, where one had been modified with GOx and the other served as a reference (Figure 2.4). This sensor is unaffected by fluctuations of the oxygen concentration in the sample and also allows for the compensation of slight temperature fluctuations. Comparable sensor schemes have been patented [27–29].

2.4.2
Sensors Based on the Use of Microparticles (μPs) and Nanoparticles (NPs)

Particle-based sensors have attracted substantial interest for intracellular glucose testing in recent years. They may be applied in the future in the bloodstream as molecular analytical machines reporting blood glucose levels, provided that the optical signal they are giving can be interrogated. Xu *et al.* incorporated GOx, sulfo-Ru $(dpp)_3$ and Oregon Green 488–dextran (as a reference-dye) in 45 nm diameter PAA nanoparticles to obtain so-called PEBBLE sensors for self-referenced ratiometric measurements [30]. The PEBBLEs were implanted into living cells with minimal physical and chemical perturbations to their biological functions. Another implantable microsensor was reported by Brown and co-workers (Figure 2.5) [31, 32].

GOx and horseradish peroxidase (HRP) conjugated CdSe/ZnS core–shell quantum dots (QDs) were used for FRET-based glucose sensing. Upon irradiation, the QDs shuttle electrons to GOx and HRP, upon which they rapidly oxidize glucose to gluconic acid and reduce H_2O_2 (or O_2). This nonradiative energy transfer results in quenching of the QD emission proportional to the concentration of glucose up to 28 mM with a 30 min response time [33].

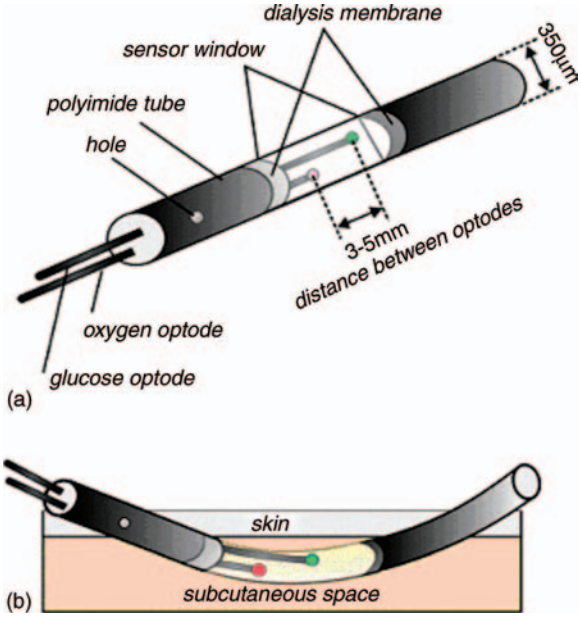

Figure 2.4 Schematic representation of (a) hybrid sensor and (b) implanted hybrid sensor [26]. Reprinted from A. Pasic, H. Koehler, I. Klimant, and L. Schaupp, Miniaturized fiber-optic hybrid sensor for continuous glucose monitoring in subcutaneous tissue, *Sens. Actuators B*, 2007, **122**, 60–68, with permission from Elsevier.

Srivastava, and M.J. McShane, Encapsulation of glucose oxidase and an oxygen-quenched fluorophore in polyelectrolyte-coated calcium alginate microspheres as optical glucose sensor systems, *Biosens. Bioelectron.*, 2005, **21**, 212–216, with permission from Elsevier.

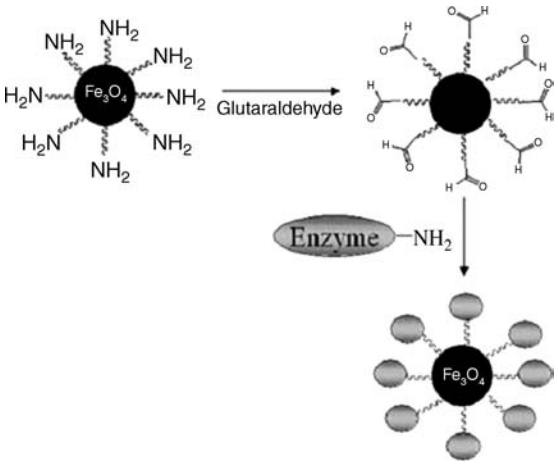

Figure 2.6 Covalent conjugation of glucose oxidase to amino-functionalized magnetic nanoparticles [34]. Reprinted from L.M. Rossi, A.D. Quach, and Z. Rosenzweig, Glucose oxidase–magnetite nanoparticle bioconjugate for glucose sensing, *Anal. Bioanal. Chem.*, 2004, **380**, 606, with permission from Springer Science + Business Media.

GOx-coated magnetite (Fe_3O_4) nanoparticles with $Ru(phen)_3$ can be used as nanometric glucose sensors in glucose solutions (Figure 2.6) [34]. This allows the magnetic separation of the nanoparticles from the analyte sample, permitting reuse in multiple samples.

The O_2 transducer is often influenced by temperature. This drawback can be compensated for by dual sensors that sense both oxygen and temperature [35]. Here, the oxygen probe Pt(porph) in a layer of PS and the europium complex $Eu(tta)_3(dpbt)$ in a layer of poly(vinyl methyl ketone) as the temperature probe allow dual lifetime determination to monitor the consumption of oxygen at varying temperatures. The layers lie upon one another on a polyester support.

2.5
Fluorescent Sensing of Glucose via Measurement of the Formation of Hydrogen Peroxide Caused by the Action of GOx

HP produced in the enzymatic reaction can be linked to the concentration of glucose, as shown in Eq. (2.1). Monitoring of HP has the advantage of a measurement against an almost zero background. Only few sensors for continuous mode operation have been reported.

A probe for HP was reported consisting of a conjugated cationic polymer incorporated with boronate-protected peroxyfluorescein. HP deprotects the fluorescein to create anionic fluorescein, which interacts electrostatically with the cationic fluorene. The FRET between fluorene (donor) and fluorescein (acceptor) can be used to monitor glucose in the nanomolar [36] to micromolar range [37].

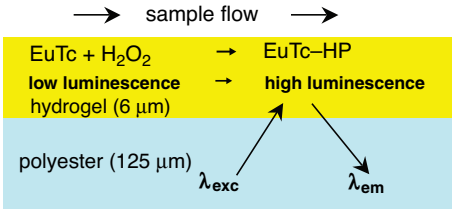

Figure 2.7 Cross-section of the membrane of a glucose biosensor using luminsecent EuTc–HP.

An enzymatic assay for glucose based on luminescent europium(III) tetracycline (EuTc) was described [38]. Weakly luminescent EuTc and enzymatically generated HP form a strongly luminescent complex (EuTc–HP). The probe can be excited at 400 nm and emits at 616 nm. It responds to HP by a 15-fold increase in luminescence and a strong increase in lifetime. This permits lifetime-based measurements of glucose with a substantially reduced luminescence background (Figure 2.7).

The reaction of EuTc with HP is fully reversible but takes about 10 min in both directions and is strongly pH dependent. The complex was used for time-resolved imaging of glucose [39]. Furthermore, GOx was covalently labeled to Mn-doped ZnS QDs. HP produced in the presence of glucose quenches the emission of the dots. The nanosensors were successfully applied to serum samples (Figure 2.8) [40].

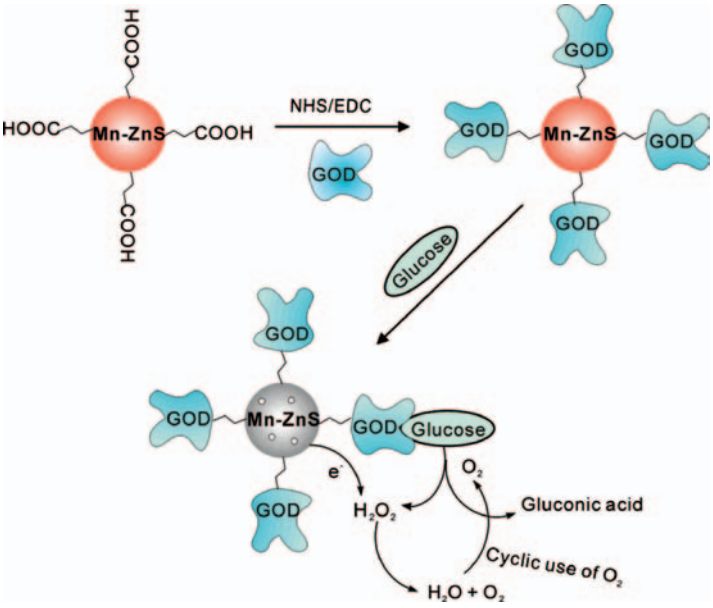

Figure 2.8 Schematic diagram for the preparation and application of GOx–Mn-doped ZnS QD bioconjugate for glucose sensing [40]. Reprinted with permission from P. Wu, Y. He, H.-F. Wang, and X.-P. Yan, Conjugation of glucose oxidase onto Mn-doped ZnS quantum dots for phosphorescent sensing of glucose in biological fluids, *Anal. Chem.*, 2010, **82**, 1427–1433. Copyright 2010 American Chemical Society.

2.6
Enzymatic Sensing of Glucose via Changes of pH

Changes of pH may also serve as analytical information to sense glucose according to Eq. (2.2). However, this approach is limited because often the initial pH of the sample and its buffer capacity are unknown. Therefore, only a few optical biosensors make use of pH transducers.

McCurley reported on a cadaverine unit linked to rhodamine that was incorporated into a hydrogel (along with GOx and catalase) placed at the end of an optical fiber [41]. The cadaverine moiety is protonated on the enzymatic reaction of glucose, which causes swelling of the hydrogel. This, in turn, decreases the fluorescence intensity of the rhodamine in the 0–1.6 mM glucose range.

Tohda and Gratzl [42] covalently immobilized GOx on cellulose acetate beads and embedded a pH-sensitive phenoxazine derivative in polymer microbeads. These beads, along with white reference beads, were arranged in a microarray to read the reversible color change caused by pH with a CCD camera. Another scheme comprises internally cationically charged biocompatible capsules containing the pH probe 8-hydroxypyrene-1,3,6-trisulfonic acid (HPTS) and electrostatically adsorbed GOx. pH changes induce ratiometric changes of emission spectra and are monitored as a function of glucose concentration in the physiological range [43]. Two different sensors with a pH-sensitive azlactone and GOx embedded in a sol–gel were reported [44]. A setup with immobilization of GOx and fluorescein isothiocyanate (FITC) as pH reporter in a polymer at the end of an optical fiber was patented by Applied Research Systems [45].

2.7
Fluorescent Sensing of Glucose via Synthetic Boronic Acids

Boronic acids can reversibly react with 1,2- or 1,3-diols in aqueous solution to form five- or six-membered cyclic esters. The state of the art in optical boronate probes for saccharides has been reviewed recently [3]. The rigid *cis*-diols found in many saccharides generally form stronger complexes than acyclic diols such as ethylene glycol and *trans*-diols. On binding a saccharide, the neutral trigonal boronic acid transforms into the anionic tetrahedral form and releases a proton (Figure 2.9). This change in geometry is accompanied by a reduction in the pK_a from ~9 to ~6 because the electrophilicity of the boronic acid group is enhanced on interaction with a diol. Hence the trigonal form is present at pH values below the pK_a but in the presence of a saccharide it is converted into its tetrahedral anionic form. The pK_a of the boronic acid is tunable to lower values with electron-withdrawing groups, whereas electron-donating groups increase the pK_a. When attached to an appropriate fluorophore, the changes in the symmetry of the boronic acid also induce changes in fluorescence emission (intensity, lifetime, and polarization). One fundamental disadvantage of most boronic acid-based probes for glucose sensing is either a higher selectivity for fructose than for glucose or/and a stronger response to fructose than to glucose.

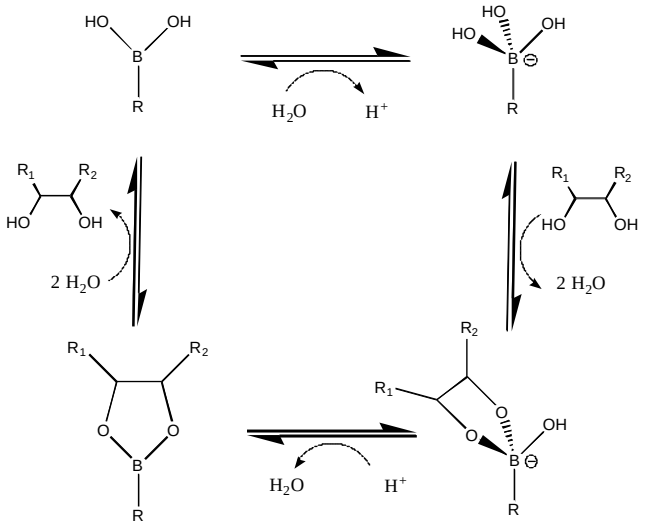

Figure 2.9 Geometries of reaction products of boronic acids with water or 1,2-diols (e.g., glucose).

Three quinoline-based probes for the determination of glucose in tear fluid were presented [46, 47]. The probes were structurally modified to allow compatibility with disposable plastic contact lenses. The sugar-bound pK_a is reduced, favorable with the mildly acidic lens environment. One probe shows a similar affinity for both glucose and fructose from the emission decrease at 450 nm. Glucose and fructose were determined at sub-millimolar levels with a response time of 10 min (Figure 2.10). The probe showed negligible leaching and was quenched only modestly by chloride.

Competitive assay schemes use the reversible interaction between Ru(2,2′-bipyridine)$_2$-(5,6-dihydroxy-1,10-phenanthroline) and arylboronic acid derivatives at pH 8 [48, 49]. Complexation is accompanied by a strong increase in fluorescence intensity at 620 nm. Addition of glucose reduces emission intensity because of intercepting the binding between boronic acid and the metal complex. The ruthenium complex may also be incorporated into a glucose-permeable and implantable polymer [50, 51].

Singaram and co-workers [52] reported on a two-component system comprising an anionic fluorescent dye and a cationic viologen quencher containing a bisboronic acid functionality to form a nonfluorescent ion pair. Their electrostatic interaction is reduced when a saccharide binds to the viologen to yield a negatively charged boronate ester and the fluorescence intensity is increased (Figure 2.11). A modular ensemble composed of three different viologen quenchers was also shown. The increase in luminescence of 11 anionic fluorescent dyes (e.g., HPTS) on addition of 12 saccharides in the presence of these three quenchers was determined and evaluated via two-dimensional linear discriminant analysis. Differentiation between glucose, fructose, mannose, and galactose at a concentration of 2 mM was accomplished [53].

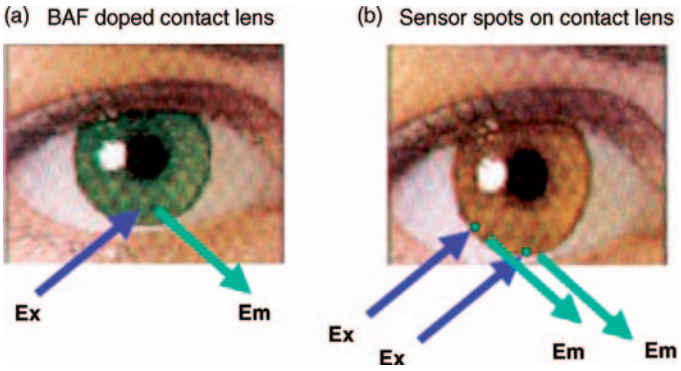

Figure 2.10 Potential methods for noninvasive continuous tear glucose monitoring. (a) Contact lens doped with optical probe for glucose. (b) Sensor spots on the surface of the lens to monitor additionally other analytes in addition to glucose, such as chloride or oxygen. Sensor spot regions may also allow for ratiometric, lifetime, or polarization based fluorescence glucose sensing [47]. Reprinted from R. Badugu, J.R. Lakowicz, and C.D. Geddes, A glucose sensing contact lens: a non-invasive technique for continuous physiological glucose monitoring, *J. Fluoresc.*, 2003, **13**, 371, with permission from Springer Science + Business Media.

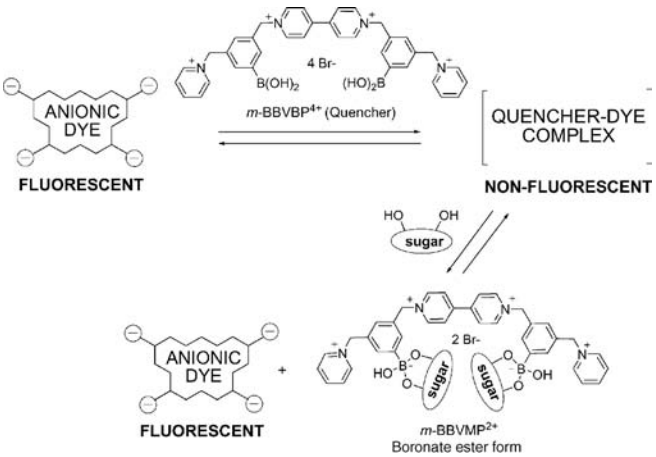

Figure 2.11 General sensing mechanism with the boronic acid-functionalized viologen quencher *m*-BBVBP^{4+} used as the saccharide receptor unit. Viologens quench the luminescence of dyes through an ionic attraction to form a nonfluorescent complex. Upon saccharide binding to the boronic acid of the viologen quencher, the negatively charged boronate ester causes a diminished electrostatic attraction resulting in a fluorescence increase [52]. Reproduced from D. B. Cordes, A. Miller, S. Gamsey, S. Zach, P. Thoniyot, R. Wessling, and B. Singaram, Optical glucose detection across the visible spectrum using anionic fluorescent dyes and a viologen quencher in a two-component saccharide sensing system, *Org. Biomol. Chem.*, 2005, **3**, 1708–1713, with permission from The Royal Society of Chemistry.

CdSe QDs were utilized as fluorescent reporters in combination with a viologen quencher with a boronic acid functionality as the glucose receptor. The fluorescence of the reporter is quenched by the viologen before addition of glucose. When glucose is added to the solution, the emission at 604 nm recovers. Both carboxy- and amino-substituted QDs are quenched by a viologen in aqueous solution at pH 7.4 [54].

2.8
Fluorescent Sensing of Glucose via Concanavalin A

ConA is a plant lectin protein originally extracted from jack beans. The ConA tetramer consists of two dimers and has four binding sites for glucose. Its specific function involves the agglutination of biologically relevant complexes such as glycoproteins, starches, and erythrocytes. ConA is used traditionally in a competitive assay where glucose and another carbohydrate such as dextran mannoside or glycated proteins compete for the lectin-binding sites. The protein and the competitor are generally labeled with appropriate fluorescent dyes. An inherent but often disregarded problem with ConA-based sensors regarding sensor stability is that unbound lectin tends to aggregate irreversibly over a period of some hours.

Schultz *et al.* [55] described a glucose sensor in which ConA is immobilized inside a hollow dialysis fiber connected to a fluorescence detection system by a single optical fiber. FITC-labeled dextran was the competing ligand to pass in and out of the fiber. Glucose displaces the competitor from ConA and increases the concentration of free dextran and, consequently, the fluorescence. Optimization steps comprised immobilization of ConA on Sepharose [56] and optical readout to reduce response times to 5 to 7 min [57].

Transdermal glucose monitoring was achieved [58] by confining Alexa488-labeled ConA and colored macroporous beads inside a sealed, small segment of a hollow-fiber dialysis membrane. Immobilized pendant glucose moieties inside the colored beads compete with glucose for binding of ConA. In the absence of glucose, the excitation and emission of Alexa488 is blocked. Glucose diffuses through the membrane into the sensor chamber and competitively displaces Alexa 488–ConA from the glucose residues of the beads. Consecutively, Alexa488–ConA is fully exposed to the excitation light, and the increase in fluorescence at 520 nm is measured (Figure 2.12). The sensor exhibits the strongest signal change between 0.2 and 30 mM, with a response time of around 4 min. *In vivo* tests were conducted with a ratiometric FRET system consisting of Cy7-labeled agarose-immobilized ConA as acceptor/quencher and unbound Alexa647–dextran as donor. In the absence of glucose, dextran is bound to ConA, therefore both are in close proximity, enabling a FRET. Glucose displaces dextran from ConA, which results in decreased FRET and an increase in Alexa647 fluorescence at 670 nm. *In vivo* tests with a small hollow fiber implanted in dermal skin tissue revealed a delay of 5–15 min in actual blood glucose concentrations [59]. PreciSense has patented a similar but lifetime-based sensor setup [60].

A hollow-fiber setup [61] uses FRET between rhodamine-labeled ConA and fluorescein-labeled dextran. The emission of dextran is restored on addition of

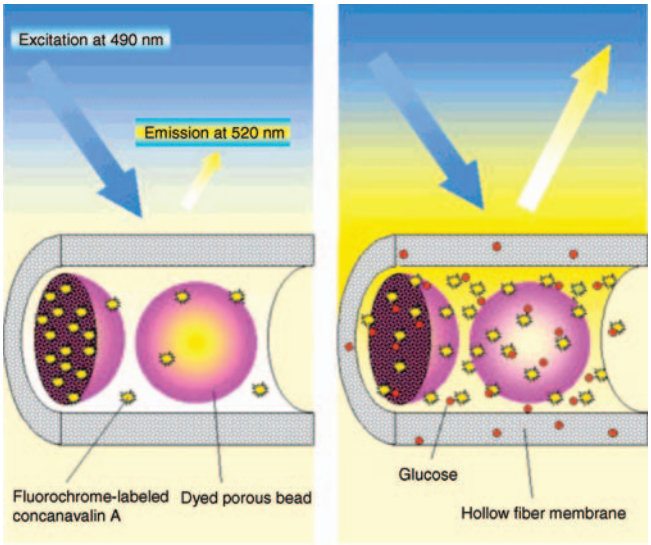

Figure 2.12 In the absence of glucose, fluorochrome-labeled ConA is bound to fixed glucose residues inside the porous beads (a) in a hollow fiber. The beads are colored with dyes to prevent the excitation light from penetrating into them and inducing ConA to fluoresce, thus keeping the fluorescence emission at 520 nm. After diffusion of glucose through the hollow-fiber membrane, ConA is displaced from the beads and diffuses out of them, and hereby fluorochrome-labeled ConA becomes exposed to excitation light, resulting in a strong increase in fluorescence (b) [58]. Reprinted with permission from R. Ballerstadt and J.S. Schultz, A fluorescence affinity hollow fiber sensor for continuous transdermal glucose monitoring, *Anal. Chem.*, 2000, **72**, 4185–4192. Copyright 2000 American Chemical Society.

glucose due to competitive displacement. Novartis has patented a related sensor that can be incorporated into a contact lens and an apparatus to irradiate the sensor dyes and detect FRET [62]. Cheung *et al.* [63] reported on a similar system in microplates (MTP). Donor and acceptor were incorporated into hydrogel pads that were then attached to hydrophobic surfaces of the wells of a microtiter plate (Figure 2.13). A layer-by-layer (LbL) self-assembly process was used to coat the surface of the hydrogel pads with polyelectrolyte multilayers with the aim of creating a permeability-controlled membrane with nanometer thickness. LbL hydrogel pads allow regeneration within 17 min with a signal reproducibility of more than 90% to yield a reusable and reagentless optical bioassay platform.

Birch and co-workers developed a non-radiative FRET sensing setup [64]. Con A was labeled with the NIR fluorescent protein allophycocyanin (APC) as donor and dextran labeled with Malachite Green (MG) as acceptor, which shields APC emission as long as dextran is bound to the lectin. Glucose competitively displaces dextran–MG and leads to restoration of the APC fluorescence at 663 nm, quantified by time-domain fluorescence lifetime measurements. Another setup exploits the luminescence decay time of Cy5-labeled ConA [65] as a FRET donor. The acceptor consisted of

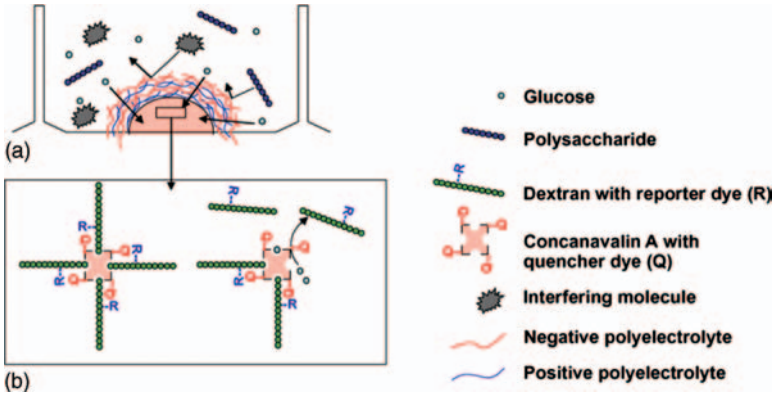

Figure 2.13 Schematic diagram of a LbL hydrogel pad (a) and the entrapped Q–ConA/R–dextran glucose sensing system (b) [63]. Reprinted from K.Y. Cheung, W.C. Mak, and D. Trau, Reusable optical bioassay platform with permeability-controlled hydrogel pads for selective saccharide detection, *Anal. Chim. Acta*, 2008, **607**, 204–210, with permission from Elsevier.

insulin covalently linked to MG and to maltose (MIMG) to provide binding affinity for ConA. MIMG was displaced competitively from ConA in the presence of glucose, and the Cy5 emission and lifetime increased. This sensor has the advantage of a reduced rate of aggregation and better reversibility in comparison with other setups by using a protein as glucose competitor instead of dextran. A further benefit is its NIR emission, allowing measurement of decay times through skin. This suggests the possibility of application as an implantable glucose sensor. Further experiments were carried out with the sensing setup, where the Cy5 label of ConA was replaced with Ru $(bpy)_3$ [66]. The advantages here are the large Stokes shift and long decay times, which simplifies instrumentation for phase-modulation lifetime measurements.

Another sensor based on FRET was described by Liao *et al.* [67]. They used QDs labeled with ConA as donor. Rhodamine-labeled β-cyclodextrin served as acceptor, showing a lower affinity to ConA to improve the signal detection sensitivity 60-fold while preserving glucose sensitivity in the physiological range. ConA and the dextrin were photopolymerized in a hydrogel at the end of an optical silica fiber with a diameter of only 250 μm (Figure 2.14). This permitted interstitial and minimal invasive *in vivo* glucose determination. The ratio of the emission at 525 and 570 nm correlated linearly with the glucose concentration up to 28 mM.

A related sensing scheme by Tang *et al.* [68] comprised ConA-labeled CdTe QDs and β-cyclodextrin-modified gold nanoparticles (AuNPs). In absence of glucose, FRET is observed between QDs as donors and AuNPs as acceptors. In the presence of glucose, the AuNP–CDs are displaced competitively by glucose, resulting in recovery of the QD fluorescence. The setup was also applied to direct glucose determination in human serum with satisfactory results.

The first solution-phase nanotube affinity sensor is based on dextran-modified single-walled carbon nanotubes (SWNTs) [69]. These were aggregated by ConA,

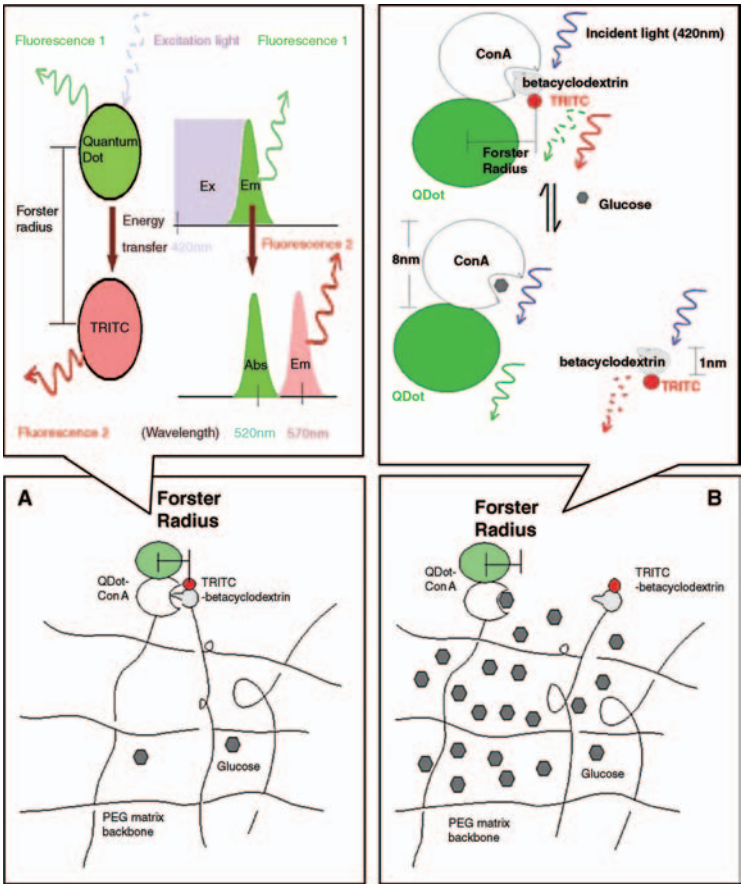

Figure 2.14 Changes in FRET between fluorophores covalently immobilized on the flexible PEG matrix depend on changes in the distance between them, which in turn depends on the competitive natural affinity between Con A and various saccharides such as betacyclodextrin and glucose.

resulting in quenched SWNT photoluminescence ($\lambda_{ex}/\lambda_{em}$ 633/>900 nm). Addition of glucose restored the initial luminescence.

2.9
Fluorescent Sensing of Glucose using Glucose-Specific Apoenzymes

In this (non-kinetic) scheme, the enzyme acts as both a molecular receptor and transducer. It represents an attractive alternative to sensing schemes utilizing the specific binding of glucose to ConA or to a bacterial or engineered glucose-binding protein. Typical enzymes used in this format include GOx and glucose

dehydrogenase (GDH). In order to prevent the oxidation or reduction of glucose but to retain enzyme specificity, the cofactors FAD or NAD, respectively, have to be removed from the holoenzyme, resulting in apo-GOx or apo-GDH. Two major sensing schemes have been reported for apo-enzyme affinity assays:

1) labeling of apo-enzyme with a polarity-sensitive dye and utilization of conformational changes on binding glucose
2) competitive assay similar to ConA using a labeled dextran as a competitor.

Lakowicz and co-workers [70] found that on binding glucose to the apo-GOx, a decrease of up to 18% of its intrinsic tryptophan fluorescence occurs. As UV wavelengths are not useful for routine diagnostic purposes, apo-GOx was non-covalently labeled with the environment sensitive dye 8-anilino-1-naphthalenesulfonate (ANS). In the presence of glucose, both the fluorescence intensity and the mean lifetime of the bound ANS decreased due to conformational changes of apo-GOx. These results suggest that apo-glucose oxidase can be used as a reversible sensor for glucose which – unlike in the case of functional enzymes – is not consumed [71]. A further approach was described using apo-GDH with similar sensitivity [72].

Chinnayelka and McShane [73] described an example of a competitive FRET assay scheme comprising tetramethylrhodamine isothiocyanate (TRITC)-labeled apo-GOx and FITC-labeled dextran. On competitive binding of glucose, a reduction in the efficiency of FRET occurs when the apo-GOx–dextran complex dissociates. A glucose concentration range from 0 to 90 mM can be monitored. The system was applied in an implantable minimally invasive sensor using the LbL self-assembly technology of the former ConA sensor [74]. TRITC–apo-GOx and FITC–dextran were encapsulated in LbL-assembled semipermeable microcapsules (Figure 2.15). These capsules showed five times better specificity for glucose over other saccharides [75]. The sensor design was later extended to longer wavelength emission [76].

2.10
Fluorescent Sensing of Glucose via Glucose-Binding Proteins

The periplasm of Gram-negative bacteria such as *Escherichia coli* comprises a family of proteins [referred to as glucose-binding proteins (GBPs)] with highly specific binding of sugars and other ligands. These proteins are primary receptors for transport and have a very similar structure in common. The monomeric arrangement consists of two globular domains linked by a hinge. The GBPs also show a minute affinity for galactose. The binding constant of native GBP for glucose is in the micromolar range and therefore not very appropriate for sensing in the physiological range. Hence engineered GBPs were developed with mutations of the binding pocket for reduced affinity to glucose. GBP-based sensing schemes are superior to enzyme-based glucose sensors in that they are not limited by enzyme substrates such as

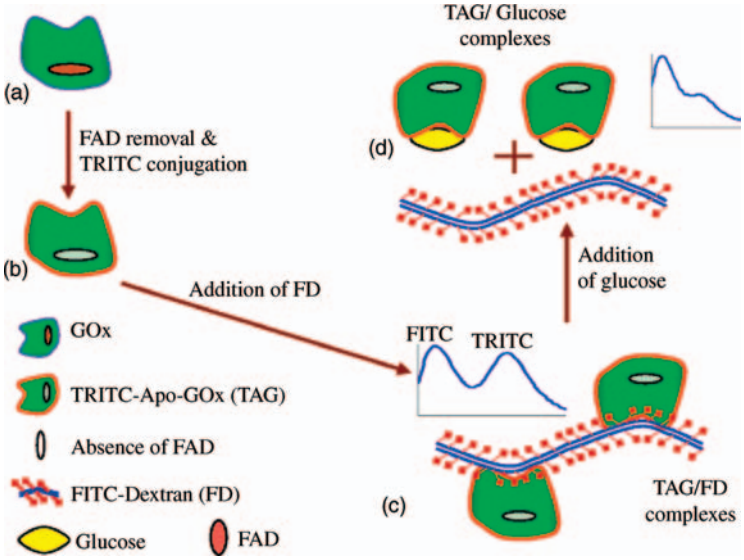

Figure 2.15 Schematic of the RET glucose assay based on competitive binding between dextran and glucose for binding sites on apo-GOx.5 [75]. Reprinted with permission from S. Chinnayelka and M.J. McShane, Microcapsule biosensors using competitive binding resonance energy transfer assays based on apoenzymes, *Anal. Chem.*, 2005, 77, 5501–5511. Copyright 2005 American Chemical Society.

oxygen or potentially toxic reaction products such as HP. Therefore, they are often referred to as reagentless sensors. All sensing schemes utilizing native or engineered GBPs are based on the large change in conformation that occurs on binding of glucose. Hence the binding event can be transduced by site-specifically attached and polarity-sensitive luminophores. Two basic approaches are reported, that is, either one fluorophore labeled on GBP or two fluorophores for ratiometric measurements. The latter have the advantage of being unaffected by variations in excitation light intensity, light path, sample positioning, reagent concentration, and so on.

In the first report on a genetically engineered GBP for use in a glucose sensor [77], two fluorophores were covalently attached to cysteines next to the ligand-binding site. The fluorescence of the first was quenched, whereas the fluorescence of the other was enhanced on addition of glucose due to changes in the polarity of the microenvironment. A series of patents cover this sensing scheme [78–80]. GBP is most often labeled with dyes such as Cy3, Cy5 [81], IANBD, Nile Red derivatives [82], and dyes with a coumarin or benzodioxazole nucleus. The conjugate is then embedded in a polymer and often attached to the end of an optical fiber.

Ye and Schultz [83] were among the first to report on a continuous dialysis hollow-fiber microsensor based on an engineered GBP showing a FRET. The so-called glucose indicator protein (GIP) contains a UV-excitable green fluorescent protein (GFPuv) and a yellow fluorescent protein (YFP) fused to the GBP. The reporter

permits efficient FRET in the absence of glucose, whereas on addition of glucose the distance between the two fluorescent proteins increases accompanied by a decreased FRET (Figure 2.16). A similar setup was used to monitor intracellular glucose levels. GBP was labeled with cyano fluorescent protein and YFP to create a FRET system. Again, addition of glucose decreased the emission of YFP at 535 nm. The developed GBP mutant showed a K_d of ~600 μM, which allowed specific monitoring of the glucose distribution and levels in cells [84]. An implantable glucose-sensing device based on the GIP–FRET sensing scheme was patented [85].

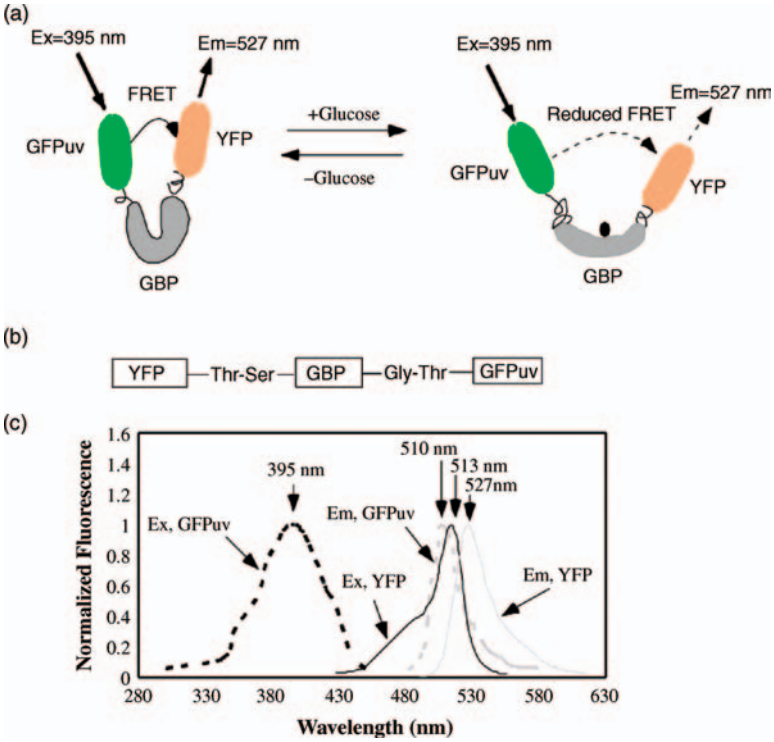

Figure 2.16 Design of a GIP (glucose indicator protein) for sensing glucose based on FRET. (a) Diagram of the GIP structure showing how FRET between two GFPs can measure glucose concentration. The GBP adopts an "open" form in the presence of the glucose, which triggers a conformation change, causing two GFPs apart from the center of GBP leading to the change in FRET. The large dot at the GBP on the right panel represents one molecule of glucose bound to the binding cleft of the GBP. (b) Domain structure of the GIP. GFPuv, green fluorescent protein with several mutations to enhance the excitation by UV light; YFP, yellow fluorescent protein; GBP, glucose-binding protein. (c) Spectral overlap of GFPuv and YFP. The absorbance spectra are denoted by black lines and the emission spectra by gray lines [83]. Reprinted with permission from K. Ye and J.S. Schultz, Genetic engineering of an allosterically based glucose indicator protein for continuous glucose monitoring by fluorescence resonance energy transfer, *Anal. Chem.*, 2003, **75**, 3451–3459. 2.11 Conclusion and Outlook

Fluorescent technologies, many involving FRET, provide attractive methods for sensing glucose. They have specific features that make them applicable to challenges not covered by electrodes, for example, intracellular sensing and imaging. Clinical sensing of glucose is the largest market and is dominated by electrochemical sensors. All the optical sensors used for routine clinical assays are based on the use of the (very robust) enzyme GOx and fluorimetric measurement of the oxygen consumed. The other schemes presented here still await commercialization. Notwithstanding this, they represent valuable tools for research and, predictably, will find their use in clinical situations where existing sensors cannot be applied.

Biochips as Novel Bioassays

Bettina Rudolph, Karina Weber, and Robert Möller

3.1
Introduction

Through new methods in molecular biology, biochemistry, and the humane genome project, the amount of genetic information and the information on biomolecules and their interactions has risen exponentially in recent years. This new information allows the in-depth investigation of biological systems but also demand simple, fast, cheap, and miniaturized analytical tools, which can be produced in large numbers. Classical bioassays, which investigate the effect of a substance on a biomolecule, cell, or even organisms, were normally performed in batch experiments, meaning that the interactions between the investigated substance and a particular biomolecule of interest were performed as one experiment. To investigate the interactions of the same substance with another biomolecule, a new experiment had to be conducted. This experimental setup was time consuming and also needed large amounts of reagents. To save time and reagents, bioassays were miniaturized, for example, using microtiter plates, and molecules were immobilized to surfaces to allow the parallel testing of multiple molecules in one experiment. These approaches for the development of paralleled and miniaturized bioassays led to the development of biochips or microarrays.

Biochips normally consist of a planar solid substrate, on which known biomolecules are immobilized in an ordered fashion. The immobilized biomolecules, which are also referred to as capture molecules, are bound to the surface in spots and each spot contains molecules of the same kind. The biochip is then incubated with a solution containing target molecules that can bind specifically to the surface-immobilized capture molecules.

Because of sophisticated production processes, a high spot density can be achieved. Typical feature sizes for DNA chips produced by photolithography are $100\,\mu m^2$ per spot, which allows the immobilization of an enormous amount of different DNA sequences even on $1\,cm^2$. Hence a biochip permits miniaturized, highly parallel investigations of biomolecular interactions.

Handbook of Biophotonics. Vol.2: Photonics for Health Care, First Edition. Edited by Jürgen Popp, Valery V. Tuchin, Arthur Chiou, and Stefan Heinemann.

In this chapter, we introduce the basics of biochip technology and their use in pathogen detection and clinical diagnostics, and also innovative trends in this field aimed at increasing the applicability and efficiency of biochip-based detection of biomolecules.

3.2 Types of Microarrays

In molecular biology and medicine, miniaturized multiplexed systems are increasingly of importance for highly complex and simultaneous (parallel) testing of tens of thousands of probes. Microarrays, also called biochips, have evolved to a mainstream tool of life science research. Depending on the immobilized biological recognition systems, microarrays can be classified in different types. A classification by the type of transducer/detection method is another possibility, but in this chapter we describe types of microarrays depending on their immobilized receptor. The most common types of microarrays are DNA microarrays. Oligonucleotide arrays provide a powerful tool to study molecular basics and interactions on a scale that is impossible using conventional methods [1]. Further applications of microarrays based on immobilization of, for example, proteins, cells, or tissues are described in the following. Nowadays, many commercial standardized microarrays with different immobilized biological recognition systems, especially oligonucleotides or antibodies, are supplied by a variety of companies, for example, Affymetrix, Agilent, Illumina, GE Healthcare, Applied Biosystems, and Agendia. Most of these companies provide custom-made microarrays for individual research. Another common option is to manufacture specific microarrays directly in the laboratory by using different commercially available technologies for their individual production.

3.2.1 DNA Microarrays

Historically, microarray technology evolved from blotting methods. DNA microarrays are based on the Southern blot [2], which is used in medical diagnostics to control DNA sequences in a DNA sample. Instead of DNA fragments, RNA can be analyzed in a Northern blot. These conventional methods are often time consuming and not effective for investigating large numbers of genes. Hence DNA microarrays became a mainstream method in research for investigations of thousands of genes simultaneously.

Basically, there are three strategies for the development of a DNA chip for gene expression studies, which were described by Lemieux *et al*. [3]. First a strategically selection of known genes that play an important role in biological pathways is necessary. A second way uses clones from a library [4] restricted to cDNA microarrays. Third, the complete expressed sequence content of an organism is used for the production of a microarray [5]. For that purpose, a DNA microarray

can consist of hundreds of thousands of spots of DNA oligonucleotides, called captures or probes. Each spot includes a specific DNA sequence, which binds complementarily to a target molecule in the investigated sample. Depending on the application, there exist different special arrays for genomic DNA, cDNA, RNA, plasmids, polymerase chain reaction (PCR) products, or long oligonucleotides. Usually complementary binding of capture and target molecules is detected and quantified by optical methods to determine the relative abundance of a nucleic acid target sequence in the sample.

Since the early 1990s, the field of DNA microarray technology has seen a constant technological evolution and intensive studies have been carried out. In 1991, Fodor and the company Affymetrix pioneered oligonucleotide arrays [6]. Numerous reviews and articles have reported and discussed the different possibilities and applications of DNA microarrays [7–25]. In 1999, *Nature Genetics* published a series of reviews about DNA microarrays and their fabrication and detection [26], gene expression profiling [27, 28], resequencing and mutational analysis [29], and also applications in drug discovery [30]. Furthermore, Southern *et al.* reported molecular interactions on microarrays [1]. In recent years, really intensive studies were carried out in the field of genomic research, pathogen detection, and clinical diagnostics, as described in Section 3.4.

In 1994, the HIV GeneChip of Affymetrix was the first commercially available DNA microarray, and is now the most widely known and applied microarray platform [31]. A good overview of the current status of used DNA microarrays was given by Shi *et al.* [15]. MammaPrint, a prognostic test for breast cancer from Agendia, became the first *in vitro* diagnostic multivariate index assay (IVDMIA) to acquire clearance from the US Food and Drug Administration (FDA) in 2007. Finally, the importance of DNA microarray technology is evidenced by its extensive literature and still increasing market share. Since the beginning of DNA microarray technology, these novel aspects of bioassays have become ubiquitous in a variety of applications in biological and medical research and drug discovery.

3.2.2 Protein Microarrays

DNA microarrays were the first described biochips applied in the investigation of the expression level of various genes of an organism. However, the evaluated results allow only a limited insight into the process of actual protein expression. Additionally, DNA microarrays provide no information about protein–protein interactions. Most of the protein monitoring on biochips is based on the analysis of the mRNA expression level. However, the data do not always correlate with the corresponding protein abundance. The main reasons for this effect are the post-translational protein modifications, which make the human proteome much more complex in composition than the coding portion of the genome. Therefore, protein microarrays notably increased the applications of biochips in many different fields, due to availability of much new and additional information.

Standard methods to analyze proteins and protein profiles are usually 2D gel electrophoresis and mass spectrometry. An alternative to standard methods is protein microarrays, which are utilized in research to analyze changes in the abundance and existence of proteins in a very high dynamic range in biological samples. Bilitewski reviewed protein-sensing assay formats and devices in general in 2006, based on affinity reactions between an immobilized capture agent and the target protein [32]. Nowadays, optimal ways to immobilize proteins to 2D surfaces to assure the retention of their biological activity and shape is a major challenge to create point-of-care devices for multianalyte diagnosis [33]. Due to their high specificity and affinity, antigen–antibody reactions are the most important tool for protein microarrays in diagnostics and biological studies. The development of protein microarrays and diagnostic applications has been reported in depth by various groups [34–42]. Critical points in antibody microarrays are the selection, production, and purification of suitable antibodies with high affinity and a reduced cross-reactivity to target molecules. Protein microarrays could be a powerful tool for the identification of biomarkers, for example, in tumor–antigen discovery and cancer diagnostics. For instance, Miller *et al.* [43] and Bouwman *et al.* [44] used antibody microarrays for the detection of prostate cancer. Other antibody applications examine the analysis of cytokine secretion by human dendritic cells with lipopolysaccharide or tumor necrosis factor-α [45] and the detection and quantification of cardiovascular risk markers [46]. Protein microarrays can also be used to identify specific targets of pharmaceutical intervention [47, 48].

A second important application of protein microarrays is to examine a multitude of protein–protein, receptor–ligand, protein–peptide [39, 49], protein–carbohydrate, and enzyme–substrate interactions and also protein interactions with small molecules. The knowledge of these interactions is important in applications of protein network profiling, drug discovery, and drug target confirmation [42, 50, 51]. Uttamchandani and Yao also gave an overview of peptide microarrays used in profiling, detection, or diagnostic applications to sense protein activity or act as ligands for potential therapeutic leads [52].

3.2.3 Tissue Microarrays

The understanding of the association between molecular changes and clinical pathology and the validation of new biomarkers are important in clinical research. Current tissue- and cell-based microarrays combine the analysis of tissue morphology with the identification, localization, and characterization of biomolecules in biological systems.

Tissue microarrays (TMAs) allow traditional tissue analysis of conventional histological paraffin blocks to become miniaturized and high throughput to study molecular alterations at the DNA, RNA, and protein level in multiple individual tissue types. Novel targets can be analyzed in hundreds to thousands of tissue samples with molecular pathology techniques in parallel on one slide.

For the construction of a tissue microarray, cylindrical core tissue biopsies from different donor paraffin-embedded tissue blocks were punched and precisely re-embedded in a blank paraffin block [53, 54]. From this new master block, several hundred to thousands of consecutive sections can be cut and molecular alterations can be detected in parallel in up to 500 or more different tissues. TMAs can be used in many fields such as cancer research and inflammatory, cardiovascular, and neurological diseases.

Today, in cancer research, different types of TMAs exist and allow the analysis of molecular alterations in multiple tumor types (multitumor TMA) or in different stages of one particular tumor (progression TMA). Also, (novel) prognostic parameters can be identified in TMAs containing tumor samples from patients with known clinical follow-up data and clinical endpoint or value testing for molecular alterations to predict chemotherapeutic agents.

The combination of tissue and cDNA microarrays will be a powerful approach for the rapid identification and evaluation of genes with clinical relevance in diagnostics and prognostics, or as therapeutic markers [55, 56].

Alterations in molecular targets such as DNA, RNA, and proteins can be visualized by classical histochemical and molecular detection techniques, for example, immunohistochemistry (IHC), *in situ* hybridization (ISH), fluorescent *in situ* hybridization (FISH), *in situ* PCR, RNA or DNA expression analysis, or TUNEL (terminal dUTP nick-end labeling) assay to detect apoptotic cells and for morphological and clinical characterization of patient tissues. Hence TMAs combine all the advantages of microarrays – low cost, high parallelism, and data collection with many other techniques of biomolecular diagnostics.

3.2.4
Cell-Based Microarrays (Transfection Microarrays)

Cell-based microarrays or so-called reverse transfection microarrays allow functional analysis in mammalian cells in parallel in a format without wells. In this array, nanoliter quantities of cDNA- or siRNA-expressing vectors and also small molecules (e.g., drug-like molecules) are printed in defined areas on a slide surface. Adherent cells are cultured on the top of the array and take up the printed molecules and create spots of localized transfections within a lawn of non-transfected cells. Each feature of 100–250 μm in diameter contains a cluster of 30–80 cells, for example, over- or underexpressing a special gene product, or are under the influence of a drug-like molecule [57]. Cell-based microarrays can be examined when the cells are still alive to visualize cellular processes in real time or after fixation. Also, a variety of detection assays can be applied such as *in situ* hybridization, immunofluorescence, autoradiography and also Western blot by transferring the cells on to nitrocellulose [51, 57]. A special form of cell-based microarrays is lentivirus-infected and *Drosophila* cell microarrays, which provide a platform for effective high-throughput loss-of-function screens through expression of short hairpin RNA/RNAi [58–61]. Lentiviruses infect a wide variety of mammalian cells but can also infect non-dividing cells, which is important for the study of primary cell types [14, 62].

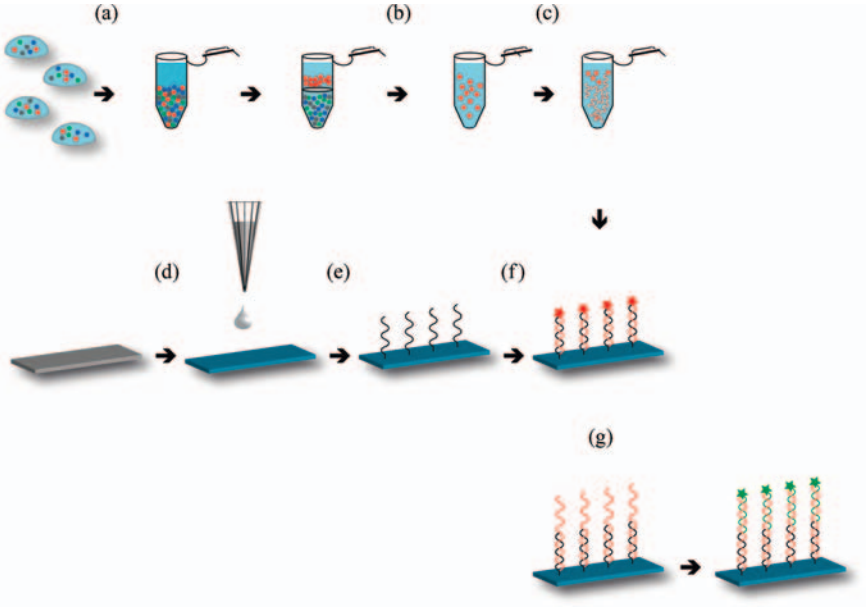

Figure 3.1 Principle process of a microarray experiment. The basic steps include sample preparation (a), purification (b), and target amplification and labeling (c). The functionalization of the solid substrate with capture molecules (e) needs a prior chemical modification of the biochip surface (d). The following hybridization of amplified and labeled target molecules (f) allows the final readout of the specific biomolecular interaction on the chip surface. Alternatively to the direct labeling of the target molecules during the amplification process, the necessary label can be introduced by a sandwich process (g).

3.3 Principle Steps of an Experimental Microarray Process

This section is focused on the microarray experimental setup process especially for DNA/RNA and protein probes. A typical microarray experiment is depicted schematically in Figure 3.1. It involves the basic steps of sample preparation (a), purification (b), target amplification, and labeling (c). The functionalization of the solid substrate with capture molecules (e) needs a prior chemical modification of the biochip surface (d). The subsequent hybridization of amplified and labeled target molecules (f) allows the final readout of the specific biomolecular interaction on the chip surface. Alternatively to the direct labeling of the target molecules during the amplification process, the necessary label can be introduced by a sandwich process (g). Finally, the huge amount of data must be analyzed by means of computational and statistical tools to generate a profile of, for example, expressed genes in a cell [63–67]. A variety of books and overviews have covered microarray analysis and different technical aspects [19, 28, 68–73].

3.3.1 Basics

The underlying principle of a microarray is based on a capture probe immobilized on a solid surface that can bind to a complementary target probe contained in a complex sample. Depending on the amount and density of spots, an array can be subdivided into low-, medium-, and high-density arrays, but overall have the same fundamental principle. Traditionally, an array consists of DNA fragments, but it also can contain other biological recognition units such as antigens or proteins. Often DNA microarrays, for example, in gene expression profiling, belong to high-density arrays due to the presence of hundreds of thousands of probes. It is possible to detect a small amount of target probes in the nanomolar to picomolar range.

3.3.1.1 Surface Biofunctionalization

Surface chemistry and modification are of great importance in microarray technology for binding capture molecules [74–76]. Especially protein immobilization is much more difficult than the immobilization of oligonucleotides or cDNA. Proteins have to be immobilized in their active form in order to bind specifically to their complementary target [33, 77, 78].

The requirements for optimal microarray performance are (a) the stable and covalent immobilization of biomolecules on the chip surface and (b) suitable mechanical and chemical properties of the substrate used [79]. Three different kinds of surfaces are used for the fabrication of microarrays: first, 2D solid structures, such as glass, silicon, silicon nitride, or gold layers, all of which have chemical modifications located on the surface, for instance thiol [80–82], amine [83], epoxy [84], or aldehyde [85] groups; second, 3D coated structures based on the gelation or polymerization of monomers, such as agarose gels [86, 87] or thin layers of polyacrylamide [88, 89], which are commonly immobilized on solid structures for support (e.g., glass); and thirdly, 3D solid structures based on mechanically stable polymeric materials such as poly(methyl methacrylate) [75] and polydimethylsiloxane [90], which do not require a mechanical support.

The advantages of the 2D solid structures are the ease and low cost of fabrication. In addition, some 2D solid structures are transparent towards different light wavelengths, hence making them the substrates of choice for optical detection. Furthermore, their mechanical rigidity allows the deposition of electrodes on their surface, making them compatible with electrochemical detection. Nevertheless, the surface of 2D solid structures is chemically inert. Therefore, these biochip substrates need chemical modification for the stable binding of biomolecules, hence the need to apply chemical reagents or coatings with gels or non-rigid polymers, increasing their fabrication costs.

Therefore, despite the advantages provided by the 2D solid structures and 3D coated structures, it is evident that the development of new materials is required. The 3D solid structures based on polymeric materials can be functionalized during their fabrication procedure. These polymeric materials can be functionalized for

biomolecule immobilization by already embedded functional groups in their monomers, gaining the advantages of 3D coated substrates, but retaining the desired mechanical properties (e.g., transparency and rigidity) of 2D solid structures without reducing the ease or increasing the costs of their fabrication.

Depending on surface modifications, the array can be prepared with capture probes, for example, oligonucleotides with defined length [normally between 20 and 60 base pairs (bps)] or proteins. Oligonucleotides bind on surfaces using combinatorial chemistry and photolithographic techniques. Affymetrix pioneered the fabrication of microarray platforms with high-density arrays. The Affymetrix GeneChip arrays use photolithography techniques for the *in situ* synthesis of oligonucleotides. Semiconductor fabrication, solid-phase chemical synthesis, combinatorial chemistry, and molecular biology are integrated in a robotic manufacturing process [6, 15, 31, 91]. Agilent used Hewlett-Packard's inkjet printing technology for array preparation [92]. Analogous to printing a document, nucleotides are printed on glass slides coated with a hydrophobic surface [15, 93].

Instead of synthesizing capture molecules directly on the surface, another method is the spotting of presynthesized oligonucleotide probes (e.g., GE Healthcare's CodeLink system, Applied Biosystems' Genome Survey Microarrays, custom microarrays printed with Operon's oligonucleotide sets) on modified surfaces. An approach to immobilization of modified oligonucleotides even on unmodified glass surfaces can be made by UV cross-linking [94]. This well known method is widely used in different applications for the attachment of DNA or proteins on membranes, solid surfaces, and polymers [95, 96]. However, the exposure to UV light can damage the DNA [97].

An innovative tool for DNA or RNA studies in genetic analysis is the Illumina bead-based microarray (BeadChip microarray), where presynthesized oligonucleotide probes are deposited on beads. The highest density array platform which is currently available is the Sentrix BeadChip from Illumina, containing 6.5 million features that are just 3 μm wide [98]. The bead-based technology represents an alternative technique that is an accurate, scalable, and flexible approach to a microarray [99].

A detailed comparison of different platforms as tools for functional genomics based on microarray technology was made by Wick and Hardiman [100] and Shi *et al.* also gave a good overview of the current status of DNA microarrays [15].

3.3.2
Preparation of Biomolecules (Sample Preparation)

3.3.2.1 DNA

The ability to extract pure DNA from a variety of sources is an important step in many molecular biological assays. Many different protocols exist for the preparation of genomic DNA. All methods include three steps: cell lysis, deproteination, and concentration/precipitation of DNA. Commonly used protocols are alkaline lysis of cells and phenol–chloroform extraction followed by ethanol precipitation of the nucleic acid. In recent years, traditional purification methods have been replaced by a variety of commercial kits available from many companies (e.g., Qiagen, Invitrogen,

Roche Applied Science, Promega). These kits include necessary solutions for preparation and solubilization of the DNA and columns for anion-exchange chromatography or glass beads. The DNA binds on the silica membranes or glass beads of the spin columns during the separation from contaminating RNA, proteins, and metabolites and can subsequently be easily eluted with high-salt buffer and should be desalted and concentrated before use. A further approach is adsorption of DNA on carboxylated magnetic beads after cell lysis. Subsequently the DNA–magnet particle complex is separated from any residual contaminants by applying a magnetic field. After separation, the purified DNA is released by heating the complex. In this way, a high yield of pure DNA can be produced quickly and conveniently [101, 102].

3.3.2.2 **RNA**

The preparation of high-quality, intact RNA is the first and often the most critical step in performing many molecular biology experiments. This procedure is complicated by the ubiquitous presence of ribonuclease enzymes in cells and tissues, which can rapidly degrade RNA.

The cell probes are first lysed in the presence of a highly denaturing guanidinium isothiocyanate buffer, which immediately inactivates ribonucleases. Then RNA is fractionated from other cellular components via phenol extraction and under conditions that suppress any RNase activity and subsequently concentrated by alcohol precipitation [103].

Several kits for RNA isolation are commercially available, including guanidinium thiocyanate/phenol–chloroform mixtures or silica membrane/glass bead spin columns for RNA extraction without organic solvents. The use of oligo[dT]-cellulose columns or oligo[dT]-magnetic beads selects mRNA from total RNA. Magnetic bead separation allows mRNA to be purified in a single tube by application of a magnetic field, thus eliminating potential sample loss during liquid handling [101, 103].

RNA extraction kits for different starting materials and applications are offered by various companies such as Qiagen, Invitrogen, and Promega.

3.3.2.3 **Proteins**

The first step in protein analysis for any cell line of interest is the lysis of cells and the extraction of total proteins. Typically, a detergent-based method is applied. The lysis method should be mild enough to deliver active and native conformation proteins. Additives such as protease inhibitors protect the proteins from enzymatic degradation whereas nucleases digest DNA. Cell debris and total protein fraction are separated by centrifugation [104].

3.3.3
Target Amplification and Labeling

Because of minimal amounts of starting material, for example from needle biopsies, cell sorting, and laser capture microdissection, an amplification step before use in analytical assays is required in most applications.

3.3.3.1 PCR – Polymerase Chain Reaction

The PCR is a rapid procedure for *in vitro* amplification of a specific DNA region. The process based on the sequence-specific annealing and extension of two oligonucleotide primers which bracket the target DNA region. Three steps, denaturation of the double-stranded target DNA by heating, specific annealing of the primer during temperature reduction, and polymerase-catalyzed extension of the primer sequences in 5′–3′ orientation, define one PCR cycle. The target DNA is enriched exponentially during each PCR cycle and the amplicons produced are also used as templates for subsequent cycles [105, 106].

For the detection of RNA, the PCR procedure is adapted to RNA templates. In this reaction, a defined primer complementary to the polyadenylated tail on the 3′ end of most eukaryotic mRNAs was used and also the reverse transcriptase substitutes/replaces the polymerase. The so-called reverse transcriptase polymerase chain reaction (RT-PCR) produces a cDNA copy of the RNA which can be used in the same context as DNA [107, 108].

During the amplification processes, the amplicon can be modified via the incorporation of altered primers or dNTPs. Hence the introduction of labels such as fluorescent dyes, radioactivity, digoxigenin (DIG), or biotin and also mutations or restriction sites are possible.

3.3.3.2 *In Vitro* Transcription – cDNA/IVT

The so-called Eberwine method and its modifications is a strategy for mRNA amplification by template-directed *in vitro* transcription. In the first step, the poly(A) + RNA pool is reverse transcribed using an oligo-dT primer bearing a specific promoter site for phage RNA polymerases. After the second strand synthesis, cRNA can be amplified by RNA polymerase using the double-stranded cDNA as template. The common RNA polymerases used in *in vitro* transcription reactions are SP6, T7, and T3 polymerases [109].

3.3.3.3 Bio-Barcode Amplification of Nucleic Acids and Proteins

The bio-barcode technology does not include enzymatic target or signal amplification, but is based on nanoparticle technology. In this two-sided sandwich system, the target is immobilized on a solid surface capture probe and is detected through binding a detection probe.

Magnetic-based microparticles of one to several diameters interact with the target molecule through biological recognition (DNA–DNA interaction or antigen–antibody interaction) and allow the separation of the sandwich from unreacted material and medium. Amplifier nanoparticles recognize and bind the target–magnetic particle complex through immobilized detection probes (Figure 3.2). Additionally bound bio-barcode oligonucleotides specific for each target can be released for representing and amplifying the target in a subsequent detection assay [110–113]. Hundreds to thousands of barcodes of one nanoparticle provide a 2–3 log amplification of a target that has been successfully captured and sandwiched. Typical materials for amplifier nanoparticles are gold and polystyrene [114].

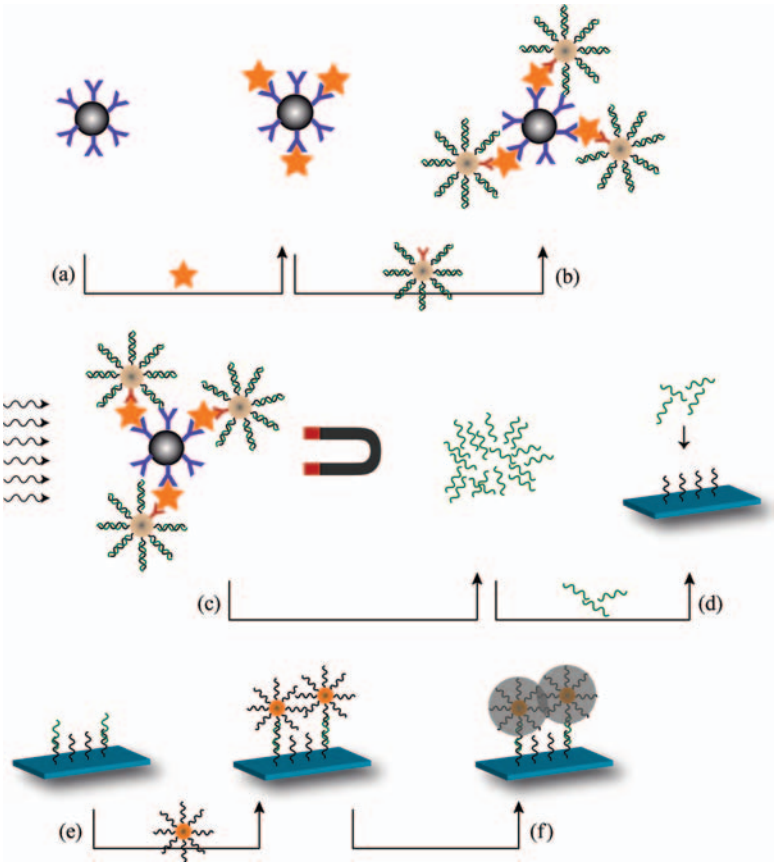

Figure 3.2 Principle of bio-barcode nanoparticle-based PCR-less DNA amplification. An antibody-labeled nanoparticle binds to the analyte (a). A second DNA-labeled magnetic nanoparticle can also bind via antibody–antigen interaction to the analyte (b). In a magnetic separation process (c) followed by barcode DNA denaturation (d), the free amplified bio-barcode DNA can hybridize to a biochip (e). After nanoparticle labeling and silver enhancement, the signal can be optically detected (f).

3.3.3.4 **Radioactive and Fluorophore Labeling**

The visualization of biomolecules can be mediated by labeling with radioactive, fluorescent, luminescent, or other chemical modifications. In nucleic acids, the incorporation of radioactive and nonradioactive labels is common. The label can be attached to one of the dNTPs or the 5′ end of one or both primers, which will be enzymatically incorporated in the amplicon [115, 116].

The efficiency of enzymatic incorporation of labeled nucleotides may be impaired due to steric effects of the bulky label. Also, the use of labeled nucleotides is more costly per reaction than 5′-labeled oligonucleotides. An indirect labeling, for example, with aminoallyl-dNTPs or DIG, allows subsequent conjugation of a fluorescent dye to

the purified amplicon, but it is more time consuming because incubation and washing steps are required.

Proteins commonly will be covalently linked to a nucleoside or nucleotide which carries radioactivity. The radioactivity can be anywhere on the nucleoside (C, N, H, S, I, Hg). Labeling of proteins is performed by reactions of the label with the N- and C-terminus or functional groups of side chains on the surface such as an amino group of lysine, sulfhydryl group of cysteine, or carbohydrate group of the protein [117].

Radioactive labeling provides a highly sensitive method for detection. However, radioisotopes are expensive, have a short half-life, and require a long exposure time before detection. Radioactive materials are also potentially hazardous and their use requires adherence to strict safety precautions. The majority of radioisotopes used in biological experiments emit ionizing radiation and impart energy in living cells. In large enough doses, this energy can damage cellular structures, such as chromosomes and membranes. Such damage can kill the cell or impair its normal functionality.

Nonradioactive labels such as fluorophores become more important due to their sensitivity and easy handling compared with radioactive labels. A wide variety of fluorophores in many different colors are available and compatible with the usual excitation/emission systems. Current fluorescent dyes achieve levels of sensitivity comparable to radioactivity and can be detected immediately, in contrast to isotope labels. Disadvantages of fluorophores are photobleaching and quenching of the fluorescence signal. Additionally, fluorescence detection requires extensive equipment such as an excitation energy source (laser beam) and can be performed only with specialized scanners and image acquisition systems.

3.3.3.5 **Enzymes**

Enzyme assays represent a special group in the field of bioassays [118]. In this labeling method, the substrate of the enzyme is often used as the analyte to be detected. However, also cofactors or even the enzyme itself, for example in clinical diagnostics, can be analyzed by enzyme assays. The advantage of this method is the high specificity. Hence there is no need for a sophisticated sample preparation to eliminate negative matrix effects. Even the investigation of complex probe material can be managed rapidly and easily by enzyme assays, without the use of expensive chromatographic processes. In most cases these assays are based on redox-active enzymes that catalyze the creation of a soluble dye in the presence of specific cofactors (e.g., nicotinamide adenine dinucleotide (NAD) or by co-products of the enzymatic reaction (e.g., H_2O_2). From the analytical point of view, the oxidoreductases and also the hydrolases are of main interest. For example, glucose oxidase and horseradish peroxidase (both belong to the group of oxidoreductases) or alkaline phosphatase and acetylcholinesterase (both belong to the group of hydrolases) are typical representatives and widely used in enzyme-based bioanalytical investigations. A further benefit of enzymes is the wide knowledge about their reactions, kinetics, structure, substrate specificity, and inhibition of catalytic processes. Nowadays, traditional systems such as enzyme-linked immunosorbent assay (ELISA) [119] and

the Western blot [120, 121] are still used as standard analytical methods in biomolecular and immunological laboratories.

3.3.3.6 **Nanoparticles**

Metallic nanoparticles have attracted increasing interest as alternative labels in analytical biochip-based assays. Due to their unique properties, metal nanoparticles allow the development of various novel approaches for the detection of biomolecules. Their attributes depend strongly on the size, shape, and composition of the single particles [122]. A large variety of fabrication methods have already been described in the literature. Different metals can be used to produce nanoparticles, such as Au, Ag, Cu, Pd, and Pt. Since the properties of metallic nanoparticles depend on their shape, a variety of shapes, such as prisms, rods, and cubes, have been synthesized in addition to the common spherical structure. A further important factor for their use in biochip and bioassay applications is the stable and reliable biofunctionalization of the metallic nanoparticles [123, 124]. The coupling of suitable ligands allows the subsequent specific interaction with complementary biomolecules. Functionalization has been studied with high intensity especially on gold surfaces, because this material provides the simplest and most stable conjugation [125].

Because of their high extinction coefficients and also the large scattering coefficients, metal nanoparticles can be used in optical setups based on absorption or scattering processes [126, 127].

In addition to their special optical properties, metal nanoparticles can be used further in electrical, electrochemical, and electromechanical setups [128–130]. By measuring the electrical conductivity of metallic nanoparticles between an electrode gap, a robust and simple approach for the detection of biomolecules can be realized [131].

Furthermore, these metallic nanoscopic structures can be used as reaction seeds for a specific, reductive metal deposition process [132]. The additional metal deposition leads to so-called "core–shell" structures. During the "core–shell" process, the metal nanoparticles increase in size, which leads in many different systems to an improvement of the sensitivity.

3.3.4 **Readout/Detection**

A key step in the microarray experimental process is the detection method or readout after the hybridization event. Therefore, optical detection methods remain the preferred technique in genomic and proteomic chip-based applications. For the evaluation of detection techniques, some criteria must be considered [23, 133].

Figure 3.3 illustrates the most frequent detection methods for optical biochips. In addition to fluorescence (a), metal nanoparticles can be used in absorbance (light microscopy in transmission mode) (b) and light-scattering setups (c). The approach to detect the scattered light of metal nanoparticles enables a multilabeling system comparable to modern fluorescence setups to be developed.

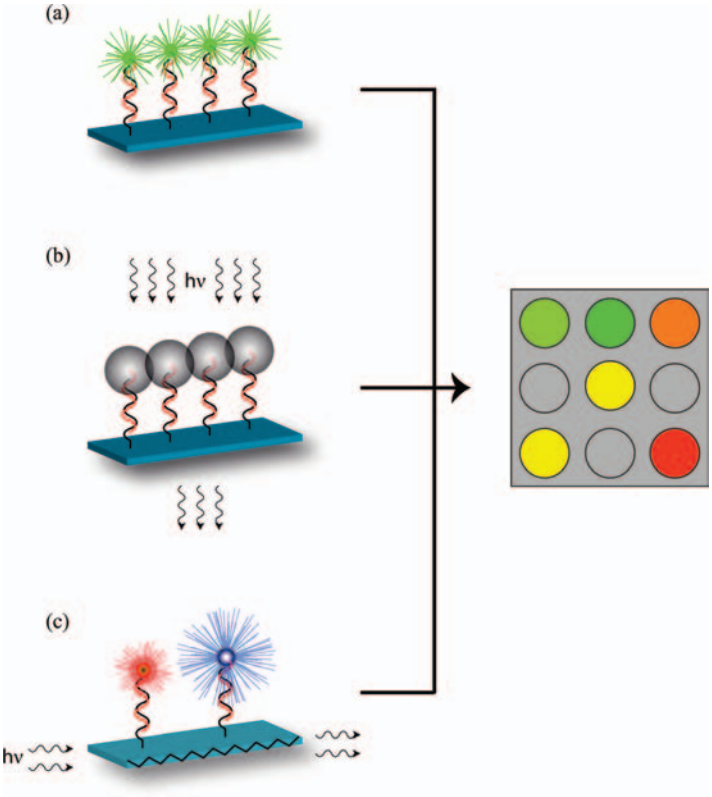

Figure 3.3 The optical detection on biochips is mainly dominated by fluorescence (a). This readout technology allows highly sensitive multilabeling of biomolecules. An alternative approach is the utilization of metal nanoparticles. In both absorbance (b) and scattering setups (c), metal nanoparticles showed the potential to replace traditional markers in biochip technology.

3.3.4.1 **Radioactivity**

Radioactive signals can be captured using autoradiography films, storage phosphor screens, and image acquisition systems, depending on the labeling method and the required levels of sensitivity and resolution. Autoradiography films are commonly used; they are inexpensive, reliable, and provide a good level of sensitivity and resolution. Results obtained with this method can be scanned and analyzed using image analysis software. Scanner-based image acquisition systems are able to detect radioactive signals using a storage phosphor screen, which is about 10 times faster than regular autoradiography films [134].

For the detection of radioactive spots on a microarray, the array is coated with a photographic emulsion. After drying, the sealed slides are stored for a few days in a radiation box. Subsequently the signals are developed with a photographic emulsion.

The reduced silver ions then can be detected and imaged with a scanning light microscope [GE Healthcare (Amersham Biosciences)].

3.3.4.2 **Fluorescence/Absorbance**

Fluorescence is the most commonly applied detection technology in biological and clinical research and drug discovery. Therefore, most of the current commercial microarrays use fluorescence signals for their readout. Reviews have already surveyed fluorescence-based nucleic acid detection methods and microarrays [19, 135–137]. Bally *et al*. described different optical sensing techniques based on microarrays and their applications [133]. Fluorescence immunoassays have largely replaced radioimmunoassay, and fluorescence dominates other detection techniques because of its high sensitivity, dynamic range, and high spatial resolution.

Briefly, the fluorescence process involves the emission of visible light by electronic excitation of molecules, called a fluorophore or fluorescent dye. These molecules have a specialized conjugated π-electron system so that they are capable of absorbing light of different, shorter wavelength than the emission wavelength. Detailed descriptions of the principle of fluorescence have been given in a variety of books and reviews and will not be repeated in this chapter [135, 138]. Microarray technology often uses organic fluorophores as labels due to their characteristics of functionalization, high stability, solubility, and biocompatibility in aqueous solutions [137, 139, 140]. Primary factors limiting fluorescence detectability are photobleaching and quenching processes. Photobleaching is a dynamic process, in which excited fluorophores undergo irreversible destruction under high-intensity illumination conditions and thus lose their ability to emit light [141]. Also, the fluorescence signal depends strongly on the environmental conditions.

In addition to the relatively small size of the microarray, a large periphery is necessary for detection and data interpretation, for instance, light sources, optical instruments, photomultipliers, or a charged-coupled device (CCD) camera. Conventional instruments include scanners and imagers – the two main designs of detection instruments. Scanners are distinguished from imagers in moving their position from the substrate or optics as a function of spatial coordinates in two dimensions. Scanner techniques include laser scanning methods and often photomultipliers for detection. Imagers often use white light sources and CCD technology to achieve images in a single step. A powerful analytical method is required for rapid and automatic data acquisition. Subsequently, the huge amount of data must be analyzed and interpreted by means of bioinformatics [142, 143].

Based on fluorescence, there are different parameters that characterize fluorescent molecules, such as fluorescence quantum yield, wavelength, and lifetime. For instance, information about the lifetime and decay of fluorescence signals is used in DNA microarray [144, 145] and protein array technology [146]. Cubeddu *et al*. presented an overview of time-resolved fluorescence in biology and medicine [147].

Förster resonance energy transfer (FRET), a special form of fluorescence quenching, is often used in biophysics and biochemistry to quantify molecular interactions

such as protein–protein or DNA–protein interactions and also protein conformational changes. FRET also plays an important role in microarray analysis. However, FRET depends strongly on the distance between two molecules, a donor and an acceptor molecule. It depends on the spectral overlap between the emission spectrum of the donor and the absorption spectrum of the acceptor. The fluorescence signals are generated or quenched due to the spatial separation of these two fluorophores. A pair of interactive fluorophores are attached to the ends of two different oligonucleotides or to the two ends of the same oligonucleotide probe. There are two possibilities for detecting the hybridization between capture and target molecules that are used in microarray technology. One possibility is a nonradiative energy transfer from donor fluorophore to acceptor fluorophore if they are in close proximity to each other. If the acceptors are quenchers, the fluorescence emission intensity of the donor fluorophore is decreased. However, if the acceptors are also fluorescent molecules, which are activated by the emission of the donor, the binding event leads to an increase in the emission intensity of the acceptor fluorophore. The other method is to separate the two fluorophores from each other to prevent the energy transfer and generate the donor characteristic emission spectrum uninfluenced by the acceptor fluorophore [11, 136, 148–152]. For instance, a microarray analysis of protein–protein interactions based on FRET using the fluorescence lifetime as an analytical parameter was investigated in the model system of bovine serum albumin and streptavidin [152].

Bio- and chemiluminescence are also useful techniques in biomedical research, diagnostics, and drug discovery and development. Chemiluminescence microscope imaging is a valuable tool for localizing and quantitating enzymes, metabolites, antigens, and nucleic acids in many kinds of specimens [153–157]. In comparison with fluorescence light emission, chemiluminescence is generated by a chemical reaction under exclusion of light. This is advantageous for this technique owing to a lower nonspecific signal and absence of light scattering. However, a disadvantage is that the light-emitting chemical reaction could be uncontrollably inhibited, enhanced, or triggered by sample matrix constituents [158]. A new chemiluminescence-based Ziplex gene expression array technology was evaluated based on Affymetrix GeneChip profiles and applied in ovarian cancer research [159].

Similarly to other methods such as localized surface plasmon resonance (LSPR) and surface-enhanced Raman spectroscopy (SERS), a surface-enhanced fluorescence effect can occur when fluorophores are in close proximity to metal nanoparticles [160]. Lakowicz *et al.* reported on plasmon-controlled fluorescence and the properties of fluorophore–metal interaction bioassays [161].

Absorption measurements have also been used in microarray analysis. Although this method is less sensitive than fluorescence, its simplicity makes it interesting and gives advantages in certain applications. In principle, absorption techniques are based on attenuation of incident light as a function of wavelength. Microarray experimental processes often detect changes in the optical density or the color of probes [162]. Metal nanoparticles have been used in absorption measurements of DNA microarrays as a novel technique [163]. Thus, binding events of target DNA to capture DNA tagged with nanoparticles can be visualized using reflection or

transmission of light depending on some characteristics of particles such size, shape, composition, and environment. Furthermore, nanoparticles are used in DNA microarray scattering detection based on by the extremely large scattering coefficient [125, 163].

3.3.4.3 Surface Plasmon Resonance

Apart from readout-based techniques such as radioactivity and fluorescence, only the development of surface plasmon resonance (SPR)-based biosensors has achieved commercial success (e.g., the Biacore system) [164]. SPR is an optical method that can be used for the real-time and label-free detection of biomolecular recognition reaction [165, 166]. This approach makes use of the interaction of plane polarized light with the free electrons at a metal surface [167]. Under certain conditions, the energy carried by the photons can be transferred to collective oscillations of the electrons, which are called plasmons [168]. The energy transfer occurs only at a specific resonance wavelength of light when the momentum of the photons and that of the plasmons are matched. To excite surface plasmons, in SPR systems, a laser beam is focused on the back of a prism covered with a thin film of metal, mostly gold or silver with a thickness of 40–50 nm. At a defined angle of incidence, the intensity of the reflected light decreases significantly. This effect appears to be due to energy absorption followed by the creation of surface plasmons at the metal surface. The surface plasmons can propagate along the metal surface, but they are not strictly located at the surface. The intensity of their electromagnetic field can be drastically decayed on going from the metal surface into the adjacent medium. Concerning the bioanalytical interest of SPR, the position of the critical angle and thereby the adsorption depend on the evanescent wave and therefore it is sensitive to the environment up to a distance close to the wavelength from the actual metal surface. When using SPR systems in bioanalytics, a major advantage is the label-free detection of biomolecules [169]. These detection units are ideally suited for the direct monitoring of binding events without the need for additional labeled substances. However, the additional use of metal nanoparticles increases the sensitivity up to the picomolar region [170, 171]. Nevertheless, the major problem in every analytical SPR-based system is the unspecific adsorption of the biological target components to the sensor surface. More recently, novel biochip assays have been combined with SPR technology to create a fast and sensitive detection system for different biomolecules [133, 172].

3.4 Examples of Biochip Applications in Biology and Medicine

3.4.1 Genomic Research

The aim of genomic research is the identification of new genes and the understanding of their function and expression levels under different conditions. Two main

applications can be identified: (1) identification of gene mutation (sequence analysis) and (2) determination and monitoring of expression level (gene expression profile) for rapid mapping and identification of disease-related genes [3, 173]. The goal of this research is not only to catalog all genes and their characteristics but also to understand how the components work together to comprise functioning cells and organisms [13]. Pastinen *et al*. developed a powerful approach to scan all possible sequence variations provided by minisequencing assays based on high-density DNA–chip arrays [174]. Several reviews of microarray technologies and applications used in genomic research have been published [14, 175–182]. Grant and Hakonarson provided an overview of recent advances and further expectations within this field [182]. Comparative genome hybridization (CGH) has been mainly used to identify relatively large insertions and deletions in cancer cell lines, for example by cDNA expression arrays [183].

cDNA microarrays are a powerful technique to identify novel biomarkers for potential use as diagnostic, prognostic, and therapeutic tools in clinical diagnosis. They facilitate the analysis of the expression of thousands of genes simultaneously to provide static and dynamic information about expressed genes [91, 184]. It is based on the same principle as Northern blot and RT-PCR analysis. An overview of cDNA microarray technology was given by de Mello-Coelho and Hess [9]. Basically, cDNA microarrays are used for identifying the role of several genes involved in cellular processes. cDNA microarray techniques play an important role in research on human cancers and are used for studying distinct types of cancers, for example, lung cancer [185–187], prostate cancer [188, 189], breast cancer [183, 190–193], and ovarian cancer [194, 195], and also the pathogenesis of infectious diseases [196, 197]. Furthermore, differentiation in gene expression patterns of nondiseased and diseased tissues has contributed to a better understanding of the regulation of molecular mechanisms and potential for therapeutic use towards personalized medicine [198]. Parissenti *et al*. demonstrated gene expression profiles as biomarkers for the prediction of chemotherapy drug response in human tumor cells [179]. Different applications of cDNA microarrays include life science areas of endocrinology, microbiology, immunology, oncology, toxicogenomics, development, genetics, endocrinology, and gerontology [9, 199].

3.4.1.1 **SNP Detection**

A large number of variations in DNA sequence, mainly single nucleotide polymorphism (SNP), are revealed with the complete sequencing of the humane genome. Millions of SNPs are deposited in public databases [200, 201]. These variations in DNA sequence play a major role in the diagnosis of a variety of genetic diseases and cancer and in drug development. SNPs serve as genomic markers for assessing disease predisposition and prediction medication [202, 203]. The analysis of SNPs can help in understanding genetic differences between individuals and disease states and will be also useful in helping researchers to determine and understand why individuals differ in their response to absorb or clear certain drugs for the improvement of medical treatments [180, 204].

The application of oligonucleotide arrays for the detection of particular mutations or polymorphism was first reported in 1989 by Saiki *et al.* [205]. They described the genetic analysis of amplified DNA (HLA-DQA genotyping and 3-thalassemia mutations) with immobilized sequence-specific oligonucleotide probes on a nylon membrane.

Commercial SNP arrays are provided by numerous companies for numerous applications. For example, Illumina has developed a bead-based flexible, accurate, highly multiplexed SNP genotyping assay. Up to 1536 SNPs can be detected in a single DNA sample with this system [204]. Each bead contains hundreds of thousands of covalently attached oligonucleotide probes. For instance, in a cDNA-mediated annealing, selection, extension, and ligation assay, 1152 cSNPs derived from 380 cancer-related genes can be investigated. In this assay, information about both genomic DNA and RNA and also allele-specific expression is obtained, which is important for studying variations and origins of diseases. Owing to the variability and scalability of the Illumina platform, the user can perform small pilot studies or large-scale SNP genotyping studies for human genetic diseases, pharmacogenomic applications, or rapid development of molecular diagnostics [99, 204]. An automated magnetic bead-based platform for pretreatment of human leukocytes, gDNA extraction, and fast analysis of genetic genes was demonstrated by Lien *et al.* [206]. Furthermore, a comparison of genotyping kits and arrays from Applied Biosystems and Affymetrix was made by Selmer *et al.* [207].

A novel genotyping technique that employs a peptide nucleic acid (PNA) zip-code microarray [208] method was described by Mun *et al.* [209]. The zip-code array technique involves unique and distinct short oligonucleotides designed for the purpose of addressing complementary target sequences. It has become an interesting method for conducting routine genetic assays, for instance, investigating mutations in susceptibility gene BRCA1, which is considered to be involved in the development of breast and ovarian cancer. Based on a zip-code microarray mutation, detection of BRCA1 was described [195, 210, 211]. Further applications based on zip-code microarrays include investigations of diabetes caused by HNF-1α mutations [212].

Other applications have been reported for sensing of low-abundance DNA point mutation in K-*ras* oncogenes, which have a high diagnostic value for colorectal cancers [95, 148]. Generally, reviews and articles have focused on the wide range of applications of SNP microarray analysis in cancer research and potential applications in cancer risk assessment, diagnosis, prognosis, and treatment selection [12, 16, 198, 213–216]. Loss of heterozygosity (LOH), genomic copy number changes, and DNA methylation alterations [217, 218] of cancer cells can be determined by SNP array genotyping [216, 219]. LOH of chromosomal regions bearing mutated tumor suppressor genes involve genomic alterations [185, 186, 189, 220]. Also in molecular karyotyping, SNP arrays are used for genome-wide genotyping [221]. Bruno *et al.* studied the feasibility of replacing targeted testing of patients with mental retardation and/or congenital abnormalities using SNP arrays [222].

3.4.1.2 Gene Expression Profile Analysis

Point mutations in the DNA sequence are mainly identified by using SNP analysis. In gene expression profiling, the analysis of point mutations is not preferentially considered. Gene expression profile analysis is used for the monitoring and determination of expressed genes. Depending on their environmental conditions, different expression patterns of genes can be obtained. SNPs are genetic variations and almost unaffected by their environment.

High-throughput molecular technologies are reshaping our understanding of diseases, and microarray-based gene expression has attracted the most attention for performing massive parallel profiling of gene expression from a single sample. General reviews of DNA microarrays include gene expression profiling by Hughes and Shoemaker [223] and also by Deyholos and Galbraith [224]. A technology review about navigating gene expression using microarrays was presented given by Schulze and Downward [225]. Gene expression profile analysis has been successfully used to derive a molecular taxonomy to gain biological insights into basic biochemical pathways and molecular mechanisms of diseases and their regulatory circuits to generate a multitude of prognostic/predictive signatures. Cancer research is one of the most important clinical fields based on microarray technology [175]. The application of biochip technologies in cancer research as a basis for individualized treatment of cancer patients was reported by Kallioniemi [198]. Polyak and Riggins included in a review the serial analysis of gene expression techniques and the implications for cancer research [226]. Other reviews have described the contribution of gene expression profiling to our understanding of breast cancer [227] and its clinical management and what still remains be done for these classifiers to be incorporated in clinical practice [192, 228].

The first customized microarray-based gene expression diagnostic breast cancer array, accepted by US FDA in 2007, called MammaPrint, was developed based on the Agilent two-color platform and method [229]. Breast cancer is the most common research field for gene expression profile analysis and the application of microarrays. Another review covered genome-wide profiling of genetic alterations in acute lymphoblastic leukemia [230]. Also, results of genomic analysis revealed few genetic alterations in pediatric acute myeloid leukemia [231]. Nannini *et al.* analyzed the state of the art of gene expression profiling in colorectal cancer using microarray technology [232]. In addition to gene expression profiling in cancer research, other exciting examples covering fields such as cardiovascular diseases [233, 234] and psychiatric disorders [222, 235] are being researched. Furthermore, gene expression analysis plays an important role in human embryonic stem cell research and the differentiated progeny [236]. It is useful for the treatment of a variety of inherited and acquired diseases. Gene expression profiles can also serve as transcriptional "fingerprints," for example to determine the target of a drug [237, 238]. Another field of expression profiling analysis is the investigation of proteins. However, achieving the equivalent genome-wide profiling of proteins is technically more difficult than investigations of DNA or RNA, due to the already described problems with the complexity of capture molecules and their immobilization [239, 240].

In addition to cancer analysis by microarray techniques, several other diseases have also been investigated, including muscular dystrophy [241], Alzheimer's disease [242–244], schizophrenia [245, 246], and HIV infection [247, 248].

3.4.1.3 **Pharmacogenomics and Toxicogenomics**

Pharmacogenomics means the application of genomic technologies to drug discovery and development. Usually, drug discovery started with a biochemical pathway implicated in a pathophysiological process, and an appropriate enzyme commonly from the rate-limiting step in the pathway or a receptor was characterized, purified, and screened against a variation of structurally diverse small molecules. Today, the monitoring of genetic polymorphisms and differential expression patterns are the most biologically informative application of microarray technology and will be an important improvement in drug discovery [249].

Genetic polymorphisms (SNPs, cSNPs) represent inherited differences in drug-metabolizing capacity. Most drugs interact with specific target proteins to exert their pharmacological effects, such as receptors, enzymes, or proteins involved in signal transduction, cell cycle control, and many other cellular events. In many cases, genetic polymorphisms are associated with altered activity of encoded proteins which influence pharmacokinetics and pharmacologic effects, and as a consequence the sensitivity of specific medications. In drug discovery, genetic polymorphism analyses will be the initiating step followed by biochemical and clinical studies to evaluate the phenotypic consequences of these polymorphisms [250].

Another approach for the discovery of potential drug targets is the investigation of differential expression patterns. The gene expression in a variety of tissues can be compared: normal, diseased, and also drug-affected tissues, in addition to model organisms, examining the effects of selected overexpressed genes or drug treatment. Yeast and mouse models are commonly used. Drug-induced gene products can be used as surrogate markers to follow readily the effect and dose of a drug in the clinical setting. Also, a highly selective tissue expression of a drug target is attractive, as the potential for unwanted side effects may be more restricted [30].

The study of pathogen gene expression during the time of acute infection or during latency and also the identification of genes and gene products turned on by the response of the host against the pathogen is a further approach to establishing new therapeutic targets.

Microarrays are a powerful tool for *in vitro* target identification. They determine drug efficacy and toxicity and improve the understanding of the mechanism of drug action. Various companies are involved in the application of pharmacogenomic technology [238] for drug target validation and identification of secondary drug target effects facilitated by DNA microarrays [251].

The field of toxicogenomics contains global mRNA, protein, and metabolite analysis to study molecular and cellular effects in relation to exposure to toxic elements. The prediction of possible side effects of pharmaceuticals is an important part of the preclinical drug development process. The comparison of gene expression patterns from toxicant-treated organisms versus a control sample, healthy versus

diseased tissue, and susceptible versus resistant tissue helps us to understand the influence of hazards and environmental stressors in biological systems.

There are increasing online resources for biological data and information for toxicogenomic studies (e.g., TOXNET, NIEHS, NCT, TRC, CEBS, and other) [252]. Toxicology microarray data sets comprising genes of different subject areas such as apoptosis, DNA repair, DNA damage, inflammation, and cell proliferation and also cell response to oxidative stress and xenobiotic metabolism have been reported. For the selection of genes from the knowledge-based microarrays, the ratio of the intensities is calculated and the induction and repression of genes inferred. Optimal microarray measurements can detect differences as small as a 1.2-fold increase/decrease in gene expression. Gene expression changes are more sensitive and comprehensive markers of toxicity than typical toxicological endpoints such as morphological changes, reproductive toxicity, and carcinogenicity [253].

Toxicology arrays, for example, the ToxBlot [254] and ToxChip [255] from the National Institute of Environmental Health Sciences Microarray Group, include gene classes related to cancer, immunology, endocrinology, neurobiology, investigative toxicology, predevelopment toxicology, and safety assessment. ToxChips will also be developed to monitor drinking water quality and identify microorganisms [256]. Toxicology biochips determine the relative security of natural and synthesized compounds and chemical mixtures to which humans are exposed.

3.4.2 Pathogen Detection and Clinical Diagnosis

3.4.2.1 Pathogen Detection

The detection and identification of pathogens are essential for ensuring the safety of humans [257]. The difficulty in implementing pathogen detection in biochip and bioassay technology lies in the complexity of most of the samples, making it hard to ensure the sensitivity and specificity of the method. Nowadays, many microbiological laboratories working on pathogen detection have to use microbiological culturing techniques to identify the pathogens reliably. After the culturing process, biochemical and immunological methods are used to detect specific antigens of the pathogen [258]. However, this procedure is very time consuming, and additionally the traditional tests do not provide information about the potential pathogenicity of the organisms.

New biochip approaches facilitate pathogen analysis. The main factors influencing this development are the assay speed, information content, and costs. Further promising opportunities such as miniaturization and integration allow the construction of "lab-on-a-chip" devices for on-site testing [259]. These point-of-care systems permit the analysis of pathogens even for slow-growing organisms. Pathogen detection at the bedside will lead to faster diagnosis and initiation of an appropriate therapy.

In recent years, many groups made remarkable progress in biochip-based pathogen detection [260]. In 2002, Wang *et al.* demonstrated the detection of viral pathogens [261]. They successfully developed a biochip platform to detect PCR products, labeled with a fluorescent dye, of 140 different viruses. Garaizar *et al.* listed a number of bacterial pathogens investigated by biochip studies [262]. A further point of interest is the analysis of host–pathogen interactions. Such an interaction causes substantial changes of the host and also the pathogen. The biochip-based detection of host–pathogen interactions was demonstrated by Diehn and Relman [263]. Especially new spectroscopic methods have the potential for the sensitive and specific detection of pathogens. Identification at the subspecies/strain level on the basis of the SERS fingerprint was reported in 2003 by Grow *et al.* [264]. The highly specific SERS fingerprint could also reflect the physiological state of the bacterial pathogens. A proof-of-principle for the point-of-care-analysis of *Escherichia coli*- and *Bacillus subtilis*-infected samples was developed by Yeung *et al.* in 2006, including sample preparation, amplification, and specific detection [265].

3.4.2.2 **Clinical Diagnosis**

In clinical diagnosis, novel biochip systems have been used in gene analysis for prognosis and treatment. The innovative biochip technology showed the ability to change the current molecular diagnosis to point-of-care analytics that allow the integration of diagnostics with therapeutics and the development of personalized medicine [213, 266]. Personalized medicine will improve the precision and outcome of treatment. Tailor-made therapy for individual patients is based on transcriptional profiling. Additionally, biochips can investigate specific factors of a disease, such as the presence of specific cell types (e.g., white blood cells), proteins, and different kinds of enzymes, in a rapid and efficient manner. For this purpose, the body fluids (e.g., blood), exhaled air, and tissue samples from the patient serve as probe materials for the final biochip analysis. Especially in cancer diagnosis, research in recent years has led to considerable progress in prognosis and tumor classification, where so-called methylation chips served for the diagnosis and prognosis of different cancer types [267].

Aberrant DNA methylation has frequently been found in cancer cells, which silenced different tumor suppressor genes and genes important for cell cycle function and DNA repair. Therefore, various groups tried to detect tumor tissue based on the investigation of DNA methylation. Yan *et al.* presented a tumor classification of breast cancer patients on the basis of their hormone receptor status and clinical aggressiveness [304]. Shi *et al.* detected and identified unique genes preferentially methylated in particular tumors [268]. DNA microarrays were used to analyze DNA methylation. Therefore, the authors analyzed methylated and unmethylated DNA targets on a chip surface after amplification (bisulfite-PCR) and hybridization of the amplified targets to the immobilized capture molecules. In 2006, Schumacher *et al.* developed a technology for unbiased, high-throughput DNA methylation profiling of large genomic regions [269]. Uunmethylated and methylated DNA fractions were enriched using a series of treatments with methylation-sensitive

restriction enzymes, and interrogated on microarrays. Estécio *et al.* introduced the methylated CpG island amplification (MCAM) technique in 2007 [270]. This technique was stated to be a suitable method to discover methylated genes and to profile methylation changes in clinical samples in a high-throughput fashion. Further array-based detection of DNA methylation in cancer diagnosis was described by Melnikov *et al.* [271] and Kimura *et al.* [272]. Other studies targeted the detection of special proteins for cancer diagnosis. Thus, in 2001 Askari *et al.* introduced the anti-p53 tumor suppressor gene antibody in human serum on a biochip [273]. A review by Pollard *et al.* addressed the development and application of protein microarrays for cancer diagnosis and clinical proteomics [34].

Of course, cancer diagnosis and prognosis represent one of the largest fields in clinical diagnosis, although smaller research topics include the investigation and detection of Alzheimer's disease [244] and autism spectrum disorders (ASDs) [180]. However, the application of microarrays in clinical diagnosis is constantly growing.

3.5 Trends in Biochip Research

A wide variety of novel exciting technologies are becoming available with potential use in analytical applications. These innovative, novel sensing techniques have great promise in the analysis of a wide range of targets and various properties in biological, chemical, and immunological problems. In this connection, most notably nanoparticles, quantum dots, and novel enzymatic technologies show the potential to improve or to replace current analytical methods. Especially with respect to the development of point-of-care systems, the new labeling methods offer robust and easy-to-use detection units that can be applied outside specialized laboratories. Another important point is the stability of the signals, which is of interest for comparisons of the received data and storage.

These methods form the basis for a new generation of biochip platforms that allow fast and sensitive on-site detection of biomolecules.

3.5.1 Metal Nanoparticles

The main reasons for the development of innovative bioanalytical approaches based on metal nanoparticles include the stability of the signals, the high signal intensities, and harmless reagents. Additionally, the utilization of metal nanoparticles allows the construction of robust, cost-effective, and portable read-out devices to realize easy-to-use point-of-care systems.

Using the scattered light of metal nanoparticles permits sensitive imaging and quantification of biomolecules. The spectrum of the scatted light is dependent on the attributes of the nanoparticles [126, 127]. As the spectrum depends on particle size, shape, and composition, a multi labeling system based on metal

nanoparticles has been demonstrated [163]. A common glass slide, functionalized with oligonucleotides, was used as a planar wave guide. After specific hybridization with target oligonucleotides, labeled with different sizes of metal nanoparticles, the size-selective scattered light could be used for sequence specific differentiation between the immobilized oligonucleotides.

Furthermore, Quinten demonstrated the influence on plasmon resonance of the interparticle spacing [274]. With this effect, a simple colorimetric DNA detection using gold nanoparticles could be realized [275, 276]. Mirkin's group modified different batches of gold nanoparticles with different sized oligonucleotides [275]. Due to mixing of the batches and by adding a single-stranded target DNA, which was complementary to the two oligonucleotides bound to the different sized particles, the particles formed DNA-linked aggregates. Thereby, the color of the colloidal nanoparticle solution shifted from red to blue. Since this color change was caused by DNA–DNA interactions, heating of the solution above the melting temperature of the double-stranded DNA removed the single-stranded target DNA. Consequently, the nanoparticle aggregate was resolved, resulting in a color shift back to red. By transferring the hybridized particle aggregate to a chromatography plate, the test could be permanently recorded [275].

In addition to the detection of light scattered directly from metal nanoparticles, metal surfaces can enhance electromagnetic fields, which has been exploited in SERS [277, 278], which is an emerging technology in the field of analytics [279]. In comparison with other spectroscopic detection techniques such as fluorescence, Raman spectroscopy is hampered by the inherently small scattering cross-section, which prevents the detection of low analyte concentrations [280, 281]. The huge SERS enhancement of more than 10^6 times the weak Raman signal was considered to be caused by interactions between the analyte molecule and a metallic surface having nanostructured morphology. Since the discovery of the SERS technique, it has become a versatile tool for chemical analysis, environmental monitoring, and biomedical applications, applying the unique properties of Raman spectroscopy, for example, the highly specific molecular fingerprint spectrum [282, 283]. Wabuyele and Vo-Dinh demonstrated the use of plasmonics-based nanoprobes that act as molecular sentinels for DNA diagnostics [284]. The plasmonics nanoprobe consists of a metal nanoparticle and a stem–loop DNA molecule tagged with a Raman label. As long as the hairpin loop is active, the Raman label is in close proximity to the metal nanoparticle, so an intense SERS signal can be detected. In the presence of a complementary target DNA, the hairpin loop will be disrupted. Thereby, the SERS signal will be decreased by removing the Raman label form the metal nanoparticle (Figure 3.4).

3.5.2 Quantum Dots

Quantum dots are most useful in biomedical research and for *in vitro* and *in vivo* clinical diagnostics. These monodisperse semiconductive nanocrystals have dimensions

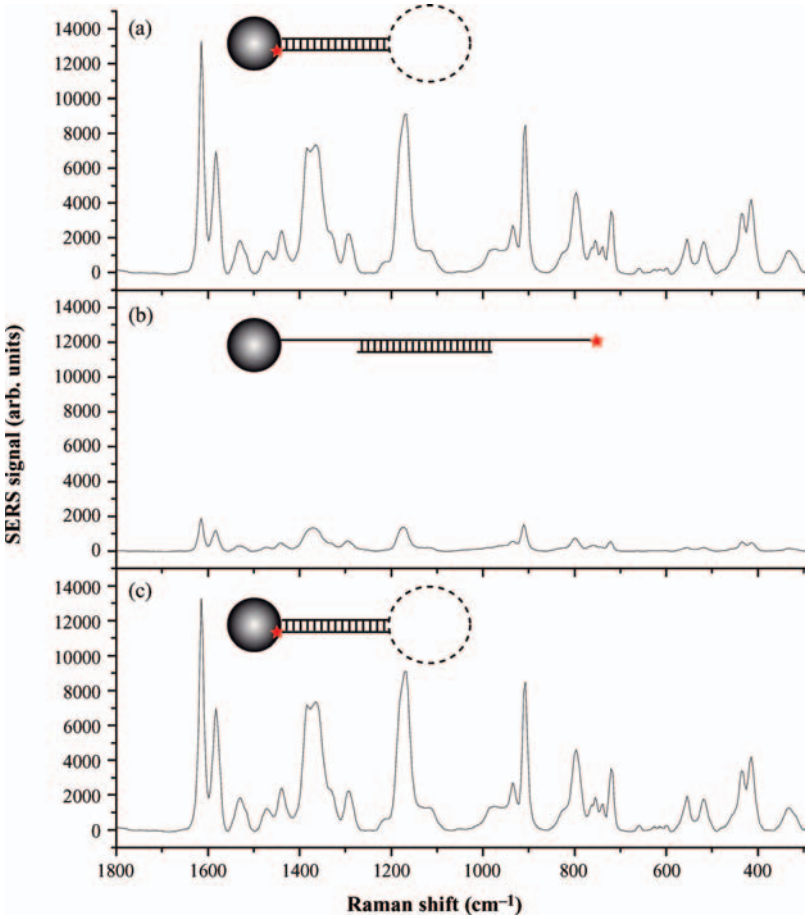

Figure 3.4 SERS intensity dependent on the presence of a plasmonic-based nanoprobe, consisting of a metal nanoparticle and a stem–loop DNA molecule tagged with a Raman label. With a closed hairpin loop the SERS signal can be detected (a). Due to the hybridization of a complementary target DNA, the hairpin loop will be disrupted (b). The SERS signal will be automatically decreased. Heating above the melting temperature of the DNA construct will rearrange the hairpin loop and consequently the SERS signal (c).

between 1 and 10 nm. Because of the small dimensions, the physicochemical properties of quantum dots depend strongly on their size. Colloidal semiconductor quantum dots are single crystals whose size can be controlled by the synthesis conditions. They have very high extension coefficients, much higher than those of organic fluorophores, and these particles adsorb light over a wide range of wavelengths. Quantum dots represent an alternative to organic or natural fluorophores with a variety of advantages, for instance, their large quantum yields, ability to excite a wide range of sizes, with emission ranging from the visible to the near-infrared region with

one laser frequency, and longer fluorescence lifetimes. Furthermore, these nanocrystals offer high photostability, in contrast to organic fluorophores there is no bleaching effect, and their optical attributes allow their use in multiplexed applications for biological microarrays [285].

Especially for *in vivo* applications, significant concerns about the use quantum dots limit their utilization in various applications. The toxicology of quantum dots is determined by their chemical make-up. An inorganic coating of quantum dots insulates the core, amplifies the optical properties, and provides chemical stability. Then an organic coating is necessary for coupling biomolecules [11]. Quantum dots can also be incorporated into latex particles (quantum beads), making them more useful to those attempting antibody conjugation. Basically, chemical coatings (silica and other materials) should provide solubility and the possibility of functionalizing the particles with biomolecules, including DNA, proteins, and antibodies. The toxicology of quantum dots is a combination of the metal, the chemical coating, and the functionalization.

Smith and Nie in 2004 reported details of surface chemistry and bioconjugation, current applications in bioanalytical chemistry and cell biology, and future research directions of quantum dots [286]. Quantum dots are utilized in fluorescence *in situ* hybridization, DNA and protein analysis, and targeting a variety of cell components. In 2005, the Ting's group demonstrated the quantum dot-based detection of proteins via biotin–streptavidin interactions [287]. Additionally, Roullier *et al.* showed the potential of the direct visualization of protein–protein interactions at the single molecule level [288]. Recent reviews have underlined the applicability of quantum dots and the challenges to be overcome to make them commercially available [137, 289–291]. Nowadays, several quantum dot antibody and secondary detection reagents, labels, and labeling kits are commercially available from different companies, for example, Invitrogen and Evident Technologies.

Figure 3.5 illustrates selected applications of quantum dots in biomolecule diagnostics: fluorescence *in situ* hybridization, donors in fluorescence resonance energy transfer, labels for microarray hybridization, and for spectral bar coding [292].

3.5.3 Enzymes

In recent years, much effort has been directed at using enzymes as catalysts to generate metal nanoparticles. The combination aimed at the fusion of the fast and highly specific enzymatic reaction with the unique properties of metal nanoparticles. This technology extended the field of application of enzymes in bioanalytics because of the generation of insoluble stable products. An enzyme-induced growth of metal nanoparticles leads to stable signals that do not fade or bleach.

The use of enzymatic reactions to generate metal nanoparticles was described for the first time in the field of immunohistology and *in situ* hybridization [293, 294].

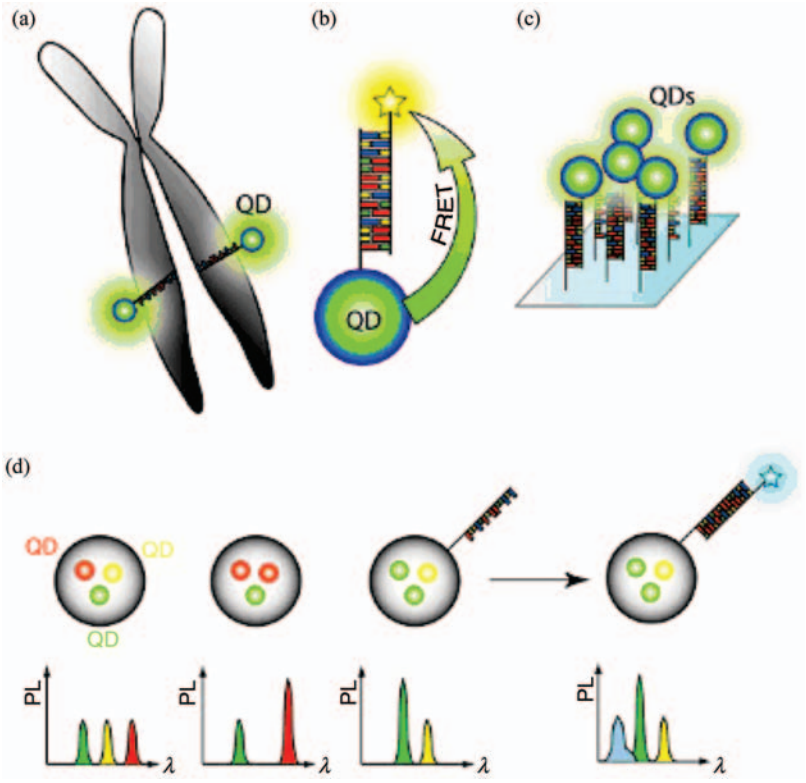

Figure 3.5 Selected applications of quantum dots in nucleic acid diagnostics: (a) quantum dots as labels for fluorescence *in situ* hybridization (FISH); (b) quantum dots as donors in hybridization-mediated fluorescence resonance energy transfer (FRET); (c) quantum dots as labels for biochips/solid-phase hybridization; (d) encapsulated combinations of quantum dots for spectral barcoding. From Algar *et al.* [292].

Both methods used enzymes as labels for the production of specific dyes. However, the enzymatically converted molecules started to diffuse after a short time into neighboring tissue, which led to a decrease in sensitivity and a reduction in resolution. Based on the demonstrated advantages such as the efficient reaction, stability, and reproducibility, different enzymes were investigated in terms of their ability to generate metal nanoparticles. The electrochemical detection of silver nanoparticles deposited by alkaline phosphatase is one of the first described reactions for a chip-based investigation of biomolecules [295–297]. In 2005, Fritzsche's group introduced the horseradish peroxidase-induced growth of silver nanoparticles [298]. The particle growth and the kinetics of the reaction were further investigated at the single-particle level to illustrate the reaction mechanism [299]. Further enzymes, widely used in molecular biological tests, such as glucose oxidase and acetylcholinesterase,

were found to be possible initiators for the enzyme-induced growth of nanoparticles [300, 301]. Silver nanoparticles produced by alkaline phosphatase were used to produce nanoscopic metallic conductor paths by Dip-Pen nanolithography [302]. In addition to nanoparticles, enzymes can generate insoluble colored products that also can be exploited to detect different microorganisms [303]. This detection method is used in biochip applications by CLONDIAG Chip Technologies (Jena, Germany).

The successful combination of enzymes and metal nanoparticles represents a powerful technique that can be used to improve analytical methods in terms of sensitivity and specificity.

3.6 Conclusion

In the last decade, biochips have revolutionized analytical diagnostics. Because of their high throughput ability, biochips save time and costs in experiments. Advantages such as miniaturization and automation led to the further development of this technology. For this purpose, different scientific and engineering fields worked closely together. Due to the collaboration of workers involved in microfabrication, microelectronics, the computer industry, molecular biology, and so on, biochip technology is rapidly growing, with a large number of applications in pathogen detection, clinical diagnosis, genomic research, gene expression profiling, toxicogenomics, and pharmacogenomics.

The method of choice for chip-based biomolecule detection is fluorescence. This technique is well established and widely used in scientific laboratories. Despite all their advantages and the wide applicability of biochips, the technology is still limited to research applications. This is generally caused by a lack of reproducibility and reliability. The rapid development of the technology led to a large number of different biochip systems using various chip platforms, materials, labeling techniques, immobilization strategies, and detection units. Unfortunately, the comparability between these different systems, in terms of sensitivity and specificity, is uncertain. Nevertheless, the development of a new biochip generation, the so-called point-of-care systems, is promising for on-site testing and will continue to advance the technology. Due to the use of alternative labels such as metallic nanoparticles, quantum dots, and enzymes, biochips can be turned into robust and mobile analytical systems. Compared with fluorescence, the nanoparticle-based automation of biochips (e.g., integration in microfluidic systems) will significantly improve the reproducibility and reliability of these on-site diagnostic devices. The required high robustness and short analysis times of point-of-care systems allow their use outside specialized laboratories.

Finally, the biochip technology has already prepared the ground for a new class of bioanalytical tools in order to realize fast, sensitive, easy-to-use, mobile, and reliable diagnostics.

4
Microstructure Fibers in Biophotonics

Aleksei M. Zheltikov

4.1
Introduction: From Early Concepts of Fiber-Based Bioimaging to Biophotonics with Specialty Fibers

The development of fiber-based methods of biomedical imaging spans more than eight decades [1]. The capability of optical fibers to transfer images was first realized in the late 1920s. In 1927, Clarence Hansell, an electronic engineer at the Radio Corporation of America, filed a patent on fiber-based imaging [2], which covered the use of optical cables consisting of many fibers. In 1929, Heinrich Lamm, a medical student at the University of Munich, reported the first successful experiments on image transfer through a bundle of optical fibers [3], motivated by the development of a flexible gastroscope (see [4] for a detailed account of the early days of the history of fiber optics). These early inventions and pioneering concepts had to wait for several decades, however, before fiber fabrication technologies and low-loss fiber materials became mature enough to support the creation of practical fiber imaging systems, leading to revolutionary breakthroughs in biophotonics.

Modern fiber-optic technologies [5] provide an advanced platform for the creation of novel fiber-based imaging systems [6, 7], optical endoscopes [8, 9], biophotonics-oriented fiber laser sources [10], and optical neural interfaces [11, 12]. Although standard single-mode fibers (SMFs) can help implement many of the biophotonic protocols in the endoscopic mode, guiding continuous-wave radiation to the area of interest in living organisms, such fibers are much less efficient in delivering ultrashort laser pulses, needed for multiphoton bioimaging, and in collecting the incoherent optical response from biotissues. The group-velocity dispersion of such fibers tends to stretch ultrashort light pulses, while the numerical aperture of SMFs is typically too low to permit efficient collection of incoherent radiation.

Novel micro- and nanostructured optical fibers, also referred to as photonic-crystal fibers (PCFs) [13, 14], have been shown to offer attractive solutions to these problems [15]. Both group-velocity dispersion and numerical aperture can be tailored in PCFs through fiber structure engineering [16]. Fibers of this class have been used to improve substantially the signal collection efficiency in nonlinear microscopy [17] and have allowed the creation of nonlinear optical fiber endoscopes [18, 19].

Handbook of Biophotonics. Vol.2: Photonics for Health Care, First Edition. Edited by Jürgen Popp, Valery V. Tuchin, Arthur Chiou, and Stefan Heinemann.

Advanced PCF lasers [10, 20], and also PCF frequency converters [16] and supercontinuum sources [21, 22], are gaining growing applications in bioimaging based on coherent anti-Stokes Raman scattering (CARS) [23]. Hollow-core PCFs [24, 25] allow the delivery of high-energy, ultrashort laser pulses for biomedical applications [26]. These fibers also offer much promise for the creation of tunable wavelength shifters for multiphoton microscopy and CARS microspectroscopy [27, 28]. The low nonlinearity of the gas filling the core of the fiber and the choice of the central wavelength of laser pulses to the zero group velocity dispersion (GVD) wavelength of the fiber help to reduce temporal envelope distortions of the transmitted light signal. In this chapter, we give a brief overview of recent developments in biophotonics based on the use of microstructure fibers

4.2
Microstructure Fiber Sensors

Microstructure fibers suggest a variety of attractive strategies for optical sensing. The most common approach involves using the evanescent field of waveguide modes, confined to a high refractive index material in a waveguide, to produce a fluorescent signal, which is employed to detect species of a certain type in the gas, liquid, or solid phase. When implemented with PCFs [29–38], this sensing strategy allows the creation of compact fiber format sensors of gas-phase media [36–38] and biomolecules in aqueous solution [31]. Another widespread approach to sensing with advanced waveguide components is based on interferometric techniques [39], most often the Mach–Zehnder interferometer configuration, intended to detect small changes in the phase of an optical signal transmitted through a waveguide sensor. Devices based on this principle can sense small changes in the refractive index of an analyte or detect the formation of thin molecular layers on a waveguide cladding.

Owing to the remarkable flexibility of their core–cladding structure (Figure 4.1), PCFs offer attractive and often unique options for biosensing. For example, double-clad PCFs, as shown elegantly by Myaing *et al.* [40], can substantially improve the efficiency of two-photon fluorescence detection of biomolecules with the fluorescence signal delivered to the detector in the backward direction through the same fiber. The possibility of extending the concept of fiber grating-based sensing to PCFs has been demonstrated by Eggleton *et al.* [41]. Rindorf *et al.* [33] developed PCF-based sensors with long-period gratings for the detection of molecular monolayers containing immobilized DNA. Advanced fiber micro- and nanostructuring technologies have been shown to permit the creation of high-performance DNA sensors for gene-expression analysis [42], and also specific genomics- and proteomics-oriented sensor systems designed to detect specific genes and proteins (see [43] for a review).

Air-guided modes of hollow-core PCFs (Figure 4.1e) have been shown to be ideally suited for gas-phase sensing using linear [44] and nonlinear [45] optical methods. The biosensing ability of ring-cladding hollow-core PCFs has been demonstrated [46]. The ring cladding in such waveguides, conveniently implemented in a PCF design, serves as a built-in Fabry–Pérot interferometer, allowing the detection of thin

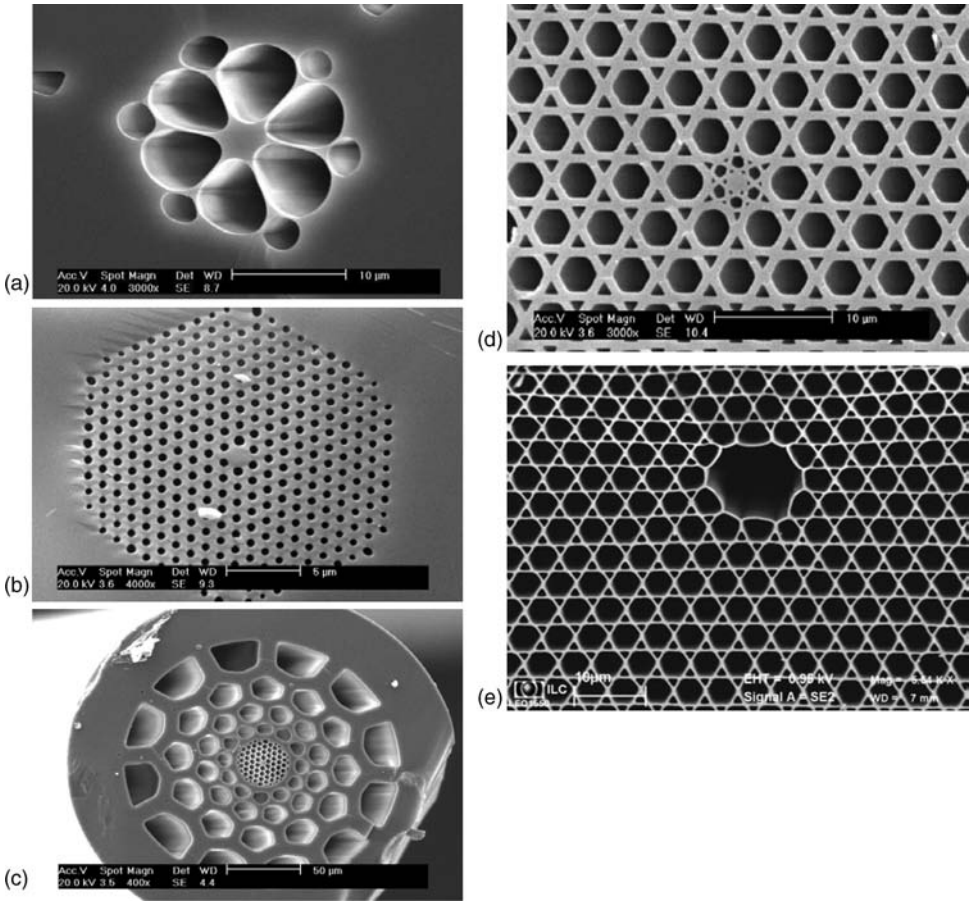

Figure 4.1 SEM images of PCFs: (a) solid-core high refractive index-step silica PCFs with a few-airhole-ring cladding; (b) periodic cladding PCF; (c) solid-core silica PCF with a dual microstructure cladding; (d) multicomponent glass PCF with a nanohole array-modified core; (e) hollow-core PCF.

molecular layers and ensuring a high sensitivity of transmission spectra of waveguide modes to small changes in the refractive index of an analyte filling the hollow core of the waveguide and air holes in the fiber cladding. We show that waveguides of this type offer a platform for the creation of compact and efficient biochemical sensors and sensor arrays. Components of this type can sense biolayers a few nanometers thick and provide a high sensitivity with respect to refractive index changes of an analyte filling the air holes of the waveguide structure.

A diversified architecture of photonic-crystal fibers (Figure 4.1) suggests various approaches to optical sensing. Experiments reported by Konorov *et al.* [32] provide a quantitative comparison of two protocols of optical sensing with PCFs. In the first protocol, diode-laser radiation is delivered to a sample through the central core of a dual-cladding PCF with a diameter of a few micrometers, while the large-diameter

fiber cladding serves to collect the fluorescent response from the sample and to guide it to a detector in the backward direction. In the second scheme, liquid sample is collected by a microcapillary array in the PCF cladding and is interrogated by laser radiation guided in PCF modes. For sample fluids with refractive indices exceeding the refractive index of PCF material, fluid channels in PCFs can guide laser light by total internal reflection, providing an 80% overlap of interrogating radiation with sample fluid. Specially designed PCFs have been shown to integrate an optical sensor with a micropipette, a sample collector, and a microfluidic polycapillary array in a single fiber-optic component, which is ideally suited for "lab-on-a-chip" applications, offering an attractive platform for fiber-based sensors and probes for genomics and proteomics.

4.3 Designing Specialty Fibers for High-Resolution Imaging

The development of subdiffraction microscopy techniques is one of the key tendencies in modern optical physics. Rapidly progressing methods of near-field microscopy [47] provide an unprecedentedly high spatial resolution on specific samples, giving an access to a unique information on the structure of matter and physical processes in subsurface layers. Methods of near-field microscopy, however, face serious difficulties when applied to a broad class of problems related to processes and details of structure in the bulk of a material and in living systems. Problems of this class can be attacked by using novel physical principles of far-field microscopy, such as multiphoton microscopy [48, 49], microscopy based on CARS [50], and stimulated Raman scattering [51], and also microscopy using stimulated emission depletion (STED) [52]. New methods of far-field microscopy have been shown to provide spatial resolution as high as a few tens of nanometers (in certain cases better than 20 nm [53]). These techniques find growing applications in studies of intracellular processes in living organisms, single-molecule detection, and analysis of a broad class of nanostructures and nano-objects.

Modern fiber-optic technologies allow the creation of optical micro- and nanowaveguide systems, including submicrometer-core optical fibers [16]. Such components open up wide opportunities for the implementation of novel methods of microscopy in the fiber format. Rapidly growing research in this field includes the development of fiber-optic sources and systems for the delivery of ultrashort light pulses for nonlinear optical endoscopy and mapping of neuronal activity in the living brain [54, 55]. Unique opportunities offered by fiber-format ultrahigh-resolution microscopy call for a detailed understanding of fundamental physical factors controlling the confinement of electromagnetic field in waveguide systems and analysis of methods of transmission of ultracompact light beams in fiber-optic networks.

The spatial resolution of fiber-based optical imaging is controlled by the confinement of the light field in the fiber core, which can be quantified in terms of the effective mode radius:

$$w = (S/\pi)^{\frac{1}{2}} \tag{4.1}$$

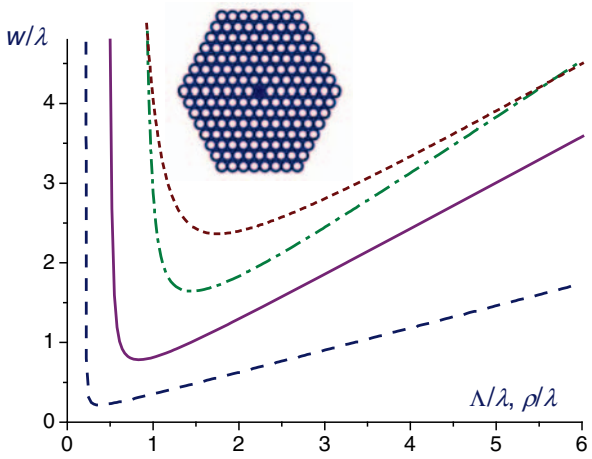

Figure 4.2 Effective radius of the PCF mode as a function of the pitch Λ of the hexagonal fiber cladding for $\lambda = 1\,\mu m$, $d/\Lambda = 0.3$ (dashed-dotted line), 0.5 (solid line), and 0.9 (dashed line). The dotted line shows the effective radius of the fundamental mode of a standard fiber with $n_1 - n_2 = 0.01$ as a function of the core size ϱ. A PCF with a hexagonal-lattice cladding is shown in the inset.

where

$$S = 2\pi\left[\int_0^\infty |F(r)|^2 r\mathrm{d}r\right]^2\left[\int_0^\infty |F(r)|^4 r\mathrm{d}r\right]^{-1} \tag{4.2}$$

is the effective mode area, $F(r)$ being the transverse field profile in the fiber mode. The mode radius w is sensitive to the refractive index contrast, $\Delta = n_1 - n_2$, where n_1 and n_2 are the refractive indices of the fiber core and fiber cladding, respectively, and generally differs from the physical size of the fiber core ϱ. This difference may become especially significant in the case of fibers with very small, subwavelength cores, where diffraction arrests a tight localization of the light field in the fiber core, making a significant fraction of the mode power propagate as the evanescent field outside the fiber core [56, 57].

Figure 4.2 compares the typical behavior of the effective mode radius w as a function of the physical radius of the fiber core ϱ in the case of a conventional step-index fiber (dotted line) and a generic-type PCF with a hexagonal structure of the cladding with a lattice constant Λ (shown in the inset). Calculations presented in Figure 4.2 suggest [58] that the light confinement in the PCF core and, hence, the spatial resolution provided by a PCF probe can be controlled through fiber structure engineering. Larger d/Λ ratios, as can be seen from Figure 4.2, provide a tighter localization of the light field in the fiber core, translating into a higher spatial resolution of a fiber probe. With $d/\Lambda = 0.9$, the minimum mode radius, achieved when $\Lambda \approx 0.4\lambda$, is $w_{\min} \approx 0.2\lambda$ (the dashed line in Figure 4.2), allowing fiber-based

optical probing of areas adjacent to the fiber end with subwavelength resolution. Interestingly, and quite importantly, for smaller core sizes, the field confinement in the fiber core becomes weaker, because of strong diffraction, leading to larger effective mode sizes (see Figure 4.2), with a significant fraction of mode power guided outside the fiber core. All these predictions are fully confirmed by fiber-probe experiments on test objects [59].

4.4 Fiber-Based Imaging of Diffusively Scattering Tissues

To illustrate the significance of the fiber structure for the regime of collection of a fluorescence signal from a diffusively scattering tissue, we consider a generic fiber (Figure 4.3a) consisting of a core with a diameter d_c, which is used to deliver the laser light to a tissue, and a cladding that includes a ring (similar to a ring seen in the PCF structure in Figure 4.1c) with an inner diameter d_r, which serves to pick up the fluorescent response from the tissue within its larger aperture. The case of $d_c = d_r$ corresponds to a standard optical fiber. In a PCF, a cross-section structure can be designed in such a way as to isolate a signal-collecting cladding ring from the central core of the fiber. When a fiber probe with such a design is used to detect the fluorescence response from a uniformly scattering biotissue, the probability of the ring in the fiber cladding to pick up a fluorescent photon generated at a depth z (measured from the fiber tip, Figure 4.3a) peaks, due to the general properties of diffusive scattering of optical signals in random media [60, 61], at $z = L_0$. The full width at half-maximum, δz, of the axial profile $I_{fl}(z)$ of fluorescence collected by the cladding ring is controlled by scattering and absorption of the tissue, and also the diameter of the ring d_r, its thickness t_r, and the refractive index step $\delta n = n_r - n_{eff}$, where n_r is the refractive index of the material of the ring ($n_r \approx 1.45$ for a silica ring in our experiments) and n_{eff} is the effective refractive index of the microstructure surrounding this ring. A ring with a larger diameter d_r will probe tissue layers lying at larger distances L_0 from the fiber tip at the cost of lower axial resolution (larger δz). The thickness of the tissue layer providing the main contribution to the signal detected by the outer ring of the PCF can be reduced by lowering the refractive index contrast δn and decreasing the thickness of the ring t_r. For the PCF shown in Figure 4.1c with $d_r \approx 300\,\mu m$ and $t_r \approx 25\,\mu m$, numerical simulations for typical brain-tissue parameters (reduced scattering coefficient $\mu'_s \approx 1\,mm^{-1}$ and the absorption coefficient $\mu_a \approx 0.1\,cm^{-1}$ [62]) give $L_0 \approx 250\,\mu m$ with $\delta z \approx 160\,\mu m$. The lateral dimensions of the interrogated volume are determined by the outer diameter of the signal-collecting aperture of the fiber probe. In our experiments, this diameter was about 325 μm.

Special measurements were performed to test how well the fluorescence-collecting ring in the PCF cladding is isolated from the central fiber core for PCFs with different cladding-ring diameters. To this end, the intensity I_s of the signal collected by PCFs of different types was measured as a function of the displacement ϱ of the fiber core with respect to a 2 μm spot of a tightly focused laser beam, intended to mimic a point light source. Results of these measurements are presented in Figure 4.3b. For a PCF

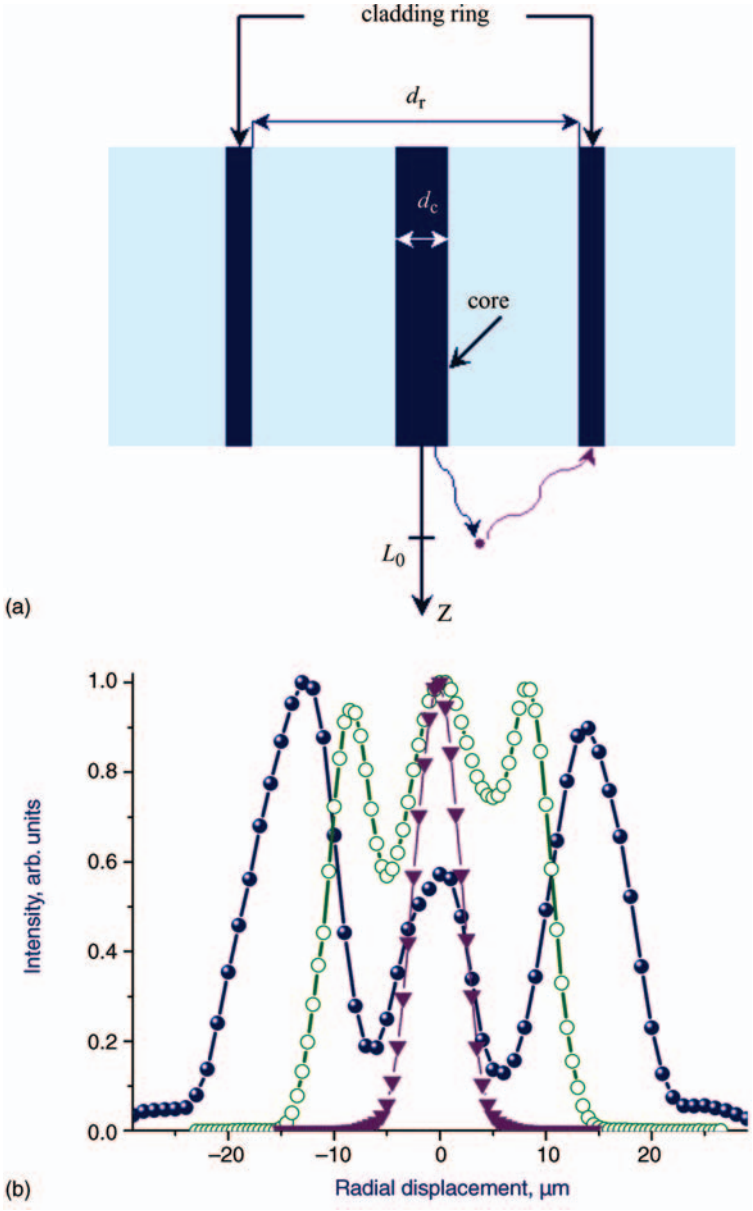

Figure 4.3 (a) Fiber probe with a fluorescence-collecting ring in the cladding. (b) Intensity of the signal collected by a PCF with a cross-section structure shown in Figure 4.1a (filled and open circles) and Figure 4.1d (triangles) measured as a function of the displacement of the fiber core with respect to a 2 μm radiation source. The diameter of the outer light collecting ring in the core of PCF shown in Figure 4.1a is 18 μm (open circles) and 28 μm (filled circles).

without a signal-collecting cladding ring (Figure 4.1a), the measured radial profile $I_s(\varrho)$ features only one maximum (triangles in Figure 4.3b), corresponding to the center of the fiber core. For fibers with signal-collecting cladding rings (Figure 4.1c), the $I_s(\varrho)$ profile displays three peaks (solid and open circles in Figure 4.3b), corresponding to the signal delivered through the central core and the cladding ring. Whereas for fibers with $d_r \leq 20\,\mu m$, the signal transmitted through the cladding ring suffers from interference due to radiation transmitted through the core and the inner part of the microstructure cladding (open circles in Figure 4.3b), PCFs with $d_r \geq 25\,\mu m$ show well-resolved peaks in the $I_s(\varrho)$ profile (solid circles in Figure 4.3b), indicating almost no interference between the signals transmitted through the central core and the signal-collecting cladding ring. The experimental results thus support numerical simulations, confirming that properly designed fiber probes can effectively resolve the fluorescence response from a brain tissue along the axial coordinate even in the regime of single-photon excitation, where high laser intensities, typically required for multiphoton methods, are not needed.

4.5 Enhancement of Guided-Wave Two-Photon-Excited Luminescence Response with a Photonic-Crystal Fiber

Two-photon absorption (TPA) is the backbone of a broad variety of bioimaging techniques and biomedical strategies, including high-resolution microscopy [48, 49, 63], photodynamic therapy [64, 65], and drug-delivery monitoring and drug activation [66]. Luminescence of TPA-excited molecules provides a measurable optical response that allows imaging of TPA-excited regions in two-photon microscopy and helps to visualize tiny objects and identify fine details of structure and morphology inside biological tissues [48, 49]. A combination of TPA approaches with capabilities of fiber-optic probes [54] offers numerous advantages [67], suggesting a convenient format for beam delivery, facilitating manipulation of excitation radiation, and allowing this excitation to be applied locally and selectively. Although many attractive fiber solutions have been developed to meet the needs of TPA-based technologies, collection of the two-photon-excited luminescence (TPL) response still leaves much room for optimization, with the main source of problems being related to the small aperture of fiber probes, making it difficult to collect efficiently the TPL signal, which is uniformly emitted in a 4π solid angle.

PCFs can substantially improve the collection efficiency of the TPL response from TPA-excited molecules in waveguide modes [68], thus allowing the sensitivity of TPA-based techniques to be radically improved. In the earlier relevant work, PCFs of various types were shown to offer numerous advantages as efficient optical sensors [30–32] and compact wavelength-tunable sources for nonlinear microspectroscopy [16, 23]. Dual-cladding PCFs have been employed to enhance the efficiency of two-photon biosensing [40]. As shown by Fedotov *et al.* [68], with only a few nanoliters of TPA-excited molecules filling air holes in a specifically designed PCF, the guided-wave TPL signal can be enhanced by two orders of magnitude relative to

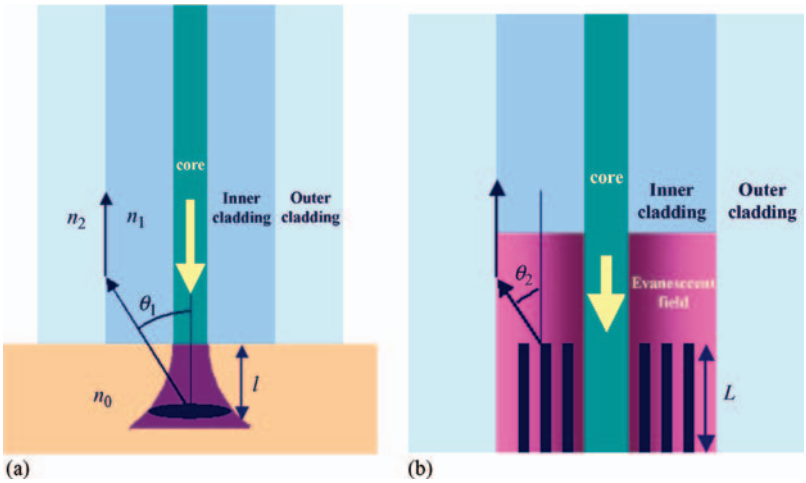

Figure 4.4 TPA excitation and TPL response collection with a dual-cladding fiber probe: (a) excitation light is delivered through the fiber core to an object adjacent to the fiber end, while the TPL signal is collected by a high numerical aperture inner part of the fiber cladding; (b) an evanescent field of the mode guided along the fiber core generates the TPL signal through a TPA excitation of dye molecules in a solution filling the air holes in the PCF cladding, with the inner part of the fiber cladding capturing the TPL response into a waveguide mode and delivering this signal to a detection system.

the maximum TPL signal attainable from a cell with the same dye excited and collected by the same PCF.

We compare two arrangements for the collection of the TPL response with a dual-cladding fiber. In the first scheme (Figure 4.4a), excitation light is delivered along the fiber core to an object adjacent to the fiber end. The TPL signal is then collected by the inner part of the fiber cladding. As shown by Myaing *et al.* [40], this method of TPA excitation using dual-cladding PCF probes offers important advantages for TPA bioimaging. In the second approach (Figure 4.4b), we let a tiny amount of the liquid- or gas-phase substance fill the air holes of the PCF. The TPL signal is then excited by the evanescent field of the mode guided along the fiber core and is captured into a waveguide mode inside the inner part of the fiber cladding.

The total TPL signal collected by the fiber probe in the first experimental arrangement (Figure 4.4a) is

$$P_1 = 2\pi \int_0^a \sigma_1 I_1(r) r \mathrm{d}r \tag{4.3}$$

where

$$I_1(r) = \mu\beta l I_0{}^2 [f_1(r)]^2 \tag{4.4}$$

is the intensity of the TPL signal, σ_1 is the TPL signal collection efficiency, μ is the quantum yield of TPA-induced luminescence, β is the TPA coefficient, l is the length

of the interaction region, I_0 is the on-axis intensity of the waveguide mode, a is the radius of the fiber core, and $f_1(r)$ is the radial profile of field intensity distribution.

The TPL signal collection efficiency σ_1 is given by

$$\sigma_1 = 2\pi \int_0^{\theta_1} \sin\xi \, d\xi \tag{4.5}$$

where θ_1 is the maximum acceptance angle of the high numerical aperture inner part of the fiber cladding:

$$\sin\theta_1 = \frac{n_1}{n_0}\left[1-\left(\frac{n_2}{n_1}\right)^2\right]^{\frac{1}{2}} \tag{4.6}$$

where n_0 is the refractive index of the medium adjacent to the fiber probe end and n_1 and n_2 are the refractive indices of the inner and outer sections of the fiber cladding, respectively.

With $({n_1}^2-{n_2}^2)/{n_0}^2 \ll 1$, integration of Eq. (4.5) yields

$$\sigma_1 \approx \pi{\theta_1}^2 \approx \pi\left(\frac{NA_1}{n_0}\right)^2 \tag{4.7}$$

where $NA_1 = ({n_1}^2 - {n_2}^2)^{1/2}$ is the numerical aperture of the inner cladding of the fiber probe.

In the case of a Gaussian field intensity profile, $f_1(r) = \exp(-r^2/{r_1}^2)$, where r_1 is the effective field intensity radius, Eqs. (4.3), (4.4), and (4.7) give

$$P_1 \approx \pi\mu\beta l {I_0}^2 \frac{S_1}{2}{\theta_1}^2\left[1-\exp\left(-2\frac{a^2}{{r_1}^2}\right)\right] \tag{4.8}$$

where $S_1 = \pi{r_1}^2$ is the effective mode area.

For a large-core fiber with $(a/r_1)^2 \gg 1$, Eq. (4.8) reduces to

$$P_1 \approx \pi\mu\beta l {I_0}^2 S_1 {\theta_1}^2 \tag{4.9}$$

For the second experimental scheme (Figure 4.2b), the total TPL signal collected by the fiber probe is

$$P_2 = 2\pi \int_a^R I_2\left[f_2(r)\right]^2 r dr \tag{4.10}$$

where $f_2(r)$ is the radial profile of field intensity distribution in a liquid-filled fiber, R is the radius of the inner part of the cladding, and the TPL intensity I_2 can be found from the equation

$$I_2 = \mu\beta\sigma_2 \int_0^L \frac{{I_0}^2 dx}{(1+\beta I_0 x)^2} \tag{4.11}$$

where L is the length of the interaction region, σ_2 is the TPL signal collection efficiency defined by

$$\sigma_2 \approx \pi\theta_2{}^2 \approx \pi\left(\frac{NA_2}{n_{co}}\right)^2 \tag{4.12}$$

θ_2 is the maximum acceptance angle, $NA_2 = (n_{co}{}^2 - n_{cl}{}^2)^{1/2}$, n_{co} is the effective refractive index of the inner part of the liquid-filled fiber bounded by the outer cladding, and n_{cl} is the refractive index of the outer part of the cladding.

Integration of Eq. (4.11) yields

$$I_2 = \mu\beta\sigma_2 \frac{I_0{}^2 L}{1 + \beta I_0 L} \tag{4.13}$$

with $\beta I_0 L \ll 1$ and a Gaussian field intensity profile, $f_2(r) = \exp(-r^2/r_2{}^2)$, r_2 being the effective field intensity radius in a liquid-filled fiber, Eqs. (4.10), (4.12), and (4.13) lead to

$$P_2 \approx \pi\mu\beta\theta_2{}^2 I_0{}^2 L \frac{S_2}{2} \exp\left(-2\frac{a^2}{r_2{}^2}\right) \tag{4.14}$$

where $S_2 = \pi r_2{}^2$ and we assume that $r_2 \ll R$.

The length of the interaction region in the first experimental scheme (Figure 4.4a) is dictated by diffraction and can be estimated as $l \approx 2\pi a^2/\lambda$, λ being the radiation wavelength, we find that the second experimental arrangement provides the following TPL signal collection enhancement with respect to the first scheme implemented with a large-core fiber with $(a/r_1)^2 \gg 1$:

$$\eta = \frac{P_2}{P_1} \approx \frac{\theta_2{}^2}{\theta_1{}^2} \frac{S_2}{S_1} \frac{L\lambda}{2\pi a^2} \exp\left(-2\frac{a^2}{r_2{}^2}\right) \tag{4.15}$$

from which it can be seen that the enhancement of the TPL response provided by a fiber with air holes partially filled with a liquid under study scales linearly with the length L of the interaction region and rapidly decreases [$\propto a^{-2} \exp(2a^2/r_2{}^2)$] with an increase in the fiber core radius a because of the evanescent character of the field inducing the TPL response in the second experimental arrangement. For typical parameters of experiments described below, with $\lambda \approx 0.8\,\mu$m, $a \approx 2.3\,\mu$m, $r_2 \approx 2.5\,\mu$m, and $L \approx 1.5$ cm, we find $L/l \approx 360$, and Eq. (4.15) gives $\eta \approx 200$. Waveguide collection of the luminescence signal using an appropriately designed fiber probe can thus provide orders of magnitude enhancement of the TPL response relative to the maximum TPL signal attainable from a cell with the same TPA medium.

Fiber probes used in experiments [68] were based on suitably designed fused-silica PCFs, produced by means of standard PCF fabrication technology. A Ti:sapphire laser, delivering 40 fs, 0.5 W pulses of 805 nm radiation at a pulse repetition rate of 90 MHz, was employed as a source of light inducing two-photon luminescence in solutions of various dyes. Light pulses with an average power of ~50 mW were coupled into the fiber probe with a micro-objective. Because of the nonlinear nature

of the TPA process, efficient TPL generation requires excitation of molecules by light pulses with a sufficiently high peak power. It is therefore critical for highly efficient TPL excitation to minimize temporal spreading of femtosecond light pulses transmitted through the fiber. To this end, the PCF was designed in such a way as to provide a low GVD at the central laser wavelength. In experiments, a laser pulse with an input pulse width of 40 fs transmitted through a 50 cm long piece of PCF with a GVD parameter $\beta_2 \approx 5 \times 10^{-3}\,\mathrm{ps}^2\,\mathrm{m}^{-1}$ was stretched up to 75 fs. This pulse width was still short enough to provide a sufficient laser peak power for efficient TPA excitation of Rhodamine 6G molecules.

In the first scheme of TPL detection, laser pulses were delivered to a 10^{-3} M solution of Rhodamine 6G in a cell through the central core of the fiber with a

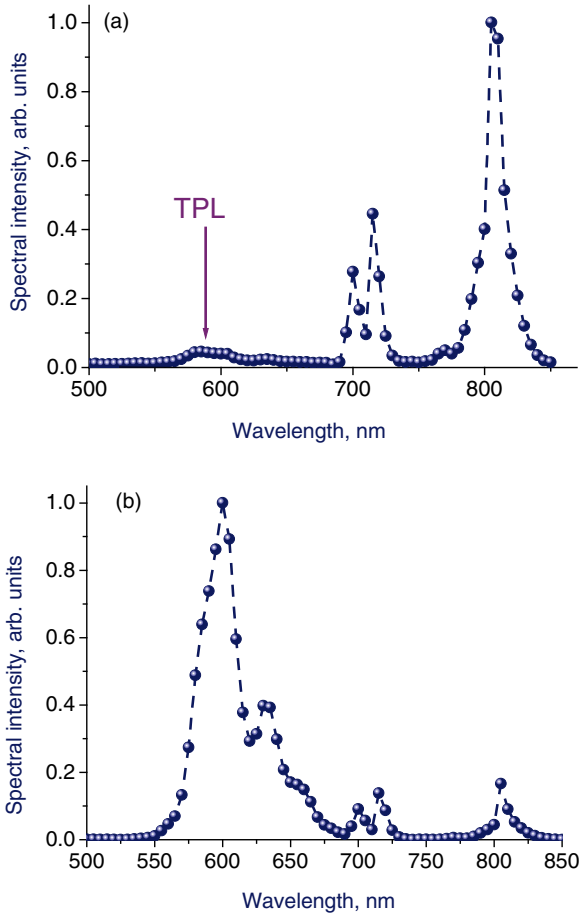

Figure 4.5 Spectra of the optical response of Rhodamine 6G solution excited by femtosecond Ti:sapphire laser pulses with a central wavelength of 805 nm detected (a) from dye solution in a cell (as sketched in Figure 4.4a) and (b) from dye solution filling the air holes in the PCF cladding (as shown in Figure 4.4b).

diameter of 2.3 μm in accordance with the generic approach illustrated in Figure 4.4a. The inner fiber cladding serves to collect the TPL response from the sample and to guide it in the backward direction, towards the input end of the fiber. Outside the fiber, the TPL signal is separated from the 800 nm light and is sent to a detection system by a dichroic mirror. In this regime, the TPL signal is reliably detectable, but is much weaker than the background signal in the spectral range 690–810 nm (Figure 4.5a), which includes back-reflected laser light centered at 805 nm and the nonlinear signal in the spectral region of 700–715 nm generated in the PCF through dispersive-wave emission by optical solitons. This type of emission originates from the instability of solitons induced by higher order dispersion [69]. Its central frequency is controlled by phase matching between the soliton and dispersive waves [70]. The dispersion profile of the PCF used in our experiments dictates emission of dispersive waves that are blue shifted relative to the central wavelength of a soliton. The ratio of the amplitude of the TPL peak in the spectrum of optical response in Figure 4.5a to the amplitude of the peak corresponding to the back-reflected laser light at 805 nm is $\xi_1 \approx 0.04$.

In the second scheme of TPL detection, sketched in Figure 4.4b, a PCF is brought in contact with a liquid-phase sample (a 10^{-3} M solution of Rhodamine 6G in our experiments) so that a small amount of liquid fills the air holes in the fiber cladding due to sample flows induced by surface tension. Dye molecules in the liquid filling the air holes in the fiber cladding are interrogated with the evanescent field of PCF waveguide modes. The TPL signal generated by dye molecules is detected in the backward direction using a dichroic mirror, a monochromator, and a photomultiplier. The fiber infiltration length was estimated from an abrupt change in the level of scattered continuous-wave laser light detected with a standard fiber probe scanned along the infiltrated fiber. With such an experimental arrangement, the ratio of the amplitude of the TPL peak in the spectrum of an optical response from Rhodamine 6G dye penetrating into the air holes inside the PCF over $L \approx 1.5$ cm is $\xi_2 \approx 6.3$ times higher than the intensity of the back-reflected laser signal at 805 nm (Figure 4.5b). The overall volume of interrogated dye solution in this experiment is about 4 nl. Using the back-reflected signal at 805 nm as a reference, we then find that the enhancement of the TPL response provided by the second regime of TPL fiber probing is $\eta = (\xi_2/\xi_1)(P_{02}/P_{01})$, where P_{02} and P_{01} are the powers of the back-reflected signal at 805 nm in the first and second schemes, respectively. With $\xi_1 \approx 0.04$, $\xi_2 \approx 6.3$, and $P_{02}/P_{01} \approx 0.85$, we find $\eta \approx 130$. This estimate agrees well with the analysis presented in the previous section. As a demonstration of a biophotonic application of the developed approach, the dual-cladding PCF shown in Figure 4.1c was used to perform TPL measurements on the Alexa Fluor® family of dyes, which are commonly used as labels in cell biology and fluorescence microscopy, and on green fluorescent protein (GFP), which has gained wide acceptance as a reporter of gene expression [71, 72].

A PCF is thus shown to increase substantially the guided-wave luminescent response from molecules excited through TPA by femtosecond near-infrared laser pulses. With only a few nanoliters of TPA-excited molecules filling air holes in a specifically designed PCF, the guided-wave two-photon-excited luminescence signal

is enhanced by more than two orders of magnitude relative to the maximum TPL signal attainable from a cell with the same dye excited and collected by the same PCF. Biophotonic implications of this waveguide TPL response enhancement include fiber-format solutions for online monitoring of drug delivery and drug activation, interrogation of neural activity, biosensing, endoscopy, highly parallelized gene and protein detection in genomics and proteomics, and locally controlled singlet oxygen generation in photodynamic therapy.

4.6
Microstructure Fibers for Nonlinear Optical Microspectroscopy

CARS [73] has long been established as a powerful tool for time-resolved studies of ultrafast molecular dynamics and diagnostics of excited gases, combustion, flames, and plasmas [74–77]. Because of the nonlinear nature of this type of scattering, the CARS field-interaction region is strongly confined to the beam-waist area, suggesting an attractive approach for microscopy and high-spatial-resolution imaging [50, 78]. Recent advances in femtosecond laser technologies have given a powerful momentum to the development of CARS imaging techniques, making CARS a practical and convenient instrument for biomedical imaging and visualization of processes inside living cells [78, 79].

In the early days of CARS, stimulated Raman scattering (SRS) was successfully used to generate the Stokes field for time-resolved measurements [74] of vibrational lifetimes of molecules in liquids and phonons in solids. Dye lasers and optical parametric sources later proved to be convenient sources of wavelength-tunable Stokes radiation [80, 81], giving a powerful momentum to CARS as a practical spectroscopic tool. The rapid progress of femtosecond lasers and the advent of novel highly nonlinear fibers put a new twist on the strategy of Stokes field generation in CARS, allowing the creation of compact and convenient SRS-based wavelength-tunable fiber-format ultrashort-pulse Stokes sources for a new generation of CARS spectrometers and microscopes [82, 83]. Below in this section, we discuss a compact CARS apparatus that relies on the use of an unamplified femtosecond laser output and two types of PCFs optimized for the generation of wavelength-tunable Stokes field and spectral compression of the probe pulse.

CARS involves coherent excitation of Raman-active modes with a frequency Ω_p by pump and Stokes fields, whose central frequencies, ω_1 and ω_2, are chosen in such a way as to meet the condition of a two-photon, Raman-type resonance, $\omega_1 - \omega_2 \approx \Omega_p$. The third (probe) field with a central frequency ω_3 is then scattered off the coherence induced by the pump and Stokes field to give rise to the anti-Stokes signal at the central frequency $\omega_a = \omega_1 - \omega_2 + \omega_3$, thus reading out the information on the physical properties of the medium projected on the Raman mode. Experiments described below in this section employed a two-color version of CARS with the pump and probe fields delivered by the same light source, implying that $\omega_1 = \omega_3$ and $\omega_a = 2\omega_1 - \omega_2$.

The CARS system that we developed recently [84, 85] (Figure 4.6) is based on a specifically designed long-cavity Cr:forsterite laser oscillator [86]. With a 10 W pump

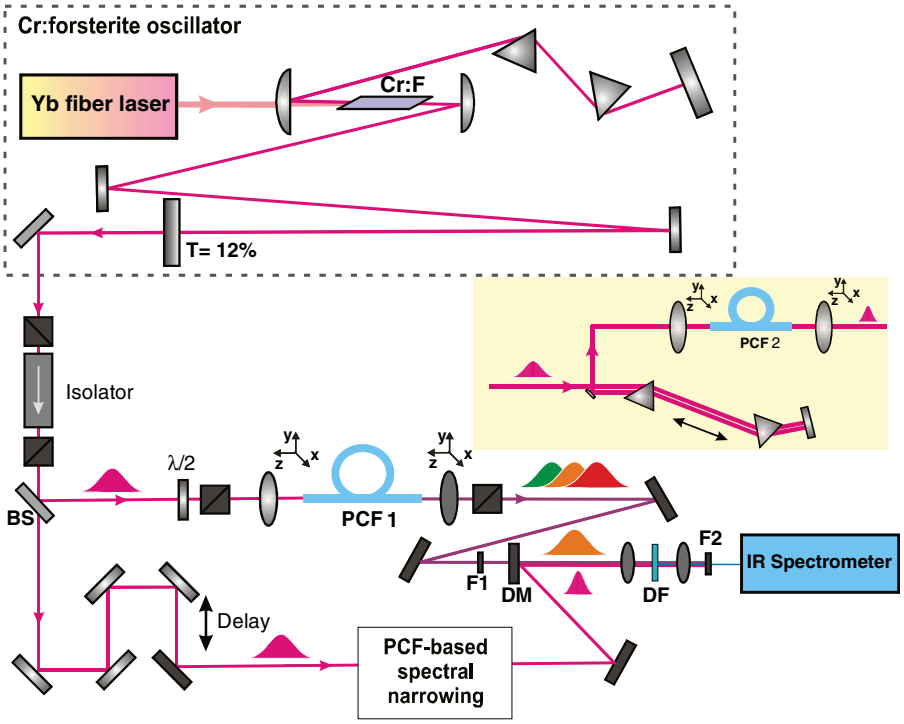

Figure 4.6 Diagram of the experimental setup: Cr:F, Cr:forsterite crystal; BS, beam splitter; PCF1, PCF2, PCFs; F1, F2, filters; DM, dichroic mirror; DF, diamond film. The PCF-based scheme of spectral narrowing is shown in the inset.

provided by an ytterbium fiber laser, the Cr:forsterite oscillator delivered 70 fs, 340 mW light pulses with a central wavelength of 1.25 m at a repetition rate of 18 MHz. A beam splitter (BS in Figure 4.6) was used to divide the Cr:forsterite laser output into two beams. The first beam was launched into a first PCF (PCF1) for the generation of a frequency-tunable Stokes field through soliton self-frequency shift. CARS with a PCF-based soliton frequency shifter as a Stokes source was demonstrated earlier by Andresen *et al.* [82] and Sidorov-Biryukov *et al.* [83]. By varying the power of laser pulses launched into the PCF, we were able to tune the soliton PCF output within the range of wavelengths from 1.35 to 1.75 μm (Figure 4.7a). The smoothly tunable wavelength-shifted soliton output of the PCF was characterized by means of cross-correlation frequency-resolved optical gating (XFROG), implemented in our experiments by mixing the PCF output with reference pulses from the Cr: forsterite laser. Typical XFROG traces of a frequency-shifted PCF1 output measured in experiments with different input peak powers are presented on one map in Figure 4.7a, with the pulse width of the PCF output varying within the range 55–65 fs for different output wavelengths. As can be seen from these XFROG traces, the PCF1 output is nearly transform limited, owing to the soliton regime of wavelength shift,

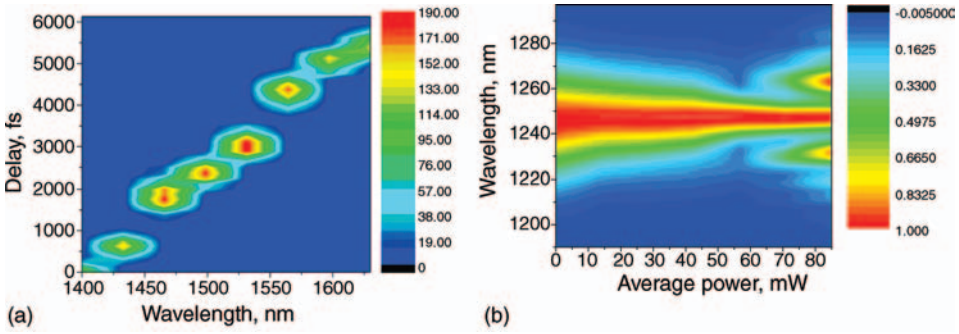

Figure 4.7 (a) A map showing XFROG traces of the frequency-tunable PCF1 output. Traces with different central wavelengths and different delay times were measured in experiments with different input peak powers. (b) Spectra of the output of the photonic crystal fiber (PCF2) used for the spectral narrowing of Cr:forsterite laser pulses measured as a function of the average power of input light pulses.

which helps to avoid unwanted oscillations in CARS spectra due to the interference of resonant and nonresonant parts of the nonlinear signal.

The second beam was intended to provide the pump and probe fields for the CARS process. To improve the spectral resolution and to enhance nonresonant background

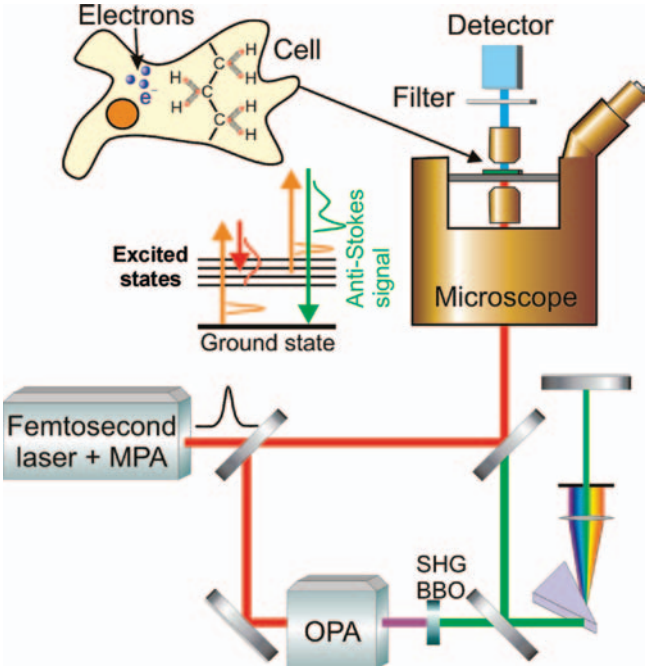

Figure 4.8 Diagram of CARS apparatus: MPA, multipass amplifier; OPA, optical parametric amplifier; SHG BBO, second-harmonic generation in a BBO crystal. A diagram of photons and quantum states involved in CARS is also shown.

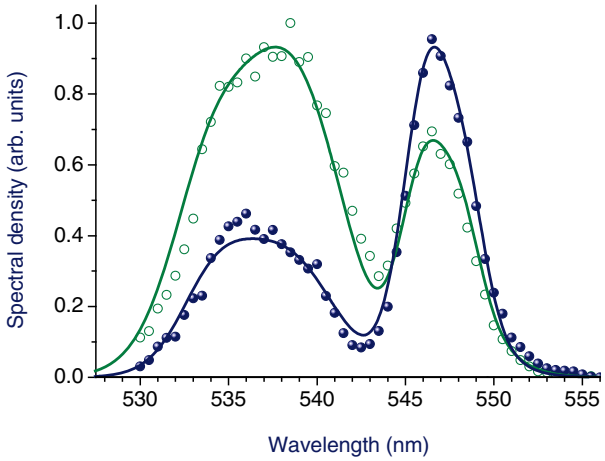

Figure 4.9 Typical CARS spectra from two different regions of mouse brain with a high (open circles) and low (filled circles) content of water versus the results of simulations (solid lines) using the model of the Raman response as described in [90].

suppression in CARS spectra, we used a second PCF (PCF2), which was adjusted to narrow the spectrum of laser pulses through a self-phase modulation process [87–89]. For efficient spectral compression, the light pulses were negatively prechirped with a prism pair, which stretched the pulses to ~700 fs, before they were launched into the PCF. Self-phase modulation in a medium with a positive nonlinear refractive index tends to red shift the leading edge of the pulse and blue shift its trailing edge. For a pulse with an initial negative chirp, such a temporally nonuniform spectral shifting transfers the energy from the wings of the field spectrum toward its central part, thus narrowing the spectrum. Figure 4.7b displays the spectra of the PCF output measured as a function of the input average power of light pulses. Spectral compression ratios of 3.5–4.0 provided an adequate level of spectral resolution in our CARS measurements with the output of the PCF spectral compressor used as a source of pump and probe fields in CARS. Although the spectral compression improves the spectral resolution and helps to suppress the nonresonant background in CARS spectra, a strong chirp of pump and probe pulses should be avoided, as it induces unwanted oscillations due to the interference of resonant and nonresonant parts of the nonlinear signal.

Typical CARS spectra from a coronal section of mouse brain measured [90] with a broadband Stokes field, as shown in Figure 4.8, are presented in Figure 4.9. These spectra are dominated by the lipid symmetric CH stretch vibrational modes (the peak centered at 547 nm in Figure 4.9), and also by the symmetric and asymmetric H_2O stretch vibrational modes of liquid water (merging into the peak centered at 537 nm in Figure 4.9). The ratio of the amplitudes of the 547 and 537 nm peaks is controlled (Figure 4.9) by the content and orientation of lipids and water in the brain tissue region probed by the focused laser beams. Myelin sheaths are especially rich in CH bonds, allowing white matter to be readily distinguished by their high CARS contrast

from gray matter in CARS images of brain tissues [91]. CARS spectra from dehydrated brain samples did not display any feature at 537 nm, confirming the assignment of this peak to vibrational modes of liquid water.

4.7 Microstructure Fibers for Neurophotonics

Advanced fiber-optic components open up a variety of new opportunities in neuroscience, including *in vivo* brain imaging, functional studies of neurons in the brain [92, 93], and the creation of unique optical neural interfaces [11, 12], allowing control over the activity of neurons with light and leading to revolutionary breakthroughs in cognitive sciences. The recently developed advanced fiber tools for high-speed fluorescence microscopy of freely moving animals [54] help to confront the long-standing challenges in experimental studies of neuronal bases of cognition and memory. Specifically designed PCFs have been shown to enhance the two-photon-excited luminescence response from fluorescent protein biomarkers and neuron activity reporters [55].

In vivo work typically imposes demanding requirements on fiber components with regard to their flexibility, compactness, and the ability to integrate multiple functions, such as an optimal geometry local optical excitation of biomolecules, pickup of optical response, and low-loss pump and signal delivery. Several attractive and elegant fiber-format solutions have been developed [5], based on advanced fiber technologies, to meet the needs of biophotonics. A combination of the capabilities of fiber-optic probes with approaches based on multiphoton absorption (MPA) techniques [48, 49, 63] offers numerous advantages, suggesting a convenient format for beam delivery, facilitating manipulation of excitation radiation, and allowing this excitation to be applied locally and selectively. However, three serious problems need to be adequately addressed to make fiber solutions fully compatible with MPA-based technologies. The first difficulty is related to fiber dispersion, which stretches ultrashort laser pulses, reducing the MPA efficiency. The second problem originates from a small aperture typical of a fiber probe, which makes it difficult to collect efficiently the MPA-excited luminescence response, which is uniformly emitted in a 4π solid angle. Finally, the third issue is the laser damage of biotissues, which imposes strict limitations on laser intensity in *in vivo* work and calls for solutions enabling the enhancement of the MPA-excited luminescence response of biomarker molecules. In this section, we show that a new generation of optical fibers offers a promising platform for the creation of wavelength-tunable sources for MPA-based imaging of stained cells and biotissues, including neural activity visualization and brain imaging applications.

In a fused-silica PCF used in experiments [55] (Figure 4.1c), a 2.7 μm diameter core serves to deliver ultrashort laser pulses to the region of TPL interrogation. The inner part of the microstructure cladding with a diameter of 20 μm is designed to provide a high optical nonlinearity and the desired dispersion profile of the fundamental waveguide mode. Along with its outer ring boundary with a diameter of 24 μm, this section of the fiber serves as a high numerical aperture ($NA \approx 0.55$) multimode

waveguide for the collection and guiding of the TPL response signal from dye molecules excited via TPA. Advantages of dual-core PCFs with a high-*NA* inner cladding for luminescent response collection have been demonstrated earlier in experiments on two-photon biosensing [40] and remote analyte detection [32].

The design of the central fiber core and the inner part of the microstructure cladding of the PCF is targeted towards achieving high nonlinearity and a dispersion profile providing (i) anomalous dispersion at the central wavelength of laser radiation used in experiments (800 nm), (ii) soliton self-frequency shift (SSFS) to a desired wavelength needed for efficient TPL excitation, and (iii) two zero points of GVD for SSFS stabilization. As a short-pulse Ti:sapphire-laser output with a central wavelength of 800 nm enters this dual-cladding two zero GVD point PCF (with zero GVD points at 690 and 1050 nm), it tends to evolve toward a soliton. In Figure 4.10, we present the results of numerical analysis of this soliton dynamics for femtosecond 800 nm input laser pulses mimicking the output of the mode-locked Ti:sapphire laser used in our experiments. Simulations were performed by numerically solving the generalized nonlinear Schrödinger equation (GNSE) [22, 94]. High-order fiber dispersion induces soliton instabilities with respect to the emission of dispersive

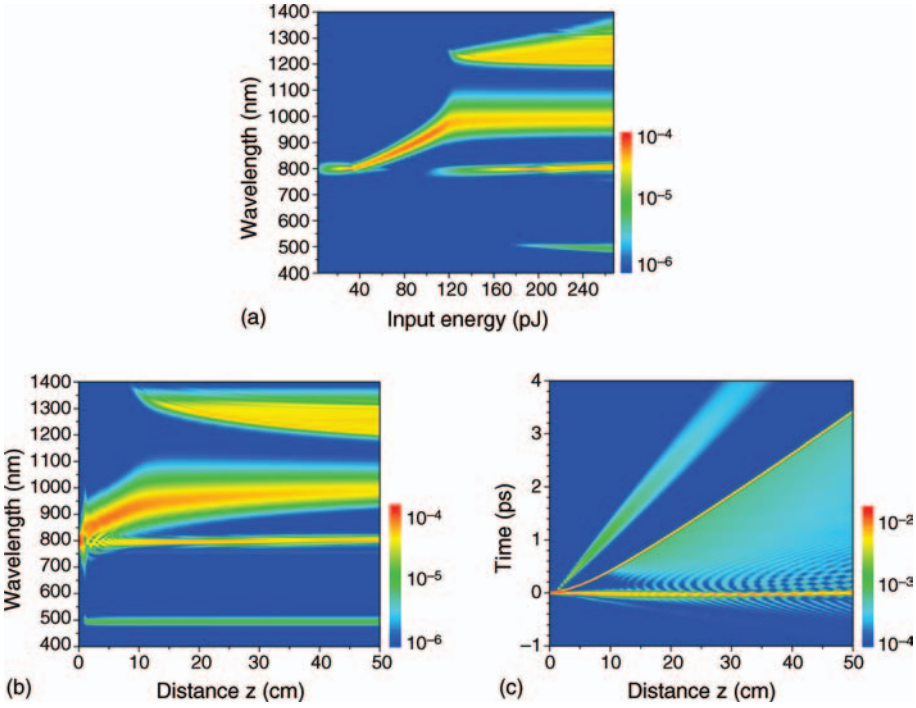

Figure 4.10 Spectrally (a, b) and temporally (c) resolved output of the dual-cladding, two zero GVD point PCF calculated with the use of the GNSE as a function of (a) the input energy and (b, c) the propagation distance *z* along the fiber: (a) the fiber length is 50 cm; (b, c) the input pulse energy is 265 pJ.

waves – a phenomenon that is often referred to as Cherenkov radiation by optical solitons [69]. At the initial stage of pulse evolution in the PCF (propagation distance z ranging from 1 to 10 cm in Figure 4.10a), phase matching between the soliton and a dispersive wave dictates a predominant emission of blue-shifted dispersive waves, observed in GNSE simulations (Figure 4.10a and b) as an intense spectral component centered at the wavelength $\lambda_b \approx 490$ nm. In the time domain, this blue-shifted dispersive-wave radiation is seen as a clearly resolved feature that branches off the soliton part of the field around $z \approx 1$ cm and becomes dispersed by normal fiber dispersion in the process of field evolution (Figure 4.10c).

The Raman effect induces a continuous red shift of a soliton. This effect is clearly seen in Figure 4.10a and b as a well-resolved feature that sweeps over the range of wavelengths from 800 to 990 nm as the pump pulse energy changes from 30 to 120 pJ and the propagation distance increases from 1 to 12 cm. Due to fiber dispersion, the red-shifted soliton accumulates a time delay of about 3.4 ps at the output of a 50 cm piece of PCF (Figure 4.10c). As the central wavelength of a soliton is shifted to the region of a negative slope of the fiber dispersion profile ($z > 10$ cm in Figure 4.10b and c), phase matching between a soliton and a dispersive wave [95] allows efficient generation of red-shifted dispersive waves, observed as a spectral component centered at $\lambda_r \approx 1300$ nm in Figure 4.10a and b. In the time domain, the red-shifted dispersive-wave radiation becomes clearly visible for $z > 10$ cm as a dispersed part of the field adjacent to the red-shifted soliton branch (Figure 4.10c). For input pulse energies exceeding 120 pJ, the central wavelength of the red-shifted soliton becomes insensitive to variations in the input peak energy (Figure 4.10a and b) and stays constant within a broad range of input pulse energies at least up to 800 pJ. This stabilization of the SSFS relative to variations in the pump power, verified by experimental results presented in the inset in Figure 4.11a, and also by earlier experiments [96], is due to the spectral recoil of a soliton by the red-shifted dispersive wave, which exactly compensates [95] for the SSFS induced by the Raman effect.

With its dispersion and nonlinearity designed to generate a stabilized frequency-shifted soliton centered at a desired wavelength, the PCF offers an ideal source for the excitation and detection of the TPL response from a variety of dyes, including fluorescent proteins used as markers of neuron activity, and also brain tissue-labeling dyes. With appropriate modifications of the PCF structure, frequency-shifted ultrashort pulses optimized for the detection of the TPL response of such dyes have been generated. In particular, the fiber design presented in Figure 4.1c, providing a stabilized soliton output with a central wavelength of 980–990 nm (inset in Figure 4.11b), is ideally suited for efficient TPA excitation of Alexa Fluor 488 dye, which is commonly used as a label in cell biology and fluorescence microscopy. Filled circles in the inset in Figure 4.11b display the spectrum of the TPL response of Alexa Fluor 488 dye, measured for a dye solution in a quartz cell with the TPL response collected by the inner, 24 μm diameter part of the microstructure cladding. Our measurements suggest that the use of a frequency-shifted PCF output enhances the TPL response power collected by the fiber by more than an order of magnitude relative to the level of TPL response attainable with a frequency-unshifted, 800 nm, 40 fs output of the Ti:sapphire laser with the same field intensity. This not only opens

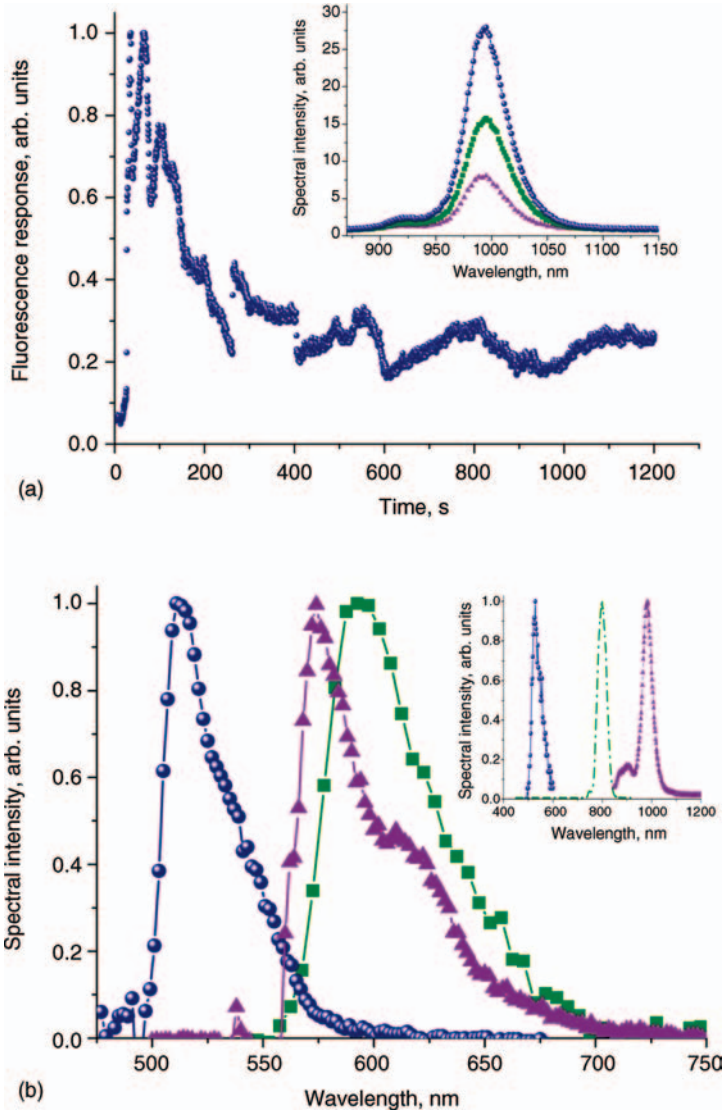

Figure 4.11 (a) Decay kinetics of the fluorescent response of EGFP from the brain of a transgenic mouse in open-skull experiments. The inset shows the spectrum of the PCF output measured for three different input energies of Ti:sapphire laser pulses: triangles, 150 pJ; rectangles, 250 pJ; and filled circles, 400 pJ. (b) Spectrally resolved fluorescent response of EGFP in the brain of a transgenic mouse (filled circles), DsRed2 fluorescent protein in the tail of a *Xenopus laevis* tadpole (rectangles), and Alexa Fluor 555 dye in stained mouse brain (triangles). The inset shows the fluorescent response of Alexa Fluor 488 dye (filled circles) TPA-excited by the frequency-shifted soliton output of a highly nonlinear PCF (triangles). The spectrum of the laser pulse is shown by the dashed-dotted line in the inset.

the ways for a higher speed and improved quality of neuron activity mapping, but also helps to maintain moderate levels of laser intensity in *in vivo* work, making it possible to reduce the laser-induced heat load and avoid radiation damage to biotissues.

The rectangles in Figure 4.11b present the results of spectrally resolved *in vivo* measurements performed on the optical response of DsRed2 fluorescent protein in the muscle tissue of a *Xenopus laevis* tadpole. In these experiments, the DsRed2 reporter gene is controlled by an actin promoter gene. Actin protein produced as a result of promoter gene expression helps build a scaffold, necessary for muscle contraction due to the force generated by myosin proteins. *In vivo* work on neuron activity mapping in brain was performed on transgenic mice, in which the expression of enhanced green fluorescent protein (EGFP) is controlled by an immediate early gene promoter, encoding the *zif*268 mammalian transcription factor. Optical detection of EGFP can thus visualize an accumulation of *zif*268, which is coordinated by a Ca^{2+} influx into a cell and indicates activation of neurons [71, 97]. For the maximum efficiency of TPL detection of EGFP, the absorption of which peaks at $\lambda_{EGFP} \approx 480$ nm, a PCF was designed to deliver a wavelength-shifted soliton centered at $2\lambda_{EGFP} \approx 960$ nm. The pulse width of this wavelength-shifted soliton PCF output was estimated as 25 fs. The spectrum of the TPL response of EGFP expressed in the brain of a transgenic mouse is shown by filled circles in Figure 4.11b. The overall fall-off kinetics of this response (Figure 4.11a), measured in experiments with an open-skull transgenic mouse, reveal the decaying activity of neurons in a fading brain. The maximum intensity of light pulses used for TPL excitation in our *in vivo* experiments (on the order of 10 GW cm^{-2}) was well below the level of light intensities where photodamage of biotissues and photobleaching of dye or fluorescent protein biomarkers became noticeable. With slight modifications of the fiber structure, a wavelength tunability range as broad as 600 nm (from 800 to 1400 nm) could be achieved for the soliton output of the type of PCF considered, suggesting a strategy for multiplex multicolor bioimaging with an appropriate combination of dye and fluorescent-protein biomarkers.

Dye–cell measurements and *in vivo* experiments [55] demonstrated that a dual-cladding PCF with two zero GVD points and properly engineered dispersion profile can substantially enhance the TPL response of fluorescent protein biomarkers and neuron activity reporters. The SSFS, stabilized against laser power fluctuations in a two zero GVD point PCF, has been shown to allow the wavelength of the soliton PCF output to be accurately matched with the TPA spectrum of dye or fluorescent protein biomarker molecules, enhancing their TPL response and allowing laser damage of biotissues to be avoided.

4.8
Toward Fiber-Based Multicolor Imaging

The use of fluorescent proteins for the simultaneous detection of multitudes of neurons in a living brain is one of the most exciting recent achievements of optical technologies in neuroscience [98]. Implementation of this technique in the

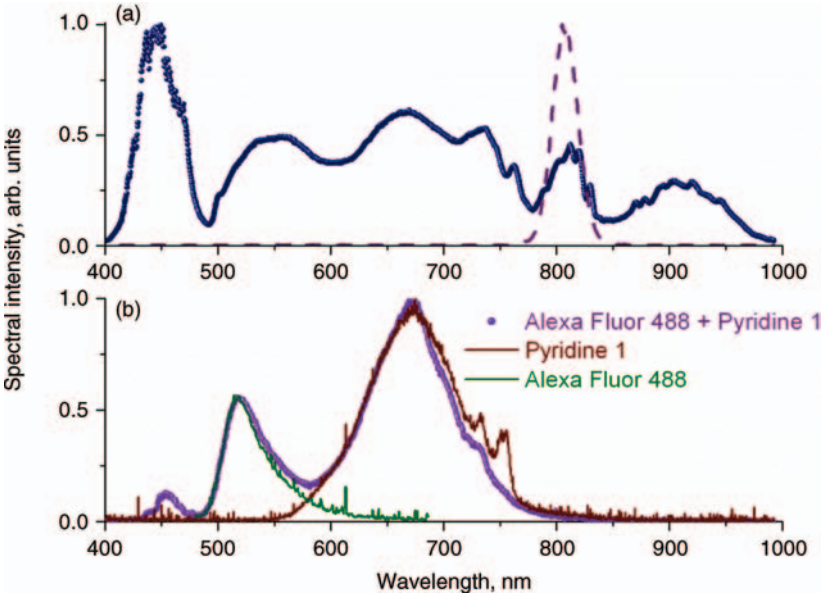

Figure 4.12 Spectrum of the mode-locked Ti:sapphire laser output (a, dashed line) and the spectrum of supercontinuum (a, filled circles) from the highly nonlinear PCF used for the simultaneous measurement of the fluorescent response of Alexa Fluor 488 and Pyridine 1 dyes in a mixture. Also shown are (b) the individual fluorescent responses of the dyes.

endoscopic mode is a challenging task and a highly promising direction for biophotonics. We show below that PCFs offer an attractive platform for the integration of fiber-optic light delivery and fluorescent response pickup with a compact fiber-format multicolor light source for a multiplex optical interrogation of a variety of fluorescent-protein reporters.

The key technology behind the integration of a multicolor light source into a fiber endoscope for neuroscience applications is supercontinuum generation [21, 22] – dramatic spectral broadening of optical waveforms induced by an involved combination of nonlinear optical effects, including self- and cross-phase modulation, pulse self-steepening, wave-mixing phenomena, and solitonic transformations of optical fields assisted by the Raman effect. In experiments [59], efficient supercontinuum generation for multicolor imaging was provided by a highly nonlinear PCF with a core diameter less than 2 μm pumped by a Ti:sapphire laser output with a typical energy of a few nanojoules, a central frequency of 810 nm, and a pulse width of 50 fs at a pulse repetition rate of 90 MHz. The spectrum of the Ti:sapphire laser output is shown by the dashed line in Figure 4.12a. The highly nonlinear PCF is optimized to transform Ti:sapphire laser pulses into a broadband supercontinuum radiation with a spectrum spanning over more than an octave from 420 to 960 nm (filled circles in Figure 4.12a), with a radiation power contained in the 400–700 nm spectral region estimated as approximately 3 mW. The supercontinuum PCF output was focused

with an objective into a beam spot with an area of about $10\,\mu m^2$. With a supercontinuum pulse width on the order of 100 fs and a pulse repetition rate of 90 MHz, such a focusing corresponds to a maximum field intensity of about $3\,GW\,cm^2$. A Keldysh-type formalism of ionization in biotissues [99] estimates the electron density induced by a 100 fs pulse with an intensity in a water-type dielectric such as $n_e \approx 10^3\,cm^{-3}$, indicating that ionization effects are negligible in this regime. The situation becomes radically different, however, in the range of intensities needed for multiphoton brain-tissue excitation and probing. In the case of two-photon excitation of EGFP with 960 nm femtosecond pulses, more than one free electron is generated per laser pulse per each photon emitted through two photon absorption-induced fluorescence (with the cross-section of TPA estimated as $\sigma_{TPA} \approx 6.5\,GM = 6.5 \times 10^{-50}\,cm^4\,s^{-1}$ per photon for wild-type GFP) for sub-TW cm^{-2} field intensities [100]. In this regime, special care should be taken in choosing the repetition rate of excitation pulses in order to prevent the accumulation of free electrons in the laser–tissue interaction region.

The supercontinuum PCF output is used to induce fluorescence in an aqueous solution of Alexa Fluor® 488 and Pyridine 1 dyes, intended to mimic a two-component mixture of fluorescent biomarkers. When this mixture of dyes was irradiated with the entire supercontinuum spectrum, a fluorescent response from both dyes was observed in the spectrum of the fluorescence signal collected with an additional standard optical fiber and studied with a spectrum analyzer. To provide individual excitation of the dyes in the solution, appropriate filters were inserted into the beam of supercontinuum in front of the cell. The spectra of the individual fluorescence responses of Alexa Fluor 488 and Pyridine 1 are shown by the solid lines in Figure 4.12b. The spectrum of the fluorescence response from the mixture of these dyes collected with a standard optical fiber is represented by the bold line in Figure 4.12b. The spectral brightness and the overall intensity of the supercontinuum output of the PCF used in our experiments were found to be ideally suited for experiments on living brain, providing a high efficiency of fluorescence response excitation and producing no photodamage of brain tissues.

Identification and Characterization of Microorganisms by Vibrational Spectroscopy

Stephan Stöckel, Angela Walter, Anja Boßecker, Susann Meisel, Valerian Ciobotă, Wilm Schumacher, Petra Rösch, and Jürgen Popp

5.1
Introduction

Vibrational spectroscopy has been successfully applied to the characterization, identification, and classification of microorganisms [1–5]. In this chapter, the applicability of vibrational spectroscopy to clinically relevant microorganisms is demonstrated.

Infrared (IR) absorption spectroscopy and Raman spectroscopy – the two main vibrational spectroscopic techniques – are based on energetic characteristics of molecular vibrations of major biopolymeric constituents within microorganisms, such as nucleic acids, proteins, lipids, and carbohydrates. Hence specific spectral information within the low-wavenumber region of the IR absorption spectra and the Raman scattering spectra can be achieved, since microorganisms exhibit complex substance compositions of varying concentrations, which depend on phylogenetic characteristics and growth conditions, for example, age, temperature, and nutrition availability [6–8]. Therefore, the fingerprint region of IR absorption and Raman spectra contains specific information, which functions as a molecular fingerprint for classification and identification. In addition to high specificity, IR absorption and Raman spectroscopy exhibit further advantages which are complementary to both techniques [9].

The investigation of microorganisms by means of IR absorption spectroscopy has been increasingly performed since the 1950s [10]. Fourier transform infrared (FTIR) spectrometers have improved the acquisition of IR absorption spectra and by introducing micro-FTIR spectroscopy – the combination of FTIR absorption spectroscopy with a microscope – spatially resolved detection of certain microcolonies was achieved [11]. FTIR absorption analyses can be performed in either transmission or reflectance mode with the transmission mode resulting in high-quality spectra provided that homogeneity and a small sample thickness are maintained. The signal intensity within the IR spectrum correlates with the polarity of particular bonds. This is extremely high for water, which consequently exhibits intense signals and masks

Handbook of Biophotonics. Vol.2: Photonics for Health Care, First Edition. Edited by Jürgen Popp, Valery V. Tuchin, Arthur Chiou, and Stefan Heinemann.

other relevant peaks within the IR absorption spectrum. This characteristic of IR absorption spectroscopy limits the application to biological samples since water is omnipresent in microorganisms, cells, and tissues.

In contrast to the IR absorption process, the scattering mechanism of Raman spectroscopy correlates with the polarizability of molecular bonds. Thus, water causes no intense signals within the fingerprint region of Raman spectra. This facilitates the analysis of microorganisms under *in vivo* conditions. Additionally, the drying step can also be omitted, which simplifies the sample preparation tremendously [12]. Micro-Raman spectroscopy, which results in better spatial resolution than micro-IR absorption spectroscopy, is capable of focusing on single bacterial cells. A preceding sample cultivation step to generate sufficient biomass for the measurements is therefore dispensable. Raman spectroscopy has been proven to be suitable for the fast and reliable investigation of microorganisms with high throughput providing real-time monitoring [13, 14].

Raman spectroscopy is limited by the weak intrinsic scattering, which has been overcome by two enhancement techniques: UV–resonance Raman (UVRR) spectroscopy and surface-enhanced Raman spectroscopy (SERS) [15, 16]. For resonance Raman spectroscopy, the excitation wavelength is shifted to an electronic absorption of the target chromophores to enhance selectively the related chromophore vibrations. An intensity increase of up to 10^6 compared with the non-resonant Raman scattering can be achieved. Hence certain biomolecules can be detected selectively and sensitively in complex biological environments even if present only in low concentrations. Within UVRR spectra excited, for example, at 244 or 257 nm, DNA and proteins are selectively enhanced, where the former functions potentially as a taxonomic marker in genotypic studies.

SERS is another approach to increase the weak Raman signal in which either silver or gold substrates are applied to accomplish an electronic enhancement in the order of 10^5–10^{14} [17].

The combination of SERS with atomic force microscopy (AFM) results in tip-enhanced Raman spectroscopy (TERS). TERS combines the high specificity of Raman spectroscopy with the high spatial resolution of AFM [16].

To illustrate the application of vibrational spectroscopy in medicine and medical-related fields, several examples especially concerning the investigation of biofilms, influence of antibiotics on microorganisms, food-borne pathogens, and epidemiological studies are introduced later in the chapter. Additionally, commonly applied sample preparation procedures are presented in the next section. Since vibrational spectroscopy of microorganisms always deals with huge databases, the necessary preprocessing and data evaluation are also discussed.

5.2
Sample Preparation Techniques

Each vibrational spectroscopic method requires its own characteristic sample preparation technique and specific sample substrates. Since both IR absorption and

Raman spectra are sensitive towards changes in environmental parameters such as different nutrition media, temperature, light, or cultivation age, these parameters should be considered for each study and implemented within databases. For bulk measurements, which require pre-cultivation, this can be achieved by rigid standardization of the cultivation conditions. For single cell measurements, all relevant parameters have to be included in the database [4].

Since the identification of bacteria was first established by means of IR absorption spectroscopy, all further preparation methods are variations of the original protocol established by Naumann [18]. Here, bacterial strains are grown on agar plates applying the so-alled four-quadrant streak pattern. For the IR measurements, a small amount of a colony is removed from the third quadrant. The bacteria are suspended in 80 µl of distilled water and an aliquot of 30 µl is then transferred to a ZnSe optical plate. Subsequently,, the bacterial suspension is dried under moderate vacuum conditions (2.5–7.5 kPa) to form a transparent film [19]. In addition to ZnSe, Si plates are also utilized as substrate for IR absorption spectroscopy [2].

The sample preparation for UVRR spectroscopy [20–22] and Raman spectroscopy with excitation wavelengths in the visible [7] and near-infrared (NIR) regions [23] is similar to that described for IR absorption spectroscopy. For Raman spectroscopic studies, either fused-silica slides or CaF_2 are utilized as substrates. Alternatively, for Raman excitation in the visible and NIR regions, bacterial smears can also be used for investigation [24, 25].

For the application of SERS, the sample preparation varies slightly. The collected bacteria are directly suspended in the corresponding colloid and not in water as described above. For the measurements, both bacteria and colloids are dried on the substrates, either CaF_2 or fused-silica slides [26, 27].

Whenever a microscope is included in the experimental setup, IR and Raman spectroscopy are additionally capable of investigating small micro-colonies [24]. For IR microscopy, a special stamping device is applied which transfers the micro-colonies from the agar plates on to the ZnSe substrate [9]. Using micro-Raman spectroscopy, it is even possible to measure the micro-colonies from the agar plates directly and the sample preparation step can therefore be omitted. Whenever micro-colonies are too small, the medium makes a contribution to the Raman spectrum, which has to be removed [24, 28].

In addition to bulk measurements, investigations of single bacterial or yeast cells can also be performed by means of micro-Raman spectroscopy. For the investigation of single bacterial cells, bacterial smears with well-separated cells are prepared [4, 25, 29]. For the localization of single bacteria inside heterogeneous sample matrices, even conventional fluorescence staining methods can be applied [30].

5.3
Statistical Analysis of Vibrational Spectroscopic Data

Spectroscopic investigations of microorganisms result in datasets which cannot be handled without statistical evaluation. First, the datasets are usually too

extensive, so an intuitive registration is impossible. Second, the chemical variations between different species or strains are so minor that the impact on the spectra cannot be seen with the naked eye. These are the two main reasons why investigations of microorganisms cannot be discussed separately from statistical analysis. Statistical analysis is able to handle huge datasets and is very sensitive to small spectral changes. Therefore, statistical methods offer immense possibilities for the evaluation of biological data but also bear the risk of interpretations induced by artifacts. Artifacts can derive from several sources, for example, sample preparation, measurement procedures, and the measurement setup. Therefore, sample preparations and measurement procedures have to be standardized and the spectrometer must be carefully calibrated. Since variances due to varying laser power intensity and varying sample thickness cannot be completely avoided, careful preprocessing has to be implemented within the data analysis. The preprocessing usually involves, for example, cosmic spike removal, baseline correction, normalization, and dimension reduction. The preprocessed dataset can then be subjected to the statistical methods, which can be divided into supervised and unsupervised methods. For supervised methods, such as artificial neural networks (ANNs), a training procedure is carried out aiming for the optimal output of the algorithm regarding the given labels. Hence, *a priori* knowledge is induced which enables the classification to be validated. Unsupervised methods, such as hierarchical cluster analysis (HCA) and principal component analysis (PCA), instead cluster the data regarding their position within the feature space and not because of their group membership. For unsupervised methods, the actual dataset is used without further information.

A crucial part of the data mining is the preprocessing step. Therefore, before the actual statistical methods are presented, the steps for preprocessing will be discussed.

One very important part is the removal of cosmic spikes. Cosmic spikes are the result of photons which are not caused by the scattering of the laser light of the sample, but derive from outer space. These signals distort the measured spectrum and change the results of the chemometric analysis, so their removal is essential. Because of their origin, the cosmic spikes are detected randomly, and as they are not correlated in either time or space they can therefore be localized by repeating the measurement were measured time or space. If, for example, two Raman spectra in at the same measuring position, a cosmic spike would increase the counts in one channel. The intensity difference between the two spectra would increase abruptly in this channel compared with all other channels of the spectra.

This property enables the algorithm to find spikes by spectra subtraction. In Figure 5.1, the result for this cosmic spike removal procedure is visualized for two Raman spectra, which are depicted in black and red. The black spectrum contains a cosmic spike and the green line is the absolute value of the difference between the black and the red spectra. The distinct green peak determines the localization of a cosmic spike within the black spectrum. With several statistical techniques, it is possible to detect the outlier (very high count) in the green spectrum and so it is possible to detect the cosmic spikes. This method is generalizable for more spectra or spectra of the same sample for different points in space.

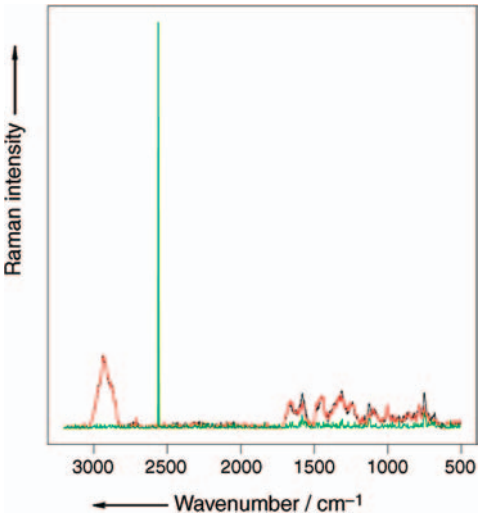

Figure 5.1 Visualization of the cosmic spike removal procedure: two Raman spectra of *P. aeruginosa* were measured at exactly the same position. The first spectrum is represented by the black line and the second by the red line. The green line is the absolute value of the difference of both spectra and clearly helps to identify the channels containing a spike.

The next important preprocessing step is background removal. Not all measured counts result from Raman scattering; other effects such as fluorescence also contribute to the spectra. Fluorescence is a much more likely process than Raman scattering and overlaps or even obscures the Raman signal. Because fluorescence changes over time and may not be constant over the whole sample, it would distort the learning procedure of the supervised method. This has an undesired impact on the outcome of the chemometric analysis and has to be minimized. Characteristically, fluorescence signals vary more slowly than the desired Raman signal over the wavenumber region. This characteristic offers the possibility to detect and remove the spectral background. There are several algorithms to accomplish this task. The most common ones are the SNIP algorithm and Lieber's algorithm [31, 32]. The SNIP algorithm is a composite of a low statistic filter and a peak clipping algorithm. The low statistic filter smoothes domains low statistics (low information) containing with a wide smoothing window. The peak clipping algorithm localizes peaks in order to remove them from the spectra. Both algorithms combined are able to estimate the background. A "background-free" spectrum is achieved by subtracting the estimated background from the measured spectrum. Exemplarily, the result of the SNIP algorithm performed on a spectrum is plotted in Figure 5.2, where the original spectrum is depicted in black, the estimated background is represented by the red line, and the green line is referred to as the preprocessed spectrum.

Lieber's algorithm is based on the assumption that the background changes much more slowly than the actual spectrum. The measured spectrum is a superposition of a

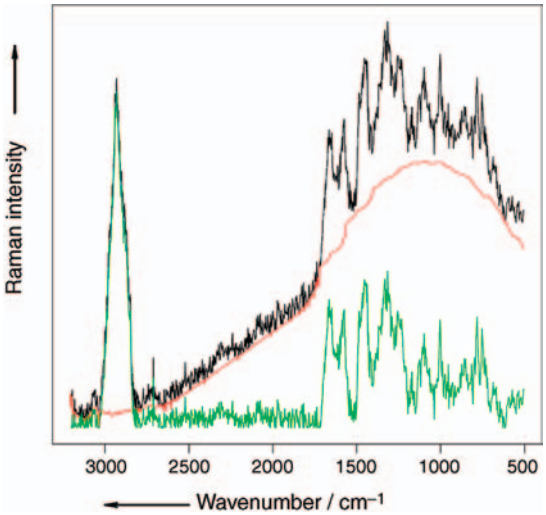

Figure 5.2 Background removal procedure: the black line is the original micro-Raman spectrum of *P. aeruginosa* and the red line shows the estimated background by the SNIP algorithm. The green line presents the difference of the original spectrum (black) and the background (red), which is then referred to as the background corrected spectrum.

rapidly changing positive spectrum and a slowly varying irrelevant background. The spectrum is fitted with a polynomial function of appropriately choser order. Every channel that is bigger than the fit is decreased to the level of the polynomial function and the algorithm starts again. This procedure is repeated until no channel is manipulated any longer.

A further preprocessing step is the normalization of the spectra. The absolute intensity values of the spectra depend on the measurement time, laser intensity, and the scattering properties of the sample. Consequently, it is important to achieve intensity-comparable spectra. There are several normalization techniques available. The first is normalization referring to one band. If all spectra share a common band, it is possible to divide the spectra by the maximum value or the area of this band. This method suffers from the presupposition that one common band is required in all spectra. Another, more general method, the so-called vector normalization, involves normalization by the area of the complete spectrum. For this method, the spectrum is divided by the area of the spectrum, which is calculated as the Euclidean distance of the spectrum to the zero spectrum (2-norm). This procedure has no further prerequisites but is not as selective as the previously mentioned procedure.

Most often the number of spectra is much smaller than or comparable to the number of spectral channels. Therefore, the dimension of the space of the spectra has to be reduced. There are several methods to reduce the dimension of the problem without losing relevant spectral information. The two most common techniques are the independent component analysis (ICA) and the PCA [33, 34]. The latter

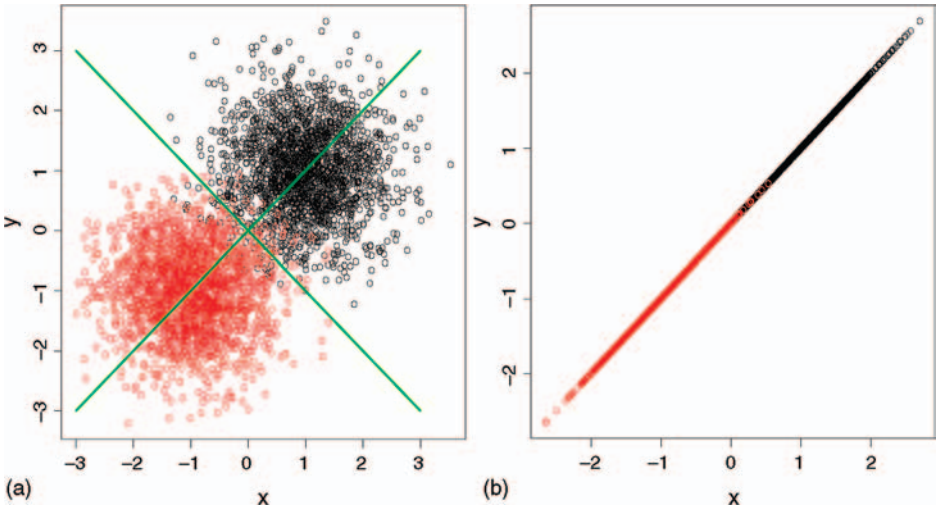

Figure 5.3 Classification of a dataset via PCA: (a) an artificial two-dimensional dataset, where the black and red points represent different classes. The green lines are the axes of the rotated feature space (PCA loadings). (b) the points in (a) projected on the first axis of the new space to achieve a group discrimination based on reduced dimensions of the dataset.

searches for a new orthogonal vector system reconstructing the spectra space. The new coordinates are sorted with falling diversity over the coordinates for the data cloud. High dimensions containing white noise can only be removed without loss of significant spectral information.

An artificial example of a PCA is shown in Figure 5.3, where Figure 5.3a contains the original positions of the elements belonging to the red and the black classes, which are depicted in a two-dimensional space. The green lines represent the new coordinate system in which the two classes are transformed to by the PCA. In Figure 5.3b, the projection of the data points to the first axis of the new space is shown and the dataset is separated into the red and the black groups. A PCA allows classification based on dimensionally reduced data. The ICA works similarly with the difference that no assumption of orthogonality between the new coordinates is required.

The reduction of the dimension has several advantages. First, it decreases the computational power needed, second, it reduces the white noise, and finally, it avoids overfitting. Overfitting is one of the major problems in chemometrics. The learning algorithms of the classifier are very powerful and are capable of learning ever white noise, which increases the accuracy of the classifiers on the training set but decreases the accuracy on unknown data. This problem is called overfitting.

The evaluation of extended datasets containing spectra with high similarities, which cannot be differentiated by the naked eye, is usually accomplished by statistical analysis. One of the most commonly applied statistics is unsupervised HCA [35]. The dataset is analyzed without any *a priori* information. The grouping is based on the

similarities of the spectra – the spectral distances. The spectral distance determines how the similarities of two elements (spectra) are calculated and depends on the applied distance measurements. Two examples are the Euclidian and Pearson correlation coefficient distance measurements. The Euclidian distance measurement refers to the geometric distance, which can corresponds to the area of the difference spectrum. Two different spectra result in a difference spectrum with intense signals and a large area below the curve. Two similar spectra create a difference spectrum with minimal spectral features and a small area below the curve. The Pearson correlation coefficient is the multiplication of two preprocessed spectra. The internal preprocessing includes the subtraction of a spectral mean and the normalization within the spectrum. This preprocessing results in spectra that contain minimized element values. By multiplying those spectral intensities, only values between 1 and −1 can be obtained. Whenever two spectra are very similar, the size of the Pearson coefficient, which is also described as degree of dissimilarities, is close to 1.

After determining the spectral distances, a clustering algorithm follows to depict the results in a tree-like structure called a dendrogram. The *x*-axis of a dendrogram represents the heterogeneity between the spectra and visualizes the spectral distances of all elements from each other by the characteristic of the dendrogram paths. The length of a dendrogram path along the *x*-axis symbolizes the heterogeneity of the connected spectra. The *y*-axis of the dendrogram does not contain any further relevant information apart from the sectioning of the cluster. The most similar spectra within a dataset are connected by short paths along the *x*-axis, which represent low heterogeneity and therefore short spectral distances. Spectra of low heterogeneity are connected via a node and are collected in subclusters. The subclusters are combined in higher level clusters via longer paths along the *x*-axis which represent higher spectral heterogeneity. The intra-cluster heterogeneity is therefore lower than the inter-cluster heterogeneity. The clusters and subclusters contain spectra of certain spectral distances which are determined by a pure mathematical procedure and based on spectral features. That does not necessarily result in classes, which can be compared with the results of microbiological methods such as phenotypic and genotypic identification. Usually the spectral distance does not exhibit "pure" genotypic or phenotypic features; more often a combination of both is expected because the complete microbes with all cell components and metabolites are measured.

The HCA is an attractive analysis method in biological and biomedical applications, since dendrograms, representing phylogenetic trees, are commonly used in "biological-related" sciences. Phylogenetic trees represent the degree of relationship between bacterial strains, species, genera, and other compared classes. The presentation of HCA in the form of a dendrogram offers easily accessible and intuitive comprehension of the results for fast visualization and interpretation. However, besides the advantages of the HCA, an objective application is challenging. The existing risks are outlined in the following after the theoretical background of supervised chemometric methods is presented.

There are numerous supervised classifiers and some of them exhibit very interesting and unique properties. Here only one will be discussed exemplarily. We

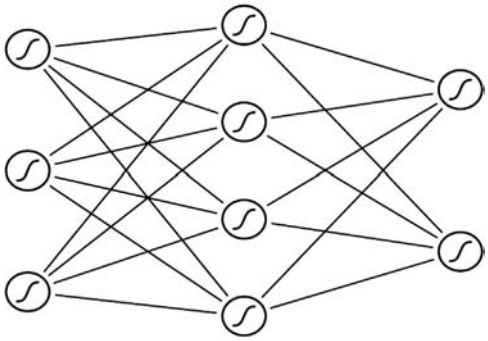

Figure 5.4 Schematic diagram of a feed-forward ANN: the input becomes first mapped to the excitation by the activation function, depicted by the line in the neurons. Subsequently, the excitation becomes mapped weighted by the weights of every connection and the procedure starts again. In this case, it is done twice. The output of the last layer is the output of the whole net.

chose the ANN, because it is one of the strongest classifiers and there are some examples of its application present in the literature [36].

ANNs comprise supervised and unsupervised statistical methods, depending on the used topology of the applied neural network. Most commonly feed-forward neural networks, a supervised technique, are applied. An example is given in Figure 5.4. The ANN is in some aspects modeled after the human brain. ANNs are basically a net of neurons with weighted connections between them. Every neuron contains a function, the so called activation function, which determines. At one step every, neuron collects the excitations of all neurons which are connected to it and sums over the neurons output for a given input weighted with the weights of every connection. The neuron reacts to this weighted sum with excitation or input disexcitation, depending on the activation function. Which activation function is used for in particular depends on the applied net.

For feed-forward nets, several layers exist and every neuron of one layer is connected to every neuron of the next layer. The excitation is propagated forwards layer by layer, giving rise to the net's name. It is obvious that the critical point of the ANNs is the right choice of the connections. Finding the best connections is called training, where several methods exist. The most prominent method for feed-forward nets is the so-called back-propagation algorithm. A systematic introduction to this field of research was given by Rojas and Feldman [36].

To emphasize the different advantages of unsupervised HCA and supervised ANNs, two examples are discussed in the following, focusing on the statistical approach.

Maquelin *et al*. presented results for the identification of pathogenic microorganisms by employing statistical analysis [24]. Figure 5.5a shows Raman spectra of clinically relevant bacterial strains: (a) *Staphylococcus aureus* ATCC 29213, (b) *Staphylococcus aureus* UHR 28624, (c) *Staphylococcus epidermidis* UHR 29489, (d) *Escherichia*

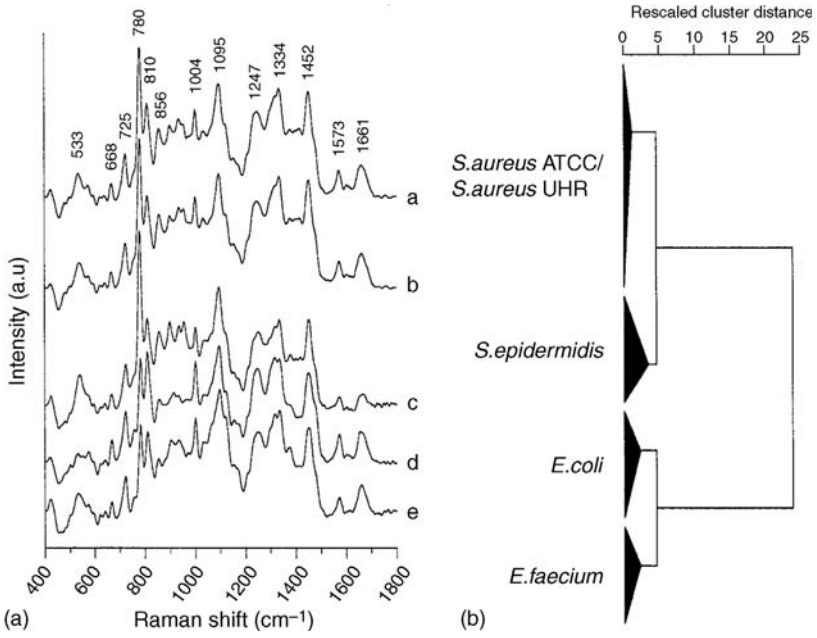

Figure 5.5 (a) Representative micro-Raman spectra of (trace a) *S. aureus* ATCC 29213, (trace b) *S. aureus* UHR 28624, (trace c) *S. epidermidis* UHR 29489, (trace d) *E. coli* ATCC 25922, and (trace e) *E. faecium* BM 4147. (b) Dendrogram as a result of the HCA performed on the principal component scores of the vector-corrected Raman spectra [24].

coli ATCC 25922, and (e) *Enterococcus faecium* BM 4147. The bacterial spectra were measured by micro-Raman spectroscopy directly from the agar plate after a cultivation time of 6 h. The spectra were recorded with an excitation wavelength of 830 nm. The Raman spectra of *Staphylococcus* spp. (Figure 5.5a–c) exhibit an intense band at 780 cm^{-1} assigned to uracil, whereas the representative spectrum of *E. coli* and *E. faecium* (Figure 5.5d and e) feature a more intense Raman signal at 1004 cm^{-1} originating from the phenylalanine vibration. With the application of an HCA, the classification of the spectra was successfully carried out and is depicted as a dendrogram in Figure 5.5b. The dendrogram is divided into two main branches: one cluster contains all *Staphylococcus* species and the other cluster combines the *E. coli* strain and the *E. faecium* strain, which are clearly divided into two clusters on a lower level. Within the *Staphylococcus* cluster, a distinct division between the *Staphylococcus* species *S. aureus* and *S. epidermidis* is obtained, but the two *S. aureus* strains cannot be differentiated and are unified in one subcluster. In the case discussed here, the HCA is capable of differentiating bacterial genera and *Staphylococcus* spp. by means of their Raman spectra, but fails to distinguish between the two *S. aureus* strains.

The phylogenetic interpretation of a dendrogram resulting from statistical analysis is limited. It seems to be certain that the *Staphylococcus* spp., which are combined in

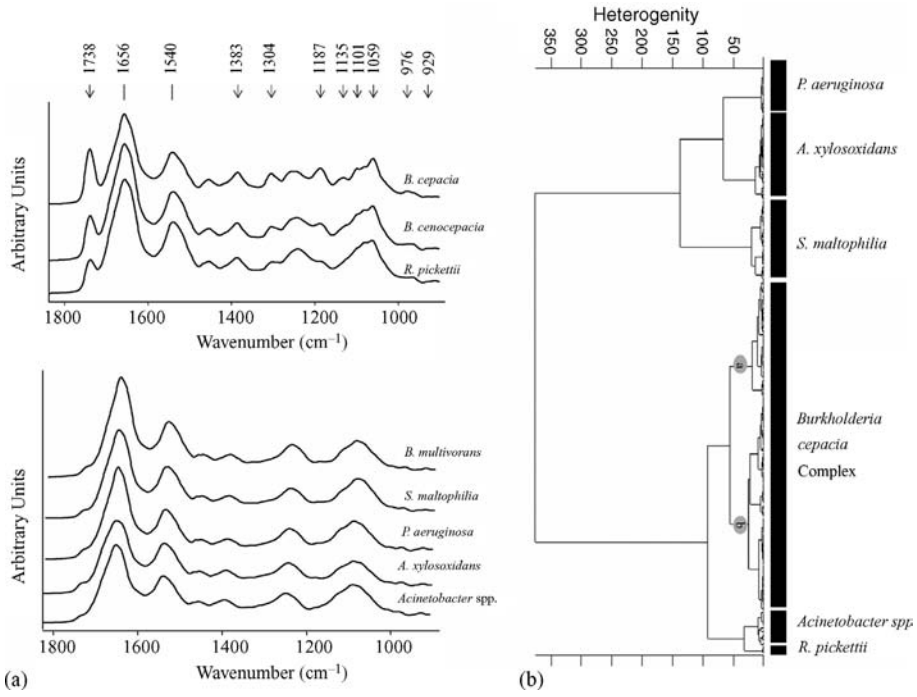

Figure 5.6 (a) IR spectra of the bacterial groups which were isolated from CF patients. (b) Dendrogram of the HCA clustering of the first derivative of the spectra within three spectral windows [38].

one main cluster, are most closely related to each other. It is also reasonable to interpret the dendrogram structure by concluding that the heterogeneity between the two main clusters is higher compared to each intra-cluster heterogeneity. However, it cannot be argued that *S. epidermidis* is genetically more similar to the closer neighbor *E. coli* than to *E. faecium* from the dendrogram, since the clusters can be reflected at their nodes, resulting in opposite relations.

Providing the phenotypic variance or heterogeneity of the culture condition is one of the challenges for the application of statistics such as HCA. Willemse-Erix *et al.* applied hierarchical cluster analysis to a Raman dataset of 785 nm excitation to differentiate between five isolates of *S. aureus* [37]. To ensure that the classification of the five isolates is based on strain specificities and not on differing growth behavior, the influence of growth was included by sampling at 18, 20, 22, and 24 h after incubation. Again, the application of the HCA is suitable to a certain extent, since two isolates could not be separated from each other.

The second example is a study by Bosch *et al.* to differentiate bacterial groups isolated from cystic fibrosis (CF) patients: *Pseudomonas aeruginosa*, *Ralstonia pickettii*, *Achromobacter xylosoxidans*, *Actinobacter* spp., *Stenotrophomonas maltophilia*, and

Burkholderia cepacia complex (BCC) by means of IR spectroscopy in combination with statistical analysis [38]. At first the sample preparation was carefully standardized and the HCA and ANN methods were applied. Figure 5.6 shows (a) the IR spectra and (b) the dendrogram resulting from the HCA. The dendrogram shows clearly six defined groups representing the six bacterial genera. However, a clear distinction of the different BCC strains could not be achieved, but a separation into two groups appeared. One subcluster contained the reference strains, whereas the second subcluster combined the clinical isolates. Although several approaches were implemented to investigate the BCC bacteria, all resulted in division of the clinical and reference isolates. The HCA model discriminated successfully between the six groups (*P. aeruginosa*, *R. pickettii*, *A. xylosoxidans*, *Actinobacter* spp., *S. maltophilia*, and BCC bacteria) but failed to differentiate between the BCC species. The presented misidentifications are considered to be caused by the insufficient phenotypic variance presented by the measured strains within the bacterial species.

The spectral data were also subjected to a two-level ANN model. Both ANN levels were independent and had different tasks that demanded individual preprocessing steps and net characteristics. The first level was applied to identify whether the spectrum originated from one of the six Gram-negative groups. The second level was switched on whenever the bacterium was identified as belonging to the BCC group to continue the identification on the species level. The complete dataset contained around 2000 spectra comprising clinical isolates and reference strains. The results of the ANN model were verified twice, by internal and external validation. For this, the complete dataset was divided into a training dataset and a test dataset. The model was exclusively trained by the training dataset and the internal validation was performed by removing spectra randomly and testing for correct identification, which resulted in 100% correct identification. The external validation was carried out by a completely independent training dataset containing spectra of clinical isolates. The combined ANN model was able to classify correctly 98.1% at the genus level and 93.8% at the BCC species level. Hence the ANN was able to differentiate on BCC species level, which could not be accomplished by the unsupervised HCA method described earlier.

5.4 Monitoring of Biofilms

The self-organization of various microorganisms in biofilms leads, especially in the field of healthcare, to serious problems. The potential of such well-organized organisms to cause infections in patients with indwelling medical devices increases in proportion to their resistance to antimicrobial agents. The process of biofilm formation takes place on either living surfaces such as tooth enamel, heart valves, the lung, and middle ear, or on inanimate surfaces such as catheters, any kind of artificial prosthesis, and intrauterine devices. Biofilm-associated microorganisms commonly isolated from selected indwelling medical devices are, for example, *Candida albicans*, *S. aureus*, *P. aeruginosa* and *E. coli* [39]. This section introduces the examination of

biofilm models by different vibrational spectroscopic techniques, which offer a beneficial approach in medical microbiology.

The multifarious aggregations of different groups of attached microbes with their excretory products have different phenotypes and antibiotic susceptibility compared with their planktonic (suspended) organisms [40]. The nondestructive (i.e., leaving the sample intact during the analysis) and direct analysis of such a multilateral matrix is essential to understand the role of biofilms in infections. Fingerprint spectra display the chemical composition of cells and allow the rapid characterization of microbial strains. The application of vibrational spectroscopic techniques is suitable for fundamental biofilm research and also for the monitoring of biofilm formation [41]. Of these techniques, IR and Raman spectroscopy are complementary concerning spectral information [9].

Investigation of biofilms that develop directly on IR-transparent materials is possible in the transmission mode. Nevertheless, this sample preparation is difficult to standardize and to integrate into a routine protocol. It also limits the possibility of analyzing intact larger samples and the utilization of thick or opaque surfaces. Recent advances in detector sensitivity allow the use of reflectance micro-FTIR spectroscopy for the analysis of raw materials without the need for previous treatment. The penetration depth of the IR beam ranges from 2 to 5 μm. Ojeda *et al.* showed that the reflectance mode is a suitable technique for studying the functional groups in biofilms in opaque or thick samples, such as stainless steel, without sample preparation [42]. The characterization of the biofilm formation of *Aquabacterium commune* was carried out by applying reflectance micro-FTIR spectroscopy. Sterile stainless-steel slides were left on the culture medium with *A. commune* to be colonized at pH 7 for 100 h. Figure 5.7 shows an optical image of stainless steel and an *A. commune* biofilm. The false color images (b–f) of the scanned sample depict the location of different molecules. Thus, the reflectance micro-FTIR analysis showed reliable results for the location of different functional groups in *A. commune* biofilms on stainless steel. According to "free" (not attached) bacteria from planktonic suspension, the carboxylate and phosphoryl groups in the biofilm could play an important role in the adhesion to stainless steel [42].

Attenuated total reflection (ATR) offers a further possibility for FTIR techniques for the observation of biofilms formed directly on the surface of an ATR crystal. Investigations can be carried out without sample preparation and spectra can be obtained nondestructively, *in situ*, and in real time. The ATR crystal is the so-called internal reflection element (IRE). It has a higher refractive index than the sample or the surrounding medium. The beam penetrates through the interface into the sample, which is adjacent to the crystal surface. If the sample absorbs part of the radiation, the reflection will be attenuated. The penetration depth of the light depends on the wavelength of the light, the incident angle, and the refractive indices of the sample and crystal [43]. Immersion of the IRE in a liquid allows the observation of the subsequent colonization of the surface by bacteria and other microorganisms. With this setup, biofilm studies can be carried out in a flow-through cell, where a biofilm grows directly on the crystal surface. Observation of biofilm formation over many days can thus be performed with such an experiment by recording absorption

spectra, which depend on the chemical nature of the cells attached to the crystal surface, which was explored by Delille *et al.* [43]. Here *Pseudomonas fluorescens* bacteria were pumped as a suspension in Luria–Bertani (LB) medium through the cell and the appropriate biofilm was formed on a germanium crystal. Figure 5.8 illustrates the accumulation of biomass on the IRE surface depicted by the acquired spectra over this period and the microscope image shows an increase in the IRE surface coverage by bacteria. After the initial bacterial attachment and biofilm detachment, the authors observed regrowth kinetics depending on the dissolved organic carbon level determined from changes in the areas of bands associated with proteins and polysaccharides [43].

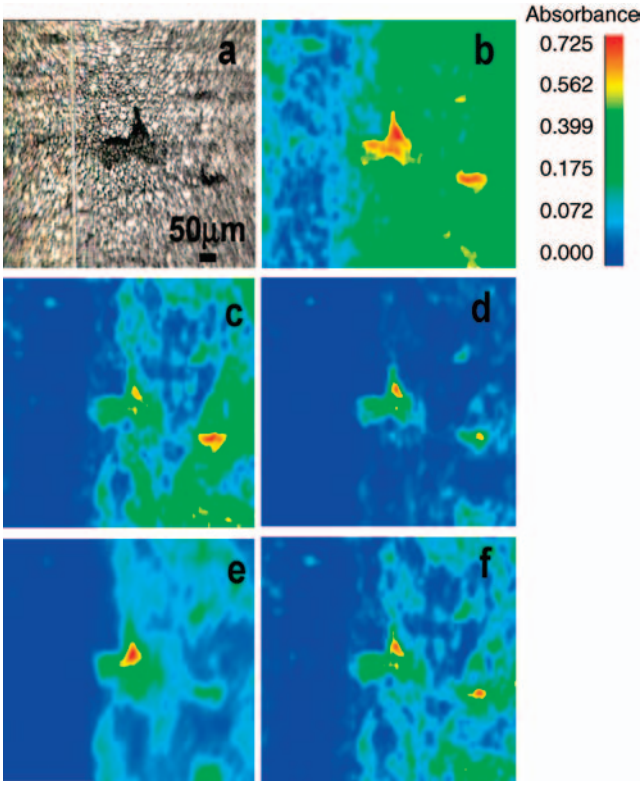

Figure 5.7 (a) Optical image of stainless steel and *Aquabacterium commune* biofilm. (b) Full-range false color image (4000–700 cm^{-1}). (c) Location of molecules with intrinsic absorption bands of amides (N—H stretching at 3550–3200, amide I at 1690, and amide II at 1540 cm^{-1}). (d) Location of molecules with absorption bands intrinsic of C—H, C=O, and C—O. (e) Location of molecules with absorption bands intrinsic of phosphorylated proteins, polyphosphates, and phosphodiester groups (1270–1220, 1100–1070, 1000–950 cm^{-1}). (f) Location of molecules with absorption bands intrinsic of hydroxyl groups (3600–3200 cm^{-1}) [42].

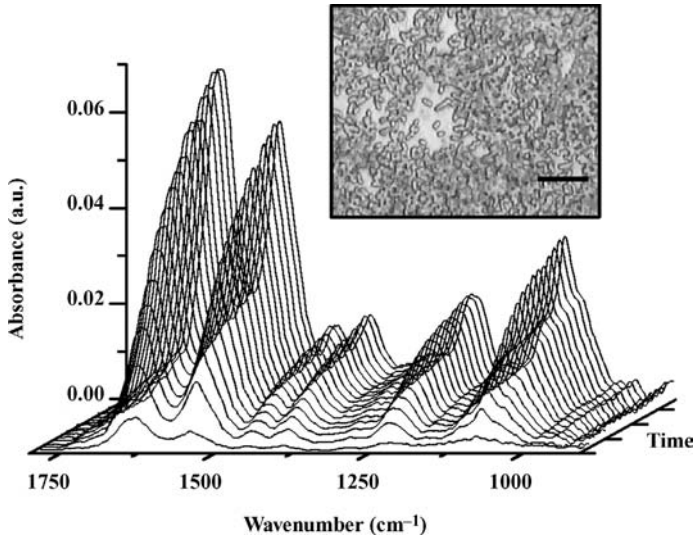

Figure 5.8 Temporal evolution of ATR–FTIR spectra during initial attachment of *P. fluorescens* to the germanium IR [43].

In fact, various groups were able to investigate the development of biofilms by means of IR absorption spectroscopy correlated with the corresponding changes in carbohydrate and protein expression or changes in persistence [42, 43]. This analytic approach could also be used to address the role of individual virulence factors, resistance against antimicrobial agents, and shear stress in the development and adhesion of pathogens grown on surfaces.

Complementary to IR absorption, a Raman "fingerprint" of the sample can be measured. This facilitates an additional analysis of hydrated and living bacterial biofilms under *in vitro* conditions. Therefore, Raman spectroscopy proved to be a suitable technique to investigate the effects of various additives and environmental factors on biofilm growth. The excitation with visible light (e.g., 532 nm) allows the use of common standard optics. Under these conditions, the sample can be visualized by a bright field image and spectra can be processed at different locations within the biofilm. Additionally, it is possible to record vertical and horizontal maps to show the spatial distribution of molecular or cellular species. The nondestructive character of Raman spectroscopy permits the observation of biofilm development and its spatial heterogeneities over a period of time. Raman spectra are furthermore considered to be more specific than IR spectra as they generate sharper bands. The spatial distribution of the biofilm biomass, for example, was analyzed by means of micro-Raman spectroscopy. The chemical mapping was successfully employed to probe directly the water and the biomass distribution within biofilms after only minimal sample treatment. The authors suggested that with this method, the penetration of solutes in biofilms can be determined [44, 45].

The composition of different microorganisms and other substances (minerals) inside an intact multispecies biofilm was characterized by Pätzold *et al.* [46]. The analyses were based on the identification of specific bands in correlation with reference materials. Ivleva *et al.* demonstrated that Raman spectroscopy can correlate various structural appearances within the biofilm to variations of its chemical composition and provide detailed chemical information about the different constituents in this complex matrix [47].

Biofilm analysis by means of SERS is characterized by a higher number of distinguishable peaks in the spectra, suggesting a promising potential of SERS to probe components of the biofilm matrix even at low concentrations. Ivleva *et al.* reported on reproducible *in situ* SERS analysis of biofilm. A heterotrophic biofilm was cultivated on a glass slide and immersed in a silver colloid suspension. SERS spectra from different constituents of multispecies biofilm were recorded [48].

The application of TERS to alginates for analyzing nanostructures in biofilm was reported by Schmid *et al.* [49]. A problem with the interpretation of TERS spectra are contaminated tips since they have a significant influence on the spectrum in contrast to weak analyte signals. An appropriate background subtraction and a careful selection of reference materials are indispensable.

5.5
Role of Vibrational Spectroscopy in Epidemiological Studies

In this section, an overview is given of recent developments in optical typing methods, namely IR and Raman spectroscopy. Here, vibrational spectroscopic methods are successfully applied as identification modalities in clinical environments. This outline mainly comprises investigations on clinical isolates of medically relevant microorganisms to validate the discriminatory power of the spectroscopic approaches and further to perform epidemiological analysis.

While micro-Raman spectroscopic identification at the single cell level allows direct presumptive analysis of isolates, in most of the publications cited here the investigated strains were precultured prior to the actual measurement. Thus, not only enough biomass is generated to perform measurements on bulk material and micro-colonies, but also possible background interferences due to the matrices, from which the microorganisms were isolated, are minimized. Although the mandatory culturing steps contradict the time efficiency of the spectroscopic methods to a certain extent, the achievable gain in time is still significant compared to the most preferred genotyping techniques up to now. In fact, in the case of epidemiological surveillance of microorganisms, pulsed field gel electrophoresis (PFGE) and multi-locus sequence typing (MLST) are mostly applied in retrospective analysis of outbreak situations due to their long turnaround times (48–72 h when starting from a pure culture) and low sample throughput.

Vibrational spectroscopy meets the requirements for a high-throughput, fast, and reliable typing method to provide real-time monitoring of the spread of bacterial

isolates, as demonstrated in several publications. The common strategy in those studies was to classify and consequently identify medically relevant microorganisms originating from clinical isolates by means of vibrational spectroscopic measurements combined with chemometric analyses. The identification results were accomplished by comparing them with typing results obtained via common established daily routine techniques, including DNA sequencing or PFGE [50].

For example, Willemse-Erix *et al.* [37] employed a custom-built Raman setup with 785 nm laser excitation to validate spectroscopic typing using the methicillin-sensitive *Staphylococcus aureus* (MSSA) and methicillin-resistant *Staphylococcus aureus* (MRSA) isolates of four different collections (118 isolates). MRSA is known to be a leading cause of hospital-acquired infections and therefore a candidate for rapid epidemiological surveillance in clinics. The reproducibility of Raman spectroscopy was tested and also its discriminatory power in comparison with established typing techniques, such as PFGE and *spa* typing. Furthermore, the concordance of the Raman spectroscopic results with epidemiological data was checked. Thus, 20 well-characterized HRSA isolates were classified by performing an HCA on their Raman spectra. Isolates with different PFGE patterns were distinguished by using Raman spectroscopy, whereas PFGE-identical isolates were not. In another retrospective study, a collection of 78 MRSA isolates, retrieved from patients and hospital staff members collected in a Dutch hospital during five outbreaks in 2002, were evaluated by two PFGE analyses and Raman spectroscopy. Raman spectroscopy differentiated 72 out of 78 isolates with an accuracy of 92–95% identical with the two PFGE results and identified the majority of unique PFGE isolates as unique Raman types. In total, only three discrepancies were documented between the three typing methods – the HCA clustering of the Raman spectra thus attained good agreement with the epidemiological data [37]. In the same study, Willemse-Erix *et al.* collected four MRSA isolates (one from an index patient and three from a colonized staff member) during a contact screening at a Dutch hospital [37]. Based on the Raman spectroscopic data, it was possible to confirm within 1 day that no transmission between the index patient and the staff member occurred. Four days later, PFGE results reaffirmed these results. This significant gain of time is based upon the protocol employed: starting from positive microbial cultures, only 45 min are needed to prepare 24 isolates for Raman measurement, which usually takes 10 s–1 min per sample or 1 s per spectrum. This rapidity of signal collection is a crucial requirement for preliminary real-time identification of clinical isolates and is achieved due to constant improvement of the Raman equipment, which entails both simplification and improved sensitivity and robustness of the spectrometer combined with a powerful laser (220 mW with 785 nm excitation).

One drawback of non-resonant Raman spectroscopy is the low probability of Raman scattering, with typically only 1 in 10^6 photons Raman scattered, which leads to rather long Raman spectra collection times. An alternative to the classical non-resonant Raman scattering is UVRR scattering, which was described earlier.

An application of this resonant Raman technique in the field of identifying pathogenic organisms is in the discrimination of urinary tract infection (UTI) bacteria [21]. The typical causal agents of UTI are Enterobacteriaceae, especially

E. coli and *Klebsiella* spp. in addition to Gram-positive enterococci [51]. Twenty well-characterized and identified clinical bacterial isolates from patients with UTI from a hospital were obtained belonging to *E. coli*, *Klebsiella oxytoca*, *Klebsiella pneumoniae*, *Enterococcus* spp., and *Proteus mirabilis*. All isolates were cultured for 12 h and were analyzed by means of UVRR spectroscopy with 0.1 mW laser power on the sample and a 120 s integration time for a single spectrum of the bacterial bulk material. This rather long accumulation time despite the aforementioned enhancement mechanism is due to the photochemical destruction or "burning effects" in the sampled microorganisms because of the high energetic nature of UV photons. The applicable laser power on the samples and thus the minimal integration time are therefore limited for the sake of the spectral quality.

The measured and preprocessed resonance Raman spectra of the UTI bacteria were analyzed chemometrically with respect to similarities among them with numerous clustering algorithms. Each of the four classes/genera analyzed was correctly resolved into four separate groups, which leads to the assumption that discrimination between these main causal agents of UCI was achieved. However, because only four *a priori* groups were fed into the cluster algorithms, the resolution at strain level was still low.

Research has also been carried out recently on the spectroscopic identification of nonfermenting Gram-negative rods isolated from sputum samples of cystic fibrosis (CF) patients. Although the major causes of the morbidity and mortality in patients with CF are chronic lung infections caused by *P. aeruginosa*, *S. aureus*, and *Haemophilus influenzae*, an increased fraction of CF patients has been colonized by other bacilli, such as members of the Burkholderia cepacia complex (BCC) [52]. Because of their high transmissibility and multiple antibiotic resistances, BCC infections are difficult to treat once a patient has become infected. Currently, the BCC comprises a group of genetically distinct but phenotypically similar bacteria and contains 17 recognized species. Despite the importance of the rapid and accurate identification of this group, only a few studies using vibrational spectroscopy have been published.

In 2008, Bosch *et al.* employed FTIR spectroscopy to identify bacteria isolated from sputum samples of CF patients [38], including *P. aeruginosa*, *R. pickettii*, *A. xylosoxidans*, *Actinobacter* spp., *S. maltophilia* and BCC bacteria in combination with HCA and ANNs. From 150 CF patients attending three different hospitals in Argentina, 169 clinical isolates of nonfermenting Gram-negative bacteria were studied in combination with 15 reference strains. The clinical isolates were characterized according to guidelines for clinical microbiology practices for respiratory tract specimens from CF patients. In particular, BCC bacteria were further identified by *recA*-based PCR followed by restricted fragment length polymorphism (RFLP), and 165 rRNA gene sequencing was performed on some bacterial species belonging to genera different from BCC. FTIR spectra have been acquired of all strains to establish a database containing 2000 IR spectra, which were fed into the statistical algorithms. Bosch *et al.* [38] managed to discriminate successfully between the six groups with the help of an HCA model. However, differentiation within the BCC was not accomplished [38]. The two-level ANN model proved to be superior to the HCA in this

respect, since a differentiation at the BCC species level was eventually achieved with a classification rate of 93.8%.

However, not only chemical modifications of the bacteria due to cultivation, sampling, and measurement parameters can be a limiting factor for some of the spectroscopic typing methods, which probe the complete biochemical makeup of the microorganisms: chemical modifications resulting from adaptation strategies to the CF lung stress environment, for example, aggressive and prolonged antibiotic therapy, can also affect the discriminatory power. The influence of the phenotypic variability of BCC isolates, for example caused by CF therapeutic procedures, on IR spectroscopy-based models for species and ribopattern discrimination was studied by Coutinho *et al.* [53]. A collection of 185 BCC isolates, representing four different BCC species, from respiratory secretions of 35 patients with CF from a Portuguese hospital, gathered from January 1995 to March 2006, was analyzed. All were previously classified by established molecular methods at species and ribopattern levels. On the basis of discriminant partial least-squares (DPLS) calculations performed on the FTIR absorption spectra, misclassification error rates at the ribopattern level of 2–8% and at the species level of 10% for the hospital isolates and 32% for the reference strains were achieved. This result indicates that the model calibrated with the hospital strains cannot be used to predict the reference strains. Whereas the latter originated from different sources, the isolates obtained in the hospital were sequential isolates from a limited number of different patients, several of them exhibiting the same ribopattern. This demonstrates the restricted generalization ability of a model calibrated with only a limited number of samples. Also, an important degree of variability for isolates belonging to the same species, same ribopattern, and collected from the same patient during prolonged colonization was registered. This may, on the other hand, indicate the possibility of revealing changes in the biochemical composition of the microorganisms due to adaptation strategies to the CF lung stressing environment by means of FTIR spectroscopy.

Another widespread cause of hospital-acquired sepsis is *Candida* spp. This serious noscomial pathogen strikes preferentially in surgical services, and especially in non-neutropenic critically ill patients in intensive care units (ICUs). *Candida*-associated infections exhibit high mortality rates of up to 46–75% and they represent the fourth most commonly recovered organisms from blood cultures [54]. Hence early and systematic antifungal therapy has a tremendously positive effect on the outcome of patients with invasive candidiasis in respect of morbidity and (attributable) mortality. Fluconazole followed by amphotericin B is often the first choice for prophylactic or empirical antifungal therapy. Unfortunately, there exist a number of fluconazole-resistant non-*albicans Candida* spp. and also the fluconazole-resistant *Candida albicans*. A prompt identification of significant isolates to the species, or even strain level, is therefore imperative to be able to decide which initial regimen for prompt antifungal therapy is appropriate, since susceptibility data for isolates may not be available immediately. However, at present the conventional yeast identification is based on an extensive series of biochemical assays, following an obligatory culture period sufficient to obtain a biomass of 10^6–10^8 cells and thus leading to up to 4 days

before a definitive report reaches the clinician. Vibrational spectroscopy might render assistance in this context: a clinical study was reported by Ibelings *et al.*, where Raman spectra of microcolonies 10–100 μm in diameter were obtained after only a 6 h incubation period [55]. Upon arrival in the microbiology laboratory, each specimen was divided into two groups, with one part used for conventional microbiological identification (via a commercially available yeast identification panel with a turnaround time of 48–96 h), and the other for identification by Raman microspectroscopy (within 1 day). A collection of 93 reference *Candida* strains, comprising 10 different *Candida* spp., backed up the Raman spectroscopy-based identification of 88 pertioneal specimens obtained from peritonitis patients from a surgical ICU and a general surgical ward. Spectra obtained from patient specimens were analyzed with a sequential identification model based on six linear discriminant models (LDAs). In three of the 29 *Candida*-positive cases, a difference between the microbiological and Raman identifications occurred, giving a prediction accuracy of 90% by Raman spectroscopy, if the conventional microbiological method is interpreted as the reference method. In a similar study by Maquelin *et al.*, an accuracy of even 97–100% for the Raman identification of *Candida* spp. was obtained with the same method but including 42 reference strains [56].

Similar approaches concerning epidemiological investigations of *Candida* have also been performed with FTIR spectroscopy. Essendoubi *et al*. studied 29 *Candida glabrata* isolates from patients within a two-step procedure [57], as described in the following. First, an internal validation phase with 16 strains was carried out to determine the statistical parameters which result in the highest discriminatory power. A genotypic technique based on randomly amplified polymorphic DNA analysis (RAPD) confirmed the outcomes of this validation step. Second, the 13 remaining clinical strains of *C. glabrata*, isolated from multiple sites in four ICU patients, were tested by FTIR and HCA in order to eliminate the possibility of inter-human infection by comparing the spectral signatures of all patient strains. In the end, six spectral groups (four from the patients and two from reference strains) led to the conclusion that no cross-infection had occurred. Again, the saving of time compared with conventional approaches is striking, since the FTIR spectra were recorded after only 24 h of cultivation of the isolates. Also, a decrease in growth time to 10–18 h seems within reach to gain enough microcolonies for FTIR microspectroscopy.

Recent studies regarding spectroscopic species identification in a clinical diagnostic setting were also focused on cultured mycobacteria. The genus *Mycobacterium* comprises more than 80 species, some of which are potentially pathogenic to humans and animals. Whereas the classically defined lung tuberculosis is predominantly caused by *M. tuberculosis* complex (TB), an increasing number of incidents of pulmonary disease are caused by nontuberculous *Mycobacteria* (NTM) [58, 59]. The clinical features of the NTM-derived disease are in some cases indistinguishable from those of tuberculosis. To stipulate an appropriate therapy and to offer comprehensive infection control, a timely and correct discrimination between TB and NTM and also an identification of causative NTM at the species and strain levels is

mandatory. A large number of commercial techniques are available for a limited number of frequently encountered species, which are rapid but expensive. For rarely emerging *Mycobacterium* isolates, DNA sequencing of the 16S rRNA gene is usually performed in reference laboratories. However, the implementation of these techniques in peripheral laboratories has various drawbacks, such as high cost, complexity, and the absence of clear, unambiguous interpretations and peer-reviewed databases. The spectroscopic data for TB and NTM isolates suggest so far that vibrational spectroscopy may provide a practical solution to identify unknown isolates rapidly in routine clinical–microbiological laboratories.

Buijtels *et al*. presented the first study on the use of Raman spectroscopy for the identification of *M*. *tuberculosis* and the most frequently encountered NTM species with the objective of assessing the reproducibility of the Raman spectra of inactivated *Mycobacteria* versus viable *Mycobacteria* and to compare the performance of this method with that of 16S rRNA sequencing [60]. The pilot inactivation study in Buijtels *et al.*'s publication on 12 level two NTM species revealed that heat inactivation is superior to formalin inactivation. Raman spectra of heat-inactivated samples showed the highest resemblance to those of viable cells. Heat inactivation did not decrease either the classification rate or the intra-species reproducibility substantially. In a subsequent identification study, a collection of 63 *Mycobacterium* strains, comprising eight different *Mycobacterium* species, was identified species-wise first with 16S rRNA sequencing before the Raman measurements were performed. The main differences in the Raman spectra of the eight *Mycobacterium* species were found in the intensity of peaks due to carotenoid vibrations. The similarity between the Raman spectra of the samples was calculated using a squared Pearson correlation coefficient (R^2). Species identification was performed via a leave-one-out approach, by which the R^2 value of one sample relative to all the other measured samples was calculated. The predicted species of a sample was assumed to be identical with the species of the sample with which the highest correlation occurred. This leave-one-out approach simulated the situation in a diagnostic setting where a new measurement is compared with an existing database.

In this study, the classification results of Raman spectroscopy versus 16S rRNA sequencing predicted 60 of 63 strains correctly at the species level, which represents an overall classification rate of 95.2%. These outcomes were achieved within 3 h after a positive signal from the automated culture system. For all strains, the differentiation between *M*. *tuberculosis* and NTM was correct. Since the model in this work was based on only a limited number of species, future research is suggested in order to extend the spectral database with more spectra of other TB and NMT strains with a larger number of isolates per species.

A promising approach to achieve cultivation-independent measurements is the analysis of single bacterial cells directly after their isolation from a patient's sample. Simple and fast enrichment and purification steps remain obligatory, but a prolonged preanalytical cultivation to gain sufficient biomass becomes obsolete, when techniques such as micro-Raman spectroscopy need hundreds of intact bacterial cells only,

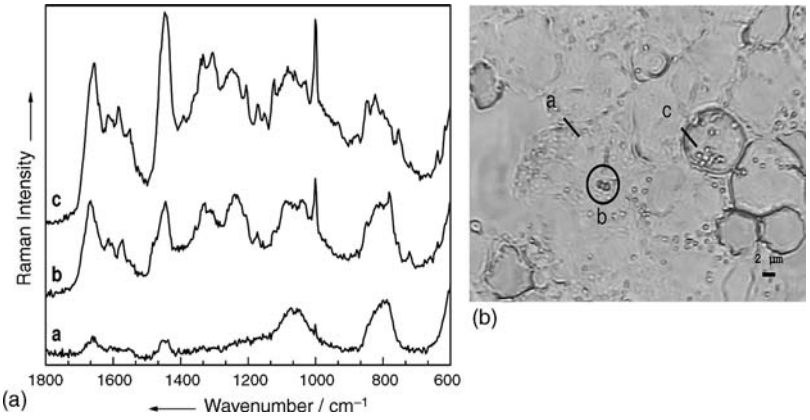

Figure 5.9 (a) Raman spectra of meningococcal patient's sample sedimented via cytocentrifugation: (trace a) background, (trace b) bacteria, and (trace c) leukocyte. (b) Microscopic image of a meningococcal patients sample: (a) background, (b) bacteria, and (c) leukocyte [61].

instead of billions in the case of measurements on bulk samples and microcolonies, as is the case in, for example, FTIR microspectroscopy.

Harz *et al.* proved in a pilot study the capability of micro-Raman spectroscopy to classify bacterial contaminants directly in the cerebrospinal fluid (CSF) of a meningococcal patient [61]. The sample was obtained from a patient with bacterial meningitis caused by *Neisseria meningitides*, who was already being treated with antibiotics. The preparation consisted simply of sedimentation of the cellular components onto fused silica slides by cytocentrifugation followed by a hot-air fixation (10 min at 110 °C) to inactivate the pathogens.

Direct targeting of individual cells, which were localized in the microscope's brightfield image as shown in Figure 5.9, was ensured due to the micro-Raman setup, which provided a focused laser beam approximately 0.8 μm in diameter. Thus, only an individual bacterial cell was probed and delivered a Raman spectrum after 30–60 s, as shown exemplarily in spectrum b in Figure 5.9. The Raman spectra a and c originated from the CSF matrix and a neighboring leukocyte, respectively. It is obvious that, except for contributions of the fused-silica substrate, the CSF did not give any strong Raman signals, which could have a serious impact on the bacterial Raman spectra. The intense Raman spectrum of the leukocyte (c) posed no problem since by targeting only the single bacterial cell any spectral disturbance of the blood cell could be avoided.

The measured spectra from the patient's sample were compared via hierarchical cluster analysis with spectra obtained from bacteria that had been cultivated *in vitro*. Among them are typical causative agents of bacterial meningitis such as *Neisseria meningitis*, *Streptococcus pneumoniae*, and *Listeria monocytogenes*. All of the patient's sample bacteria spectra were correctly placed in the *N. meningitis* cluster; the overall

classification rate at the species level was 95.7% (121/127 spectra). It could be shown that the CSF matrix did not mask the signals of bacterial cells. Furthermore, other cellular components such as leukocytes also did not seriously hamper the detection of individual meningococci cells. In cases with lower cell numbers, where the localization time might increase to impractical dimensions, direct fluorescence staining of the bacteria can be advantageous, requiring an appropriate dye [62]. With a fluorescence detection modality it is then possible to find stained bacteria selectively.

Overall, it can justifiably be concluded that vibrational spectroscopy is suitable for real-time application in medical microbiology. In short, clinicians can benefit from spectroscopy based typing methods because of several advantages: Recording vibrational spectra does not require qualified specialists, the number of essential or expensive chemicals is limited, and, above all, microbial fingerprints are generated at tremendously high speed while still allowing a good discriminatory power. An appropriately equipped medical diagnostic laboratory therefore has the means to identify microbial cultures rapidly, preferably on the same day that an initial culture is obtained from patient material. Additionally, as the spectroscopic methods rely on the identification of variable biological and biochemical features of bacterial strains and thus are phenotypic methods, they supplement perfectly molecular methods, such as sequence-based identification schemes, for example, pulsed-field gel electrophoresis (PFGE) and multilocus sequence typing (MLST), which are mostly applied in retrospective analyses of outbreak situations due to their long turnaround times (48–72 h when starting from a pure culture) and low sample throughput [24, 63].

5.6
Effect of Antibiotics on Microorganisms

During the last two decades, the number of newly discovered antimicrobial agents has decreased drastically with a concomitant increase in multidrug-resistant pathogens. This alarming development is partially due to the prescription frequency of antibiotics and the use of a broad spectrum of antibacterial agents. The only solution for the increasing bacterial resistance is to continuously develop new drugs. However, the development of new antibiotics is affected by the lack of detailed information about the modes of action of various antibacterial agents [64].

To establish a detailed understanding of bacterial metabolism and the effectiveness of various antibacterial agents, noninvasive, highly sensitive techniques are required. In recent years, different vibrational spectroscopic methods have been applied to characterize the interaction between various bacteria and drugs. The vibrational spectroscopic approaches were applied to unravel the mode of action of the antibiotics.

For example, the investigation of the effects of β-lactam antibiotics on microorganisms can be performed successfully by means of the SERS technique [65]. β-Lactam substances inhibit the biosynthesis of the cell wall. The SERS enhancement

originates from the strong optical intensity localized within 10 nm from the surface of metallic nanostructures. Hence SERS is particularly suitable for investigating the interactions of the antibiotics with the microbial cell wall. For example, oxacillin, a β-lactam agent, was found to affect the cell wall of the Gram-positive (*S. aureus*) and Gram-negative (*E. coli*) bacteria differently due to the diverse cell wall composition. The concentration of oxacillin used in the experiment was five times the minimal inhibitory concentration (20 mg l^{-1}). After the initial SERS perturbation of oxacillin, the Gram-positive *S. aureus* bacteria exhibited a transitory SERS recovery. The compensation of synthesis inhibition by the thick peptidoglycan layer is discussed as a possible explanation. Gram-negative bacteria do not possess any reserve of peptidoglycan and their response to oxacillin was found to be irreversible. The time required by β-lactam agents to affect the cell wall integrity was found to be ∼1 h. The changes in the SERS spectra of the investigated microorganisms were related to the destruction of the cell wall. SERS spectra of the Gram-positive *S. aureus* treated with antibiotics that inhibit protein synthesis, for example, gentamicin and tetracycline, exhibited changes after relatively long treatment times of about 9–12 h. This is due to the maintenance of the cell wall integrity during the inhibition of the protein synthesis [65].

Huleihel *et al.* investigated the effect of the commonly applied β-lactam antibiotic ampicillin (100 μg l^{-1}) on Gram-negative bacteria (*E. coli*, *Serratia marcescens*, *P. aeruginosa*, *H. influenza*, and *Salmonella enteridis*) and also on Gram-positive bacteria (*S. aureus*, *Staphylococcus olysgalacticae*, *Staphylococcus mitis*, *Bacillus subtilis*, *Bacillus cereus*, *Bacillus megaterium*, and *Bacillus thuringiensis*) by means of FTIR spectroscopy [66]. In contrast to SERS, which provides chemical information only about the bacterial cell wall, FTIR spectroscopy gives information about all the bacteria cell components. In contrast to the previously presented study, no spectral changes were detected 2 h after the antibiotic (β-lactam) treatment of a bacterial culture. This outcome was attributed by the authors to the relatively low sensitivity to cell wall composition of the FTIR technique compared with SERS. Moreover, no differences in the spectral response between Gram-positive and Gram-negative bacteria treated with antibiotics were observed on applying FTIR spectroscopy.

Huleihel *et al.* also compared the impact of ampicillin on the effect of caffeic acid phenylethyl ester (CAPE) on bacteria [66]. CAPE is a protein synthesis inhibitor and therefore changes of the relative proteins to nucleic acids ratios within the cells were expected. Significant spectral changes were observed 2 h after treatment. Interestingly, Gram-positive and Gram-negative bacteria presented distinctive changes in the biochemical composition. Considerable increases in band areas assigned to proteins and sugars were detected for Gram-positive bacteria, concomitant with major reductions in band areas arising from nucleic acid vibrations. These alterations were considered to be due to the reduced activity of the treated microorganisms, thereby causing an accumulation of carbohydrates in the cells. The increase in the protein level was reasoned to result from an overexpression of other bacterial genes. The IR spectra of Gram-negative bacteria showed an increase in the relative sugar to

protein content. The reported results suggest that FTIR spectroscopy can be used as an effective tool to evaluate rapidly the efficiency of the antibacterial effect of various protein synthesis inhibitors.

In contrast, investigations focused on fluoroquinolones targeting the bacterial enzyme gyrase were mainly performed by means of UVRR spectroscopy [67–70]. This technique was preferred due to the abundant information supplied regarding the DNA/RNA and aromatic amino acids within the investigated microorganisms. Gyrase catalyzes the introduction of negative coils into the DNA structure. Thus, the DNA transcription and replication is blocked by binding the fluoroquinolones to the gyrase–DNA complex. UVRR spectroscopy is applied to study minor modifications of the nucleic acid and protein contents within bacteria. The effect of ciprofloxacin (0.9 and 5 $\mu g\,ml^{-1}$) as a representative of the fluorquinolones on *Bacillus pumilus* was investigated by Neugebauer *et al.* by means of UVRR spectroscopy in combination with statistical methods (PCA and HCA) [67, 69]. By increasing the concentration of ciprofloxacin, notable changes in the band intensity of nucleic acids and proteins were detected. The main changes in the spectra were assigned to nucleic acids, especially guanine and adenine, to proteins represented by tyrosine and tryptophan, and to a CC-stretching vibration assigned to the drug ciprofloxacin itself. For more precise assignment of the detected changes, the Raman spectrum of a relaxed plasmid was compared with that of a superhelical plasmid and also with a spectrum recorded from a mixture of a relaxed plasmid with a subunit of gyrase. The outcome suggests that the Raman spectra of the bacterial cells contain valuable information about the DNA topology and the impact of antibiotics on the DNA structure can be detected by means of UVRR spectroscopy.

The effect of various concentrations of moxifloxacin, another fluoroquinolone drug, on *Streptococcus epidermidis* bacteria was investigated using complementary spectroscopic techniques including FTIR absorption, nonresonant Raman and UVRR spectroscopy [71]. Although the IR spectra of *S. epidermidis*, recorded 80 min after the drug addition appeared to be very similar, quantitative differences according to the drug concentration could be found. HCA was used successfully to differentiate between untreated bacteria and bacteria exposed to small amounts of moxifloxacin (0.08 and 0.16 $\mu g\,ml^{-1}$). The Raman spectra of the bacteria exposed to higher doses of the drug (0.27 and 0.63 $\mu g\,ml^{-1}$) were combined in one cluster and were therefore not differentiated. The results suggest that the antibiotic applied at low concentrations (around the minimal inhibition concentration) did not reach the saturation level and the effect of the drug on the bacteria was still increasing. At high concentrations, saturation was achieved and no further changes in the chemical composition of the cells were detected with increasing amount of drug.

The underlying variances in the IR spectra were elucidated by means of the PCA. Moxifloxacin targets mainly the DNA and protein structures. The drug causes structural changes in the DNA backbone, which suggested to involve reorientation of the phosphate groups, and an additional decrease in the phosphate bindings was observable. Also, an increase of intermolecular β-sheet aggregates (characteristic of

denatured proteins) concomitant with a decrease in ordered α-helical and β-sheet proteins was deduced from the IR absorption spectra. Neugebauer *et al*. interpreted this as a consequence of protein (gyrase)–drug interaction. The nonresonant Raman measurements were performed using an excitation laser in the green region at 532 nm. HCA applied to IR absorption spectra resulted in clear separation of untreated and treated bacteria. The bacterial spectra formed individual clusters dependent on moxifloxacin concentration, exhibiting the inner-class variation. To identify the main changes in the bacterial spectra, PCA was additionally applied. Drug treatment induces an intensity increase in Raman bands assigned to guanine and adenine, to adenosine and thymidine, to glycosidic linkages, and to the phosphate stretching vibration of the DNA backbone. Additionally, an increase in random coil structure upon drug addition was obtained within the Raman spectra. A simultaneous interaction of moxifloxacin with DNA and the protein gyrase was concluded to be the reason.

The results obtained by means of UVRR spectroscopy are in good agreement with the FTIR results, since similar bacteria clusters were obtained using HCA. The PCA outcomes supported the proposed mechanism of interaction between drug and bacteria by focusing on DNA and protein moieties.

The mode of action of amikacin, an aminoglycoside drug, on *P. aeruginosa* bacteria was monitored using UVRR spectroscopy [64]. In contrast to the above-mentioned studies, the antibiotic was provided in various sub-inhibitory concentrations. The spectral changes were ascribed to tryptophan and tyrosine. To study the dynamic nature of the spectral changes over the full antibiotic range below the inhibitory concentrations, the authors applied two-dimensional (2D) correlation analysis.

Generalized 2D correlation spectroscopy is a cross-correlation method that provides information regarding the dynamic spectral changes due to an external perturbation of the system such as increasing antibiotic concentration. The synchronous 2D correlation spectra are characterized by autopeaks along the diagonal and cross-peaks off the diagonal for bands that exhibit similarities in the dynamic behavior. In turn, the asynchronous 2D correlation spectrum contains only cross-peaks that reveal out-of-phase (dissimilar) behavior of two bands. Peaks that do not change their intensities throughout the series will not appear in the 2D spectra. Thus, 2D correlation asynchronous analysis provided information about the order of the changes registered in the Raman spectra [72].
