- Progressively improve strength, flexibility, proprioception, and endurance training until near-normal function is attained.
- Return to exercise and sports symptom free.

Abbreviation: RICE, rest, ice, compression, elevation.

[a] Modified from Hergenroeder AC. Prevention of sports injuries. *Pediatrics.* 1998;101(6):1057–1063.

Prevention

Injury prevention is an important aspect of sports medicine with which the primary physician should be familiar. One element of injury prevention is the recognition of risk factors associated with sports injuries. In general, risk factors can be divided into 2 subgroups: nonmodifiable and modifiable. Nonmodifiable risk factors include sex, individual physical features, and the type of sport. Modifiable risk factors include flexibility, alignment, strength, endurance, and proprioception. Additionally, exercise preparation, hydration, and adequate warm-up are important in preventing injury. According to research, stretching before exercise may help reduce the risk of muscle strain regardless whether the stretching is dynamic or static.

Because many injuries are the result of "trying to do too much too soon," proper physical training and conditioning are essential, no matter how fit the athlete appears. Stretching, warm-up and cool-down exercises, and the type of equipment used for the sport should be reviewed with the athlete during the sports physical visit. The type of sport to be played should be reviewed as well and, if participating in a contact sport, the adolescent should be matched with other athletes based on weight and pubertal development rather than age. Some studies suggest that such matching greatly reduces the risk of injury to the smaller, less mature athlete. Because an old or incompletely healed injury is a significant risk factor for reinjury, the athlete should receive proper treatment and rehabilitation of all previous injuries before returning to play. Protective equipment, especially for collision and contact sports, as well as for sports involving a ball or racquet, also should be emphasized to athletes and their parents or guardians.

The National Strength and Conditioning Association advises that under correct supervision, strength and resistance training in both children and adolescents can have numerous health benefits when age-appropriate guidelines are stringently followed. Benefits include enhanced strength and endurance, resulting in fewer injuries and improved bone health. Strength training should not be

confused with competitive weight lifting, which involves the use of maximum loads and shear forces that may hinder growth and damage skeletal structure and development in active youth. The American Academy of Pediatrics recommendation for avoiding weight training and advanced resistance training until Tanner stage 5 of pubertal development should be followed in most cases, particularly those in which adequate supervision and expertise is unavailable. The risk of overuse injuries and overtraining should be discussed with the patient and parents or guardians. Education about the hazards of anabolic steroid use and creatine also may be indicated.

Prognosis

Orthopedic injuries in young athletes and active adolescents have a great capacity for healing if given the opportunity. Early medical intervention to prevent irreversible tissue damage ensures complete recovery in most cases. Long-term sequelae are associated with repeat trauma, incomplete treatment, and chronic inflammatory changes. Some conditions, however, such as Osgood-Schlatter disease, resolve even without treatment and do not result in permanent joint damage.

CASE RESOLUTION

The teenager has symptoms and physical findings consistent with patellofemoral pain syndrome, which is traditionally referred to as chondromalacia of the patella. Because plain radiographs are rarely helpful in confirming the diagnosis, none are necessary at this time. Management should include strength training for the quadriceps muscles, activity modification, nonsteroidal anti-inflammatory drugs, and ice compresses after activity.

CHAPTER 118

Evaluation of Limp

Andrea Fang, MD

CASE STUDY

A 6-year-old boy with a 2-day history of right knee pain and limp is brought to the office. He has no history of knee trauma, swelling, redness, or associated fever. The medical history is unremarkable. The boy is afebrile, and his height and weight are at the 10th percentile for age. Examination of the right leg reveals decreased abduction and internal rotation of the hip; the knee is normal. The boy limps when he walks and favors his right leg.

Questions

1. What is the differential diagnosis of painful and painless limp in children?
2. What is the differential diagnosis of knee pain in children?
3. What laboratory tests and radiographic studies are indicated in the evaluation of children with limp?
4. What is the appropriate treatment of the child with a suspected infectious cause of limp?

A *limp* is a gait disturbance that occurs when an effort is made to minimize weight bearing on an affected leg to reduce pain and instability. The disturbance may be secondary to muscle weakness, deformity, pain, or a combination thereof. Muscle weakness may be caused by primary muscle disease, neurologic conditions, or disuse atrophy. Structural causes of limp include leg length discrepancy and joint stiffness, whereas painful causes of limp include trauma; synovitis; infection of bone, joint, or soft tissue; or neoplasm. A limp may be a sign of significant underlying disease, and accurate diagnosis and appropriate management are essential to prevent potentially serious morbidity.

Epidemiology

A patient may limp because of pain originating in a leg or because of pain referred from the abdomen or spine. Age often defines the diagnostic possibilities; certain disorders are more common among particular age groups. Infectious causes of limp occur more frequently in infants and young children, and noninfectious causes are more common in school-age children and adolescents (Table 118.1).

Clinical Presentation

Painful limp typically has an acute onset and may be associated with systemic signs, such as fever, especially when the etiology is infectious. The toddler may simply refuse to walk or walk with a slow, cautious gait when in pain rather than limp. Painless limp often has an insidious onset and is commonly caused by weakness (eg, muscular dystrophy) or deformity (eg, leg length discrepancy).

Pathophysiology

Normal gait has 2 phases: stance and swing. During the stance phase, both feet are on the ground as 1 heel strikes while the opposite foot moves to pre-swing; during the swing phase, 1 foot is not touching the ground as the limb is moved forward. Stance phase is shortened in limp to decrease the amount of time spent bearing weight on the affected side or to minimize instability.

Normal adult gait is smooth and efficient, requiring the coordinated actions of the muscles of the legs and pelvis. Normal gait in children varies according to age and developmental maturity. The toddler typically walks with a broad-based, tiptoe, "bouncing" gait with the arms abducted for balance. A toddler may initiate the stance phase with either toe or heel strike. By 2 years of age, a child should initiate the stance phase consistently with heel strike. At 3 to 4 years of age, a child should exhibit normal adult gait with reciprocating arm swing most of the time.

Several types of abnormal gait are recognized. An *antalgic gait* has a characteristic shortened stance phase resulting from pain. *Trendelenburg gait* is caused by weakness of the hip abductors (eg, gluteus medius muscle) in which the pelvis dips down during stance phase, producing a swaying type gait. A tiptoe gait or toe-to-heel gait is normal in children for several months after they learn to walk. Persistence of such a gait beyond 2 years of age is abnormal, however, and may result from idiopathic heel cord contracture or contracture secondary to cerebral palsy.

Differential Diagnosis

Trauma is a frequent cause of limp in children and adolescents. In toddlers, a fall may not be witnessed, and they may present with limp or refusal to walk because of an occult fracture, such as toddler fracture (Figure 118.1). *Toddler fracture* is an oblique or spiral fracture of the middle or distal tibia that occurs after a fall or jump involving a twisting motion. Toddlers are at risk for such injuries because of their unsteady gait. Tpyically, standard anteroposterior (AP) and lateral radiographic views are obtained to determine if a fracture is present. The radiographic appearance may initially be normal, and

Table 118.1. Differential Diagnosis of Limp in Children

Limp Type	*1–3 Years of Age*	*4–10 Years of Age*	*≥11 Years of Age*
Painful	Septic arthritis/osteomyelitis Transient synovitis Intervertebral diskitis JIA Neoplasia (ie, leukemia, metastatic disease) Trauma (ie, toddler fracture) Child abuse	Septic arthritis/osteomyelitis Transient synovitis Trauma LCPD (acute phase) Intervertebral diskitis JIA Sickle cell pain crisis Lyme arthritis Neoplasia (ie, leukemia, primary bone tumor, metastatic disease)	Trauma Septic arthritis/osteomyelitis SCFE Osgood-Schlatter disease JIA Sickle cell pain crisis Lyme arthritis Neoplasia (ie, leukemia, primary bone tumor, metastatic disease)
Painless	DDH Neuromuscular disease (ie, cerebral palsy) Leg length discrepancy	LCPD (chronic phase) DDH Neuromuscular disease (ie, cerebral palsy, muscular dystrophy) Leg length discrepancy	SCFE Leg length discrepancy Neuromuscular disease (ie, cerebral palsy, muscular dystrophy) Scoliosis

Abbreviations: DDH, developmental dysplasia of the hip; JIA, juvenile idiopathic arthritis; LCPD, Legg-Calvé-Perthes disease; SCFE, slipped capital femoral epiphysis.

Figure 118.1. Anteroposterior (left) and lateral (right) radiographs of toddler fracture evidenced by elevation of the periosteum.
Courtesy of Michael Diament, MD.

oblique views may be helpful in visualizing the fracture. Follow-up radiographs or bone scanning may be necessary to make the diagnosis. The older child usually can recall a specific injury and localize pain to a specific area. In the patient with tenderness over an open growth plate, a splint should be applied and the patient should be closely followed even if radiographs appear normal because of the possibility for a Salter-Harris type I fracture, which occurs through the growth plate and may not be evident radiographically.

Painless limp in the toddler may be the result of developmental dysplasia of the hip, cerebral palsy, or leg length discrepancy (ie, anisomelia). As a result of developmental dysplasia of the hip, a child may have a Trendelenburg gait secondary to leg length discrepancy or to weakness of the hip abductors. Children with spastic cerebral palsy often walk on their toes because of increased tone or heel cord contracture. Functional or apparent leg length discrepancies may be the result of pelvic obliquity or spinal deformity. Children with true leg length inequality compensate by walking on tiptoe on the shorter side or bending the knee on the longer side. Limb discrepancies may be managed with orthoses (eg, heel lifts) for mild cases, whereas surgical lengthening or shortening procedures may be necessary for more severe cases.

Transient synovitis of the hip is a benign, self-limited inflammatory process involving the synovial lining and is among the most common causes of limp in the young child. The exact cause of the inflammation is not known. Although an association has been noted with certain upper respiratory infections, no infectious agent has been identified. Compared with the general population, children who were subsequently diagnosed with Legg-Calvé-Perthes disease (LCPD) have been noted to have a higher incidence of transient synovitis. This may be related to misdiagnosis or the historical use of traction to manage transient synovitis. Age of onset varies, but transient synovitis typically affects children 4 to 10 years of age, although it can present in younger or older persons. Males are affected at approximately twice the rate as females. Individuals usually present with acute onset of unilateral hip pain associated with a limp. A patient may experience referred pain to the anterior thigh or knee. Associated systemic symptoms, such as fever, are rare or absent and should prompt an investigation for another cause. A child may hold the leg in a position of abduction, flexion, and external rotation to reduce intracapsular pressure and associated pain. Symptoms are usually unilateral, but fewer than 10% of patients have bilateral involvement, often with 1 side more symptomatic than the other.

Transient synovitis is a diagnosis of exclusion and must be differentiated from more concerning diagnoses, such as septic arthritis. Consequently, laboratory evaluation typically consists of complete blood cell count (CBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). Usually, the results are within normal limits or are slightly elevated. Radiographs are often obtained, which usually are normal or show signs suggestive of an effusion. Ultrasonography often is performed to evaluate for the presence of an effusion within the joint, which may occur with this condition. If arthrocentesis is performed, the fluid in transient synovitis usually has a white blood cell (WBC) count of less than 50,000/mm^3 and a negative Gram stain. Individuals with normal laboratory values or with a fluid aspirate that is not suggestive of septic arthritis (when arthrocentesis has been performed) typically are managed with supportive care and close follow-up within 24 to 48 hours. Rest and nonsteroidal anti-inflammatory drugs (NSAIDs) are the mainstays of therapy. Nearly all children recover within 3 to 10 days with no significant sequelae. Recurrence rates can be as high as 69% within the first year of an episode of synovitis.

Septic arthritis occurs as the result of infection within the joint space. In children, this usually occurs in the setting of bacteremia, with hematogenous spread to the highly vascular synovial membrane. It can also occur from contiguous spread of an adjacent infection (eg, osteomyelitis) or by direct inoculation (eg, surgery, penetrating trauma). *Staphylococcus aureus* remains the most common pathogen identified across all age groups, with increasing incidences of community-acquired methicillin-resistant strains. Infants younger than 2 months also can be infected by neonatal pathogens, such as *Streptococcus agalactiae* (eg, group B streptococcus) and gram-negative enteric organisms (eg, *Escherichia coli*). Septic joints in children between 2 months and 5 years of age are usually caused by *S aureus, Streptococcus pyogenes, Streptococcus pneumoniae,* and *Kingella kingae*. Children older than 5 years usually have infections caused by *S aureus* or *S pyogenes. Neisseria gonorrhoeae* infections may be seen in sexually active adolescents. Historically, *Haemophilus influenzae* type b (Hib) was a common pathogen of osteoarticular infections in children; however, its incidence dropped dramatically after the introduction of the Hib vaccine.

Infants and children with septic arthritis often present with fever, decreased use of the affected extremity, limp, or refusal to walk. The most commonly affected joint is the hip, which is classically held in a position of abduction, flexion, and external rotation to reduce intracapsular pressure and associated pain. Passive range of motion typically elicits significant discomfort and resistance. Parents or caregivers of infants may notice increased crying with manipulation of the legs with activities such as diaper changing.

Subtle or early cases of septic arthritis often present a diagnostic challenge because of the potential for considerable clinical and laboratory overlap with transient synovitis. Unfortunately, no highly sensitive or specific laboratory test exists that can readily distinguish these 2 entities. Temperature higher than 38.5°C (101.3°F) was shown to be the single best predictor of septic arthritis in 1 study, with no children diagnosed with transient synovitis having a temperature above 38.5°C (101.3°F). Other predictors include refusal to bear weight, ESR greater than 40 mm/hour, a CRP greater than 2.0 mg/dL, and serum WBC count greater than 12,000/mm^3. The presence of 1 of these 5 factors was associated with a probability of approximately 37% for having septic arthritis, whereas the presence of all 5 factors was associated with a probability of 98% for the condition. Imaging often consists of plain radiography and ultrasonography. Radiographs usually are nondiagnostic but may demonstrate joint space widening suggestive of an effusion. Ultrasonography usually demonstrates the presence of an effusion.

Analysis of synovial fluid remains the standard for the diagnosis of septic arthritis, and arthrocentesis of any effusion under sedation or anesthesia is indicated if a clinical suspicion of septic arthritis exists. A WBC count greater than 50,000/mm^3 within the fluid aspirate generally is considered diagnostic for septic arthritis; however, elevated counts also occur with certain rheumatologic conditions. Regardless of WBC count, the presence of bacteria on Gram stain of joint aspirate is suggestive of infection. Routine cultures of joint aspirate as well as peripheral blood cultures should be obtained. Additionally, with the increasing recognition of *K kingae* as a causative agent in septic arthritis in young children, joint aspirations should be directly inoculated into blood culture bottles to enhance isolation because this organism is difficult to recover with standard culture techniques. In most studies, only approximately 50% of joint aspirate cultures grew out an identifiable pathogen. In 1 study, close to 50% of the aspirates that were sterile on standard culture media grew out *K kingae* from blood cultures. Other studies suggest sending a polymerase chain reaction assay, which is better for detecting *K kingae*, or a nasopharyngeal and throat culture, given this is often an area of colonization for patients with *K kingae* infection.

Joint damage from the purulent effusion can occur within 6 to 8 hours, which is why emergent evaluation and treatment is necessary. Complications occur in 10% to 25% of all cases of septic arthritis of the hip, and that rate increases in cases in which 5 days or more have passed before initiation of therapy. These complications include abnormal bone growth, permanent limp, unstable articulation of the affected joint, and decreased range of motion.

Osteomyelitis is an infection of the bone that typically is caused by a bacterial organism. Nearly 50% of pediatric cases of osteomyelitis occur in children younger than 5 years. Most cases of osteomyelitis in children occur from hematogenous deposition of bacteria into the bone marrow during a transient episode of bacteremia. Other cases may be the result of contiguous spread of an adjacent infection or direct inoculation. Osteomyelitis most commonly begins in the highly vascularized metaphysis of long bones of young children. The femur, tibia, and pelvis account for most cases. As with septic arthritis, *S aureus* remains the most common organism identified across all age groups, with an increasing incidence of methicillin-resistant *S aureus* (MRSA). Other organisms include *S pyogenes, S pneumoniae,* and *K kingae.* Young infants can also be infected by neonatal pathogens, such as group B streptococcus and enteric gram-negative organisms. Individuals with sickle cell disease (SCD) are at increased risk for infection with

Salmonella. *Haemophilus influenzae* type b should also be considered in unvaccinated children.

Children often present with pain or localized symptoms at the affected site. More than one-half have a fever. Younger children may present with limp, reduced range of motion, or refusal to bear weight. In the setting of subperiosteal spread, erythema, warmth, and swelling may be evident at the affected site.

Laboratory tests can be supportive of a diagnosis of osteomyelitis but usually are not specific. Typically, a CBC, ESR, and CRP are obtained along with blood cultures. Leukocytosis may be present, but in more than one-half of cases, the WBC count is normal. Inflammatory markers are elevated in up to 90% of patients. A CRP greater than 10 mg/L (1.0 mg/dL) may also increase the suspicion for osteomyelitis complicated by septic arthritis. Blood cultures are positive in 40% to 55% of patients. Because of the importance of discerning the causative organism, the physician should consider ordering polymerase chain reaction assays for *K kingae* given its increasing incidence and difficulty to isolate. Radiographs are often normal or show only soft tissue changes early in the course of the disease. Periosteal reactions and lytic lesions rarely present before 10 to 21 days into the disease course. Bone scanning can be helpful in the preverbal child or in individuals who cannot localize their pain. Magnetic resonance (MR) imaging has become the study of choice, with a reported sensitivity of 97%. It is quite useful for distinguishing between bone and soft tissue infections.

Diskitis refers to an inflammatory process involving the intervertebral disks. This disease typically occurs in children younger than 5 years. It occurs almost exclusively in the lumbar region, causing progressive limp, back pain, and refusal to walk. Most children with the condition are afebrile. Diskitis is thought to occur in younger children because of the presence of vascular channels in the cartilaginous region of the disk space as well as abundant intraosseous arterial anastomoses. These vascular channels disappear with age. Laboratory studies are often nonspecific, with slight elevations in the peripheral WBC count and ESR. Radiographs are abnormal in 75% of patients, with decreased vertebral disk space and erosion of adjacent vertebral end plates being the most common abnormalities seen. Bone scanning demonstrates nonspecific increased marker uptake in the affected area. Computed tomography (CT) rarely provides a specific diagnosis and is not generally used. Magnetic resonance imaging demonstrates characteristic inflammatory changes and allows for differentiation from other conditions, such as vertebral osteomyelitis.

The exact etiology of diskitis is not known, and the treatment is somewhat controversial. Several authors propose that diskitis is the result of an infectious process and warrants antibiotic therapy. Others propose that it is simply a benign self-limited inflammatory disease because most cultures are sterile and patients can recover without any antimicrobial therapy. In most cases, broad-spectrum antibiotics and strategies to prevent kyphosis are initiated.

Legg-Calvé-Perthes disease is an idiopathic avascular necrosis of the femoral head. The exact etiology is unclear but involves some disruption in the vascular supply of the capital femoral epiphysis. The disease most commonly occurs in children 3 to 12 years of age (median age, 7 years), and it is 4 to 5 times as common in boys as in girls. The condition is bilateral in up to 15% of cases. Children typically present with a chronic intermittent limp that can be painful or painless. It is not uncommon for the child to be symptomatic for months before a diagnosis is made. Pain is usually worsened with internal rotation and abduction.

Laboratory tests are usually normal. Radiographs early in the course of the disease may be negative or show widening of the joint space. In later stages, radiographic findings include increased density and decreased size of the femoral head (ie, necrosis), patchy areas of radiolucency near the epiphysis (ie, fragmentation), and flattening of the femoral head (ie, reconstitution; Figure 118.2).

Slipped capital femoral epiphysis (SCFE) is a displacement or slipping of the femoral epiphysis from the neck of the femur through the open physis (ie, growth plate). This is the most common hip disorder affecting adolescents. It is more common in boys than girls and occurs more frequently among blacks and Hispanics than non-Hispanic whites. Typical age of onset is 9 to 16 years. Individuals often have overweight and frequently present with a chief symptom of knee pain. They often have an antalgic gait. The foot is externally rotated in severe slips but may be neutral or pigeon-toed in mild slips. Examination of the knee is normal without discomfort, despite the report of knee pain. Passive flexion of the hip often results in obligate external rotation. Typically, pain is elicited on internal rotation. With stable SCFE, the individual can walk with or without crutches; with unstable SCFE, walking is not possible. Laboratory testing is not indicated. Anteroposterior and batrachian (ie, frog-leg) radiographs of the hip are diagnostic in approximately 80% of patients. Early radiographic findings include widening of the physis, whereas slippage is noted radiographically later in the disease process (Figure 118.3). Imaging assessment of both hips is important because SCFE is bilateral in up to 20% of patients. When done by an experienced technician, ultrasonography has been shown to be an effective diagnostic tool, with a sensitivity of 95%. A slip can be visualized on CT or MR imaging; however, MR imaging is much more sensitive and can detect physeal widening in the pre-slip condition.

Osgood-Schlatter disease (OSD), or traction apophysitis of the tibial tubercle, is an overuse injury of the knee that occurs most commonly

Figure 118.2. Anteroposterior pelvic radiograph of a patient with Legg-Calvé-Perthes disease.

Courtesy of Michael Diament, MD.

in adolescent athletes, particularly those who participate in running or jumping sports. Repetitive microtrauma causes partial avulsion of the patellar tendon at its insertion on the tibia. Individuals typically present with a localized bony prominence, swelling, and tenderness over the tibial tubercle at the insertion of the patellar tendon. Osgood-Schlatter disease can be diagnosed clinically, although radiographs are commonly obtained to rule out other pathology and typically demonstrate soft tissue swelling or edema of the skin and tissues, as well as ossific fragments within the tendon (Figure 118.4). Symptoms tend to resolve at approximately 14 to 15 years of age after the tibial tubercle closes.

Figure 118.4. Lateral radiograph of the knee in a patient with Osgood-Schlatter disease.
Courtesy of Michael Diament, MD.

A limp can also result from certain systemic disease processes, such as juvenile idiopathic arthritis, SCD, Lyme arthritis, and neoplastic disease. Juvenile idiopathic arthritis may involve multiple joints or have an associated rash. Evidence of inflammation (eg, warmth, swelling or effusion, redness) is typical (see Chapter 156). Usually, the pain is worst in the morning and improves throughout the day. Currently, SCD is detected on newborn screening, and most patients know of their diagnosis. Acute pain crises with SCD can affect multiple areas, resulting in significant discomfort, limp, and refusal to walk. Careful consideration for infectious etiologies (ie, osteomyelitis) is necessary in the highly febrile or ill child with SCD who presents with a limp or bone pain. Additionally, patients with SCD are at risk of avascular necrosis of the hip secondary to vasoocclusive episodes. Patients with Lyme arthritis typically are able to bear weight despite having a joint effusion, most commonly in the knee. A patient may have had earlier clinical symptoms of Lyme disease, such as the target-sign lesion, erythema chronicum migrans, or a viral prodrome. Other disseminated symptoms include meningitis, carditis, and cranial nerve palsy. Diagnosis can be made via enzyme-linked immunosorbent assay and Western blot. The arthritis usually is self-resolving but can be managed with antibiotics. Neoplastic disease processes, such as leukemia and primary bone tumors (eg, Ewing sarcoma, osteosarcoma) can present with bone pain and limp. The presence of pallor, petechiae, disseminated lymphadenopathy, or hepatosplenomegaly may be suggestive of leukemia. Peripheral CBC usually shows the presence of blasts and varying degrees of involvement of the various cell lines (ie, anemia, thrombocytopenia). Primary bone tumors may present with bony deformities or overlying soft tissue swelling. Characteristic bony lesions often are evident radiographically, although MR imaging may be necessary to ascertain the extent of involvement. Computed tomography may be necessary to assess for metastases. It may be necessary to refer a patient to an orthopedic surgeon for biopsy to ascertain a definitive diagnosis and for possible amputation. Referral to an oncologist is necessary to initiate appropriate therapy, including chemotherapy or radiation.

Evaluation

History

The history should focus on the time of onset of the limp, chronicity, and the resulting degree of disability. Often, a history of trauma is provided, even in the setting of a nontraumatic cause. Young toddlers often fall as they learn to walk, and parents and caregivers frequently relay some trivial or unrelated injury. Delayed motor development may be a sign of neuromuscular disease (eg, cerebral palsy), whereas a history of loss of motor milestones may be indicative of muscular dystrophy or spinal cord tumor. It is important to remember that pelvic pathology may be referred to the hip, and hip pathology is often referred to the knee or thigh.

Physical Examination

Physical examination begins with observation for any overt deformity (eg, leg length discrepancy, joint swelling). All joints and the spine should be palpated, and the presence of swelling, tenderness,

erythema, or warmth should be noted. A thorough evaluation of the hips is essential in the child with knee pain. The type of gait abnormality may be determined by observing the child walk or run.

The child should be examined supine and standing, if possible. The standing child can be assessed for pelvic obliquity and spinal deformities. Range of motion of the hips, knees, ankles, and feet can be assessed in the supine child, comparing the affected side with the nonaffected side. Muscle strength should be assessed, and leg length measurements should also be obtained as indicated. The child should be supine for a true measurement of leg length, which is the distance from the anterosuperior iliac spine to the medial malleolus. A discrepancy of more than 2 cm is considered significant in adults. The significance of discrepancies can be confirmed on imaging studies.

Laboratory Tests

Laboratory studies are usually necessary in the child with an acute onset of limp with no clear trauma, especially in the child who refuses to bear weight or is febrile. Complete blood cell count, CRP, and ESR are useful markers of systemic disease and significant inflammation. Significant overlap may exist between the differing etiologies, and no single screening test can reliably distinguish between the various inflammatory and infectious causes of limp. Blood and local cultures (eg, joint fluid, bone) may be useful in the evaluation of suspected infectious entities. In addition to the culture, effusion studies should also include a cell count, Gram stain, glucose, and protein. Additional testing for rheumatologic causes may be clinically indicated, such as antinuclear antibody or rheumatoid factor (see Chapter 156).

Imaging Studies

Radiographs are the most commonly obtained images. At least 2 views should be obtained. For examination of the hip, both AP and batrachian views are necessary. It is important to include both hips in these images for comparison and to assess for the presence of bilateral disease. Ultrasonography is helpful if concern exists for an effusion within the joint space and can also be used to guide diagnostic and therapeutic interventions (eg, arthrocentesis) (Figure 118.5). Useful information is sometimes gleaned from CT, but MR imaging with gadolinium contrast is increasingly being used because of the superior resolution it affords and lack of radiation.

Management

Management depends on the etiology. Management of septic arthritis consists of surgical drainage and intravenous (IV) antibiotics. Empiric therapy typically consists of an antistaphylococcal penicillin (eg, nafcillin sodium, oxacillin sodium). In a region with high rates of community-acquired MRSA, administration of clindamycin or vancomycin may be necessary until sensitivities can be performed. The addition of a third-generation cephalosporin is often indicated pending Gram stain and culture results to cover gram-negative pathogens, such as *K kingae*, or in cases in which *N gonorrhoeae* is suspected in an adolescent patient. Length of therapy typically consists of 2 to 4 weeks of IV antibiotics. Prognosis is generally good with prompt diagnosis and management within 4 days of symptom onset. Nonsteroidal anti-inflammatory drugs and low-dose steroids can also be considered to manage inflammatory pain.

Initial management of osteomyelitis also consists of IV antibiotics. Occasionally, surgery may be indicated, particularly in the setting of a subperiosteal or soft tissue abscess or sequestra. In communities in which methicillin-susceptible *S aureus* is more prevalent, empiric antibiotic therapy consists of an antistaphylococcal penicillin (eg, nafcillin sodium, oxacillin sodium) or a first-generation cephalosporin (eg, cefazolin). In areas in which community-acquired MRSA is of concern, clindamycin or vancomycin may be necessary. Neonates and individuals with SCD require the addition of a third-generation cephalosporin pending culture results. In individuals with a presumed pseudomonal infection, an extended spectrum β-lactam (eg, ceftazidime, cefepime, piperacillin/tazobactam) plus an aminoglycoside are indicated. Currently, 4 to 6 weeks of antibiotic therapy is recommended. Increasing data support switching to oral

Normal is less than 5 mm or a difference of less than 2 mm compared with the contralateral hip. C, A notable hip effusion with a joint space measuring 7.4 mm indicated by the dotted line and letter "A."

Courtesy of Kathryn Pade, MD.

antibiotics after receiving as little as 2 to 4 days of parenteral therapy if compliance is likely, an organism has been identified, clinical improvement is noted, the patient is afebrile, and the inflammatory markers have begun to normalize. Oral dosages 2 to 3 times those normally recommended for nonosseous infections are often used for β-lactam antibiotics. Other oral antibiotics (eg, clindamycin, trimethoprim plus sulfamethoxazole, fluoroquinolone) have excellent bioavailability, and the usual oral dosages may be administered. Amoxicillin should be considered in children younger than 4 years who have not been vaccinated to cover *H influenzae*. Consultation with an infectious disease specialist is often indicated.

Supportive measures with NSAIDs are generally indicated for the management of diskitis. Broad-spectrum antibiotics are generally given, and the addition of anti-staphylococcal antibiotics should also be considered and have been shown to speed improvement of symptoms. A brace may be helpful for support and pain relief. Most patients recover without complications.

Prompt referral to an orthopedic surgeon is indicated in the patient with LCPD or SCFE. The goal of management of LCPD is to maintain full joint mobility and prevent femoral head deformity. Bed rest and immobilization decrease the pain and help restore range of motion. Traction and abduction casts or braces are used to contain the femoral head within the acetabulum in an effort to maintain its spherical shape. Surgical correction of gross deformities of the femoral head may be necessary in severe LCPD. Patients younger than 6 years are most likely to benefit from surgical treatment.

Management of SCFE consists of surgical reduction and stabilization with placement of screws through the epiphysis. The screws typically are left in place and do not need to be removed. Non-weight bearing is maintained until early callus is noted on the posteroinferior metaphysis and the pain has resolved. Gradual and progressive weight bearing is allowed, and progression to full weight bearing usually occurs 3 to 4 months after fixation. No running or jumping is allowed until the physis closes.

Treatment of OSD consists of rest, ice, NSAIDs, and strengthening exercises for the quadriceps and hamstring muscles. Surgical treatment is rarely indicated and is reserved for those patients who do not respond to nonsurgical therapy.

Prognosis

The prognosis depends on the etiology of the limp, time to diagnosis, and appropriate therapy.

In most cases of septic arthritis and osteomyelitis, the prognosis is good if the infection is diagnosed early and managed appropriately. The prognosis of osteomyelitis usually is good, with a less than 0.1% mortality rate and with less than 2% of patients who receive at least 3 weeks of antibiotic therapy developing chronic osteomyelitis. Management of chronic disease can be difficult, often necessitating prolonged courses of antibiotics (≤6–12 months) and multiple surgeries for débridement. Rare complications include disturbances in bone growth, leg length discrepancy, joint destruction, arthritis, abnormal gait, and pathologic fracture. Prognosis is also worse if treatment is delayed, the patient is younger, or the infection involves the hip, ankle, or knee. The main complication is degenerative arthritis of the hip. Regular follow-up with an orthopedic surgeon is necessary during the first year after diagnosis.

The prognosis of LCPD is related to the degree of femoral head involvement and age at onset of the disease. Children younger than 6 years have the best prognosis. The risk for developing degenerative arthritis in adulthood increases in children whose disease is more extensive and whose condition is diagnosed later (ie, after 8 years of age).

Untreated SCFE has the potential for further slippage of the femoral head until the growth plate closes. Potential treatment-related complications of SCFE include chondrolysis of the femoral head and acetabulum, avascular necrosis, and fracture at the site of pin placement. Generally, the prognosis is good and is based on the degree of slippage. The main complication is the development of avascular necrosis of the femoral head, which typically results in degenerative hip disease later in life. Degenerative hip disease later in life occurs in up to 15% of patients with SCFE and is more common in unstable SCFE. Only 7% of patients with a moderate slip have a poor outcome, compared with 24% of patients with a severe slip.

In approximately 5% to 10% of patients, OSD may become chronic, with persistent swelling and tenderness. In such cases, the formation of an ossicle over the tibial tubercle may be evident radiographically; because of the possibility that surgical resection of the ossicle may be required, the patient should be referred to an orthopedic surgeon.

CASE RESOLUTION

The child's history and physical examination seem to be consistent with LCPD. The child's knee pain is found to be secondary to hip pathology. The diagnosis may have been missed had the physician not examined the hips and noted the abnormality in range of motion. Anteroposterior and batrachian radiographs of the hips were obtained, which showed joint space widening. Orthopedic consultation was obtained, and hospitalization for bed rest and ensured immobilization were recommended.

CHAPTER 119

Musculoskeletal Disorders of the Neck and Back

Aaron W. Beck, MD, MMS; Kier Maddox Blevins, MD; Andrew K. Battenberg, MD; and Carol D. Berkowitz, MD, FAAP

CASE STUDY

A 4-week-old male infant is brought to the office by his mother, who reports that her son always holds his head tilted to the right. She states that he has held it in this position for approximately 1 week and prefers to look mainly to the left. The infant is the 3.86 kg (8 lb, 8 oz) product of a term gestation born via forceps extraction, and he had no complications in the neonatal period. He is breastfeeding well and has no history of fever, upper respiratory symptoms, vomiting, or diarrhea.

On examination, the head is tilted toward the right side with limited lateral rotation to the right and decreased lateral side bending to the left. Except for the presence of a small palpable mass on the right side of the neck, the examination is within normal limits.

Questions

1. What laboratory or radiologic studies are indicated in infants with torticollis?
2. What is the differential diagnosis of torticollis in infants?
3. What are some of the common musculoskeletal abnormalities that may occur in association with torticollis?
4. What are other common musculoskeletal problems in children and adolescents?
5. What is the current recommended management of children and adolescents with idiopathic scoliosis?

Children with disorders of the spine can present with deformity or back pain or occasionally, both. Atraumatic congenital and developmental deformities of the spine are frequently encountered in pediatric practice. Torticollis and scoliosis are 2 of the most common disorders in children that present as spinal deformity. *Torticollis*, or wry neck, is a positional abnormality of the neck resulting in abnormal tilting and rotation of the head. *Scoliosis* refers to any lateral curvature of the spine that measures more than 10° as determined on an anteroposterior radiograph of the spine. Scoliosis is classified as congenital, neuromuscular, or idiopathic. Idiopathic scoliosis itself is further categorized based on patient age: infantile, younger than 3 years; juvenile, 3 through 10 years; and adolescent, older than 10 years. Back pain is far less common in children than in adults. In children, such pain usually signals the presence of organic disease. In adolescents, however, back pain can result from musculoskeletal strain or from spondylolysis (ie, fracture of pars interarticularis).

Epidemiology

The most common type of torticollis in children is congenital muscular torticollis. The prevalence in the United States is estimated to be between 0.3% and 2% and is increased in breech presentations (eg, 1.8% breech presentation vs 0.3% vertex presentation). It occurs in up to 1 in 250 live births and is associated with developmental dysplasia of the hip (DDH) in up to 10% to 20% of affected infants. Family history may be positive in up to 10% of cases.

Acquired torticollis is much more common in older children and usually is secondary to trauma or infection, including cervical lymphadenitis, retropharyngeal abscess, myositis, and even upper respiratory tract infections. Episodes of benign paroxysmal torticollis, which often begin in the first year after birth and generally resolve by 5 years of age, may have a familial basis. An association with benign paroxysmal vertigo and migraines has been noted.

Some degree of spinal asymmetry or scoliosis occurs in approximately 2% to 5% of the population. Infantile scoliosis is rare in the United States and usually spontaneously resolves. The prevalence of juvenile scoliosis among school-age children in the United States is 3% to 5%. A right thoracic single curve is the most common curve seen by physicians. Seventy-five percent to 80% of cases of structural scoliosis are idiopathic, 10% are the result of neuromuscular causes, 5% are congenital, and the remaining 5% to 10% are the result of trauma or miscellaneous causes. Scoliosis that begins in childhood affects boys and girls equally, and affected boys outnumber girls from birth to age 3 years. Idiopathic scoliosis that manifests after age 10 years is more common in girls than boys, however, with a ratio estimated between 5:1 and 7:1. In children with cerebral palsy, the incidence of scoliosis is increased, occurring in approximately 20% of children with cerebral palsy.

Back pain is quite uncommon in preadolescent children. Unlike in adults, in whom it is often difficult to identify the cause, most instances of back pain in children have an identifiable etiology.

Clinical Presentation

Although torticollis may be noted at birth, it usually presents at 2 to 4 weeks of age. Infants with congenital muscular torticollis present with a characteristic head tilt toward the affected side with the chin pointing toward the opposite side; this positioning is secondary to unilateral fibrosis and contracture of the sternocleidomastoid muscle (Figure 119.1). Unrecognized or untreated torticollis may present as plagiocephaly (see Chapter 85) or facial asymmetry during infancy. Benign paroxysmal torticollis of infancy may present as recurrent episodes of head tilt that may be associated with vomiting, ataxia, agitation, or malaise (Box 119.1).

Mild scoliosis may not present with obvious deformity. Shoulder height asymmetry, scapular prominence or position, rib prominence or hump, waistline asymmetry or pelvic tilt, and leg length discrepancy may all be presenting signs of scoliosis (Box 119.1) (Figure 119.2A). Scoliosis may be detected during school-based screening programs or preparticipation sports physical examinations. Back pain is reported in 25% of adolescents with idiopathic scoliosis. When pain is present, further examination for some other cause (eg, bone tumors, spondylolysis, spondylolisthesis) is warranted. Preverbal children with back pain may present with limp or refusal to bear weight.

Pathophysiology

Torticollis may be either congenital or acquired. The etiology of congenital muscular torticollis is unknown. It is believed to be the result of intrauterine positioning or trauma to soft tissue of the neck during delivery, resulting in venous occlusion and ischemia of the sternocleidomastoid muscle. This causes edema and degeneration of the muscle fibers with eventual fibrosis of the muscle body. However, a prospective study of 821 patients with congenital muscular torticollis found that 55% of patients had a sternocleidomastoid tumor, 34% patients had thickening and tightness of the sternocleidomastoid, and 11% had head tilt without tumor or thickening of the sternocleidomastoid. Deformities of the face and skull may result if the condition is left untreated. Plagiocephaly (ie, cranial asymmetry), with flattening of the face on the affected side and flattening of the occiput on the contralateral side, is an associated finding.

Unlike kyphosis and lordosis, which are curves in the anterior-posterior plane, scoliosis is a lateral curvature of the spine occurring in the coronal plane. Scoliosis can be either functional (ie, nonstructural) or structural. In functional scoliosis, there is no fixed deformity of the spine and the apparent curvature disappears on lying down or on forward flexion. Individuals with leg length discrepancies may appear to have scoliosis but have no spinal abnormality.

Box 119.1. Diagnosis of Torticollis and Scoliosis in the Pediatric Patient

Torticollis

- Head tilt
- Limited neck range of motion
- Contracture of the sternocleidomastoid muscle
- Plagiocephaly associated with congenital torticollis
- Firm, nontender, mobile mass within the body of the sternocleidomastoid muscle (congenital torticollis with intramuscular hematoma)

Scoliosis

- Lateral curvature of the spine
- Some pain
- Back or truncal asymmetry

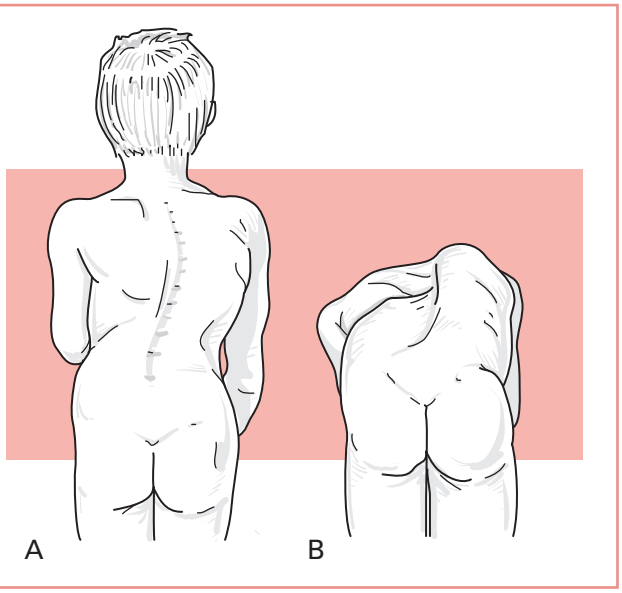

Figure 119.2. Illustration of a child with scoliosis. A, Rear view with the child standing. B, Rear view of the forward bend test.

Figure 119.1. Illustration of an infant with congenital muscular torticollis with the characteristic head tilt.

Structural scoliosis may be idiopathic or caused by various underlying disorders, such as muscular dystrophy or cerebral palsy in the nonidiopathic neuromuscular forms. The cause of idiopathic scoliosis is unknown, but there appears to be a higher incidence of scoliosis amongst other family members. Abnormalities of fibrillin have also been noted in some patients with scoliosis, a finding that is reported in patients with Marfan syndrome as well. In structural scoliosis, the spine has both a coronal curvature and a rotational component, which results in deformity of attached structures. For example, a "rib hump" may be produced as a result of scoliosis in the thoracic spine (Figure 119.2B). Pelvic obliquity or flank prominence may be produced when the curvature is in the lumbar spine.

Differential Diagnosis

The differential diagnosis of congenital and acquired torticollis is presented in Box 119.2. Torticollis not at birth is termed congenital muscular torticollis and is differentiated from acquired torticollis, which occurs in older infants and children and is secondary to another condition. When torticollis occurs in association with nystagmus and head nodding, this clinical triad is referred to as "spasmus nutans." Cervical lymphadenitis is a common cause of acquired torticollis that is seen in children 1 to 5 years of age, whereas trauma to the soft tissues or muscles of the neck is seen more frequently in school-age children. Acute episodes (eg, benign paroxysmal torticollis of infancy) must be differentiated from chronic conditions (eg, Sandifer syndrome, rheumatoid arthritis) based on the history.

Functional or nonstructural scoliosis may occur secondary to poor posture, leg length discrepancy, or muscle spasm. Structural scoliosis can be classified as idiopathic, congenital, neuromuscular, or miscellaneous (Box 119.3). Idiopathic scoliosis, which is by far the most common type of structural scoliosis, may be divided into 3 categories based on age: infantile (<3 years), juvenile (3–10 years), and adolescent (>10 years). The adolescent form occurs most frequently, accounting for up to 85% of cases.

Congenital scoliosis arises from anomalies in the development of the spine resulting in hemivertebrae or unsegmented vertebral bars. Because of the high incidence of anomalies in other body systems, such as cardiac and genitourinary anomalies, patients with congenital scoliosis require screening for associated abnormalities. Although neuromuscular scoliosis is most often seen in children with spastic cerebral palsy, it may be apparent in other conditions as well, such as poliomyelitis, meningomyelocele, muscular dystrophy, Friedreich ataxia, and spinal muscular atrophy. The miscellaneous causes of scoliosis are uncommon and include trauma, metabolic disorders, and neurocutaneous diseases.

The most common causes of back pain in children may be classified into 5 distinct categories (Box 119.4). When pain is significant enough that a child presents to the emergency department, common causes include trauma (25%), muscle strain (24%), sickle cell crisis (13%), idiopathic cause (13%), urinary tract infection (5%), viral syndrome (4%), and not categorized (16%). Other infectious causes, such as diskitis, occur much more frequently in children than adults. However, diskitis is rare in the pediatric population, with an estimated 1 to 2 cases per 32,500 pediatric emergency encounters. A child presenting with back pain should also be considered for an oncologic process, such as

Box 119.2. Common Causes of Torticollis

Congenital

- Congenital muscular torticollis
- Occipitocervical spine anomalies (eg, Klippel-Feil syndrome)
- Pterygium colli (ie, skin web)

Acquired

Infectious

- Cervical lymphadenitis
- Osteomyelitis of cervical vertebrae
- Retropharyngeal abscess

Traumatic

- Atlanto-occipital, atlas-axis (C1-C2), or C2-C3 subluxation
- Cervical musculature injury (eg, spastic torticollis)
- Cervical spine fractures

Neurologic

- Dystonic drug reactions
- Ocular disturbances (eg, strabismus, nystagmus)
- Syringomyelia
- Tumors located in the posterior fossa or cervical cord

Other

- Benign paroxysmal torticollis of infancy
- Hysteria
- Rheumatoid arthritis
- Sandifer syndrome (hiatal hernia with gastroesophageal reflux)
- Soft tissue tumors of the neck
- Spasmus nutans

Box 119.3. Common Causes of Scoliosis

Functional Scoliosis

- Back injury
- Herniated disk
- Leg length discrepancies
- Muscle spasm
- Poor posture

Structural Scoliosis

- Congenital
- Idiopathic
- Intraspinal tumors
- Marfan syndrome
- Metabolic disorders (eg, juvenile osteoporosis, osteogenesis imperfecta, mucopolysaccharidosis)
- Miscellaneous
- Neurocutaneous syndromes (eg, neurofibromatosis)
- Neuromuscular
- Trauma (eg, fractures or dislocations of the vertebrae)

Box 119.4. Common Causes of Back Pain in Children

Infectious
- Diskitis (more common in children younger than 5 years)
- Myalgias (eg, influenza)
- Referred pain (eg, pyelonephritis, pneumonia)
- Vertebral osteomyelitis (ie, pyogenic, tuberculous [ie, Pott disease])

Inflammatory
- Crohn disease/ulcerative colitis/psoriatic arthritis
- Disk space calcification
- Rheumatologic diseases (eg, juvenile rheumatoid arthritis, ankylosing spondylitis)

Neoplastic
- Benign tumors (eg, eosinophilic granuloma, osteoid osteoma)
- Metastatic disease (eg, neuroblastoma)
- Primary vertebral and spinal tumors (eg, Ewing sarcoma, osteosarcoma, neuroblastoma)

Developmental
- Scheuermann kyphosis (adolescents)
- Spondylolysis, spondylolisthesis (adolescents)

Traumatic
- Compression fracture of vertebrae
- Herniated nucleus pulposus (disk herniation)
- Ligamentous or muscle strain (eg, overuse syndromes)

Other
- Child abuse
- Osteoporosis (eg, rickets, osteogenesis imperfecta)
- Psychogenic
- Sickle cell crisis

Box 119.5. What to Ask

Torticollis
- Is there any family history of torticollis?
- What type delivery did the mother have (eg, cesarean section, vaginal delivery)? Were forceps required?
- When was the head tilt first noticed?
- Does the infant move the neck in all directions, or does the infant always prefer to look in 1 direction?
- Does the infant have any recent history of trauma to the head or neck area?
- Is the head tilt persistent, or does it come and go?
- Has the infant been sick or febrile?
- Does the child exhibit nystagmus or head bobbing?

Scoliosis
- Is there a family history of scoliosis?
- Have the parents or guardians noticed the curvature of the spine? If so, how old was the child when the condition was first noted?
- Has the curvature increased since it was first noticed?
- Does the child have any back pain?
- Has the child had any previous treatment for the condition?
- (If appropriate): Has the child begun menstruating?
- Is the child experiencing neurologic symptoms?
- Does the child have concerns about cosmesis?

Back Pain
- How long has the child had the pain?
- Where is the pain localized?
- Is the pain persistent, or does it come and go?
- Does the pain radiate anywhere (eg, down the legs)?
- Is the child limping or having difficulty walking?
- Has the child lost any motor milestones (eg, skills such as walking or standing that the child could previously perform)?
- What makes the pain better? What makes it worse?
- Is there a recent history of trauma, or has the child begun participating in a new sport or physical activity?
- Has the child had a fever?
- Has the child had any problems with bowel or bladder function?
- Is the child taking any medication?

osteoid osteoma, osteoblastoma, or hemangioma. Because the spine of children is smaller and has greater flexibility and ligamentous strength than the adult spine, children are at lower risk of traumatic injury than adults. Common causes of back pain in adults, such as musculoskeletal back pain (ie, muscle strain) and discogenic pain, are uncommon in children. Individuals who are predisposed to musculoskeletal back pain often experience their first episode during adolescence or young adulthood; only 1% to 4% of disk herniations occur in children.

Evaluation

History

A careful history may provide clues to diagnosis and etiology (Box 119.5). Approximately 25% of adolescents with scoliosis experience back pain.

Physical Examination

In the child with suspected torticollis, a thorough examination with specific attention to the head and neck region should be performed. Limited head rotation toward the affected side with decreased lateral side bending to the opposite side may occur. During the first 4 to 6 weeks after birth, a firm, nontender, mobile mass (ie, pseudotumor) may be palpated within the body of the sternocleidomastoid muscle; the mass gradually regresses by 6 months of age. Because torticollis is associated with DDH, the hips should be examined for stability. A neurologic examination should also be performed for any neurologic deficits that may be indicative of an underlying tumor. Fever or signs of inflammation are indicative of infectious causes. Because torticollis may be secondary to visual disturbances (eg, strabismus), a careful eye examination is warranted. The presence of nystagmus or head nodding is suggestive of spasmus nutans.

Screening for scoliosis should be part of the routine health maintenance examination of school-age children and adolescents.

Children should be examined with the back fully exposed. School screening methods have proven to be effective for evaluation and early referral to an appropriate health professional. The posture should be observed from the front, back, and both sides. The presence of any skin lesions, such as café au lait spots, should be noted. Any midline skin defects, such as dimples or hair patches, also should be noted because often they are associated with underlying spinal lesions. The spine should be palpated for any signs of tenderness, and a complete neurologic examination should be performed.

The back should be observed for asymmetry of the shoulders, scapulae, or pelvis. The Adam's Forward Bend Test may demonstrate a characteristic rib hump. The physician should have the child bend forward at the waist to an angle of 90° with the knees straight and the palms held together. This maneuver accentuates the curvature of structural scoliosis and emphasizes the rotational deformity of the spine. For example, in thoracic scoliosis, a characteristic rib hump is apparent on the convex side of the curve (Figure 119.2B). A scoliometer can be used to estimate the degree of scoliosis. More than 7° of rotation correlates with a Cobb angle of 20° and warrants referral to an orthopedic surgeon. Screening using a scoliometer in combination with the forward bend test is effective in early identification and screening.

Scoliosis is described in terms of the primary (ie, major) curve. The major curve may be accompanied by a secondary (ie, minor) curve. The location of the curve is defined by the apical vertebra (eg, T2-T11, thoracic; T12-L1, thoracolumbar), the direction of the curvature by the side of convexity, and the severity by the degree of curvature as measured on the spinal radiograph. Curves greater than 15° are abnormal. Mild scoliosis is defined as curvature of less than 20°, moderate as curvature of 20° to 40°, and severe as curvature greater than 40° to 45°.

The evaluation of back pain begins with observation of the child's posture and gait. Any midline skin lesions should be noted. A thorough general physical examination is important, because referred pain (eg, pancreatitis, pyelonephritis, nephrolithiasis) may be causing the symptoms in the back. The spine should be palpated for any signs of tenderness. A complete neurologic examination should be performed, and any motor or sensory deficits should be noted. The motor examination should emphasize evaluation of the hips and the lower extremities, including range of motion and strength. Any "red flag" symptoms associated with back pain should raise concern for an oncologic process.

Laboratory Tests

In cases of congenital torticollis, laboratory studies are rarely necessary. In the patient with acquired torticollis in whom infection is suspected, however, a complete blood cell count and blood and local cultures may aid in the diagnosis.

No specific laboratory tests are required in the evaluation of idiopathic scoliosis. Specific laboratory studies may be performed in the evaluation of other forms of scoliosis as indicated by the history and physical examination (eg, urine metabolic screening for suspected metabolic disturbances).

Laboratory assessment for back pain depends on the history and physical examination. A complete blood cell count, blood culture, and erythrocyte sedimentation rate may be useful in the evaluation of suspected infectious etiologies. After the diagnosis of diskitis is established, image-guided aspiration or blood cultures should be drawn to identify the bacterial organism. Rheumatologic studies, such as a rheumatoid factor or human leukocyte antigen typing, may aid in the diagnosis of inflammatory conditions. If the back pain is of acute onset, a laboratory study may be warranted to determine whether the pain is referred rather than musculoskeletal. For example, urinalysis or a serum amylase test may be performed to diagnose pyelonephritis or pancreatitis, respectively.

Imaging Studies

In the child with suspected torticollis, radiographs generally are not useful unless bony anomaly is suspected. Anteroposterior and lateral views of the cervical spine can identify subluxation of C1-C2; however, less than 1% of children with torticollis have a subluxation. Ultrasonography may reveal the location of a sternocleidomastoid mass. Magnetic resonance (MR) imaging of the sternocleidomastoid muscle mass may be considered if an underlying condition (eg, branchial cleft cyst) is suspected. Computed tomography or MR imaging of the head or cervical spinal cord is indicated if a neurologic tumor is suspected.

Routine radiographs are not required in the evaluation of all children with mild scoliosis (ie, minor degrees of curvature noted on physical examination). It may be best to obtain radiographs after orthopedic evaluation is complete. Radiographic imaging should be used as sparingly as possible to limit the radiation dose incurred by the child during the course of treatment of the scoliotic curve. Standing posteroanterior and lateral spine radiographs are obtained to determine the location and direction of the curvature, measure the degree of asymmetry (ie, Cobb angle), and evaluate the vertebrae. Shoe lifts should be used prior to radiography to compensate for leg length discrepancy. Repeat radiographs of the spine are obtained to follow the progression of the curvature over time. Because the risk of curve progression before skeletal maturity is a primary concern, radiographs of the hand and wrist should be obtained to assess bone age in the prepubertal child with scoliosis. Magnetic resonance imaging is recommended in the individual with rapid progression of the curve (ie, 1° per month), an atypical curve (eg, left thoracic curve), or abnormal physical examination findings (eg, abnormal abdominal reflexes). Magnetic resonance imaging should include the cervical, thoracic, and lumbar spine to identify deformities such as Arnold-Chiari malformation, tethered cord, or syrinx.

As with scoliosis, routine radiographs are not indicated in all patients with back pain. Various radiologic studies may be ordered depending on the suspected diagnosis. Radiographs may be useful in the evaluation of suspected vertebral abnormalities, such as spondylolysis and spondylolisthesis. However, these conditions may represent incidental findings and may not be the source of the back pain. If diskitis is suspected, bone scanning may be more appropriate than radiography. Similarly, bone scanning or MR imaging is useful in the evaluation of suspected vertebral tumors.

Management

Management of congenital muscular torticollis consists of passive stretching exercises of the neck. With the neck in a neutral position (ie, not in hyperextension), the head is bent to 1 side so that the ear on the side opposite to the contracted muscle is brought to the shoulder, or alternatively the chin is lowered to touch the shoulder on the affected side. These exercises are done 3 times per week, with each session consisting of 3 repetitions of 14 manual stretches of the affected sternocleidomastoid muscle. Additionally, changing the placement of the crib in relation to the nursery door and repositioning toys and mobiles in the crib stimulate children to look toward the side opposite the preferred gaze. The child should also be fed with the chin turned toward the shoulder of the affected sternocleidomastoid muscle. Torticollis resolves spontaneously in most infants. When the deformity persists beyond the age of 1 to 2 years, surgical release of the contracted muscle may be indicated. Newer, less invasive methods of arthroscopic or radiofrequency release under local anesthesia have been proposed and used to provide better functional outcomes and reduce the risks associated with open surgical procedures.

Management of acquired torticollis is dependent on the etiology. The evaluation and management of many of these conditions can be complex and often requires consultation with specialists in otolaryngology, head and neck surgery, neurology, and orthopedic surgery.

The 3 types of management of scoliosis are observation, bracing, and surgery. An estimated 10% of individuals with adolescent idiopathic scoliosis require some form of treatment. Observation involves close follow-up with careful repeat physical examinations and radiographic studies. The child who has not undergone the rapid growth phase is at greatest risk of marked progression of the curve. The Risser sign is a common radiographic tool to estimate skeletal maturation. The sign is based on the degree of ossification of the iliac apophysis, with Risser 0 signifying no ossification and Risser V representing full ossification. An initial consultation with an orthopedic surgeon is generally advisable, even for minor degrees of curvature. The goal of follow-up is early detection of curvature with implementation of treatment to prevent or minimize curve progression. The child with a curve of less than 20° to 25° should undergo assessment every 4 to 6 months at a specialist clinic to monitor for curve progression. To minimize radiation exposure, only posteroanterior radiographs are obtained at each subsequent visit. A curve of between 25° and 45° in the skeletally mature individual (ie, Risser IV or V) does not require bracing; however, such curves should be braced (eg, with a Milwaukee brace) in the growing child (ie, Risser 0 or I). The goal of bracing is not to correct any existing curvature but to prevent further curve progression. The efficacy of bracing is determined by adherence to the regimen; however, poor compliance is common and is thought to be the result of social ostracism. Evidence has shown that greater than 18 hours of wear daily is required to achieve optimal results. Surgery (eg, Harrington rod placement, posterior spinal fusion) may be indicated for the child with a curve of greater than 45° to 50°. These curves have a high likelihood of progression into adulthood. The goals of surgery include arrest of curve progression, improved cosmesis, and improved functional capacity. The development of pedicle screws has advanced the process of spinal fusion.

Although the management of back pain is diagnosis dependent, rest and immobilization are principles of treatment that apply in many instances. Management of diskitis is reliant on culture-specific antibiotics, and surgery usually can be avoided. If spondylolisthesis and spondylolysis are not responsive to rest and immobilization, surgical stabilization may be required. In the adolescent with low back pain related to muscular injury, conservative treatment, including bed rest, heat, and nonsteroidal anti-inflammatory drugs, may be tried for 1 to 2 weeks followed by a gradual return to normal activity. It is not advisable to institute such treatment in younger children without pursuing a more extensive evaluation or consultation with an orthopedic surgeon, because the risk of serious disease is significant in this age group.

Prognosis

Congenital muscular torticollis responds to conservative management in approximately 90% of infants. The asymmetry of the face and skull also corrects over time after the contracture of the sternocleidomastoid muscle resolves. Spasmus nutans, which manifests between 4 and 12 months of age, usually resolves spontaneously by 3 years of age.

The direction and location of the curvature in scoliosis do not change with age; however, the degree of curvature may remain stable or progress. The earlier the age of onset, the worse the prognosis because of the amount of remaining growth and the potential for curve progression. Factors associated with a high risk of curve progression include female sex, a positive family history for scoliosis, younger age at diagnosis (especially before the adolescent growth spurt), and a larger curve at the time of diagnosis. Additionally, a double curve is more likely to progress than a single curve, and a thoracic curve is more likely to progress than a lumbar curve. Left untreated, severe scoliosis can cause cardiopulmonary impairment or cosmetic deformity, resulting in low self-esteem and poor body image. Decreased exercise tolerance has been reported in individuals with curves as small as 20°. Individuals with infantile and juvenile scoliosis can experience increased mortality from pulmonary and cardiac conditions during their 40s and 50s in comparison to the adolescent form.

Most cases (80%–90%) of low back pain in adolescents and young adults resolve spontaneously in 2 to 8 weeks. It is important for patients to learn how to prevent recurrence by improving posture, learning how to lift heavy objects appropriately, and instituting a program of exercises to help strengthen the muscles of the abdomen, back, and core stabilizers.

CASE RESOLUTION

The history of the infant is consistent with congenital muscular torticollis. Physical examination helps confirm the diagnosis. The hips should be evaluated thoroughly because of the association of congenital muscular torticollis with DDH. A program consisting of neck stretching exercises and repositioning of interesting toys and objects in the infant's crib to the side opposite the preferred gaze should be instituted. The infant can be reevaluated in 2 to 3 weeks to monitor progress.

PART 11

Gastrointestinal Disorders

CHAPTER 120

Vomiting

George Gershman, MD

CASE STUDY

A 10-month-old previously healthy infant was brought to the emergency department by his mother, who reported the sudden onset of green emesis and abdominal pain over the last 4 hours. Vomiting was not associated with meals. The mother denied recent illness, travel, or sick contacts. The patient's past medical history is unremarkable. His birth weight was 3,200 g (7.05 lb), and his current weight is 9,080 g (20.0 lb). The physical examination is significant for distended abdomen tender to palpation.

Questions

1. What is the mechanism of vomiting?
2. What are the common causes of vomiting in newborns and infants?
3. What are the common causes of vomiting in older children?
4. What is the significance of bilious vomiting?
5. What are the unique features of vomiting related to increased intracranial pressure?
6. What are some strategies for the management of vomiting in older children?

Vomiting is a common symptom in infants and children and led Thomas Phaire to write, "Many tymes the stomake of ye child is so feble that it cannot retayne eyther meate or drynke..." (*The Boke of Chyldren*, 1544). *Vomiting* is defined as the forceful ejection of the stomach contents through the mouth. The mechanism involves a series of complex, neurologically coordinated events under the control of the central nervous system (CNS). Vomiting is often accompanied by autonomic signs such as pallor, diaphoresis, hypersalivation, listlessness, and tachycardia. Nausea and vomiting are common symptoms in infants and children and may be associated with gastrointestinal (GI) illnesses, other acute or chronic disorders, and medications.

In contrast, *regurgitation* (commonly called "spitting up" by parents) is the effortless bringing up of 1 or 2 mouthfuls of food without distress or discomfort. This is a frequent symptom of gastroesophageal reflux in infants (see Chapter 121). *Rumination,* a form of autostimulation, is the voluntary induction of regurgitation. It is most often noted in infants between the ages of 3 and 6 months. Rumination occurs in infants with developmental delays or with a disturbed mother-infant relationship. Rumination should be considered in infants from deprived environments (eg, neglectful homes).

Epidemiology

Fifty percent of infants have spitting up or vomiting as an isolated symptom, and less than 5% of these infants have significant underlying disease. Vomiting occurs less frequently in older children, who often experience acute, self-limited illnesses, such as gastroenteritis.

Clinical Presentation

Vomiting is categorized by its color (bilious or non-bilious) and temporal pattern (ie, acute, chronic, or cyclic [episodic]). The vomitus is considered bilious if it has a green or bright yellow color, indicative of large amounts of bile in the stomach and usually associated with intestinal obstruction. When vomiting occurs suddenly in a previously healthy child, it is acute. Most frequently, vomiting is related to acute gastroenteritis, urinary tract or other extraintestinal infections, or toxic ingestion. Acute vomiting may be indicative of a surgical condition, such as appendicitis, intestinal obstruction, or other acute condition. Chronic vomiting consists of a low-frequency (ie, once or twice daily) vomiting that never leads to dehydration. Chronic conditions such as peptic ulcer disease, Crohn disease, and cow's milk protein allergy can be associated with chronic vomiting. Children with cyclic vomiting experience intense, unremitting nausea and paroxysmal vomiting lasting hours to days, often leading to dehydration.

Infants and children may present with vomiting as an isolated symptom or in association with other symptoms, including faintness, diaphoresis, sweating, pallor, tachycardia, fever, anorexia, abdominal pain, and diarrhea (Box 120.1). When vomiting has persisted over a period, weight loss or failure to thrive (FTT) may occur. Neurologic symptoms, including headache and gait disturbances, may be noted in children with CNS problems. Other neurologic symptoms of altered muscle tone, lethargy, seizures, or coma in young infants suggest inborn errors of metabolism.

Pathophysiology

Vomiting is a reflex reaction that occurs in response to numerous stimuli, such as enteric infections, toxins, drugs, chemotherapy, and radiation. The final common pathway involves expulsion of food from the relaxed stomach into the mouth due to coordinated contraction of the abdominal wall, respiratory muscles, increased

- Lethargy

intra-abdominal and thoracic pressure, and relaxation of the lower and upper esophageal sphincters.

Anything that delays gastric emptying may be associated with vomiting. Gastric emptying may be delayed by a high-fat meal, swallowed mucus (eg, maternal mucus after birth, nasal mucus with an upper respiratory infection), fever, infection, and malnutrition. Delayed gastric emptying may develop with long-standing diabetes mellitus.

Vomiting can be divided into 3 phases: nausea, retching, and emesis. However, nausea may occur without retching and vomiting, and retching may occur without vomiting.

Nausea is a significant and difficult-to-define discomfort related to the sensation of a need to vomit. It can be produced by various stimuli (eg, bacterial toxins, drugs, intestinal distention, visceral pain, unpleasant memories, labyrinthine stimulation, noxious odors, visual stimulations, unpleasant taste, increased cerebral pressure). Peripheral receptors in the stomach and the small and large intestines detect emetic stimuli, distention and contractions are recognized by mechanoreceptors, and toxins are sensed by chemoreceptors. Emetic stimuli may also originate from the obstructed or inflamed bile ducts, peritoneal inflammation, mesenteric vascular occlusion, pharynx, and heart. Vagal pathways mediate emetic responses to a variety of peripheral stimuli. Most afferent vagal fibers project to the nucleus tractus solitarius and some to the area postrema or dorsal vagal motor nucleus. The serotonergic pathway plays the central role in nausea induced by peripheral stimuli.

The area postrema on the dorsal surface of the medulla close to the fourth ventricle is considered the chemoreceptor trigger zone to a variety of neurochemical stimuli. Bacterial toxins, drugs, toxic products of metabolic disorders, and radiation therapy may induce nausea by stimulation of numerous central receptors: dopamine D_2, muscarinic M_1, histaminergic H_1, serotonergic 5-HT3, and vasopressinergic subtypes located in the area postrema. However, afferent excitation of multiple brain sites, including the nucleus tractus solitarius, dorsal vagal and phrenic nuclei, medullary nuclei controlling respiration, hypothalamus, and amygdala, is responsible for coordinated activities of various organs and muscles and the induction of retching and emesis.

Retching is the second phase of vomiting. It is produced by concurrent contractions of inspiratory thoracic, diaphragmatic, and abdominal muscles against the closed glottis. The generated high positive intra-abdominal pressure forces gastric contents into the esophagus and herniates the gastric cardia into the thorax. At this phase, the high negative thoracic pressure prevents emesis of gastric fluids.

Emesis is the final stage of vomiting. Synchronous contractions of the inspiratory and expiratory muscles generate high positive intrathoracic pressure sufficient to produce expulsion of gastric contents into the mouth. Oral propulsion of the vomitus is facilitated by the elevation of the hyoid bone and larynx. Airways are protected from aspiration by glottis closure. Elevation of the soft palate prevents passage of the vomitus into the nasal cavities. Hyperventilation may occur before emesis. During vomiting, breathing is suppressed.

With emesis, retrograde giant contractions originate from the middle of the small intestine. Intestinal contents move into the stomach, causing duodenogastric reflux. Within the stomach, the fundus remains flaccid, but the antrum and pylorus contract. Relaxation of the lower esophageal sphincter also occurs.

In children with pyloric stenosis, duodenogastric reflux is prevented by hypertrophy of the pylorus. Projectile vomiting is facilitated by giant, often-visible contractions of the antrum and relaxation of the proximal stomach and low esophageal sphincter. Nausea is not associated with vomiting related to pyloric stenosis, and affected infants are frequently eager to eat immediately after vomiting.

Vomiting induced by increased intracranial pressure (ICP) is also not associated with nausea. In addition, such vomiting frequently occurs first thing in the morning on awaking and on an empty stomach. Regurgitation is a return of undigested food back up the esophagus to the mouth without the force and displeasure associated with vomiting. It could be manifested by visible spitting up after feeding or could be silent. Clinical evidence of regurgitation is not always associated with gastroesophageal reflux disease.

Differential Diagnosis

Vomiting can be a manifestation of GI, renal, metabolic, allergic, and CNS disorders, and the age of the patient influences the differential diagnosis and management. Some conditions respond to medical management, and others mandate surgical intervention (Box 120.2). The green color of the vomitus, referred to as *bilious vomiting,* is a serious sign, usually indicative of intestinal obstruction distal to the major duodenal papilla and of the need for surgical intervention. Bilious vomiting can also occur in children with pseudo-obstruction or acute pancreatitis and other conditions associated with paralytic ileus.

The presence of blood in the vomitus is another ominous sign and is discussed in Chapter 122.

The most common cause of vomiting is acute viral or bacterial gastroenteritis. Acute gastroenteritis is discussed in greater detail in Chapter 123. In cases that are not related to acute gastroenteritis, considering the age of the patient is the best approach to the differential diagnosis of vomiting.

Newborns and Infants

Vomiting in neonates may be associated with the ingestion of irritants such as maternal blood or mucus. Either of these substances

Box 120.2. Differential Diagnosis of Vomiting in Infancy

Medical Conditions

- Gastroenteritis
- Ingestion of maternal blood or mucus
- Overfeeding
- Food allergies
- Gastroesophageal reflux

Surgical Conditions

- Atresia/stenosis of gastrointestinal tract
- Pyloric stenosis
- Volvulus
- Inborn errors of metabolism
- Congenital adrenal hyperplasia
- Infections (eg, otitis media, urinary tract)
- Congenital megacolon (Hirschsprung disease)
- Intussusception
- Appendicitis

delays gastric emptying. Structural anomalies of the GI tract may also cause vomiting in neonates. The onset of symptoms is directly related to the level of obstruction—the higher the structural obstruction, the earlier the onset of vomiting. Lesions of the esophagus, such as esophageal atresia, may be evident in the delivery room, with an unsuccessful attempt to pass a nasogastric tube. Lower GI lesions, such as ileal atresia, may not present for several days. These lesions require surgical intervention. Infants with atretic lesions may also have a history of polyhydramnios or a single umbilical artery.

Overfeeding is the most common reason for regurgitation in young infants. Frequently, infants who present with vomiting are actually experiencing regurgitation. Overfeeding is less likely to occur in breastfed infants because they have better control of their satiety. The physician should approach breastfed infants who are vomiting with care and concern.

Mothers of formula-fed infants may feel that the volume of formula consumed by their infants is insufficient. Some non-nursing mothers feel the need to reinsert a nipple in the infant's mouth, and infants who are still interested in nonnutritive sucking continue to feed, often exceeding the capacity of the stomach.

Food allergies are another common cause of vomiting during infancy. Infants with cow's milk formula intolerance may experience vomiting. At least 30% of these infants are also allergic to soy protein. Associated symptoms such as diarrhea, rhinorrhea, eczema, and growth failure frequently occur.

Gastroesophageal reflux is a common cause of regurgitation. It is described in detail in Chapter 121.

Achalasia, which is a rare cause of vomiting during infancy, is defined as an absence of effective esophageal peristalsis and coordinated relaxation of the low esophageal sphincter. Ingested food that is unable to pass into the stomach may be regurgitated. Children with achalasia usually do not present until later in childhood, although they may have a prenatal history of polyhydramnios, a sign suggesting an abnormal swallowing pattern, even in utero.

Metabolic disorders, including inborn errors of metabolism and endocrine problems, may also be associated with vomiting. For example, children with galactosemia may present with vomiting as well as with jaundice, dehydration, cataracts, and hepatomegaly. Other inborn errors of metabolism include methylmalonicacidemia, disorders of the urea cycle, phenylketonuria, maple syrup urine disease, renal tubular acidosis, hypercalcemia, and diabetes insipidus. Some of these disorders induce symptoms suggestive of sepsis, such as lethargy and seizures.

Male newborns and infants with congenital adrenal hyperplasia may present with vomiting and electrolyte disturbance, symptoms indicative of adrenal insufficiency. Affected male newborns usually present at about 10 to 14 days of age with vomiting and hyperkalemia (which should not be attributed to hemolysis of the specimen); hyponatremia manifests later. In females, congenital adrenal hyperplasia is usually detected in the newborn nursery because of ambiguous genitalia. Diagnosis of this potentially lethal condition is critical to ensure the institution of replacement therapy and survival of affected newborns and infants.

Vomiting may be induced by infection in parts of the body other than the GI tract. Most notably, urinary tract infections (UTIs) in infants may cause projectile vomiting, a symptom highly suggestive of pyloric stenosis. These infants are usually febrile, and the diagnosis is considered when the urinalysis or culture result is positive. Otitis media may also be associated with vomiting.

Vomiting, especially if unrelated to meals, may occur with increased ICP. In young infants, this suggests the possibility of an intracranial hemorrhage, such as that which occurs with abusive head trauma.

Pyloric stenosis, a condition caused by hypertrophy of the muscle surrounding the pyloric channel, is the most common surgical condition associated with vomiting in infancy. The condition affects males significantly more frequently than females and usually appears in newborns and infants between the ages of 2 weeks and 2 months. Factors that are known to increase the risk of pyloric stenosis include being firstborn and male and having a greater birth weight and early exposure to erythromycin. The emesis is projectile and non-bilious and frequently contains curdled milk, which reflects delayed gastric emptying, a problem caused by failure of the hypertrophied pylorus to relax. Affected newborns and infants have an intact appetite and are eager to eat. In some newborns and infants, starvation leads to few bowel movements and constipation; in others, there may be small, frequent, mucus-laden stools (ie, starvation diarrhea) that represent intestinal juice. If pyloric stenosis is not diagnosed promptly, newborns and infants may fail to gain weight or may exhibit FTT. Symptoms suggestive of pyloric stenosis may result from an antral membrane or duplication of the GI tract.

Children

Vomiting in children is frequently associated with gastroenteritis. Infections elsewhere in the body, particularly UTIs, streptococcal

pharyngitis, and otitis media, are also associated with vomiting. Labyrinthitis presents with vomiting associated with dizziness. Older children with new-onset diabetes mellitus may present with vomiting. Vomiting may also appear in children who are already known to have diabetes; this is particularly true when ketosis is present. Slow gastric emptying (ie, gastroparesis) is a complication of long-standing diabetes mellitus. Vomiting is also a component of peptic ulcer disease, which is described in more detail in Chapter 125.

Vomiting may be a major symptom of CNS-related problems, such as tumors, infections, hydrocephalus, malformations, and other causes of increased ICP. As previously noted, vomiting associated with CNS-related conditions is often unrelated to meals and may not be associated with nausea. Autonomic epilepsy and migraine headaches are also associated with vomiting. Cyclic vomiting is an unusual condition characterized by recurrent episodes of vomiting with intervals of complete wellness between attacks. There is a frequent association of cyclic vomiting with a family history of migraine headaches. Emotional upset and other factors, such as infection and physical exhaustion, can precipitate events. As a rule, cyclic vomiting lasts an average of 2½ to 5½ years, resolving in late childhood or early adolescence. A few patients continue to be symptomatic through adulthood.

Vomiting is among the hallmarks of Reye syndrome, a disorder that involves an encephalopathy in association with fatty infiltration of the liver. The etiology of the condition is unclear, but the root of the disorder seems to be related to mitochondrial dysfunction. Affected children usually have a history of viral illness, most commonly influenza or chickenpox. Following a period of recovery, they experience altered consciousness with vomiting. Hepatic enzymes and serum ammonia are elevated. Aspirin, which uncouples oxidative phosphorylation, is apparently linked to Reye syndrome, epidemiologically as well as theoretically. There has been a marked reduction in the incidence of Reye syndrome related to the decrease in the use of aspirin as well as for children vaccinated against varicella and influenza.

Certain medications, including theophylline, erythromycin, and digitalis, may also be associated with vomiting. Some of these medications cause transient relaxation of the lower esophageal sphincter; others affect the chemoreceptor trigger zone.

Familial dysautonomia (also called Riley-Day syndrome), a rare condition that affects Ashkenazi Jews almost exclusively, results in vomiting. The disorder is inherited in an autosomal-recessive manner and consists of an imbalance in the autonomic nervous system. Children experience intractable vomiting in addition to excess perspiration, inability to produce tears, difficulty swallowing and chewing, and cold hands and feet. They also have hyperpyrexia and hypertension. These children require fluid replacement and management with antiemetics.

Surgical conditions such as appendicitis, gall bladder disease, and twisted ovarian cysts are discussed in Chapter 125.

Adolescents

Vomiting during the adolescent years may be caused by any of the previously mentioned conditions. In addition, adolescents may develop vomiting in association with intentional ingestion of illicit drugs or alcohol. Many adolescents have incorrect notions of the sexual activity needed to initiate pregnancy; teenaged girls who have been vomiting, especially for a time, should be evaluated for pregnancy, regardless of their disclosed sexual activity status.

Adolescents with eating disorders, particularly bulimia, vomit but may not disclose their vomiting. They may ingest emetics, such as ipecac, to help control their weight (see Chapter 64).

Evaluation

History

A complete history is essential for correct diagnosis (Box 120.3). A positive family history of vomiting may suggest a diagnosis of food intolerance or allergy, gastroesophageal reflux or peptic ulcer disease, migraine, or familial dysautonomia.

Physical Examination

The examination can show the effect of vomiting on children's growth. The weight may provide evidence of the chronicity of the process; weight loss suggests a protracted course. Evidence of other infections, such as otitis media or pneumonia, may also be apparent. An abnormal neurologic examination would suggest a CNS process or an inborn error of metabolism. The fundi of the eyes should be assessed for the presence of papilledema or retinal hemorrhages. Nystagmus may be noted in children with labyrinthitis or CNS disturbances. The examination of the abdomen may show abdominal distention due to surgical or nonsurgical conditions such as Hirschsprung disease, malrotation, adhesions after previous surgery, pancreatitis, celiac disease, chronic idiopathic constipation, and abdominal, pelvic, or retroperitoneal masses.

Laboratory Tests

Laboratory assessment is determined by the differential diagnosis. If gastroenteritis or enterocolitis is suspected, an examination of the stools for leukocytes and occult blood is appropriate. Specimens for bacterial or viral cultures or viral antigen detection can be submitted. A complete blood cell count may support the diagnosis of infection

Box 120.3. What to Ask

Vomiting

- What is the nature of the vomiting (eg, projectile, bilious, non-bilious)?
- How long has the child been vomiting?
- Are any symptoms, such as fever, diarrhea, dizziness, or lethargy, associated with the vomiting?
- What is the relationship of the vomiting to meals?
- Does the vomiting occur at night, indicating possible hiatal hernia and gastroesophageal reflux?
- Is there a family history of migraine headache?
- Is the child taking any medications?
- Have any measures been taken to relieve the vomiting?

or reveal signs of anemia. In breastfed neonates and infants, vomited blood should be evaluated using the Apt test to determine whether it came from the mother or infant.

Electrolytes should be obtained in infants or children with a history of significant vomiting and may confirm dehydration, acid-base imbalance, or electrolyte disturbance. Infants with pyloric stenosis who vomit stomach contents typically develop a hypochloremic-hypokalemic metabolic alkalosis, although symptoms must be present for 3 weeks for this disturbance to be noted. Currently, infants with pyloric stenosis are diagnosed earlier in the course of their illness using ultrasonography, and only a mild metabolic acidosis may be seen. A urinalysis also may show evidence of dehydration as well as signs of a UTI. Tests for inborn errors of metabolism, such as urine for acid analysis, are appropriate if this is suspected.

Imaging Studies

Radiographic procedures, such as esophagography or an upper GI series, are the procedures of choice for the diagnosis of esophageal and duodenal atresia and intestinal malrotation. An abdominal ultrasound is most effective in the diagnosis of pyloric stenosis or intussusception. A flat plate of the abdomen may show stomach distention, a double bubble sign (ie, air in the stomach and duodenum), or a paucity of intestinal air in cases of high-level obstruction. Consultation with a pediatric gastroenterologist may lead to additional diagnostic tests, such as endoscopic evaluation, 24- to 48-hour esophageal pH, or combined esophageal pH and impedance monitoring and upper GI endoscopy.

Management

The initial step in the management of vomiting in infants or children is to ensure adequate hydration and integrity of the cardiovascular bed. This may require the administration of intravenous fluids. Oral rehydration is the mainstay of therapy in infants and children whose vomiting is related to gastroenteritis. Small, frequent feedings with clear fluids are better tolerated than large, infrequent feedings, although the latter may be necessary in infants with diarrhea because each feeding may result in a bowel movement. Antiemetics such as phenothiazines are discouraged in children because of the high incidence of side effects, including dystonic posturing. Drugs commonly used in pediatric practice include antihistamines, dopamine D_2, and serotonin 5-HT3 receptor antagonists. Oral ondansetron hydrochloride is frequently used as a single dose to manage the vomiting seen in acute viral gastroenteritis in the pediatric emergency department or as repeated doses for hospitalized children with other conditions associated with vomiting.

Further management depends on the diagnosis. Bacterial infections should be treated with the appropriate antibiotics. Surgical conditions, such as pyloric stenosis or intussusception, should be managed urgently. Inborn errors of metabolism require consultation with a geneticist and dietary manipulation. Congenital adrenal hyperplasia should be managed in consultation with an endocrinologist. This condition necessitates replacement hormonal therapy.

Prognosis

Most cases of acute vomiting resolve spontaneously or are readily managed once the underlying condition is diagnosed. The overall prognosis is, therefore, quite good.

Protracted vomiting may result in starvation and FTT, however. Severe vomiting may cause tears in the esophagus and lead to hematemesis (Mallory-Weiss syndrome). Obstructive causes of vomiting in infants respond to surgical intervention.

CASE RESOLUTION

Bilious vomiting in a previously healthy infant is the warning sign of midgut volvulus and intestinal malrotation. It is a medical emergency due to high risk of extensive small bowel necrosis, which can lead to short bowel syndrome and even death. A prompt fluid resuscitation and urgent upper GI series or Doppler ultrasonography are mandatory to confirm the diagnosis and prepare the child for urgent surgery.

CHAPTER 121

Gastroesophageal Reflux

George Gershman, MD

CASE STUDY

A 9-year-old boy reports frequent episodes of epigastric pain right after eating. The pain is associated with nausea and infrequent vomiting. The pain is described as dull and lasts less than 15 to 20 minutes. The patient also reports a burning sensation in his chest after eating and a cough at night. The patient lacks energy, and his voice is hoarse in the morning. There is no history of dysphagia, odynophagia, or weight loss. The physical examination is normal.

Questions

1. What are the characteristics of gastroesophageal reflux?
2. What is the difference between gastroesophageal reflux and gastroesophageal reflux disease?
3. What groups of children are at risk for gastroesophageal reflux disease?
4. What is the appropriate workup for an infant with suspected gastroesophageal reflux disease?
5. What is the appropriate management of infants and children with gastroesophageal reflux and gastroesophageal reflux disease?
6. What is the natural history of gastroesophageal reflux in children?

Gastroesophageal reflux (GER) is the passage of gastric contents into the esophagus. It is a normal physiological process that occurs in healthy children and adults. Most episodes of reflux in healthy individuals are brief and asymptomatic and are rarely accompanied by *regurgitation,* defined as passage of gastric fluid into the pharynx or mouth. In otherwise healthy, thriving infants, GER is often associated with effortless expulsion of refluxate from the mouth; the condition is colloquially known as spitting up. Those infants fall into the category of "happy spitters."

In contrast with uncomplicated GER, symptomatic GER is defined as GER disease (GERD) and induces conditions such as esophagitis, failure to thrive, and aspiration pneumonia. While GER may require only anticipatory guidance and monitoring, GERD necessitates further evaluation and medical therapy. Thus, although GER could be a sign of GERD, it is important to distinguish these 2 entities for proper patient care.

Epidemiology

Gastroesophageal reflux is very common in infants; at least one-half of healthy infants experience some degree of GER. Most infants with GER or GERD who are brought in for medical care became symptomatic before 6 months of age. Regurgitation occurs at least once daily in one-half of infants younger than 3 months and in nearly two-thirds of infants by 4 months. The frequency and volume of spit-up decrease after age 7 to 8 months, when infants are upright for more of the day. By 12 months of age, only 5% of infants will remain symptomatic. By 18 months of age, most infants become asymptomatic.

Little is known about the prevalence of GERD in children and adolescents. A cross-sectional observational study in more than 10,000 children and adolescents (mean age 3.8 ± 5.6 years) in France revealed the prevalence of GERD as 6%. One retrospective study in the United States showed that 5% to 8% of children and adolescents suffered from weekly symptoms of GERD.

Available data suggest that children who were diagnosed with GERD at 5 years or older have a high prevalence of GERD symptoms in adolescence and as young adults. A small retrospective study of adults who had been diagnosed with GERD in infancy or childhood showed increased symptoms of GERD in those who had a history of GERD in childhood but not in infancy.

High-risk Groups

Patients with neurological disorders have an increased prevalence of GERD. Management of these individuals requires a more aggressive approach. Individuals with neurological impairments are more likely to have esophagitis or aspiration. Infants who have undergone repair of esophageal atresia also have more severe disease, with at least one-half requiring anti-reflux surgery. Chronic respiratory disease, such as cystic fibrosis, is associated with GERD. Gastroesophageal reflux disease is described in two-thirds of patients with asthma, but this association is controversial. It is not clear whether the altered physiology of these diseases causes reflux or if reflux exacerbates the pulmonary dysfunction. Similar triggers for asthma and GERD are described, so it may be that they coexist and are unrelated. Studies with intraluminal impedance monitoring (see the Evaluation section) show that nonacid reflux occurs frequently in patients with asthma. This helps explain the lack of success of therapy aimed at acid suppression in this group of patients.

Clinical Presentation

The most frequent presentation for infants with GER is recurrent non-forceful and small volume emeses (Box 121.1). Vomiting typically occurs after feeding and does not seem to disturb the patient. Some parents report a link between fussiness and crying with feeding, but this is not reproducible in trials comparing symptoms with pH studies. Additional symptoms, such as poor weight gain, anemia, or swallowing difficulties, could be linked to GERD. Sandifer syndrome is a rare presentation of GERD in infants, with characteristic paroxysmal movements involving spasmodic torticollis and dystonia. Nodding and rotation of the head, neck extension, gurgling, writhing movements of the limbs, and severe hypotonia can also be witnessed. Infants and children can develop extraesophageal manifestations of GERD such as nighttime cough, sleep apnea, wheezing, and recurrent pneumonia. Children older than 8 years and adolescents may have symptoms of adult-type GERD, such as frequent heartburn, chest and abdominal pain, and dysphagia.

Pathophysiology

Gastroesophageal reflux occurs when intra-abdominal pressure surpasses intrathoracic pressure. There are 3 main preventive barriers to GER: lower esophageal sphincter (LES), the crus of the diaphragm, and the intra-abdominal esophagus. A contracted LES generates a pressure gradient of 8 to 30 mm Hg between the esophagus and the stomach. The LES relaxes during swallowing, allowing a food bolus to enter the stomach. The skeletal muscle of the crus diaphragm contracts during inspiration or straining, augmenting the pressure of the LES. Contraction of the intra-abdominal esophagus in response to rising of intra-abdominal pressure adds to GER preventive forces.

Most episodes of GER occur during transient esophageal relaxation of LES that is not related to swallowing or straining. Transient esophageal relaxation of LES is considered to be a venting mechanism of the distended stomach and is manifested by belching in typical individuals. Transient esophageal relaxation of LES occurs up to 6 times per hour in typical adults, more frequently with gastric distension after meals, and rarely at night. In children, including preterm and term infants, transient esophageal relaxation of LES is responsible for most GER. Transient esophageal relaxation of LES is mediated by a brain stem reflex involving the vagal nerve and release of nitric oxide. Consumption of a large quantity of milk, poor compliance of the stomach, and a relatively short esophagus of a rapidly growing infant leads to frequent effortless regurgitation of gastric fluid into the esophagus. Posterior location of the gastroesophageal junction in the supine position and raised intra-abdominal pressure when the infant is resting in a car safety seat also facilitate regurgitation.

Transient esophageal relaxation of LES that is too frequent or prolonged exposes the esophageal mucosa to noxious material. Swallowed saliva and coordinated esophageal peristalsis neutralize gastric fluid within the esophagus and sweeps the fluid into the stomach. Inflammation of the esophagus may disrupt this process by decreasing peristaltic activity. Lack of mucus secretion by the esophageal mucosa and poor esophageal clearance increase the risk of esophagitis by exposing the esophageal mucosa to hydrochloric acid, pepsin, bile acids, and pancreatic enzymes. In contrast, frequent feedings with large volume of human milk or formula neutralize gastric acidity and decrease caustic damage of the esophagus in infants.

Before food leaves the esophagus, the stomach must be ready to accept it. The gastric fundus normally relaxes without an increase in pressure. Dysfunction of this fundic accommodation or delay in gastric emptying can increase pressure in the stomach and exacerbate GER.

Box 121.1. Diagnosis of Gastroesophageal Reflux Disease in the Pediatric Patient

Presenting Signs and Symptoms

- Regurgitation
- Vomiting
- Fussiness or sleep disturbance
- Poor weight gain
- Hematemesis or anemia
- Odynophagia or dysphagia
- Asthma/apnea/aspiration

Differential Diagnosis

A diverse group of symptoms, each with its own list of potential diagnoses, are associated with reflux disease. Regurgitation and vomiting are the most commonly reported symptoms. Many of the causes of vomiting in the newborn can be separated from reflux with a history and physical examination (Box 121.2). Forceful, bilious, or bloody emesis is not typical of reflux. Fussiness and crying are nonspecific symptoms with etiologies ranging from infantile colic to meningitis. Eosinophilic esophagitis (EoE) should be considered in toddlers and children with recurrent emesis and atopic dermatitis, food allergy, or asthma and older children and adolescents with dysphagia. Children with EoE may also experience recurrent food impaction in the esophagus. The primary therapy for EoE focuses on dietary manipulation and the elimination of identified foods to which the child is allergic.

Evaluation

Infants who fit into the definition of happy spitter (normal appearing, thriving, with recurrent emesis) do not require any diagnostic workup. It is important to reassure parents or guardians and encourage proper feeding technique. However, the presence of red flag symptoms, such as bilious vomiting, poor weight gain, food avoidance, chronic cough, unexplained anemia, or significant chest or abdominal pain, should prompt thorough diagnostic evaluation.

History

Targeted questions about the timing and volume of feedings and their relationship to regurgitation can help build the case for reflux. Specific attention should be paid to respiratory symptoms such as nighttime cough or previous episodes of pneumonia. Difficulties with feeding and swallowing should be outlined carefully. Gagging or dysphagia with different consistencies of food should be noted. Family history of reflux, especially as an

Box 121.2. Common Non-reflux Causes of Vomiting

Infections
- Sepsis
- Meningitis
- Urinary tract infection
- Otitis media

Obstruction
- Pyloric stenosis
- Malrotation
- Intussusception

Gastrointestinal
- Eosinophilic esophagitis
- Peptic ulcer disease
- Achalasia
- Gastroparesis
- Gastroenteritis
- Gall bladder disease
- Pancreatitis
- Celiac disease
- Pill esophagitis
- Crohn disease

Metabolic/Endocrine
- Galactosemia
- Fructose intolerance
- Urea cycle defects
- Diabetic ketoacidosis

Toxic
- Lead poisoning

Neurological
- Hydrocephalus and shunt malfunctions

- Renal insufficiency

Cardiac
- Congestive heart failure

Other
- Overfeeding
- Self-induced vomiting

Other (Seen in Adolescents)
- Recreational drugs
- Alcohol
- Pregnancy

infant, may be helpful. Clinical questionnaires, including the Infant Gastroesophageal Reflux Questionnaire, have been validated but do not predict prognosis or severity. They are more useful in the research setting.

Physical Examination

A full physical examination should be performed, including an observance of feeding. Neurological deficits or delay should be noted. The abdomen should be carefully palpated for masses or distension. Growth parameters should be reviewed longitudinally, and the child's body habitus, particularly the amount of subcutaneous tissue, should be noted.

Laboratory Tests

Most patients with reflux will need no laboratory testing. Urinalysis and culture are reasonable tests in an infant with sudden onset of emesis. Children with large-volume emesis or weight loss should be assessed for acidosis or other electrolyte abnormalities. Markers of kidney and liver function are reasonable to obtain. Anemia workup should be initiated in a child who is pale, irritable, and undernourished.

Intraesophageal pH Monitoring

Currently, measurement of the intraesophageal pH for periods of 24 to 48 hours is considered the standard for the diagnosis of GERD. This is performed by placing a catheter trans-nasally into the distal esophagus to measure the intraluminal pH as the patient records the symptoms, such as cough and pain. Meals are also recorded. Monitoring of pH can be performed safely in all age groups, and certain parameters of this procedure correlate with esophagitis. Such monitoring does not detect nonacid reflux, however, making its utility in linking respiratory disease to GERD questionable. It may be combined with multichannel sleep studies to investigate apnea or nighttime symptoms. A wireless device that attaches to the esophageal mucosa has been used in children. The device can be placed with or without endoscopy, but the size of the capsule may prohibit its use in smaller children.

Combined Multiple Intraluminal Impedance and pH Monitoring

Impedance monitoring is being used more often to diagnose GER in children. This technology involves the placement of a catheter trans-nasally into the esophagus for measurement of ionic conductivity, which is low when the esophagus is empty and increases when it contains liquid. The catheter has multiple sensors that can detect the direction of liquid flow. Decrease of intraesophageal impedance by liquids moving from the distal sensors upward determines reflux. The addition of a pH sensor to the distal end of the catheter allows the defining of reflux as acid or nonacid. It is superior to pH monitoring alone for evaluation of the temporal relation between symptoms and GER. This study is equally effective in both breastfed and formula-fed infants because it eliminates the buffering effect of human milk or formula on gastric acid to detect nonacid reflux.

Upper Gastrointestinal Series

Upper gastrointestinal radiography is not useful for the diagnosis of GERD because of low sensitivity and specificity. It should be used only to confirm or rule out anatomical abnormalities such as malrotation, esophageal or intestinal webs, or hiatal hernia that may cause symptoms similar to those of GERD.

Nuclear Scintigraphy

The test is based on administration of an age-appropriate feeding of technetium-labeled food. It is designed to assess gastric emptying and detect the reflux of a tracer in the esophagus. The standards for interpretation of this test are poorly established. According to limited published literature, scintigraphy may have a role in the diagnosis of pulmonary aspiration in patients with chronic and refractory respiratory symptoms. A negative test result does not rule out possible pulmonary aspiration of refluxed material. Gastric emptying studies by themselves do not confirm the diagnosis of GERD and are recommended only in individuals with symptoms of gastric retention. Nuclear scintigraphy is not recommended for the routine evaluation of pediatric patients with suspected GERD.

Endoscopy With Biopsy

Endoscopy of the upper gastrointestinal tract allows direct visualization of the esophagus and attainment of mucosal biopsies. The presence and severity of esophagitis can be documented. Other disease processes, including infection, EoE, and Crohn, can be detected. Biopsies should always be taken, even in the absence of macroscopic findings.

Management

Infants who are thriving with no symptoms other than regurgitation or vomiting will benefit primarily from alleviation of parental anxiety. Discussion involving the normal course and benign nature of GER may be all that is required. The infant should be followed by a pediatrician until the resolution of symptoms. Referral to a pediatric gastroenterologist should be considered when GERD is suspected.

Lifestyle Changes

Life in recumbence has its disadvantages for infants, namely allowing the esophagus and stomach to reside at the same level. This concept has led to the use of positioning in infants. Multiple positions are used, including prone, prone at a 30° angle, or supine at a 30° angle. The only proven position seems to be prone, which has been associated with an increased rate of sudden unexpected infant death (SUID). The health professional must balance the risk of GERD with that of SUID in the individual patient. The 30° supine position does not seem to be more effective in decreasing reflux than the flat supine position, but there is conflicting evidence on this point.

Infants with reflux are often put through "formula roulette." Cow's milk or soy-based formulas are used, and some infants progress to other formulas, such as hypoallergenic, predigested, or elemental types. This is more likely in the patient with a family history of atopy. Nearly half of infants intolerant of milk protein will also exhibit symptoms with soy; thus, protein hydrolysate formulations may be of more use. There is no indication for lactose-free cow's milk formulas in this patient population. Rice cereal may be used as a thickening agent. This does not change findings on esophageal pH monitoring, but it may decrease the frequency of regurgitation. Patients with poor weight gain will benefit from the increased caloric density of the thickened formula. One tablespoon of rice cereal per 2 oz of formula will increase the content from 20 to 27 cal/oz. Increasing amounts of rice cereal will increase the viscosity and caloric density, but this also increases osmolarity. Excessively concentrated formulas may worsen vomiting. Nipples used with thickened formula will need to be tailored by crosscutting, but this may lead to increases in coughing or gagging. Formulas containing commercial "anti-regurgitant" agents are now available. Although no more effective than rice cereal for regurgitation, they do not increase the caloric density and may require less energy to pull from the nipple. This must be balanced with the unknown long-term risks of these newer ingredients as well as the increased cost.

Environmental and dietary factors have been studied in the older child and teenager. Currently, only caffeine, chocolate, and spicy foods that provoke symptoms should be avoided. Obesity and exposure to tobacco smoke have also been implicated.

Medications

The pharmacological agents used in reflux disease are felt to be safe and, therefore, are sometimes used empirically without diagnostic confirmation (Table 121.1). Although this approach may be useful in adolescents for up to 4 weeks, it should be used with caution in infants or young children. There is emerging evidence of harm caused by acid suppression, especially proton pump inhibitors (PPIs), although acid suppression is the mainstay of treatment. The goal is to reduce exposure of the esophagus to acid. The 3 main types of drugs that can be used are antacids, H_2-receptor antagonists, and PPIs. The only clinically effective antacids are those that contain aluminum, which has been associated with bone and nervous system toxicity, especially in infants. H_2-receptor antagonists inhibit acid production in the gastric parietal cell. They are effective in the healing of esophagitis; however, tachyphylaxis has been seen as early as 1 week after initiation. Further complicating this class of medications are adverse effects, such as fussiness, that may be mistaken for reflux symptoms. Cimetidine and famotidine have the most evidence for effective and safe use in pediatrics.

Proton pump inhibitors bond and deactivate hydrogen, irreversibly inhibiting hydrogen potassium adenosine triphosphatase, the final pathway of gastric acid. Proton pump inhibitors should be taken 30 minutes prior to a meal so that the drug is in the bloodstream in the largest concentration at mealtime. Omeprazole, lansoprazole, and esomeprazole magnesium have been studied in children. No PPI has been approved for use in infants younger than 1 year. Proton pump inhibitors may be used as the initial drug or following failure of H_2-receptor antagonists.

There are emerging studies in children and adults showing adverse effects from long-term acid suppression. Up to 14% of patients can have adverse effects of headache, diarrhea, constipation, or nausea. Increased rates of community-acquired pneumonia, gastroenteritis, and necrotizing enterocolitis have been described. Adult studies have shown increased hip fractures and vitamin B_{12} deficiency, suggesting malabsorption secondary to hypochlorhydria, but these have not been reproduced in children. More studies are needed to understand the significance of these adverse effects. Currently, the efficacy of empiric therapy with PPI in children is not established, and empiric therapy should be used with caution, especially in young children. Administration of long-term acid suppression without a diagnosis is inadvisable. When acid suppression is required, the smallest effective dose should be used.

Prokinetic agents are indicated in the patient with evidence of delayed gastric emptying. Cisapride, a mixed serotonergic agent, was the model drug for this class. It has been shown to improve reflux symptoms and pH parameters in infants. However, it has been associated with QT prolongation and arrhythmia with some deaths. The use of cisapride has been severely restricted since the

Table 121.1. Pharmacological Agents Used for Reflux Disease

Drug	*Pediatric Dose*	*Adverse Effects*
Cimetidine	20–40 mg/kg/day, divided 3–4 doses per day	Hypotension, gynecomastia, reduced hepatic metabolism of other drugs, neutropenia, agranulocytosis, thrombocytopenia
Famotidine	0.5–1 mg/kg/day as a single dose or divided into 2 doses	Headache, dizziness, constipation, diarrhea
Omeprazole	0.7–3.3 mg/kg/day divided into 2 doses	Headache, diarrhea, abdominal pain, nausea, rash, vitamin B_{12} deficiency, constipation
Lansoprazole	15 mg (weight ≤30 kg) 30 mg (weight >30 kg)	Headache, nausea, constipation, diarrhea, abdominal pain, proteinuria, hypotension, elevated transaminases
Metoclopramide	0.1 mg/kg/dose 4 times per day before meals	Drowsiness, restlessness, dystonia, gynecomastia, galactorrhea
Erythromycin	3–5 mg/kg/dose 3–4 times per day before meals	Diarrhea, vomiting, cramps, antibiotic effect, pyloric stenosis

year 2000. Other drugs in the group are less likely to improve reflux but are still widely used. Metoclopramide also has mixed serotonergic effects, in addition to antidopaminergic and cholinomimetic actions. Adverse effects, including central nervous system complications, limit the use of this drug; it now carries a black box warning from the US Food and Drug Administration. Erythromycin is a motilin receptor agonist that is also used less commonly in GERD. There is evidence that its use in pregnancy or young infants may increase the risk of pyloric stenosis. Many interactions have been seen with this macrolide antibiotic, which also limits its use. Thus, potential adverse effects of currently available prokinetic agents outweigh the potential benefits of these medications for treatment of GERD.

Buffering agents, alginate, and sucralfate are useful on demand for occasional heartburn. Chronic use of buffering agents or sodium alginate is not recommended for GERD because some have absorbable components that may have adverse effects with long-term use. Special caution is required in infants.

Anti-reflux Procedures

Patients who continue to have reflux on maximum medical therapy, or those who have serious extraesophageal manifestations, such as recurrent aspiration, should be considered for surgery. Patients requiring long-term drug therapy may also be selected for surgery. The most popular procedure is the Nissen fundoplication. The laparoscopic approach to fundoplication is used widely and entails a full wrap of the fundus of the stomach around the esophagus to increase LES tone and create a more acute angle of His. More than 90% of patients remain symptom-free up to 11 years postoperatively. Complications, including gas bloat, dumping syndrome, and dysphagia, are reported at variable frequencies. Failure rates are higher in children who have neurological impairment and those with esophageal atresia repair. There are several other fundoplication procedures that have variable degrees of wrapping.

Significant delay in gastric emptying may require an additional surgical procedure at the gastric outlet. Pyloroplasty enhances the exit from the stomach. There is some concern that fundoplication itself results in accelerated gastric emptying and additive effects of pyloroplasty might result in dumping of gastric contents into the duodenum too rapidly, but this has not been shown to be a significant problem, and this procedure should be given strong consideration in infants or children with documented moderate or severe delayed gastric emptying.

Endoscopic anti-reflux procedures have mixed results in adults. The most studied and effective procedure is trans-oral incisionless fundoplication, which involves placing sutures through the gastroesophageal junction, pleating the mucosa and reinforcing LES. Pediatric experience with trans-oral incisionless fundoplication is limited to a few dozen cases. The preliminary results showed that the procedure is safe and efficacious in a highly selected group of older children and adolescents.

Prognosis

Complications arising from untreated GERD include esophagitis, Barrett syndrome, strictures, and esophageal adenocarcinoma and aspiration. However, most infants with GER have a more favorable outcome. Regurgitation resolves in most children by 18 months of age and is absent by 24 months of age in 98%. There is some evidence that a portion of patients who become asymptomatic will continue to have abnormal histology in the esophagus at follow-up endoscopy. Therefore, it is unclear if the disease process continues into later childhood. Future studies that follow infants with reflux longitudinally into adulthood will be of great benefit. There is much to be learned in the area of nonacid reflux and its role in respiratory disease as intraluminal impedance becomes more widely used.

Children with reflux symptoms that persist into later childhood have a worse prognosis. Patients with a history of esophageal atresia repair or severe neurological injury may have a poor prognosis, often requiring high-dose medication or anti-reflux surgery. They are more likely to experience complications of GERD.

CASE RESOLUTION

The patient has symptoms suggestive of GERD (ie, epigastric pain after eating associated with nausea, burning sensation in his chest, and nocturnal cough). Consideration can be given to initiating medications such as H_2-receptor antagonists. Alternatively, an upper gastrointestinal endoscopy can be obtained to document the presence of reflux or other forms of esophagitis.

CHAPTER 122

Gastrointestinal Bleeding

George Gershman, MD

CASE STUDY

A 5-year-old boy is evaluated for a history of hematemesis. The mother reports that her son experienced a sudden onset of vomiting of a large amount of blood. She denies that her son picks his nose or has had recent trauma. The boy's past medical history is significant for a double volume exchange blood transfusion as an infant. The boy has no history of recent upper respiratory infection, chronic cough, recurrent vomiting, abdominal pain, weight loss, or jaundice. He takes no medications. The family has no pets and has not traveled recently.

On physical examination, the boy is pale, frightened, and anxious. His temperature is normal, pulse is 120 beats per minute, blood pressure is 90/60 mm Hg, and respirations are 25 breaths per minute. Weight and height are at the 75th percentile for his age. The sclerae are white and the neck is supple, and there is no lymphadenopathy. Lung sounds are clear, heart sounds are normal, and the abdomen is soft, slightly distended, and nontender, with normal bowel sounds. The liver is not palpable, but the spleen is enlarged, with the tip palpable approximately 6 cm below the left costal margin. There is no evidence of ascites or caput medusae. The boy's skin is pale without rash or bruises. His extremities are cold, with capillary refill of more than 3 seconds. The results of a complete blood cell count and blood chemistry, including liver function test, are normal except for mild thrombocytopenia. A prothrombin international normalized ratio and partial thromboplastin time determination yield typical results.

Questions

1. What is a proper means of assessing children with gastrointestinal bleeding?
2. What are the specific characteristics of upper and lower gastrointestinal tract bleeding?
3. What age-related conditions account for upper and lower gastrointestinal tract bleeding in children?
4. What is the appropriate approach to the child with gastrointestinal bleeding?

Bleeding from the gastrointestinal (GI) tract in infants and children is always stressful and frightening for patients and their parents. Diagnosis and management can also be challenging for a physician, especially if bleeding is severe, although fortunately, encountering life-threatening GI bleeding in pediatric practice is rare. When it does occur, acute GI bleeding in children is a true medical emergency, associated with significant morbidity and mortality, even in high-income countries. A recent retrospective analysis of acute GI bleeding in patients admitted to 47 pediatric tertiary centers in the United States (data extracted from Pediatric Health Information System Database) revealed a mortality of almost 0.4% and 3% in children with the primary and secondary diagnosis of acute GI bleeding, respectively. Therefore, a pediatrician or emergency department (ED) physician should be prepared to initiate effective resuscitation and a diagnostic workup focusing on common age-specific causes of GI bleeding. The primary goal of this approach is a reduction of morbidity associated with significant hemorrhage.

Epidemiology

Upper GI bleeding is uncommon in infants and children, although the exact incidence is unknown. Clinical experience suggests that the incidence in children is significantly less than in adults. This assertion is supported indirectly by epidemiological data from the United Kingdom and United States, which indicate that the incidence of upper GI bleeding in adults younger than 29 years is approximately 18 to 23 per 100,000 adults per year, which is almost 4 to 5 times lower than among older age groups. The risk of upper GI bleeding is relatively high (between 6% and 25%) in pediatric patients admitted to pediatric intensive care units. Clinically significant upper GI bleeding, defined as a drop in hemoglobin level of 2.0 g/dL; indication for blood transfusion; emergent endoscopy; or surgery has been documented in 4% of children presenting to an ED with hematemesis.

Low GI bleeding is quite common in pediatric practice. However, the epidemiology of this problem is not well established. In 1 study, rectal bleeding was the presenting symptom in 0.3% of all visits to a tertiary ED during a 10-month period.

Clinical Presentation

Bleeding into the GI tract can present as hematemesis, melena, occult bleeding, or hematochezia.

Hematemesis is vomiting of bright-red "fresh" blood or coffee-ground (dark-brown) "old" blood exposed to hydrochloric acid. Usually, hematemesis reflects acute bleeding from the esophagus, stomach, or proximal duodenum. Swallowed maternal blood in neonates and epistaxis in older children should be ruled out to avoid unnecessary invasive procedures.

Melena is characterized as liquid, coal-black, shiny, sticky, tarry, foul-smelling stool. It suggests bleeding from the upper GI tract. Occasionally, bleeding from the ileum can be associated with melena. However, in this case, the stool is black but not tarry. Melena suggests a minimum loss of 50 to 100 mL of blood in adults (1%–2% of total blood volume) or 2% of the total blood volume in children. Stool may remain black or tarry for a few days after massive hemorrhage, even though active bleeding has ceased.

Occult bleeding is defined as the presence of a non-visible quantity of blood in stool. It usually occurs as chronic, recurrent losses of small amounts of blood, which can lead to severe microcytic anemia. The most commonly used technique for detection of blood in stool is a fecal occult blood test. This test is based on the chemical reaction of a dye (guaiac) with peroxidase-containing substances and hydrogen peroxide. It is not specific for the presence of blood (hemoglobin) in stool. False-positive results could be secondary to peroxidase activity in food products such as cantaloupes, radishes, bean sprouts, cauliflower, broccoli, grapes, and red meat or iron preparations. False-negative results are associated with prolonged colonic transient time and bacterial degradation of hemoglobin to porphyrin, which does not have peroxidase activity.

Currently, a fecal immunochemical test is available for detection of blood in stool based on labeling of human hemoglobin by specific antibodies. The test does not require a special diet. It is more specific for the detection of bleeding from the colon due to enzymatic digestion of the hemoglobin from the upper GI tract.

Hematochezia is the passage of bright-red or maroon-colored blood from the rectum. This may be pure blood, bloody diarrhea, or blood mixed with stool. Typically, it is a sign of lower GI bleeding from the distal colon or, less frequently, from the right colon or distal ileum. Rarely, hematochezia may occur in children with massive bleeding from the duodenum.

Pathophysiology

Compensatory responses to acute bleeding restore depleted intravascular volume, maintain a normal cardiac output and adequate oxygenation of vital organs (ie, brain, heart, lungs, adrenal gland), and mobilize internal energy stores.

Two parameters determine the degree of compensation: volume of blood loss and velocity of bleeding.

Mild Blood Loss (<15% of Circulatory Volume) or Class 1 Bleeding

Relatively slow blood loss of less than 15% of the total blood volume triggers redistribution of depot blood from the venous system to the systemic circulation and a shift of extracellular fluids into the vascular space. Adequate cardiac output without changes in heart rate and blood pressure is maintained, and there are no hemodynamic abnormalities. However, a rapid blood loss (even <10% of blood volume) may compromise cardiac output and trigger tachycardia and other compensatory mechanisms to restore normal blood circulation.

Moderate Blood Loss (Between 15% and 30% of Circulating Volume) or Class 2 Bleeding

Blood loss of more than 15% of the total blood volume leads to *tachycardia,* an increased systemic vascular resistance caused by activation of the sympathetic nervous system and hypothalamic-pituitary-adrenomedullary axis. In children, cardiac output depends on heart rate rather than stroke volume due to a smaller ventricular mass. With hemorrhage, tachycardia is the principal mechanism for maintenance of an adequate cardiac output in pediatric patients; however, prolonged tachycardia increases myocardial oxygen demand and decreases diastolic-dependent coronary perfusion. This eventually leads to cardiovascular decompensation if fluid resuscitation is delayed or insufficient.

Normal blood pressure and adequate perfusion of vital organs in children with moderate bleeding is maintained by increased systemic vascular resistance and redistribution of blood from skin, muscle, splanchnic organs, and kidney to the brain, heart, lungs, and adrenal gland due to local production of adenosine, nitric oxide, and prostaglandins. Therefore, blood pressure is a poor indicator of cardiovascular homeostasis in children with moderate GI bleeding. In contrast, persistent tachycardia is the red flag of pending cardiovascular collapse.

Severe Blood Loss (>30% of Circulating Volume) or Class 3 Bleeding

Failure of compensatory mechanisms and decreased cardiac output lead to hypotension and tissue hypoxia. Compensatory tachypnea contributes to respiratory alkalosis in the initial phase of severe bleeding. Tissue hypoxia compromises mitochondria functional capacity to generate energy as adenosine triphosphate. This leads to metabolic acidosis due to excessive production of lactic acid and cellular death.

Hypoperfusion of the kidney causes acute spasm of the preglomerular arterioles and acute tubular necrosis and renal failure. Hypoxia and excessive cytokine production can induce liver failure—sudden onset of jaundice due to hepatocellular necrosis, elevation of transaminases, coagulopathy, hypoglycemia, and encephalopathy. Myocardial ischemia is a common consequence of severe bleeding. Sepsis, thrombotic microangiopathy, and a systemic inflammatory response syndrome may occur in the late stages of uncontrolled or inadequately treated severe hemorrhage.

Evaluation

The initial assessment of the child with suspected GI bleeding should be focused on signs of hemodynamic instability and clues for the etiology of bleeding. Four major questions must be answered promptly: Is the patient stable? Is the bleeding real? What is the source of the bleeding? What is the best treatment option?

The first and most important step in the initial assessment of the child with suspected GI bleeding is recognition of hemodynamic instability (Box 122.1).

Box 122.1. Procedural Management of Gastrointestinal Bleeding

Endoscopic Hemostasis of Non-varicose Bleeding

Indications

- Active bleeding from a gastric or duodenal ulcer
- Stigmata of recent bleeding: a non-bleeding visible vessel in the ulcer base and a densely adherent clot
- Bleeding arteriovenous malformation
- Bleeding after polypectomy

Methods

- Injection of vasoconstrictive agent
- Thermal coagulation
  - — Bipolar coagulation
  - — Heater probes
  - — Argon plasma coagulation device
- Metal clips

Endoscopic Hemostasis of Varicose Bleeding

Indications

- Active bleeding from esophageal or gastric varices
- History of bleeding secondary to portal hypertension
- Failure of shunting procedure

Techniques

- Sclerotherapy
- Endoscopic varicose ligation

Polypectomy

Indication

- Juvenile polyps <3 cm
- Multiple polyps <2 cm

A prompt assessment of estimated blood loss and the degree of hemodynamic instability should be done using objective criteria, such as mental status, skin color, capillary refill, pulse, blood pressure, and orthostatic maneuvers (Table 122.1). Special attention should be focused on tachycardia and narrowed pulse pressure, which are the earliest signs of impending shock. Hypotension usually occurs in the late phase of shock in children and is an ominous finding. The value of the initial hematocrit may not accurately reflect the severity of blood loss. First, the hematocrit does not fall immediately with hemorrhage due to proportionate reductions of plasma and red cell volumes. Second, the hematocrit begins to fall due to compensatory restoration of the intravascular volume by the shift of extravascular fluids into the vascular bed. This process begins shortly after the onset of bleeding; however, it is not complete for 24 to 72 hours. At this point, plasma volume is larger than normal, and the hematocrit reaches its true nadir, assuming that bleeding has stopped.

Differential Diagnosis

The 3 essential components of the diagnosis of GI bleeding are confirmation that bleeding is real, allocation of the bleeding area to the upper versus lower GI tract, and detection of the specific cause of bleeding.

Table 122.1. Clinical Manifestations of Gastrointestinal Bleeding According to Blood Loss Volume

	Blood Loss		
Symptoms and Signs	*<15%*	*15%–30%*	*> 30%*
Normal appearance	+	–	–
Anxiety	–	+	+
Disorientation	–	–	+
Lethargy	–	–	+
Tachycardia	–	++	+
Pallor	–	+	++
Livedo reticularis	–	+	++
Cold extremities	–	+	+
Capillary refill >2 seconds	–	+	+
Hypotension	–	–	+
Narrowed pulse pressure	–	+	+
Elevated diastolic pressure	–	+	–
Low diastolic pressure	–	–	+

Abbreviations: –, absent; +, present, mild; ++ present, moderate.

Red staining of emesis or stool can be induced by cranberries, cranberry juice, cherries, strawberries, beets, tomatoes, candies, amoxicillin, phenytoin, red-colored rehydrating drinks (eg, Gatorade, Powerade), and rifampin. Bismuth preparations, activated charcoal, iron, spinach, blueberries, and licorice can simulate bleeding by staining emesis and coloring stool black. An appropriate history, a normal physical examination, and guaiac-negative stool are sufficient to rule out a true bleeding episode.

It is important to remember that hematemesis or melena can be secondary to epistaxis. History of recent tonsillectomy and adenoidectomy, nasal allergies, dry environment, or nose-picking habits increases the probability of epistaxis. Thorough examination of the nose and oropharynx can help to establish the correct diagnosis.

Detailed history and physical examination help narrow the diagnostic workup. For example, treatment with nonsteroidal anti-inflammatory drugs (NSAIDs) is a risk factor for acute gastric ulcers and bleeding from the stomach. Jaundice, hepatomegaly, spider hemangiomas, prominent vessels of the abdominal wall, or ascites are the signs of chronic liver disease and are suggestive of portal hypertension. However, GI bleeding in a febrile child with hemodynamic instability and jaundice could be secondary to sepsis-related coagulopathy or acute liver failure.

Careful assessment of the perineum can reveal anal fissures, fistulas, or perianal inflammation.

If the source of bleeding is not obvious, the placement of a nasogastric tube is very useful. A tube with the largest bore tolerable should be placed for adequate gastric lavage. A 10F to 12F sump tube is a reasonable choice for small children; a 14F to 16F tube is reasonable for older patients. Room temperature saline is the optimal fluid for irrigation. Iced saline lavage is no longer recommended

because it compromises platelet function at the bleeding site and may induce hypothermia (especially in infants) with subsequent clinically significant arrhythmia. A bloody or coffee-ground aspirate indicates upper GI bleeding, if epistaxis was ruled out. The absence of blood in the stomach does not exclude upper GI bleeding because the source of hemorrhage can be in the duodenum. The presence of coffee-ground fluid in gastric aspirate, which promptly clears by gastric lavage, suggests that bleeding has stopped. Failure to obtain clear return on gastric lavage indicates ongoing bleeding.

Results of blood tests give some clues to the nature of bleeding. Low hemoglobin and hematocrit with normal mean corpuscular volume (MCV) are typical for acute blood loss. Elevated levels of blood urea nitrogen is suggestive of volume depletion and absorption of the blood proteins in the small intestine, which supports the diagnosis of upper GI bleeding. Very low hemoglobin, hematocrit, and MCV levels in a hemodynamically stable patient are consistent with chronic GI blood loss.

Knowledge of common causes of GI bleeding in an age-specific group of children helps with diagnostic strategy (Table 122.2).

In general, endoscopy is the method of choice for the diagnosis of the specific causes of acute and chronic GI bleeding related to mucosal and submucosal lesions of the GI tract. The choice of the particular type of endoscopic procedure is related to suspected pathology. Upper and lower GI endoscopy and enteroscopy are routine methods for diagnosis of diseases such as acute or peptic ulcers, esophagitis, gastritis, esophageal varices, vascular malformations, ulcerative colitis, Crohn disease, polyps, and other causes of GI bleeding. Capsule endoscopy is the minimally invasive method of endoscopic investigation of the entire small intestine. It is used for diagnosis of GI bleeding of obscure origin, usually after negative results of conventional endoscopic procedures.

Plain radiography and abdominal ultrasonography are useful for diagnosis of structural abnormalities such as intussusception, necrotizing enterocolitis, and malrotation.

Technetium Tc 99m pertechnetate scanning is indicated in children with suspected Meckel diverticulum. It is 85% sensitive and 95% specific.

The calculated rate of blood loss serves to guide the method to diagnose the source of hemorrhage. Angiography (rate ≥0.5 mL/minute), computed tomography angiography (0.35 mL/minute), and technetium-labeled red blood cell scanning (0.2 mL/minute) are alternatives to endoscopy for diagnosis of source of active GI bleeding.

These modalities should be considered when vascular anomalies or hemobilia are suspected.

Table 122.2. Common Causes of Gastrointestinal Bleeding in Children

Age	*Upper GI Bleeding*	*Lower GI Bleeding*
Neonates (0–30 days)	Swallowed maternal blood Stress ulcers/sepsis Hemorrhagic gastritis Hemorrhagic disease of the newborn	Necrotizing enterocolitis Midgut volvulus Congenital megacolon (Hirschsprung disease) Vascular malformation
Infants (30 days–6 months)	Cow's milk or soy protein allergy Esophagitis Prolapse gastropathy	Anal fissure Allergic proctitis or enterocolitis Intestinal lymphoid hyperplasia Intussusception
Infants and children (6 months–6 years)	Epistaxis Esophagitis Prolapse gastropathy Portal hypertension Drug-induced ulcers Gastritis Mallory-Weiss tear	Anal fissures Intussusception Meckel diverticulum Intestinal lymphoid hyperplasia Polyps Infectious colitis Hemolytic uremic syndrome Henoch-Schönlein purpura
Children and teenagers (7–18 years)	Epistaxis Drug-induced gastropathy and acute ulcers Peptic ulcer Esophagitis Gastritis Portal hypertension	Infectious colitis Ulcerative colitis Crohn disease Anal fissure Polyps

Abbreviation: GI, gastrointestinal.

Age-Associated Causes of GI Bleeding

Neonates

In healthy breastfed neonates and infants, hematemesis could be caused by swallowed maternal blood. In such cases, careful examination of maternal breast and areola can lead to correct diagnosis. In addition, the Apt test can be useful, especially in the first 3 to 4 weeks after birth, while concentration of fetal hemoglobin is still high. The test is based on the chemical reaction of adult hemoglobin with sodium hydroxide, which leads to a color change from bright red to yellow or crusty brown. Fetal hemoglobin is resistant to hydroxylation, and blood from the neonate remains bright red.

Acute gastric or duodenal ulcers should be suspected in neonates who are sick and preterm or who are septic or asphyxiated and full term, or in patients with intracerebral bleeding, increased intracranial pressure, congenital heart disease, respiratory failure, or hypoglycemia. The typical scenario includes sudden onset of hematemesis or melena and signs of hemodynamic instability. Occasionally, severe upper GI bleeding can occur in healthy full-term neonates within the first few days after birth.

Gastrointestinal bleeding is a common manifestation of necrotizing enterocolitis. The warning signs of necrotizing enterocolitis are abdominal distention, feeding intolerance with increased gastric residuals, mild diarrhea, hematochezia, or stool that tests positive for occult blood.

Plain radiographs can be diagnostic if they show pneumatosis intestinalis or gas in the portal vein.

Rare causes of GI bleeding in the first month after birth include Hirschsprung enterocolitis, midgut volvulus, duplication cyst, vascular malformation, and hemorrhagic disease of the newborn, particularly in breastfed neonates who did not receive vitamin K.

Infants Up to First 6 Months of Age

One of the leading causes of GI bleeding in infants younger than 6 months is cow's milk or soy protein allergy. The spectrum of symptoms includes recurrent vomiting, hematemesis, failure to thrive, and diarrhea with guaiac-positive stools or hematochezia.

Exclusively breastfeeding infants may develop similar symptoms on rare occasions. Elimination of cow's milk, eggs, peanuts, fish, and tree nuts from maternal diet may lead to resolution of allergic symptoms in the breastfeeding infant. For infants with persistent symptoms or whose mothers are unable to restrict their diet according to current recommendations and for formula-fed infants with cow's milk protein allergy, hypoallergenic (extensively hydrolyzed and free amino acid–based) formulas can be used to relieve the symptoms. Most infants with GI manifestations of cow's milk protein allergy will improve within the first 2 weeks of treatment.

An anal fissure is another common cause of bleeding in infants. The diagnosis is made by careful examination of the anus.

Intermittent rectal bleeding with streaks of frank blood mixed with normal-appearing stool can be secondary to intestinal lymphoid hyperplasia of the colon or terminal ileum. During endoscopy, multiple hemispheric smooth nodules of less than 4 mm can be found in clusters or diffusely throughout the GI tract. It is considered an excessive reaction of the GI tract lymphatic tissue (lymphoid follicles and Peyer patches) to food-related or other antigens. Spontaneous regression of lymphoid follicles is quite common. In addition to parental reassurance, an elimination diet for breastfeeding mothers is a reasonable initial treatment. Feeding with extensively hydrolyzed protein formula is the next therapeutic step. Corticosteroid therapy is restricted to infants with a severe form of this disease—recurrent abdominal pain, significant anemia, persistent rectal bleeding, diarrhea, and failure to thrive. In such cases, immunodeficiency has to be excluded.

Esophagitis should be suspected as a cause of bleeding in infants with a history of recurrent emesis and interrupted feeding patterns associated with crying, irritability, or arching. Patients with repaired esophageal atresia with or without tracheoesophageal fistula are at increased risk of severe reflux disease and esophagitis. Bleeding induced by esophagitis is usually recurrent and not intensive. The patients may have hematemesis with streaks of blood or guaiac-positive stool.

Infants or older children can develop minor bleeding due to prolapse of gastric mucosa into the esophagus through the gastroesophageal junction (prolapse gastropathy). This condition is manifested by recurrent emesis with food and appearance of flecks of denatured blood at the end of vomiting. The presence of large amounts of frank blood or clots at the end of recurrent emesis is suggestive of a more serious problem, such as Mallory-Weiss tear.

Infants and Children Younger Than 7 Years

Several diseases have a higher prevalence in this age group compared with other children.

The signs and symptoms of *portal hypertension* are a large-volume hematemesis, history of omphalitis secondary to catheterization of the umbilical vein, presence of splenomegaly or hepatosplenomegaly, and other stigmata of chronic liver disease, such as jaundice, spider angiomas, caput medusa, and ascites. Esophageal varices are the most common site of bleeding in children with intrahepatic-sinusoidal and extrahepatic-presinusoidal forms of portal hypertension. Two-thirds of children with portal hypertension will bleed before 5 years of age. The diagnosis is based on the presence of esophageal or gastric varices or hypertensive gastropathy during an upper GI endoscopy.

Intussusception, which is more common in the first 2 postnatal years, is strongly considered in infants and children with sudden onset of severe, cramping abdominal pain intercepted by pain-free episodes and currant jelly stools. A lead point is often present in children older than 2 years. Diagnosis is confirmed by ultrasonography (positive: "concentric circles" or the "target-shaped sign") or barium enema. Hydrostatic reduction of intussusceptions is successful in more than 90% of children.

Meckel diverticulum is the most common congenital anomaly in children. It is estimated that approximately 2% of infants have a remnant of the omphalomesenteric duct. However, fewer than 5% of children will develop complications, including GI bleeding. The predominant location of Meckel diverticulum is the distal ileum (40–60 cm above the ileocecal valve). Ectopic tissue is present in up to 80% of symptomatic patients. Gastric mucosa is the most common type of ectopia. The cause of bleeding is peptic ulceration at the junction of the ectopic gastric mucosa and normal ileum, the so-called marginal ulcer. Bleeding can be massive, but it may cease spontaneously secondary to contraction of the splanchnic vessels in response to hypovolemia. This phenomenon explains the intermittent nature of bleeding from Meckel diverticulum. Bleeding is usually painless but sometimes coincides with recurrent abdominal pain.

The diagnostic procedure of choice is technetium Tc 99m pertechnetate scanning.

Juvenile polyps may occur in as many as 1% of children, with peak incidence from 2 to 5 years of age. The common clinical presentation is recurrent, painless bleeding with a small amount of blood on formed stool. Diarrhea and tenesmus can occur when the polyp is large and located in the left colon.

Typical juvenile polyps are smooth, rounded, and red. Polyps of less than 1 cm are usually sessile; polyps larger than 1 cm have short or long stalks. Juvenile polyps are composed of normal but cystically dilated crypts embedded in an abundant lamina propria. Colonic mucosa adjacent to the large polyp has a distinguished, so-called chicken skin appearance. Colonoscopy is indicated due to the high incidence (almost 50%) of coexisting of the rectal polyps with polyps in the more proximal portions of the colon.

Endoscopic polypectomy is the treatment of choice. There is a general consensus that a single juvenile polyp is not a premalignant condition. Therefore, removal of a solid juvenile polyp is curative. Surveillance colonoscopy is not indicated unless the child develops a new episode of rectal bleeding or retains 5 or more juvenile polyps.

Hemolytic uremic syndrome (HUS) should always be suspected in infants and toddlers with bloody diarrhea, which is present in three-quarters of children with epidemic HUS. In two-thirds of these children, *Escherichia coli* O157:H7 can be isolated. Bloody diarrhea in HUS results from hemorrhagic colitis caused by the presence of endothelial damage produced by verotoxin and Shiga toxin and submucosal hemorrhages. Tenesmus is common. Diffuse, severe abdominal pain with peritoneal signs can occur.

The presence of the so-called thumbprinting sign on a contrast enema or a computed tomography scan reflects a submucosal hemorrhage of the colon. Colitis-related symptoms last no longer than a week, followed by signs of hemolytic anemia and oliguria. Known GI complications of HUS are intussusception, pancreatitis, and intestinal obstruction. Small or large bowel perforation may occur during peritoneal dialysis, which may be performed to manage the acute renal failure that can accompany HUS.

Henoch-Schönlein purpura is most common in children younger than 7 years; the median age of appearance is 4 years. It should be suspected in children with sudden onset of severe diffuse abdominal pain, vomiting, and hematochezia following a viral illness during the winter and early spring and about a week after the appearance of purpuric-type skin lesions on the buttocks or lower extremities.

On rare occasions, GI manifestations may precede the skin rash. Severe anemia is uncommon. The small and large bowels have different degrees of hemorrhagic lesions. These may be apparent on a small bowel radiograph series or contrast enema with coarsening of folds and thumbprinting. Abdominal pain and hematochezia are self-limited. Treatment with corticosteroids is controversial, although it may shorten the course of GI symptoms of abdominal pain by 1 or 2 days.

Children 7 Years and Older

The common causes of GI bleeding in this age group are listed in Table 122.2.

Drug-induced gastritis or *acute ulcer* should be strongly suspected in children treated with NSAIDs or oral steroids. The degree of bleeding ranges from mild to moderate. The typical clinical presentation is the sudden onset of abdominal discomfort followed by hematemesis or melena. Two types of lesions can occur: gastropathy or acute gastric ulcers due to alteration of the mucosal microcirculation, and mucosal cytoprotection related to suppression of local synthesis of prostaglandins. The incidence of NSAID-related GI bleeding is much higher in patients with *Helicobacter pylori* gastritis. Therefore, eradication of *H pylori* infection is recommended before long-term therapy with NSAIDs.

Although peptic ulcer disease is relatively rare in pediatric patients, it accounts for at least one-third of the cases of upper GI bleeding in school-age children. Most bleeding ulcers are located in the duodenal bulb. At least 80% of bleeding episodes from duodenal ulcers cease spontaneously. However, if the bleeding is arterial, it may become life-threatening. Urgent endoscopy is necessary as soon as the patient becomes more stable after fluid resuscitation.

Risk factors for recurrent bleeding are large ulcer (>2 cm), location of the ulcer on the posteroinferior wall of the duodenal bulb, blood spurting from the base of the ulcer, a visible vessel, or an adherent clot. In these circumstances, the risk of recurrent bleeding is relatively high even after initially successful endoscopic hemostasis and acid suppression with intravenous (IV) infusion of proton pump inhibitors. The most critical time for rebleeding is the first 3 days following the initial hemostasis.

The risk of recurrent bleeding is minimal in children with a clear base ulcer or a pigmented spot sign, a small flat thrombus in the center of an ulcer. Endoscopic hemostasis is not indicated in these cases. Hemodynamically stable children without the endoscopically identified risk factors can be treated safely on an outpatient basis.

Colitis is the most common cause of rectal bleeding in older children and teenagers. Infectious colitis is by far more common than inflammatory bowel disease. In general, *bacterial colitis* is an acute, self-limited disorder manifested by sudden onset of fever, tenesmus, and bloody diarrhea lasting from 5 to 7 days.

Diarrhea lasting 4 weeks or longer is usually associated with chronic inflammatory bowel disease. Rare causes of chronic infectious colitis are *Yersinia enterocolitica,* tuberculosis, *Entamoeba histolytica, Strongyloides stercoralis,* and opportunistic infections in immunocompromised patients.

Clostridium difficile colitis should be ruled out, especially in children treated with antibiotics or hospitalized patients.

Ulcerative colitis usually presents with insidious onset of diarrhea, nocturnal diarrhea, and subsequent hematochezia. Clinical manifestations of moderate to severe forms of ulcerative colitis include bloody diarrhea, abdominal cramps, urgency to defecate, malaise, anorexia with weight loss, intermittent low-grade fever, and some degree of anemia and hypoalbuminemia.

Crohn disease has a more indolent onset associated with abdominal pain, diarrhea, poor appetite, and weight loss. Diarrhea is not grossly bloody unless there is bleeding from an anal fistula or colitis that is diffuse or left sided.

Differentiation between bacterial colitis and the early stage of chronic inflammatory bowel disease is always a challenge. A high index of suspicion and negative bacterial stool culture results, including *Yersinia* species and other rare pathogens, are essential parts of early diagnosis. The definitive diagnosis of chronic inflammatory bowel disease is based on the results of upper and lower GI endoscopy, including multiple biopsies.

Management

Resuscitation

It is imperative to initiate resuscitation of the patient who is hemodynamically unstable almost immediately before any diagnostic procedure is considered. Two large-bore peripheral IV catheters or a central catheter should be placed and secured. Blood is typed and crossmatched and sent for baseline laboratory assessment of levels of hemoglobin, hematocrit, MCV, platelets, electrolytes, creatinine, blood urea nitrogen, liver enzymes, and clotting factors. Oxygen

supplementation and large boluses of saline target restoration of circulation and tissue oxygenation. The volume of isotonic solution should be sufficient to improve tachycardia and reverse narrow pulse pressure. Blood transfusion is indicated for patients with

- Persistent tachycardia, abnormal pulse pressure, or orthostatic hypotension after replacement of 15% to 20% of blood volume with isotonic solution.
- Estimated blood loss of 30% or more.
- Hemoglobin of 6 g/dL or less.
- Uncontrolled bleeding.
- Hemorrhagic shock.
- Hemoglobin of 7 to 9 g/dL in children with chronic heart and lung diseases and signs of hypoxia.

Packed red blood cells are the product of choice for replacement of blood loss. Matched whole blood is preferred for patients with massive bleeding. Fresh-frozen plasma is indicated for children with suspected or documented clotting factor deficiency, including those with acute or chronic liver disease. Platelet transfusion is indicated in rare cases of severe bleeding with estimated blood loss of more than 50% of the patient's blood volume or children with active hemorrhage and platelet count less than 50,000 platelets/mm^3. Early blood transfusion is reasonable for children with active bleeding and known chronic heart or lung diseases. Monitoring of vital signs is a more accurate means of assessing the effect of blood transfusion than monitoring of hematocrit soon after transfusion. It is reasonable to wait 6 hours before checking a posttransfusion hematocrit.

Octreotide (a synthetic somatostatin analogue) is an effective adjuvant medical therapy of severe bleeding from esophageal or gastric varices. It should be given to the child with active hemorrhage and any evidence of chronic liver disease or previously diagnosed portal hypertension. The initial IV bolus of 1 mcg/kg is followed by continuous infusion of octreotide with the initial rate of infusion as 1 mcg/kg per hour. The dose can be increased every 6 hours up to 5 mcg/kg per hour.

Endoscopic hemostasis is a standard therapy for moderate to severe upper GI bleeding related to peptic ulcer disease, esophageal or gastric varices, and vascular malformation.

Surgery should be reserved for children with severe uncontrolled bleeding from a known source or specific disorders, such as Meckel diverticulum.

Prognosis

The prognosis for infants and children with GI bleeding depends on the condition causing the bleeding. Early, aggressive treatment of the consequences of blood loss is essential to decreasing morbidity and mortality. Generally, prognosis is good, and overall mortality is less than 5%.

CASE RESOLUTION

The young child with hematemesis and splenomegaly had esophageal bleeding secondary to extrahepatic portal hypertension. The diagnosis was established during upper GI endoscopy and a negative workup for liver disease. The bleeding was controlled with a banding procedure. Long-term follow-up is indicated for proper management of this patient's condition and timely referral for surgery, if indicated.

CHAPTER 123

Diarrhea

George Gershman, MD

CASE STUDY

An 11-month-old boy is evaluated for poor weight gain, decreased appetite, and diarrhea for the past 3 months. The parents report 3 to 4 bowel movements a day. They describe stool as "mushy" and "foul smelling." There are no ill contacts and there is no history of recent travel. The vital signs are normal. The patient appears pale and malnourished with wasted buttocks. His weight is at less than the 5th percentile, and his length is at the 25th percentile. The mucous membranes are moist without ulcers. The abdomen is soft and distended. Bowel sounds are active. There is no hepatosplenomegaly. Extremities are warm and well perfused.

Questions

1. What are the major categories of diarrhea?
2. What are the common infectious agents that cause diarrhea in infants and children?
3. What are the manifestations of acute and chronic diarrhea?
4. What conditions lead to persistent diarrhea in infants and children?
5. How is diarrhea managed in infants and children?

The word "diarrhea" is derived from Greek and means "to flow through." Diarrhea is associated with increased volume of stool caused by loose consistency and increased frequency of bowel movements. However, frequency of bowel movement and consistency of stool varies significantly from person to person and according to type of diet. For example, some healthy breastfed infants have a bowel movement once a week, whereas others may pass stool 7 to 10 times a day. The stool of breastfed infants is usually looser than that of formula-fed infants.

Diarrhea is a manifestation of various disorders, such as acute and chronic infections, chronic inflammatory bowel disease, food allergy or sensitivity, enzymes deficiency, hormonal imbalance, adverse effects of medications, mucosal atrophy, and short bowel syndrome, that affect either absorption of nutrients and water from the small and large intestines or secretion of fluids toward the intestinal lumen.

Epidemiology

Diarrhea is extremely common worldwide. In the United States, acute gastroenteritis is second in frequency only to upper respiratory tract infections. According to the World Health Organization, 2.5 million children in Latin America, Asia, and Africa die annually of dehydration secondary to diarrhea. In contrast, approximately 400 children die of this condition in the United States each year. These children often come from families of lower socioeconomic status.

In the United States, each child experiences an average of 0.9 episodes of diarrhea per year unless enrolled in a child care facility. In that case, the number increases to up to 3.2 episodes per year, a figure similar to that experienced by children in developing countries. In developing countries, the reported episodes of acute diarrhea vary from 3 to 6 to 8 in certain areas per year in children younger than 5 years. The severity of the infection is influenced by the underlying state of nutrition. An episode of acute gastroenteritis can be devastating for a child who has malnourishment. The fecal-oral route is the major path for the spread of infectious diarrhea. In developing countries, poor sanitation and contaminated drinking water perpetuate the problem. In the past 2 decades, the childhood mortality rate associated with diarrhea declined slowly but steadily primarily because of improved access to oral rehydration solution.

Many pathogens can be responsible for infectious diarrhea. The prevalence of individual pathogens varies widely between geographic areas and among different age groups. For instance, bacterial infections are more common in the first few months after birth and then again in school-age children. Rotavirus, the single most ubiquitous cause of infectious diarrhea worldwide, peaks between 6 and 24 months of age. In recent years, because of the widespread use of rotavirus vaccine in US children, norovirus has become the leading cause of medically attended acute gastroenteritis in the United States and is not only responsible for at least 50% of all outbreaks but the major cause of foodborne illness. On the contrary, *Escherichia coli* occurs frequently as a sporadic bacterial cause of diarrhea in the United States.

Definitions

Diarrhea is defined as stool mass more than 10 g/kg in infants and more than 200 g in older children. In clinical practice, and in accordance to the World Health Organization, it is acceptable to define diarrhea as "the passage of 3 or more loose or liquid stools per day, or more frequently than is normal for the individual."

Acute diarrhea is characterized by sudden onset and resolution of diarrhea within 2 weeks. *Persistent diarrhea* implies an acute onset of diarrhea that lasts at least 14 but less than 30 days. The definition is based on acute-onset diarrhea that continues beyond the expected duration of an infectious etiology. *Chronic diarrhea* is defined as diarrhea lasting 30 days or more and associated with specific causes (eg, celiac disease, inflammatory bowel disease).

Clinical Presentation

The manifesting symptoms of diarrhea include frequent, watery stools, which may contain blood or mucus. Affected children may experience fever, vomiting, bloating, and abdominal pain. Signs and symptoms of dehydration such as decreased skin turgor, dry mucous membranes, depressed fontanelle, diminished tearing, and tachycardia may be present. Persistent diarrhea may be associated with weight loss and inability to gain weight at an appropriate rate (Box 123.1).

Pathophysiology

Regardless of etiology, diarrhea by definition results from an imbalance in intestinal handling of water and electrolytes. Water transport through the wall of the intestine is always a passive process linked to the active absorption of sodium and chloride. Regulatory mechanisms of water and electrolyte transport across the intestine require integration of the enteric nervous system, cells in the lamina propria mucosae, and epithelial cells. This complex system works through the generation of hormone peptides, active amines, arachidonic acid metabolites, and nitric oxide. The bulk of absorbed water crosses the intestinal epithelium between the cells (tight junctions) following generation of the osmotic gradient by the transport of nutrients and electrolytes. The normal flow of water across the intestine can be disrupted, leading to diarrhea, by 2 processes: (1) excessive osmolality within the intestine caused by either consumption of large amounts of nonabsorbable sugars, such as lactulose, or maldigestion or malabsorption of 1 or more nutrients (eg, monosaccharides or disaccharides) and (2) active secretion of water by enterocytes affected by viral or bacterial infection, toxins, and other substances.

Box 123.1. Signs and Symptoms Used in the Diagnosis of Persistent Diarrhea

- Liquid stools
- Frequent stools
- Blood in stool
- Mucus in stool
- Fever
- Poor weight gain, or weight loss
- Dehydration
- Vomiting
- Abdominal pain

Osmotic diarrhea occurs whenever digestion or absorption is impaired. In general, it is relatively small-volume diarrhea, which is dependent on oral intake and abolished with fasting. The most common causes of osmotic diarrhea are

1. Malabsorption of carbohydrates caused by either excessive consumption (eg, concentrated formulas or carbonated beverages) or decreased production of brush-border enzymes or the presence of nonabsorbable substances such as lactulose, sorbitol, or magnesium salts in the intestinal lumen.
2. Decreased absorptive capacity of the intestine caused by acute or chronic inflammation of the small-bowel mucosa (eg, acute viral gastroenteritis, cow's milk protein allergy, bacterial overgrowth, giardiasis, celiac disease).
3. Lack of pancreatic enzymes or bile acid.
4. Decreased absorptive capacity of the small intestine secondary to congenital or acquired short bowel syndrome. Recent data suggest that improper differentiation of intestinal enteroendocrine cells has profound effects on the nutrient absorption by the small intestine.

In general, unabsorbed nutrients create an osmotic load that stimulates water leakage into the intestinal lumen across the tight junction. In addition, unabsorbed nutrients, such as carbohydrates, are the substrate for fermentation by colonic bacteria with liberation of short-chain organic acids, which create a secondary osmotic load in the large intestine and exacerbation of osmotic diarrhea.

Secretory diarrhea can be induced by any process, which creates a state of active intestinal secretion. In general, *secretory diarrhea* is associated with intestinal loss of large volumes of fluids, which continues despite cessation of eating. In the case of isolated small-bowel involvement, the large intestine will partially compensate losses of water and electrolytes. The most common cause of secretory diarrhea is bacterial infection. The other triggers of secretary diarrhea could be viruses (eg, rotavirus, HIV) or protozoan enterotoxins (eg, *Cryptosporidium parvum* in compromised immune systems). Secretory diarrhea is also seen in patients with neuroendocrine tumors, such as carcinoid tumors, gastrinomas, ganglioneuroblastomas, and congenital disorders of fluid and electrolyte metabolism, such as congenital chloridorrhea. The classic example of secretary diarrhea is infection with enterotoxigenic *E coli,* and *Vibrio cholerae.* Both bacteria produce toxins that bind to specific enterocyte membrane receptors and activate adenyl cyclase and production of cyclic adenosine monophosphate (by cholera toxin and heat-labile toxin from enterotoxigenic *E coli*) or cyclic guanosine monophosphate (by heat-stable toxin produced by *E coli*). The ultimate pathway involves the opening of chloride channels and massive water loss. Secretory diarrhea is particularly common in the developing countries, where it is related to infection with organisms such as enterotoxigenic *E coli,* and *V cholerae.* In the United States, the most common cause of secretory diarrhea is rotavirus infection. Vasoactive intestinal peptide-secreting tumors such as ganglioneuroma and neuroblastoma must be considered in children with persistent secretory diarrhea.

Both osmotic components and secretory components are present in many cases of diarrhea.

Motility disorders such as pseudo-obstruction syndrome or colonic inertia can be associated with persistent nonspecific diarrhea.

Inflammatory diarrhea can be acute, self-limiting (caused by intestinal infections) or chronic (eg, caused by inflammatory bowel disease or a few bacterial pathogens, such as *Yersinia enterocolitica,* or tuberculosis).

Steatorrhea is defined as presence of excessive amount of fat in the stools. Normally, at least 95% of fat is absorbed. In infants younger than 12 months, 10% of ingested fat may appear in the stool. Steatorrhea can result from fat malabsorption in children with mucosal atrophy (eg, celiac disease) or maldigestion secondary to chronic liver and pancreatic disorders (eg, biliary atresia, cystic fibrosis). Steatorrhea may also be seen in patients who have giardiasis.

Differential Diagnosis

Acute Diarrhea

The major cause of diarrhea in children and infants is acute viral gastroenteritis. The most common virus causing it is rotavirus, which usually spreads during the winter months, hence the term "winter vomiting disease." Infants present with a history of antecedent mild upper respiratory tract symptoms, followed by fever and vomiting. Watery diarrhea, which is usually free of blood or mucus, then occurs. About 10% of children who have rotavirus infection have signs of otitis media. Dehydration may also occur. Patients typically exhibit mild hypernatremia, with serum sodium values reaching 150 mEq/L. The incidence of rotavirus infection is markedly reduced following the universal administration of rotavirus vaccine. Enteric adenovirus infection is the second most common cause of acute diarrhea.

The most common bacterial agents associated with gastroenteritis in the United States are *Shigella, Salmonella,* and *Campylobacter. Aeromonas,* a common pathogen in developing countries, is recovered in less than 1% of cases of diarrhea in the United States.

Campylobacter produces signs of colitis, with blood and mucus in the stools. Patients are usually febrile and experience abdominal cramps. As a rule, children infected with *Shigella* have more systemic symptoms (eg, higher grade fever, marked leukocytosis). In addition, infants and toddlers are particularly prone to seizures. Tenesmus and blood in stool are common. Infection with *Salmonella* may also be associated with high fever. Stools may be watery or mushy and often contain a large amount of mucus. Parasitic infections, particularly with *Giardia lamblia, Entamoeba histolytica,* and *C parvum,* may be associated with diarrhea and may follow a more protracted course. Infestation with these organisms does not usually result in fever.

Otitis media and urinary tract infection may also be accompanied by diarrhea. Sixty percent of children with hepatitis A develop diarrhea in the first week of illness. Other conditions may also result in diarrhea. In newborns, infection with *E coli* may produce epidemic outbreaks of large, explosive green stools without blood. Such outbreaks could result in closure of newborn nurseries. Changes in stool consistency in conjunction with feeding intolerance and abdominal distention could be related to necrotizing enterocolitis, especially in preterm infants. Although the exact etiology of necrotizing enterocolitis remains unknown, it is believed that intestinal immaturity leads to a compromised intestinal epithelial barrier, an underdeveloped immune defense, and altered vascular development and tone. The compromised epithelial barrier and underdeveloped immune system, when exposed to luminal microbiota that have been shaped by formula feedings, antibiotic exposure, and cesarean section, can lead to intestinal inflammation and sepsis. Feeding intolerance, bloody stools, pneumatosis intestinalis, and air in the portal vein are the hallmarks of the disorder. Enterocolitis may also occur in infants with Hirschsprung disease (ie, congenital megacolon). Adrenal insufficiency, as well as certain inborn errors of metabolism (eg, galactosemia), may lead to diarrhea. In general, other symptoms such as vomiting occur. Infants may present in shock because of hypovolemia related to dehydration.

Food intolerance may result in diarrhea in infants as well as in older children. Overfeeding or the ingestion of large quantities of fruit juices, dried fruits, or sorbitol-containing products can produce osmotic diarrhea. Food allergies may also be associated with malabsorption. Infants with cow's milk protein allergy can experience diarrhea, growth impairment, anemia, hypoproteinemia, edema, respiratory symptoms, and eczema. Eosinophilia and elevated levels of immunoglobulin E are uncommon in infants with cow's milk protein allergy. High cross reactivity between cow's milk protein and soybean protein in up to 50% of children with cow's milk protein allergy explains a lack of clinical response after substitution for soy protein-based formula. However, soy-containing formulas are very effective in infants with lactase deficiency. Congenital lactose intolerance is an extremely rare disorder. Acquired lactase deficiency is fairly common, especially in certain racial groups; it is reported in 10% of white patients, 70% to 80% of black patients, and 90% of Asian patients. The disorder is associated with diarrhea, cramping, and bloating after consumption of lactose. The stool has an acid pH, floats because it contains air, and is positive for reducing substances. Lactase deficiency may occur following an episode of acute gastroenteritis, when the brush border of the small intestine has been disrupted.

Persistent Diarrhea

Infants and children may have a protracted course of loose stools following an episode of acute gastroenteritis. Risk factors for persistent diarrhea are caloric and protein malnutrition, vitamin A and zinc deficiency, prior infection (eg, measles), male biological sex and young age (6–24 months), and young maternal age.

In most cases, no cause for persistent diarrhea can be detected, but infestation with *Shigella* species or enterotoxigenic *E coli* may be a contributing factor. The possibility of infection with HIV should be considered in infants and children with protracted diarrhea, especially in geographic areas in which disease prevalence is high.

Certain children with acute diarrhea have such a modified diet (eg, clear fluids) that they develop starvation stools. These slimy, dark green or golden stools represent *succus entericus*, the secretion of the small intestine. Starvation stools do not have a fecal odor. Insufficient fat in the diet may contribute to starvation-associated diarrhea.

Chronic Diarrhea

Inflammatory bowel disease, which occurs more commonly in older children and adolescents, is associated with chronic diarrhea. Ulcerative colitis manifests with infiltration of the lamina propria mucosae with inflammatory cells, distortion of the glands, and crypt abscesses. Fever, weight loss, and anorexia are often present. Diarrhea is the hallmark of the disease, and patients experience tenesmus as well as mucus-laden and bloody stools. Inflammation always affects the rectum. It can be localized in the descending colon (left-side colitis) or spread out through the entire large intestine (pancolitis).

Crohn disease may also lead to chronic diarrhea, although lower abdominal pain aggravated by defecation may be a more prominent part of the medical history. Affected individuals frequently experience extraintestinal manifestations of the disease, such as fever, anorexia, weight loss or growth impairment, recurrent stomatitis, uveitis, arthralgia and arthritis, and clubbing. Perianal disease, such as fistulas, may be noted in 30% of patients.

Irritable bowel syndrome (IBS) may lead to chronic diarrhea in infants and children. Affected children do not experience diarrhea at night, which is the sign of infectious or secretory diarrhea. Partially formed or liquid-first stool in the morning and increased frequency during the day are characteristic of IBS. Bowel movement tends to occur after each meal, suggesting a prominent gastrocolic reflex. Children have 3 to 10 mucus-containing stools per day. Alternating periods of constipation may occur. Affected children appear well throughout this illness, without weight loss, growth impairment, fever, leukocytosis, steatorrhea, or protein malabsorption. Their appetite remains good. The first line of treatment of children with IBS-predominant diarrhea is a high-residue diet. Different probiotics have been used recently for treatment of IBS in children with various success rates.

Other frequent causes of chronic diarrhea are consumption of a large amount of fruit juice or carbonated beverages and adverse effects of medications such as antibiotics or nonsteroidal anti-inflammatory drugs.

Many rare conditions can lead to chronic diarrhea: autoimmune enteropathy, microvillus inclusion disease, and intestinal polyposis. Chronic diarrhea may also be associated with maldigestion, as with cystic fibrosis, or malabsorption, such as with celiac disease, or gluten sensitive enteropathy.

Newborns with cystic fibrosis may present with meconium ileus or, rarely, with acute appendicitis. Failure to thrive is common among patients with cystic fibrosis even though many of them have voracious appetites. Stools are large, bulky, and foul smelling secondary to the steatorrhea. Isolated gastrointestinal (GI) concerns are reported in 15% to 20% of patients with cystic fibrosis. Rectal prolapse is not uncommon. Most affected children also experience recurrent pneumonia and chronic pulmonary disease.

Celiac disease is an immune-mediated disorder related to gliadin, a portion of gluten, a protein found in wheat, barley, rye, and oat. Characteristically, a various degree of villous atrophy is apparent on tissue from a small intestinal biopsy. This flattening restricts the absorptive capacity of the intestine and leads to malabsorption. Children with the classic form of celiac disease have short stature, pale skin, sparse hair, protuberant abdomen, and wasted buttocks. In recent reports, subtle signs of celiac disease have been recognized and usually reflect the growth impairment, anemia, iron and folate deficiency, short stature, abnormal liver enzyme levels, dental enamel defects, osteoporosis, delayed puberty, and neurological abnormalities. Symptoms appear a few months after grains are introduced into the diet, usually between the ages of 9 and 12 months. Stools are mushy, bulky, and foul smelling. Fat content in the stool may be 2 to 3 times the normal level.

Evaluation

History

A comprehensive history derived from proper structured and targeted questions is the key for correct approach to the accurate diagnosis of diarrhea (Box 123.2).

Physical Examination

Children should be assessed for the presence of dehydration: altered vital signs, delayed capillary refill, decreased skin turgor, a sunken fontanel, dry mucous membranes, and reduced tearing. Detailed physical examination may reveal signs suggestive of specific diagnosis. For example, persistent severe skin changes in the perianal area or the perianal fistula should trigger a further workup to rule out acrodermatitis enteropathica and Crohn disease, respectfully. Evidence of growth impairment should be determined by assessing the growth parameters. Inability to gain

Box 123.2. What to Ask

Diarrhea

- How long has the diarrhea been present?
- How frequent are the bowel movements?
- What is the consistency of the stools?
- Is the diarrhea related to eating, which is a sign of osmotic diarrhea, or does it occur even if the child does not eat, which is a sign of secretory diarrhea?
- Do the stools contain any blood or mucus, which suggests a bacterial or parasitic infection?
- Is the child febrile?
- Does the child have any symptoms associated with the diarrhea?
- Does the child have a recent history of travel or exposure to animals?
- Is anyone at home ill?
- Has the child experienced any change in the frequency of urination, which is an important measure of the state of hydration?
- What is the child's diet now? What has it been?

weight over a period of months should initiate the workup of GI disorders such as chronic inflammatory bowel disease, celiac disease, or cystic fibrosis.

Laboratory Tests

The characterization of acute or chronic diarrhea begins with 4-step stool analysis. First, stool is evaluated for its quantity as well as its gross appearance. Undigested pieces of fruits and vegetables in stool of toddlers are often a sign of poor chewing. Small, threadlike bodies that resemble worms could be bile concretions common in infant stool. A fluctuation of stool volume with fasting is important: resolution of diarrhea with fasting is a sign of malabsorption and osmotic diarrhea. Second, stool is subjected to chemical and microscopic analyses to detect the presence of unabsorbed nutrients such as carbohydrates and fats. The presence of carbohydrates could be detected by adding reducing substance tablets (eg, Aim Tab Reducing Substance Tablets) to a small amount of stool liquefied in 1 mL of water. A change in color from blue to green or orange is indicative of undigested carbohydrate. If the main source of dietary sugar is sucrose, as determined by the history, the specimen must be hydrolyzed by heating with hydrochloric acid. The specimen should be analyzed quickly because the normal stool bacteria may break down the carbohydrate and lead to a false-negative result. The presence of fat can be determined both qualitatively and quantitatively. A microscopic examination of stool treated by Sudan or Carmine red stains highlights neutral fat inclusions. Presence of 10 or more globules of fat per high-power field indicates a 3-day stool collection for quantification of undigested fat. Fecal elastase test is a valid alternative to 3-day stool collection.

Third, stool is examined for the presence of blood and leukocytes. Blood may be present in stool but originate from excoriations in the diaper area rather than from the GI tract. A simple way to find stool leukocytes is to smear a mucous component of the stool onto a glass slide and stain it with methylene blue. More than 2 to 4 leukocytes per high-power field is abnormal and is suggestive of a bacterial infection. The sensitivity of the fecal leukocyte test is 85%, but the specificity is only 50% to 60%. Absence of leukocytes or erythrocytes in the stool signifies a very low probability of an invasive bacterial infection (predictive value of a negative test is 95%). A liquid stool should be submitted for culture of potential ova and parasites. Stool analysis using an antibody immunoassay test (eg, Rotazyme) will detect rotavirus.

Fecal calprotectin and lactoferrin tests are sensitive and specific tests to assess the activity of chronic intestinal inflammation.

Fourth, stool is assessed for levels of sodium and potassium and stool osmolarity to calculate the so-called ion gap (ion gap [mOsm/kg] = stool osmolarity [290 mOsm] – 2[(sodium [mEq/L] + potassium [mEq/L])]). Ion gap exceeding 100 mOsm/kg and low sodium concentration in stool (<40 mEq/L) is typical with osmotic diarrhea. On the contrary, ion gap equal to or lower than 100 mOsm/kg and sodium concentration in stool higher than 70 mEq/L is consistent with secretory diarrhea.

Additional studies, especially in the face of dehydration or fever, include serum electrolyte levels study, complete blood cell count, urinalysis, and urine culture. Upper GI endoscopy with a small bowel biopsy is indicated for diagnosis of such diseases as celiac disease or other causes of persistent or chronic malabsorptive diarrhea. Colonoscopy should be considered after consultation with a gastroenterologist if inflammatory bowel disease is suspected.

Management

Initial management of children with gastroenteritis involves adequate oral hydration and correction of electrolyte deficits (see Chapter 80). Intravenous fluid therapy may be necessary in children who cannot tolerate oral rehydration. Children with significant dehydration may require admission to the hospital. Less severely affected children could be managed as outpatients using glucose-based oral rehydrating solutions such as Pedialyte or Infalyte. Alternatively, parents can be advised to make oral rehydrating solutions by using water (1 L [4 c]), sugar (20–39 mL [4–8 tsp]), and salt (2½ mL [½ tsp]).

Dietary manipulation in the treatment of diarrhea is somewhat controversial. Traditionally, affected children have been placed onto clear fluids for 1 or 2 days, with a gradual return to a more regular diet with time. A BRAT diet (bananas, rice or rice cereal, applesauce, and tea or toast diet) was often recommended because of the intrinsic binding properties of the particular food. Authors of recently published studies recommend a full resumption of a normal diet, including dairy products, as the way to ensure adequate nutrition during the acute illness. A high-fat, low-carbohydrate diet accelerates improvement. A lactose-free diet is beneficial for infants and children with persistent diarrhea.

Antimicrobial therapy is indicated for infection with certain pathogens, such as *Campylobacter* species, *E histolytica, G lamblia,* and *Shigella* species. Antimicrobial agents are used to treat *Salmonella* species infection in certain populations, such as neonates, immunocompromised children, and children with sickle cell anemia. Antidiarrheal agents are not usually recommended for the management of diarrhea in children. Diarrhea is believed to be the body's way of eliminating a toxic substance that has been ingested.

Zinc supplementation has been found efficacious in preventing and treating acute diarrhea in developing countries. The World Health Organization and UNICEF (United Nations Children's Fund) recommend zinc supplementation of 10 mg as syrup for infants younger than 6 months and 20 mg for children as dispersible tablets per day for 10 to 14 days.

Probiotics such as of lactobacilli, *Bifidobacterium* species, and *Saccharomyces boulardii* may shorten the course of diarrhea or prevent complications associated with acute diarrhea.

The management of children with chronic diarrhea should target the underlying disorder.

Prognosis

Most cases of acute diarrhea in infants and children in the United States are self-limited and resolve without consequences. Chronic diarrhea may lead to malnutrition and other complications, such as growth impairment. Enteral feedings or hyperalimentation may be used to ensure adequate nutrition and a good outcome. Some children require consultation with a pediatric gastroenterologist.

CASE RESOLUTION

A constellation of chronic diarrhea, poor weight gain, decreased appetite, and foul-smelling stool is suggestive of steatorrhea as seen in patients with celiac disease. Laboratory tests for celiac disease can be requested by the primary care physician and consultation with a pediatric gastroenterologist considered.

CHAPTER 124

Constipation

Doron D. Kahana, MD, CPNS, and Khalid M. Khan, MD

CASE STUDY

A 9-year-old girl is brought to the office by her mother with a report of bloody stool. The mother states that the blood is bright red and seen on the toilet paper and dripping into the bowl but that no blood is mixed into the stool. The child reports perianal pain that is burning during defecation and says that the bleeding is noted toward the end of the bowel movement. On further history, the child has been complaining of intermittent, colicky abdominal pain. This occurs mostly in the afternoon and evening and is relieved with bowel movements. Passage of stool is reported to be infrequent, with multiple skipped days in between. The mother recalls that the toilet has been plugged a few times after her daughter used it. The child has not experienced weight loss and eats an age-appropriate diet that is high in pasta, cheese, processed meat, breads, and candy. At times the child is gassy and looks bloated, but she is otherwise healthy, exhibiting normal growth and development. On examination, vital signs are normal. The patient is at the 65th percentile for height and the 80th percentile for weight. The abdomen is soft and nontender but mildly full in the left lower quadrant. Perianal examination reveals a deep anal fissure, and rectal examination reveals a firm fecal mass. The remainder of the examination is normal.

Questions

1. What is the definition of constipation?
2. How is the stooling pattern related to diet?
3. What conditions are associated with constipation?
4. How do familial factors influence stooling patterns?
5. What is the management of chronic constipation?

Constipation is a common and significant complaint that accounts for approximately 3% of visits to pediatric clinics and up to 25% of pediatric gastroenterology visits. Constipation is often associated with fecal incontinence and abdominal pain, can cause significant distress to the child and family, and has a significant effect on health care costs. Stools that are dry, hard, and difficult to pass define constipation. Although reduced stool frequency is a common characteristic of constipation, it is not universal. The guidelines of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition define constipation as "a delay or difficulty in defecation, present for two or more weeks and sufficient to cause significant distress to the patient." This definition is less stringent that the Rome III criteria, which classifies constipation into 2 groups based on patient age, with children younger than 4 years needing to meet 2 criteria for at least 1 month and those older than 4 years for at least 2 months. The 6 Rome III criteria are defecation frequency 2 times or fewer per week, fecal incontinence, retentive posturing, pain during defecation, large-diameter stools, and palpable rectal fecal mass. The average stool frequency is 3 to 4 per day during the first weeks after birth, which decreases to 1 to 2 per day with introduction of table foods by 1 year of age. After age 4 years and into adulthood, normal stool frequency can range from 3 per day to 3 per week.

Many factors influence the stool frequency in normal newborns, infants, and young children, including diet, familial pattern of intestinal motility, personal sensitivity, hygiene habits, hydration status, variable stressors, and intake of medications. Newborns and infants who are fed mother's milk exclusively may have long intervals—sometimes several days—between normal bowel movements, usually starting in the third month after birth, although the stool will remain loose and seedy. Introduction of solids starting at 6 months of age is often associated with additional slowdown in bowel frequency, and functional constipation may initiate as early as this time.

Functional constipation is constipation in the absence of organic disease; however, it is important to note that chronic constipation is also a condition that begets disease and, thus, must be managed appropriately. Constipation is 1 of several unique medical conditions that create a positive feedback loop—stool withholding results in worsening constipation as stretch receptors accommodate a distended rectum and contractile forces fail to result in a complete evacuation.

In infancy, peristaltic motility may be weak or poorly coordinated, and the lack of physical mobility or ambulation requires the infant to exert a physiologic effort (ie, Valsalva maneuver) to allow passage of stool. Parents or guardians may interpret "straining" as a sign of constipation despite the passage of soft, normal stools. Therapy in such cases, if necessary, is usually nonmedical and involves manual stimulation of the anal sphincters and bringing of the knees toward the chest in a "bicycle kick." Older infants and toddlers may have constipation secondary to food intolerance, such as cow's milk protein allergy, and removal of the inciting agent may result in complete resolution. Toilet training can prove to be a challenge, especially in toddlers with constipation, and stressful parent/guardian-child interactions may result in resistance to toilet training on the part of the child.

Commonly, chronic constipation in childhood is triggered by a painful evacuation that results in an unpleasant experience. School-age children may elect to withhold stool because of fear of toileting outside the home or because of social stressors (eg, parental divorce, bullying). Assessment of the etiology of constipation requires a careful medical history to determine the age of onset, characteristic of the stool, and presence of contributing or confounding factors. Comorbidities, such as anal fissures or overflow encopresis, may manifest over time and usually signify a more chronic course.

Epidemiology

Functional constipation is a common problem in childhood, with an estimated prevalence of 3% worldwide. Prevalence of constipation in infants is lower, but it increases between the ages of 2 and 4 years. The onset often coincides with toilet training and dietary changes and is partially a product of increased colonic transit time. Prevalence of constipation in infants and toddlers is equal among males and females, but it becomes 3 times more frequent in boys than girls by age 5 years. Fecal soiling is a significant comorbidity and is reported in up to one-third of females and one-half of all males with severe, chronic constipation (see Chapter 56).

Clinical Presentation

Infants often present with infrequent passage of stool, with some parents or guardians reporting facial grimacing and grunting during defecation as well as apparent discomfort or fussiness with bowel movements, defined by Rome III as *infant dyschezia*. History of delayed passage of meconium or onset of symptoms before 1 month of age, recurrent vomiting, poor weight gain, or family history of congenital megacolon (ie, Hirschsprung disease) or cystic fibrosis indicate the need for further evaluation. Toddlers usually present with abdominal pain and report the passage of hard or large stools. School-age children may present with fecal soiling, which usually represents overflow incontinence. (Only 10%–15% of all cases of encopresis consist of non-fecal retention.) Parents and guardians describe a stool-withholding posture in which the legs are clamped together and the gluteal muscles are contracted in an effort to suppress defecation (Figure 124.1). Poor appetite and episodic vomiting in severe cases are secondary to a persistent sense of fullness from a dilated and impacted colon. In infants, toxic megacolon resulting from Hirschsprung disease can present with lethargy and signs of sepsis, peritoneal signs, and bloody diarrhea. Hydronephrosis, urinary tract infections, and enuresis also are historically associated with chronic constipation and an impacted colon.

Physical examination should include growth parameters, abdominal examination, perianal inspection, digital rectal examination, inspection of the lumbosacral region, and neurologic evaluation for tone and deep tendon reflexes. The abdomen may be distended and contain a fecal mass on palpation; anal position must be confirmed, and the presence of stool present around the anus or on the undergarments, erythema, rash, skin tags, or fissures should be noted. Lumbosacral dimple, hair tuft, gluteal cleft deviation, and sacral agenesis must be excluded.

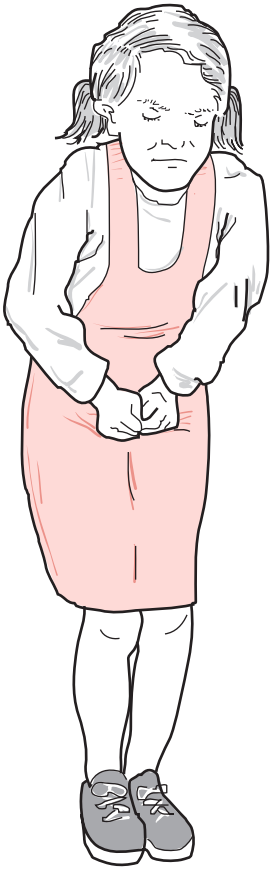

Figure 124.1. Child exhibiting retentive posture.

Pathophysiology

The Colon

The colon is a muscular organ that processes dietary residue through bacterial fermentation, salvaging nutrients and reabsorbing more than 90% of the water that enters, and prepares stool for transient storage and eventual excretion (Figure 124.2). Fermented food residue produces gas (eg, hydrogen, methane) and short-chain fatty acids; the latter provide colonocytes with readily available fuel (via butyric acid) that enters the portal circulation for calorie salvage in the liver (eg, propionic acid, acetic acid). The fermentation process may release other micronutrients and vitamins (eg, vitamins K_2 and B_{12}, folic acid, biotin) and is thus an important component of colonic function.

Normal Physiology

Digested food normally takes approximately 2 to 6 hours to reach the cecum from the duodenum (following gastric emptying, which has a normal half-time of 60–90 minutes). The propagation of food in the small intestine occurs via peristaltic waves called the *migrating motor complex.* Once chyme is in the cecum, peristalsis slows, and it may take several hours or days for it to be expelled as stool. The longer the transit time, the more extensive the water resorption and the more likely it is for the stool to be dry and hard. The rectosigmoid is the sensing organ that initiates the process of defecation and

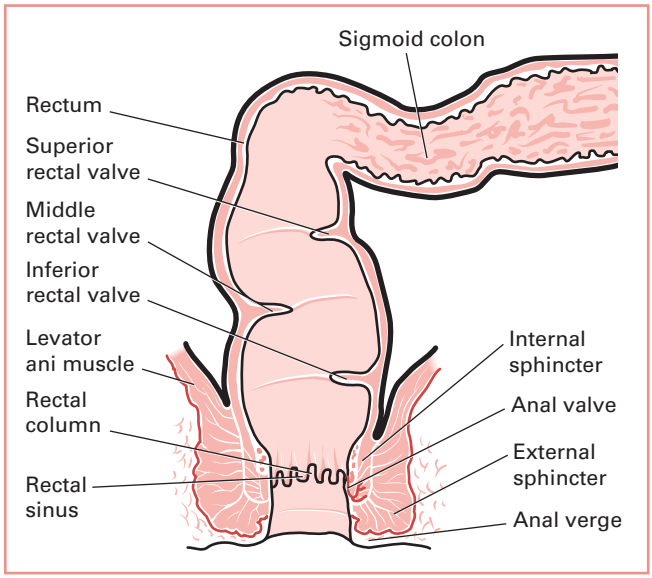

Figure 124.2. Diagram of the anus, rectum, and sigmoid colon.

can store stool until it is socially acceptable to expel it. Contraction and emptying of the rectosigmoid is stimulated by eating, a process called the *gastrocolic reflex.* In the rectum, the pelvic floor muscles (ie, levator ani, puborectalis muscle) regulate fecal retention and defecation. The puborectalis muscle suspends the rectosigmoid and imposes constraints that facilitate voluntary stool retention (ie, continence). Continence is also promoted by contraction of the internal and external anal sphincters.

Defecation

The urge to defecate is signaled by the propulsion of feces from the sigmoid colon to the rectum. Distention of the rectum causes relaxation of the internal anal sphincter; the external anal sphincter and puborectalis muscle must voluntarily relax through parasympathetic action. The pelvic floor muscles descend, permitting straightening of the anus and rectum (Figure 124.2). Thus, defecation is facilitated by squatting or sitting and by increasing intra-abdominal pressure. The urge to defecate can be consciously repressed by voluntary contraction of the external anal sphincter and likely subconscious sympathetic reflex inhibition and contraction of the puborectalis muscle. The process of defecation is learned early in childhood and remains spontaneous throughout life. The spontaneity of this process may be lost for a variety of reasons, including secondary to trauma, pelvic floor dysfunction, pseudo-obstruction, and surgical resection.

The Vicious Cycle of Constipation

If the urge to defecate is suppressed, the rectosigmoid and eventually the entire colon become dilated and impacted, and defecation may become difficult. The increased caliber of the colonic lumen makes contractions weaker and less effective in propagating stool. Moreover, the child with constipation may become desensitized to rectal distention. Eventually, delayed defecation results in the formation of hard, bulky stool, which makes defecation difficult and painful. The child learns to tighten the external anal sphincter and gluteal muscles, pushing feces higher into the rectal vault and suppressing the urge to defecate; this is the vicious cycle of constipation (Figure 124.3). In children, the initiating event may be a painful evacuation, possibly after an acute illness (eg, cold, respiratory infection) or a course of antibiotics. Intentional and prolonged suppression of defecation is an important factor in the pathogenesis of chronic constipation.

Familial Factors

Some families are predisposed to constipation. Concordance for constipation is 4 times more common in monozygotic twins than dizygotic twins. It may be related to increased absorption of water or an unusually long or poorly motile colon. Poor sensitivity to a critical rectal volume or the need for a particularly large rectal volume may delay the initiation of defecation in genetically predisposed individuals.

Differential Diagnosis

The differential diagnosis of constipation can be divided into congenital versus acquired and then into the following etiologic categories: anatomic; neurologic; hormonal; infectious/toxic; drug-induced/metabolic; functional; and other, such as genetic or allergic (Box 124.1). Functional constipation is often supported by a history that includes poor dietary and hydration habits, stool-withholding behavior, and a normal physical examination. Dietary history may reveal high consumption of cow's milk (>24 oz/day), cheese, or sugary fruit juice, as well as poor intake of fruits, vegetables, and whole grains. Stool withholding most commonly occurs in young, school-age children and often is a product of a stressful environment, such as a new sibling, a move, parental struggles, or a new school environment.

Chronic constipation that is resistant to medical therapy should not be ignored. Conditions such as congenital megacolon and congenital intestinal malrotation can present past the neonatal period and may result in intestinal devastation (eg, volvulus, ischemia). Several conditions are particularly important to consider when evaluating

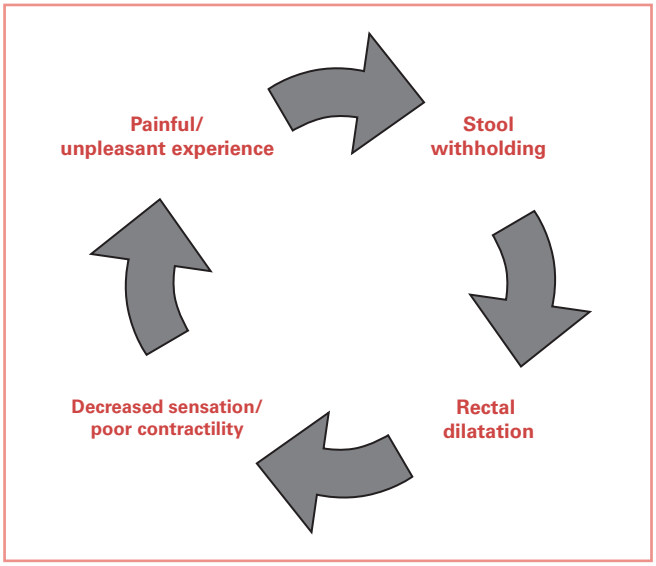

Figure 124.3. The vicious cycle of constipation.

Box 124.1. Differential Diagnosis of Constipation

Anatomic
- Anal stenosis
- Imperforate anus
- Ectopic anus
- Postoperative stricture

Neurologic
- Congenital megacolon (ie, Hirschsprung disease)
- Cerebral palsy
- Hypotonia
- Spina bifida occulta
- Meningomyelocele
- Sacral agenesis
- Intestinal pseudo-obstruction syndrome

Hormonal
- Hypothyroidism
- Panhypopituitarism
- Multiple endocrine neoplasia
- Pheochromocytoma

Infectious/Toxic
- Postinfectious ileus
- Botulism

Drug-induced/Metabolic
- Analgesic agents (eg, opioids)
- Antacids
- Anticholinergic agents
- Bismuth
- Iron
- Cholestyramine resin
- Hypocalcemia
- Hyperkalemia

Functional
- Dehydration
- Stool withholding
- Stress
- Anxiety
- Fear of painful evacuation

Other
- Cystic fibrosis
- Celiac disease
- Cow's milk protein allergy or sensitivity

constipation in infants, including congenital megacolon, hypothyroidism, anal stenosis or atresia, meningomyelocele, and cerebral palsy. Failure to pass meconium or a delay in the passage of meconium beyond 24 hours should raise suspicion for a congenital or genetic aberration (eg, congenital megacolon, cystic fibrosis).

Congenital megacolon is an intestinal motility disorder resulting from aganglionosis of the myenteric plexus that affects the rectosigmoid. In rare instances the entire colon is involved, although in most cases the distribution is distal to proximal. The severity of the disease and complexity of surgical treatment is directly proportional to the length of the affected colon. When ganglion cells are missing in the very distal portion of the rectum, the disorder may resemble chronic idiopathic constipation, which often may also be recalcitrant to medical therapy. The prevalence of congenital megacolon is approximately 1 in 5,000 live births and may account for up to 3% of all cases of constipation referred to a gastroenterologist. Physical examination of a patient with congenital megacolon may reveal some degree of abdominal distention and an empty rectal vault. In infants, a rectal examination frequently induces a gush of air and an explosive stool resulting from digital bypass of the diseased lumen. Early recognition of this condition is important to prevent the development of toxic megacolon and enterocolitis, a condition that carries high morbidity and significant mortality. Congenital megacolon may occur in conjunction with syndromes such as Down syndrome (ie, trisomy 21), Smith-Lemli-Opitz syndrome, and Waardenburg syndrome, and several genetic mutations in the receptor tyrosine kinase gene *RET* have been described as responsible for the pathogenic mechanism.

Infants with hypothyroidism secondary to hypopituitarism may also present with constipation and are not diagnosed through the newborn screening process because of normal (ie, low) levels of thyroid-stimulating hormone. These children may appear clinically normal or may display some of the features of hypothyroidism (eg, large fontanel, umbilical hernia, coarse facies, macroglossia).

Anal stenosis, imperforate anus with a perineal fistula, or an anteriorly displaced anus may not be recognized immediately in the newborn period because the condition may be quite subtle. Anorectal malformations occur in approximately 1 in 7,000 live births, which reinforces the need for a perianal and rectal examination with every constipated child.

Severe constipation that begins prior to toilet training is suggestive of an organic etiology, such as congenital megacolon, malrotation, or pseudo-obstruction. Pseudo-obstruction may present in the older child with a history of intermittent constipation, abdominal distention, pain, nausea, and vomiting. Onset of constipation around the time of toilet training, when stool consistency and pattern had been normal in the past, is suggestive of functional constipation.

In some children, constipation may develop in association with the use of medications such as iron or bismuth subsalicylate (eg, Pepto-Bismol), codeine or other narcotics, chemotherapeutic agents (eg, vincristine sulfate), and agents with anticholinergic properties (eg, pseudoephedrine, imipramine).

Evaluation

History

Commonly associated historical signs and symptoms of constipation include abdominal pain (especially during and after meals), abdominal distention, excessive flatulence, hard stools, dyschezia (ie, painful evacuations), bright-red blood per rectum, toilet plugging, and urinary symptoms (eg, enuresis, recurrent infections) (Box 124.2). Overflow incontinence may mislead the clinician to a differential diagnosis of chronic diarrhea. Fecal soiling resulting from stool retention and overflow is noted in many children with severe, chronic constipation, although a complete physical examination in such a setting should reveal a stool mass in the lower left abdominal quadrant and an impacted colon or rectum on digital manipulation. As with all conditions that present with abdominal pain, it is important to screen for the presence of recurrent mouth sores, skin rashes, joint pain, weight loss, bloody or mucous stools, incomplete evacuations, and tenesmus, which in the case of constipation consists of rectal spasm accompanied by a strong urge to defecate, often with the passing of blood or mucus. Family history of inflammatory bowel disease, celiac disease, irritable bowel syndrome, constipation, and atopy (eg, food allergy) should also be noted with every child presenting with abdominal pain.

Box 124.2. What to Ask

Constipation

- What is the child's stooling pattern? How often does the child have a bowel movement? What is the appearance and consistency of the stool?
- What was the child's age when the problem began?
- What makes up the child's diet?
- Does the child take any medications?
- Does the child have any symptoms associated with constipation, such as recurrent abdominal pain? If so, how long have these been occurring?
- Has the child been sick recently with any illnesses that might cause constipation?
- Has the child recently experienced any changes in routine that could cause constipation?
- Is there a family history of constipation?
- At what age was the child toilet trained?
- Is there any bleeding with passage of stool?
- Is there pain with passage of stool?
- Have any remedies, such as laxatives, enemas, or suppositories, been used to relieve the symptoms?

Physical Examination

The physical examination in individuals with functional constipation is usually normal. If the child reports abdominal pain, ask the child to indicate the area of greatest pain with 1 finger. In functional disease, the child most often points directly to the umbilicus. Palpation may reveal a firm stool mass in the left lower quadrant that is classically nontender. Consistency and color of the stool in the rectum varies, but a hard and dry stool is strongly suggestive of stool impaction. An empty rectum should raise suspicion for an organic etiology. Digital manipulation followed by an "explosive" passage of stool is suggestive of congenital megacolon (ie, Hirschsprung disease). The physician should examine the child's back for a sacral dimple or a hair tuft, especially in infants, which may be a sign of occult spinal cord anomaly.

Signs of pallor, mouth sores, hepatosplenomegaly, arthritis, or skin rashes may be suggestive of another underlying disease process.

Laboratory Tests

Malnourishment is possible if the child consumes a restricted diet (eg, >24 oz/day of cow's milk or soda) or has a suggestive physical examination (eg, pallor, dry skin). Iron deficiency anemia and mineral deficiencies (eg, calcium, zinc) are signs of poor nutritional intake. A lipid panel may reveal high triglyceride levels (from excessive sugar intake) and low high-density lipoprotein levels (from poor-quality fat intake). In some patients it may be necessary to evaluate thyroid function. Routine laboratory testing for hypothyroidism, celiac disease, and hypercalcemia is not recommended in children without suggestive symptoms.

Imaging Studies

Usually, a plain radiograph of the abdomen (ie, flat plate of the abdomen) is not indicated; however, it may help on a clinical level by showing the child and parents or guardians the significant amount of stool present. Anatomic studies, such as a barium enema to evaluate for malrotation, a congenital stricture, imperforate anus, or congenital megacolon, may be indicated if the history or physical examination is concerning. It is recommended for barium enema to be performed without a prior clean out to sensitize the study for the presence of a transitional zone. Evidence does not support the routine use of magnetic resonance imaging of the spine in patients with constipation without other neurologic abnormalities.

Additional Tests

Anorectal manometry and a suction rectal biopsy may be performed by a gastroenterologist to help diagnose congenital megacolon (ie, Hirschsprung disease); however, only a full-thickness rectal biopsy will confirm the presence or absence of aganglionosis, and this must be performed by a surgeon. Colonic manometry can also measure colonic peristaltic waves and help diagnose pseudo-obstruction and other dysmotility disorders. Evidence is conflicting for the role of allergy testing to diagnose cow's milk protein allergy or other food sensitivities.

Management

The Primary Care Setting

Most cases of constipation can be evaluated and managed by the primary care physician. In functional constipation, the mainstay of management involves a 3-pronged approach of dietary therapy, behavioral modification, and medications (Figure 124.4).

Diets that predispose to constipation are rich in simple carbohydrates (eg, sugar), refined and processed carbohydrates (eg, pasta), saturated fat (eg, fried food), processed meat (eg, hot dogs), and dairy (especially milk and cheese). Dietary therapy should begin by decreasing the intake of these food items and increasing the intake

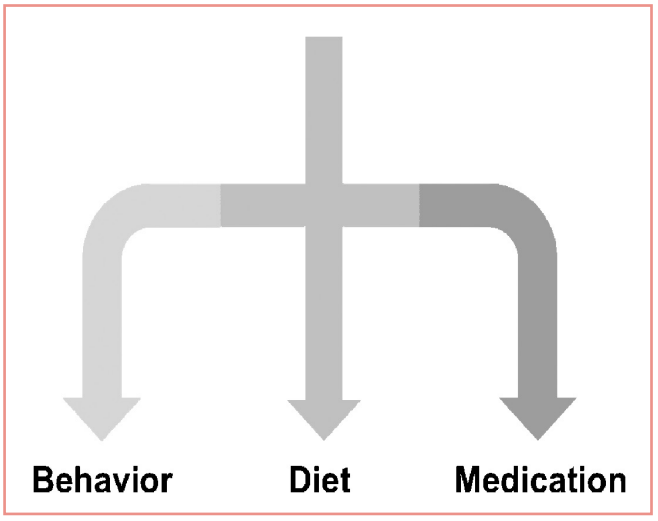

Figure 124.4. Three-pronged management of constipation.

of fruit, vegetables, whole grains, legumes, and tree nuts. Prune juice and fruit nectars (eg, pear, peach, apricot) may be supplemented, are well tolerated and effective, and may be mixed with the child's favorite drink. Most fruit, such as pears, papaya, and cantaloupe, as well as vegetables, roots, and tree nuts, are high in beneficial fiber. Dried fruits (eg, raisins, cranberries) are rich in sorbitol and thereby cathartic. It is important to continuously introduce new food items to the diet, especially fruit and vegetables. Introduction of certain foods, such as whole-grain breads and brown rice, may need to be gradual and may require some adjustment but will render lifelong benefits (Box 124.3).

Behavior modification can be challenging, but it is essential to breaking the vicious cycle. Teaching of proper toilet hygiene to the child should be done in a firm and consistent manner; engaging the child with a sticker or star chart may help. It is recommended that the child sit on the toilet once or twice daily for 8 to 10 minutes at a time, preferably after a meal, thereby taking advantage of the gastrocolic reflex. Longer toilet sitting should be discouraged, because it may result in perianal disease, such as a fissure or hemorrhoids. Even if the child does not have a bowel movement with each toilet sitting, good toilet hygiene will make the experience routine and, it is hoped, help prevent further reluctance to use the toilet. Biofeedback is useful when available, especially in the child with encopresis or paradoxical contraction of the external anal sphincter.

Medications are generally safe and mainly over-the-counter (Box 124.4). The 2 most commonly used medications are polyethylene glycol (PEG 3350), a nonabsorbable high–molecular weight synthetic polymer (nonfermentable), and lactulose, a nonabsorbable high–molecular weight sugar (fermentable). Both work by helping the colon retain water and thus prevent the complete dehydration of stool. Lactulose is a prebiotic that is fermented into short-chain fatty acid and can beneficially reduce stool pH. The process may cause gassiness and bloating in some patients, however, and therefore it may be necessary to gradually increase dosing. Suppositories or enemas and manual disimpaction should be avoided, because high-dose polyethylene glycol administration has demonstrated equal efficacy with less invasiveness. Mineral oil is useful in lubricating hard stool and decreasing the pain associated with fissures, but it should not be given to infants or neurologically impaired patients because of the risk of aspiration and chemical pneumonitis. Dietary fiber supplements (ie, prebiotics), such as psyllium husk, guar gum, inulin, and fructosan, are helpful for maintenance therapy. Probiotics, notably the strains *Lactobacillus reuteri, L plantarum, Bifidobacterium longum, B breve,* and *B animalis* subsp *Lactis,* have also shown usefulness in the management of constipation.

The most important element in the management of functional constipation is persistence and long-term therapy. Six to 12 months of medication and follow-up are often necessary, because the colon must heal from a chronic injury to regain

Box 124.3. Dietary Therapy for the Management of Chronic Constipation

Avoid/Decrease

- Simple/Processed carbohydrates
  - Sugar
  - Corn syrup
  - Soda
  - White bread
  - White rice

Box 124.4. Pharmaceutical and Supplement Therapy for the Management of Constipation

Osmotic Laxatives

- Polyethylene glycol
- Lactulose
- Magnesium hydroxide
- Phosphate

Psyllium Husk

- Bulking agents
- Guar gum
- Bran
- Calcium polycarbophil
- Methylcellulose

Prebiotics/Probiotics

- Inulin
- Fructo-oligosaccharide
- *Lactobacillus reuteri, L plantarum*
- *Bifidobacterium longum, B animalis, B breve*

Lubricant/Detergent

- Mineral oil
- Docusate sodium

Stimulants

- Senna
- Bisacodyl

Enemas/Suppositories

- Phosphate
- Saline
- Mineral oil
- Glycerin

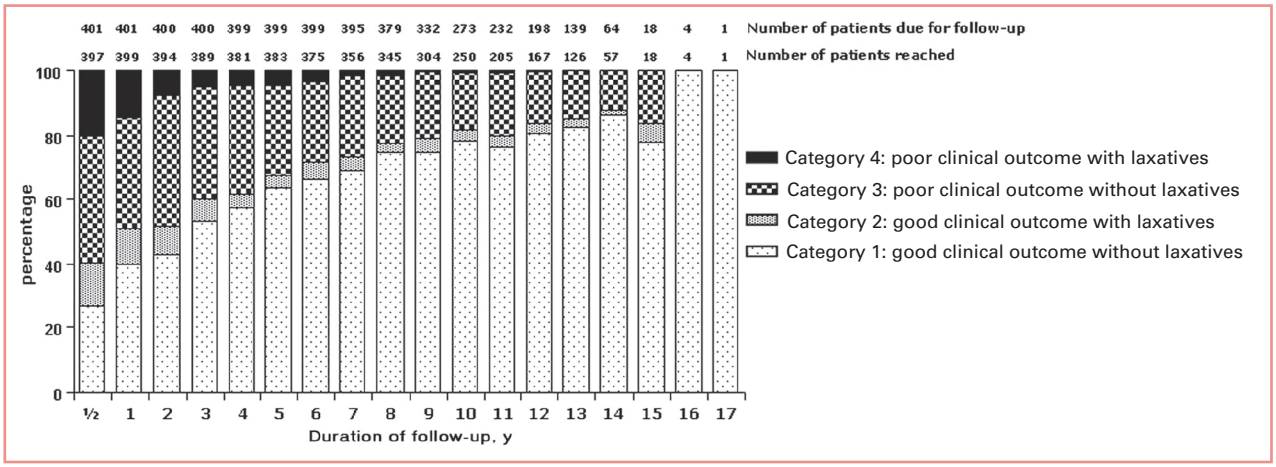

Figure 124.5. Clinical outcomes of pediatric patients treated for constipation according to follow-up year and outcome category.
Reprinted with permission from Bongers ME, van Wijk MP, Reitsma JB, Benninga MA. Long-term prognosis for childhood constipation: clinical outcomes in adulthood. *Pediatrics*. 2010;126[1]:e156–e162.

regularity and a normal caliber. Dietary changes and toilet hygiene should be incorporated into a healthy lifestyle and practiced into adulthood.

When to Refer to a Gastroenterologist

Constipation that is refractory to medical therapy should not be ignored. Although uncommon, anatomic aberrations (eg, malrotation), congenital megacolon, and intestinal pseudo-obstruction may manifest after infancy and cause toxic megacolon or intestinal or colonic volvulus, resulting in intestinal ischemia and devastation. These conditions may necessitate surgical intervention and long-term follow-up, and the affected patient should be referred to a specialist. Special attention should be paid to the infant with persistent constipation because of the high risk of serious conditions, such as congenital megacolon and malrotation.

Prognosis

Prognosis varies with etiology. Functional constipation usually is amenable to routine management, but treatment failures are reported in 20% of children with functional fecal retention, and some long-term studies suggest persistence of symptoms in 25% to 50% of children. A long delay in presentation increases the risk of poor clinical outcome. Age at presentation and stool frequency are also strong predictors of clinical outcome. The relapse rate at 1 year, after a successful initial intervention, is less than 5% but increases to 10% to 40% after 5 to 7 years, with significantly higher rates for women. Long duration of symptoms, poor self-esteem, and prior sexual abuse are among risk factors for a poor prognosis. Nonetheless, long-term studies support 2 important findings: prolonged laxative use is important initially, and dietary and behavioral modifications are ultimately successful in weaning laxative use (Figure 124.5).

CASE RESOLUTION

The child has functional constipation with a fissure. The bleeding is very distal, and bright red blood is noted on the toilet paper and in the bowl, not mixed into the stool. The belly pain is visceral, related to gas distention and stool retention, and relieved with defecation. Gassiness implies stool retention and fermentation in the colon. Normal appetite and growth parameters are reassuring. The rectal examination establishes the diagnosis of an anal fissure, and no further testing is necessary for this child at this time.

CHAPTER 125

Abdominal Pain

George Gershman, MD

CASE STUDY

A 14-year-old boy is seen by his pediatrician for chronic pain in his epigastric area. According to the patient, he has experienced dull pain in the area since seventh grade, 2 years ago. Pain usually occurs about 1 hour after eating and at night. The pain is intense and lasts longer than an hour. He often drinks water or milk to alleviate the pain. He also reports frequent heartburn after spicy food but denies weight loss or diarrhea. The physical examination reveals abdominal tenderness in his epigastric area. The patient's bowel sounds are normal. There is no evidence of hepatosplenomegaly or ascites. A rectal examination shows a normal rectal vault and absence of a palpable mass. A stool guaiac test result is positive for occult blood.

Questions

1. What types of abdominal pain occur in children?
2. What characteristics distinguish functional from organic abdominal pain?
3. What are the common organic causes of recurrent abdominal pain in children?
4. What functional gastrointestinal disorders manifest with recurrent abdominal pain in children?

Abdominal pain, which may be acute or chronic, is among the most common symptoms of childhood and accounts for 2% to 4% of pediatric visits. Most children with acute abdominal pain have self-limiting conditions such as viral or bacterial gastroenteritis. However, a sudden onset of abdominal pain can be caused by serious, life-threatening conditions (eg, acute appendicitis, intussusception, hemolytic uremic syndrome). Chronic abdominal pain is among the most common chronic pain entities in children and adolescents, affecting an estimated 0.3% to 19% of children worldwide. Furthermore, chronic abdominal pain can have significant psychosocial and financial costs, which often persist into adulthood, making this a global health problem with an effect well beyond the individual child and family. In clinical practice, it is generally believed that pain that exceeds 2 months' duration can be considered chronic. Most children with chronic abdominal pain experience so-called functional abdominal pain (FAP). Over the last 20 years several functional gastrointestinal (GI) disorders associated with FAP have been established on a symptoms-based Rome classification system. In the latest version (Rome IV), a new category of FAP disorders has been included: FAP not otherwise specified (FAP-NOS), for children and adolescents whose symptoms do not match a specific FAP-associated disorder, such as functional dyspepsia, irritable bowel syndrome (IBS), or abdominal migraine. The diagnostic criteria for FAP-NOS must be fulfilled at least 4 times per month for a minimum of 2 months prior to diagnosis and include all of the following: episodic or continuous abdominal pain that does not occur solely during physiological events (eg, eating, menses); insufficient criteria for IBS, functional dyspepsia, or abdominal migraine; and after appropriate evaluation, abdominal pain that cannot be fully explained by any other medical condition.

An organic etiology is found in fewer than 10% of school-age children with chronic abdominal pain. However, failure to recognize the cause and/or delaying therapy can have devastating effects.

Epidemiology

Chronic abdominal pain is one of the most common symptoms in children, with a reported prevalence approaching 19%. Available data indicate an even higher prevalence of FAP disorders in school-age children in low-income countries. According to community- and school-based studies, up to 38% of children and adolescents experience abdominal pain weekly, with up to 24% of children reporting symptoms persisting longer than 8 weeks.

There is evidence to suggest a steady rise of abdominal pain symptoms in children approaching age 5 years and between ages 8 and 10 years.

There is no sex-related difference in the prevalence of abdominal pain until adolescence, when girls become more vulnerable to abdominal pain (the female to male ratio approaches 1.4:1).

Additional factors associated with a high prevalence of chronic abdominal pain are a positive family history and low socioeconomic status. Abdominal pain is an essential part of several functional GI disorders, such as IBS, functional dyspepsia, and abdominal migraine.

Pathophysiology

The 3 main causes of acute or chronic organic abdominal pain are inflammation, distention of the viscera, and ischemia.

Abdominal pain can originate from abdominal viscera (visceral pain), parietal peritoneum, abdominal wall, retroperitoneal skeletal

muscles (somatic pain), and extra-abdominal sites (so-called referred pain). Impulses of visceral pain are carried out primarily by small, unmyelinated, slow-conducting afferent C fibers incorporated into the autonomic sensory pathways. Each visceral organ receives dual sympathetic and parasympathetic innervations. Sensory fibers associated with the sympathetic nervous system traverse prevertebral (ie, celiac, superior, and inferior mesenteric ganglion) and paravertebral ganglion and terminate in the spinal cord. Sensory fibers contained in the vagus and pelvic nerves (ie, parasympathetic branch of the autonomic nervous system) terminate in the brain stem and lumbosacral spinal cord, respectively. Sensory fibers from visceral organs that connect with the spinal column terminate across 4 to 5 spinal segments, explaining why visceral pain is poorly localized and often perceived along the midline as a dull or aching sensation. For example, the onset of acute appendicitis is usually manifested by pain in the periumbilical or epigastric areas before the pain migrates to the right lower quadrant. It is frequently accompanied by symptoms of autonomic disturbance (eg, nausea, pallor).

Somatic pain is induced by irritation of parietal peritoneum and supportive tissue. The signals from the pain receptors (ie, nociceptors) are transmitted for the most part by rapid conducting myelinated A delta fibers responsible for tactile, thermal, and chemical stimulation and discrimination of location and intensity of stimuli. As a result, somatic pain is well localized, intense, and sharp. The important characteristic of somatic pain is aggravation by movement. Therefore, the child with somatic abdominal pain is likely to lie still, in contrast with the restless patient with visceral pain.

The classic example of referred pain is abdominal pain induced by inflammation of parietal pleura at the onset of pneumonia as the result of shared central projections of the parietal pleura and abdominal wall.

The location of abdominal pain is determined by the level of spinal cord connection with the corresponding visceral organs through the afferent sensory fibers. The structures of foregut origin, such as distal esophagus, stomach, duodenum, liver, and pancreas, are innervated by the nerves that enter the spinal cord at the level T5-9 segments. Pain from these organs is perceived between the xiphoid and umbilicus. The structures related to the primitive midgut (ie, small intestine, appendix, and right colon) project the afferent fibers to the T8-9 segments of the spinal cord. As a result, the associated pain affects the periumbilical area. The structures related to the embryonic hindgut, including the left colon and the rectum, share the innervations, which involve the spinal segments T10-L1 and allocate the pain between the umbilicus and symphysis pubis.

Radiation of the pain may help in diagnosis (eg, pain related to acute cholecystitis or biliary colic is often referred to the area just under the inferior angle of the right scapula or above the right clavicle). Another example of referred pain is pain between the scapulae and middle back region in patients with pancreatitis.

The pathophysiology of FAP is different from acute or chronic organic abdominal pain. The genesis of FAP is related to abnormalities in the enteric nervous system and dysregulation of the brain-gut interaction. Currently, it is believed that children with FAP may have abnormal responses to the normal physiological functions related to eating, such as intestinal distention during peristalsis, and hormonal changes during digestion. Functional abdominal pain may also be related to psychological conditions such as anxiety and parental separation.

Research data suggest that visceral hyperalgesia is the key element in the pathophysiology of FAP. This theory implies sensitization of the various receptors associated with afferent innervation of the GI tract by an infectious or allergic process or abnormal processing of afferent signals by the central nervous system.

Clinical Presentation

Children who experience abdominal pain may present with pain that may be characterized as persistent or intermittent, waxing and waning or steady and unrelenting, sharp or dull, and worsened or unaffected by movement. They may have associated symptoms, including vomiting, diarrhea, constipation, fever, weight loss, headache, and anorexia (Box 125.1).

Pain from distention of smooth muscle also waxes and wanes, is poorly localized, and is unaffected by motion. Distention of any hollow viscus, including the stomach, intestines, biliary tree, fallopian tubes, or ureters, can result in such symptomatology. A classic example of such pain is renal colic, from which the patient is writhing because of the discomfort.

Differential Diagnosis

In assessing the possible disease entities that may account for abdominal pain, patient age and duration of symptoms are the key differential components. The location of the pain may provide a clue to the etiology. Disease affecting the stomach is usually appreciated in the epigastrium. Duodenal problems are noted between the xiphoid and the umbilicus, small intestinal pathology is appreciated in the periumbilical area, and cecal inflammation may be felt from the epigastrium to McBurney point. Disease in the colon is less specifically noted but is usually felt in the hypogastrium. Pain related to the urinary bladder and rectum may project to suprapubic

or sacral areas. Pain may also be referred to the back. Renal colic is also noted in the back but more in a lateral or costovertebral angle site.

Acute and Chronic Abdominal Pain

Infants

Medical Conditions

A unique disorder of infants, infant colic has been referred to as paroxysmal fussiness of infancy and defined as prolonged, hard-to-soothe, and unexplained crying behavior (see Chapter 49). The onset of colic is usually between 2 and 4 weeks of age, with resolution by 3 to 4 months of age. Although colic has been attributed to recurrent abdominal pain, such pain has never been established as the cause of colic. Colic is characterized by fussiness and crying. Symptoms usually appear after feeding, particularly late in the day around family dinnertime. Infants cry, clench their fists, and flex their legs. A gas-cry-air-swallowing cycle seems to occur. The symptoms may respond to a number of measures, including rhythmic motion and anti-gas medications. Infants with colic usually appear well otherwise and often have accelerated weight gain secondary to repeated feeding made in efforts to soothe them.

Abdominal pain may also occur with food allergy, particularly cow's milk protein allergy. Generally, symptoms such as vomiting, diarrhea, stools positive for occult blood, failure to thrive, rhinitis, eczema, pallor, irritability, and a positive family history of allergies are associated findings. Disaccharidase deficiency (eg, lactose intolerance) may result in abdominal pain, but diarrhea is also usually present.

Surgical Conditions

Intussusception occurs most often in infants 6 months and older. The infant or toddler may have been previously well or have experienced a recent bout of diarrhea. Vomiting is reported in about 50% of patients, and pallor is frequently present. Lethargy is a not-uncommon associated symptom. An etiology is noted in fewer than 2.5% of affected infants, although a lead point (lymphoma or Meckel diverticulum) may be found in 5% to 10% of older children. The intussusception most often involves the area around the ileocecal valve. Compression of the vessels within the bowel wall may lead to necrosis and gangrene. The presence of blood and mucus in the stools gives a currant jelly appearance, although the initial stool is often normal, having been the stool that was present in the rectum prior to the intussusception.

The abdominal examination of affected children may be benign except for pain over the area of the intussusception or the presence of a mass. Bowel sounds may be increased secondary to the obstruction. A rectal examination may reveal blood and the presence of a mass. Fever and leukocytosis may also be noted. A flat radiograph of the abdomen is usually nonspecific. Intussusception is diagnosed by abdominal ultrasonography or barium enema. Hydrostatic reduction is the treatment of choice of intussusception; it is successful in almost 90% to 95% of children. Failure of hydrostatic reduction or associated complications is related to delayed diagnosis and severe edema and necrosis of the affected bowel. Surgical intervention is then required.

School-age Children

Medical Conditions

As noted previously, most children with chronic abdominal pain suffer from FAP disorders. By definition, abdominal pain in children with FAP-NOS is not affected by eating, defecation, menses, or other physiological functions. It may be triggered by a new environment, difficulties at school, or domestic problems. The pain is usually periumbilical and quite severe. It can be recurrent or continuous and may affect daily activity.

Abdominal pain in children with IBS is associated with changes in stool frequency and appearance, and pain that improves with defecation. Additional symptoms associated with IBS are increased frequency of stools (ie, ≥4 stools per day) or decreased stooling (ie, ≤2 stools per week), lumpy/hard or loose/watery stool, straining, urgency or feeling of incomplete evacuation, passage of mucus, and bloating or feeling of abdominal distention. Children with IBS are often anxious and experience multiple somatic symptoms.

Although many children seem to outgrow FAP and IBS, long-term follow-up studies suggest that a significant number remain symptomatic into adulthood.

Children with *functional dyspepsia* experience postprandial fullness, early satiety, nausea, vomiting, and epigastric pain.

Epigastric pain syndrome (1 of 2 subtypes of functional dyspepsia in the Rome IV classification) includes bothersome (severe enough to interfere with normal activities) pain or burning localized to the epigastrium. The pain is not generalized or localized to other abdominal or chest regions and is not relieved by defecation or passage of flatus. Supportive criteria can include burning quality of the pain but without a retrosternal component, and pain commonly induced or relieved by ingestion of a meal but that may also occur while fasting. Acid blockade with H_2-receptor antagonists and proton pump inhibitors can be offered for predominant symptoms of pain.

Abdominal migraine is characterized by recurrent paroxysmal episodes of intense, acute periumbilical, midline, or diffuse abdominal pain that lasts from 1 to several hours. Pain is often incapacitating. Children return to their usual state of health for weeks or months between the paroxysms of pain. The pain interferes with normal activities and is often accompanied by pallor, anorexia, photophobia, headache, nausea, and vomiting. There is an increased incidence of maternal migraine in children with abdominal migraine.

As mentioned previously, an organic etiology is found in fewer than 10% of school-age children with chronic abdominal pain. The symptoms and signs of organic diseases are persistent right upper and right lower quadrant pain, pain that awakens the child from sleep, dysphagia, persistent vomiting, arthritis, perirectal disease, GI blood loss, nocturnal diarrhea, involuntary weight loss, deceleration of linear growth, delayed puberty, unexplained fever, and

a family history of inflammatory bowel disease, celiac disease, or peptic ulcer disease.

Peptic ulcers may develop in children in 3 circumstances. Acute infantile ulcers may occur in newborns secondary to stress and hypoxia. Stress ulcers may also occur in children who experience trauma, including burns and hypoxia (eg, after submersion). The routine uses of H_2-receptor antagonists or proton pump inhibitors has reduced the incidence of ulcers in hospitalized children who were critically ill.

The most common type of ulcer in children is acute, drug-induced ulcerations of the stomach and the duodenum caused by nonsteroidal anti-inflammatory drugs. Chronic peptic ulcers may develop in prepubertal children and teenagers with no apparent precipitating factors. A positive family history of peptic ulcer disease is reported in 25% to 50% of children. Unlike the classic ulcer symptoms of adults, in which pain occurs on an empty stomach and is relieved by eating, children may find that ulcer-related pain does not follow a specific clinical pattern. Positive family history, microcytic anemia, and stools positive for occult blood should raise clinical suspicion and prompt referral of the child to the pediatric gastroenterologist. There is clear evidence linking ulcer disease and infection with *Helicobacter pylori* in adults. The relationship between *H pylori* and peptic ulcer disease in children is less strong, although two-thirds of pediatric patients with endoscopic evidence of peptic ulcer disease have *H pylori* infection.

Mesenteric adenitis may produce symptoms indistinguishable from appendicitis, although affected children may not appear as ill as patients with acute appendicitis. Nausea and vomiting and a history of an antecedent upper respiratory infection are often present.

Infections such as tonsillitis or pneumonia may present with fever and abdominal pain. In addition, acute viral hepatitis could result in pain and tenderness localized to the right upper quadrant in association with anorexia. Young children with hepatitis A may be anicteric (see Chapter 127).

Pancreatitis produces abdominal pain that is often felt in the back. Historically, mumps was the most common cause of pancreatitis. Other infections, such as hepatitis B, Epstein-Barr virus, coxsackievirus B, and *Mycoplasma pneumoniae,* are the common infectious etiologies of acute pancreatitis.

Acute pancreatitis can be induced by some medications (eg, steroids, chemotherapeutic agents). Familial and recurrent forms of pancreatitis are also reported. Trauma, particularly from injuries sustained as a result of an impact against handlebars of bicycles, is a common cause. In children with pancreatitis and no apparent etiology, trauma related to child abuse should be considered.

Parasitic infestations, particularly with *Giardia intestinalis,* may produce abdominal pain, often with bloating and diarrhea.

Genitourinary problems may result in abdominal pain. An abnormal urinalysis provides clues to the etiology. Renal stones occur infrequently in children, and boys are more often affected than girls. In two-thirds of affected children, stones are detected incidentally or in association with a urinary tract infection. Stones may be composed of calcium phosphate or oxalate, magnesium, uric acid, cystine, or xanthine. In addition to flank or abdominal pain, patients may also experience hematuria, fever, recurrent urinary tract infection, and persistent pyuria.

Hematologic and vascular disorders, such as sickle cell disease, rheumatic fever, and Henoch-Schönlein purpura, may also present with abdominal pain. Sickle cell anemia should be considered in black children with abdominal pain. Pain may be related to vaso-occlusive events, including bowel ischemia and splenic infarction or cholecystitis. Henoch-Schönlein purpura, which is also referred to as anaphylactoid purpura, is characterized by a hemorrhagic skin rash, joint pain, and renal abnormalities in addition to abdominal pain. This pain may result from a number of processes, including vasculitis, inflammation and ischemia of the bowel wall, and intussusception of the small intestine.

Diabetes mellitus may precipitate to abdominal pain secondary to cramping of accessory muscles of respiration during a bout of ketoacidosis.

Acute intermittent porphyria is an uncommon cause of abdominal pain in children. The pain is often colicky and may be associated with constipation, nausea, and vomiting. Neurologic symptoms such as pain or paresthesia in the extremities may be present. Often, symptoms are precipitated by the ingestion of medications (eg, barbiturates, sulfa drugs). Some antispasmodic medications, such as Donnatal elixir, contain phenobarbital and can precipitate an attack. The diagnosis is made by evaluating the urine for the presence of protoporphyrin.

Primary peritonitis is secondary to infection with *Streptococcus pneumoniae* and is seen in children with nephrotic syndrome, cirrhosis, and sickle cell disease and in young girls with fever, abdominal pain, and vaginal discharge and no predisposing condition.

Surgical Conditions

Appendicitis is the most common surgical condition that produces abdominal pain in school-age children. Appendicitis may even occur in newborns, in whom it is seen in association with conditions that lead to diminished passage of stool, such as cystic fibrosis and Hirschsprung disease. The condition is frequently difficult to diagnose in children younger than 3 or 4 years for 2 reasons: examination of such young children for pain is difficult, and symptoms are similar to those of acute gastroenteritis (eg, fever, abdominal pain, anorexia). Classically, patients report periumbilical pain that localizes to the right lower quadrant in 1 to 5 hours. They often have a low-grade fever, with a temperature of 38°C (100.4°F). Vomiting and increased urinary frequency may occur. Stool consistency and pattern are variable (see Chapter 77).

The physical examination may reveal guarding and localized pain as well as rebound tenderness. A positive psoas or obturator sign may be present, indicating inflammation of these muscles. Tenderness may also be noted on rectal examination. Leukocytosis greater than 10,000/mL is also usually present. A radiograph of the abdomen may reveal 1 of 4 signs: a fecalith in the appendix (appendicolith), air in the cecum (sentinel loop), blurring of the shadow of the psoas muscle, or edema of the abdominal wall on the right side. A chest radiograph

is also useful to rule out the presence of pneumonia, which may produce symptoms that mimic appendicitis.

Meckel diverticulum may be responsible for abdominal pain in a number of ways. It may serve as the lead point for an intussusception, cause symptoms of ulcer disease (pain or hemorrhage) secondary to the presence of ectopic gastric mucosa, or become acutely inflamed as in appendicitis. Meckel diverticulum follows the rule of 2s: it affects 2% of the population, is 2 feet from the ileocecal valve, is 2 inches in length, and is 2 times more common in males than in females.

Adolescents

In female adolescents, gynecologic problems such as torsion of the ovary, mittelschmerz, dysmenorrhea, and pelvic inflammatory disease must be considered as causes of abdominal pain (see Chapter 61). In addition, pain may result from gall bladder disease secondary to cholelithiasis or cholecystitis. Cholelithiasis is also a consideration in adolescent patients with abdominal pain and fatty food intolerance who were previously pregnant.

Evaluation

History

A thorough history should be obtained (Box 125.2). A detailed description of pain may suggest a specific etiology. For example, pain worsened by eating can occur in children with gastroesophageal reflux disease, gastritis, cholecystitis, or pancreatitis. Nocturnal pain or pain relieved by a meal is more common in children with peptic ulcer disease. Pain relieved by defecation is suggestive of IBS. Pain aggravated by defecation raises suspicion of chronic inflammatory bowel disease. Localization of abdominal pain is an important additional diagnostic clue; FAP is usually localized along the midline or periumbilical area. Associated symptoms, such as fever, weight loss, anorexia, vomiting, diarrhea, leukocytosis, and an elevated sedimentation rate, also suggest an organic etiology.

Box 125.2. What to Ask

Abdominal Pain

- What is the nature of the pain? Is it sharp or dull, well or poorly localized, intermittent or relentless, worsened or unaffected by movement?
- How often does the pain occur?
- How long has the pain been present?
- Do any maneuvers, such as eating or lying down, reduce the symptomatology?
- Is the pain related to meals in any way? Is it worse after eating?
- Are any symptoms, such as fever, weight loss, anorexia, vomiting, diarrhea, constipation, dysuria, or headache, associated with the pain?
- Does anyone else in the family have similar symptoms?
- Does the pain occur at night and on weekends?
- Is there a history of travel?

Physical Examination

The physical examination should include an assessment of the severity of the pain. Children should be observed when they do not suspect that they are being watched. For example, a child who stands up and hops around when the physician leaves the room may have pain with a psychosomatic basis. Detection of abdominal tenderness may be ascertained during auscultation of the abdomen by pressing down with the stethoscope.

A rectal examination is also an integral part of the evaluation. In prepubescent girls with genitourinary symptoms or adolescent females, a genital assessment should be included.

Growth parameters should be evaluated for evidence of impairments, especially in children with recurrent abdominal pain. Abnormal findings such as abdominal masses or perianal skin tags are clues to an organic etiology. Children who appear vigilant and keep their eyes open during the examination often have organic problems.

Laboratory Tests

The laboratory assessment is determined by the differential diagnosis. In general, laboratory tests include a complete blood cell count, a urinalysis, and an erythrocyte sedimentation rate (in recurrent cases). In children with suspected lactose intolerance, a hydrogen breath test is recommended by some physicians, although a trial of dietary manipulation or use of exogenous lactase (eg, Lactaid, Lactase Enzyme) may be more cost-effective. Other laboratory tests, such as serum amylase or liver function studies, are appropriate if pancreatitis or hepatitis is suspected. Detection of *H pylori* antigen in the stool supports the diagnosis of *H pylori* infection. Stool evaluation for occult blood and parasites is also helpful. Consultation with a gastroenterologist should be considered in patients suspected of having peptic ulcer disease or inflammatory bowel disease. Gastroenterologists may perform diagnostic procedures (eg, endoscopy) to arrive at the diagnosis.

Imaging Studies

In general, a flat radiograph of the abdomen should be obtained, especially if an acute surgical condition is suspected. Ultrasonography or abdominal computed tomography can be useful in some children with right low quadrant pain to confirm the diagnosis of acute appendicitis. Abdominal ultrasonography and a barium enema are indicated to diagnose intussusception. Technetium scans help detect Meckel diverticulum if ectopic gastric mucosa is present. Ultrasonography is useful in suspected cases of cholelithiasis and cholecystitis. It may also detect pancreatic edema or pseudocyst, hydronephrosis, or abdominal masses. Upper GI endoscopy is very useful for patients with red flag symptoms.

Management

The management of abdominal pain in children depends on the suspected cause. Children with peptic ulcer and concomitant *H pylori* infection require triple or quadruple therapy with proton pump inhibitors and antimicrobial agents. Children with celiac disease

improve on a gluten-free diet, and those with lactose intolerance improve by avoiding lactose or ingesting lactase tablets with meals.

The management of FAP disorders in children is more challenging. The first obstacle is the lack of data related to the efficacy of pharmacological and behavioral therapy in children. The second is a very high placebo response rate in nearly all clinical trials in adults, ranging from 16% to 70% (average, 40%); there is no reason to believe this would be different in children.

Currently, the treatment of children with FAP begins with support and empathy for the family and assurance that the child is not seriously ill and will most likely outgrow the pain. With this approach, up to 75% of patients have resolution of their symptoms. However, patients with more severe illness will require a multidisciplinary approach, including education, identification and modification of physical and psychological stress factors, dietary interventions, and pharmacological and psychological therapies.

Prognosis

In general, the prognosis for children with acute abdominal pain is good, although it varies depending on the condition. In 30% to 50% of children with chronic abdominal pain, the symptoms often resolve within 2 to 6 weeks of diagnosis. Thirty percent to 50% of affected children experience abdominal pain as adults, although the pain does not limit their activities. As adults, these individuals may experience IBS or other chronic nonspecific symptoms, such as headache, backache, and chronic pelvic pain.

CASE RESOLUTION

The patient has symptoms suggestive of peptic ulcer disease. Although less common in pediatric patients than in adults, postprandial epigastric abdominal pain improved by eating, along with a family history, should raise suspicion for peptic ulcer disease, which is often associated with gastroesophageal reflux and chronic gastritis. Male teenagers are affected more frequently than female adolescents. Esophagogastroduodenoscopy is the standard diagnostic method. The patient has evidence of peptic ulcer disease on endoscopy along with *H pylori* infection. He is started on triple therapy, including proton pump inhibitor and 2 antibiotics for 10 days, followed by 2 months of acid suppression medications. On follow-up, the patient's symptoms had fully resolved.

CHAPTER 126

Jaundice

Doron D. Kahana, MD, CPNS, and Khalid M. Khan, MD

CASE STUDY

A 4-week-old boy is brought to the office for a routine weight check because he is breastfeeding. He was the product of a full-term, normal, spontaneous vaginal delivery, with a birth weight of 3,600 g (7 lb, 15 oz). He has been feeding well, exclusively at the breast, with loose stools after each feeding. On physical examination, the infant weighs 4,900 g (10 lb, 13 oz). The examination is normal except that the boy appears jaundiced. On further questioning, the mother states that her son was jaundiced shortly after birth, but she was told that the bilirubin level was all right. She thinks the jaundice may be more noticeable now. His stool is yellow and pasty, although sometimes it appears lighter in color.

Questions

1. What are the common causes of unconjugated hyperbilirubinemia in young infants?
2. What are the common causes of conjugated hyperbilirubinemia in young infants?
3. What are the usual causes of jaundice in older children and adolescents?
4. What is the appropriate management of hyperbilirubinemia in breastfed infants?
5. What diagnostic studies are done to determine the etiology of jaundice?

Jaundice occurs when bilirubin reaches a level in the blood that makes it visibly apparent. In newborns, this level is 5 mg/dL. In older children and adolescents, jaundice becomes apparent at serum bilirubin levels of 2 mg/dL. The term *physiologic jaundice* is used to denote the jaundice that normally occurs after birth. In full-term neonates, bilirubin reaches its peak of approximately 6 mg/dL between the second and fourth days after birth. Levels above 10 mg/dL likely are not physiologic. Typically, bilirubin returns to a normal level (≤1 mg/dL) by 12 days of age. Preterm newborns experience their peak level of bilirubin, which may be up to 10 to 12 mg/dL, between the fifth and seventh days after birth. Levels above 14 mg/dL are probably not physiological. Levels may be elevated in preterm neonates for up to 2 months.

Physiologic jaundice is a benign finding that affects all newborns; however, other, more serious disorders may present with jaundice in the newborn period. The physician must be able to differentiate between physiologic and pathologic causes of jaundice to ensure appropriate intervention and management. New-onset jaundice in older children and adolescents is never physiologic; the natural history is determined by the underlying disorder.

Epidemiology

Physiologic jaundice is nearly universal in neonates because of the rapid turnover of red blood cells and the relative immaturity of the liver, which give rise to unconjugated hyperbilirubinemia. The most notable disorder associated with increased levels of unconjugated bilirubin in the newborn period is hemolysis from maternal antibodies to the neonate's blood group (eg, ABO incompatibility). *Breastfeeding jaundice* results from inadequate milk intake, mild dehydration, and mild elevation in the level of conjugated bilirubin. The condition should be distinguished from pathologic cholestasis. Breast milk jaundice is different from breastfeeding jaundice and affects approximately 1% of newborns and infants fed breast milk exclusively. Factors in the breast milk as well as the immature neonatal microflora that promote recirculation of bilirubin from the gut (ie, enterohepatic circulation) give rise to unconjugated hyperbilirubinemia. Various illnesses, particularly bacterial infections, also may precipitate jaundice in newborns. *Cholestasis*, which is defined physiologically as a reduction in canalicular bile flow, manifests as conjugated hyperbilirubinemia. Neonatal cholestasis, which occurs in a small number of patients with neonatal jaundice, may be caused by neonatal hepatitis (often without a discernible cause), extrahepatic biliary atresia (BA), or genetic and metabolic diseases. Jaundice occurs much less frequently in the postneonatal period and is most often secondary to viral hepatitis (see Chapter 127).

Clinical Presentation

Children with jaundice have yellow skin, conjunctiva, and mucous membranes. In newborns, the coloration may not be appreciated by parents or caregivers because of its gradual onset and the inexperience of the parents or caregivers. The finding may be apparent in otherwise asymptomatic newborns and infants during routine health maintenance visits but may go unappreciated by the examining physician. In addition to the yellow color, the child with jaundice also may present with symptoms related to the cause of the jaundice, including vomiting, anorexia, failure to thrive, acholic (ie, pale, poorly pigmented) stools, dark urine, fatigue, and abdominal pain or fullness, and rickets (Box 126.1).

Box 126.1. Diagnosis of Jaundice in the Pediatric Patient

- Yellow skin, mucous membranes, and conjunctiva

- Hepatomegaly
- Anorexia
- Acholic stools
- Vomiting
- Pruritus

Pathophysiology

Bilirubin, a red pigment found primarily in bile, forms from the breakdown of heme-containing compounds, mainly hemoglobin, but also muscle myoglobin, cytochromes, catalases, and tryptophan 2,3-dioxygenase. Disruption along any point in the synthesis and transport of bilirubin or anatomic obstruction in the processing and excretion of bile may result in increased levels of bilirubin and the appearance of jaundice (Figure 126.1). After the breakdown of hemoglobin, unconjugated bilirubin is taken up by the hepatocyte plasma membrane carrier, bilitranslocase, and bound to intracellular proteins (Y proteins or glutathione *S*-transferase). Uptake depends on hepatic blood flow and the presence of the necessary binding proteins. Once in the liver, unconjugated bilirubin is conjugated by the enzyme glucuronosyltransferase. Conjugated bilirubin, which is water soluble, can be eliminated through the kidneys; unconjugated bilirubin is not water soluble and can be taken up in tissues and stored. After conjugation, bilirubin passes into the bile through the bile canaliculi. It then moves to the gastrointestinal tract, where some of it may be reabsorbed (ie, enterohepatic circulation) or acted on by bacteria to form urobilinogen and stercobilinogen, which may appear in the urine or stool, respectively.

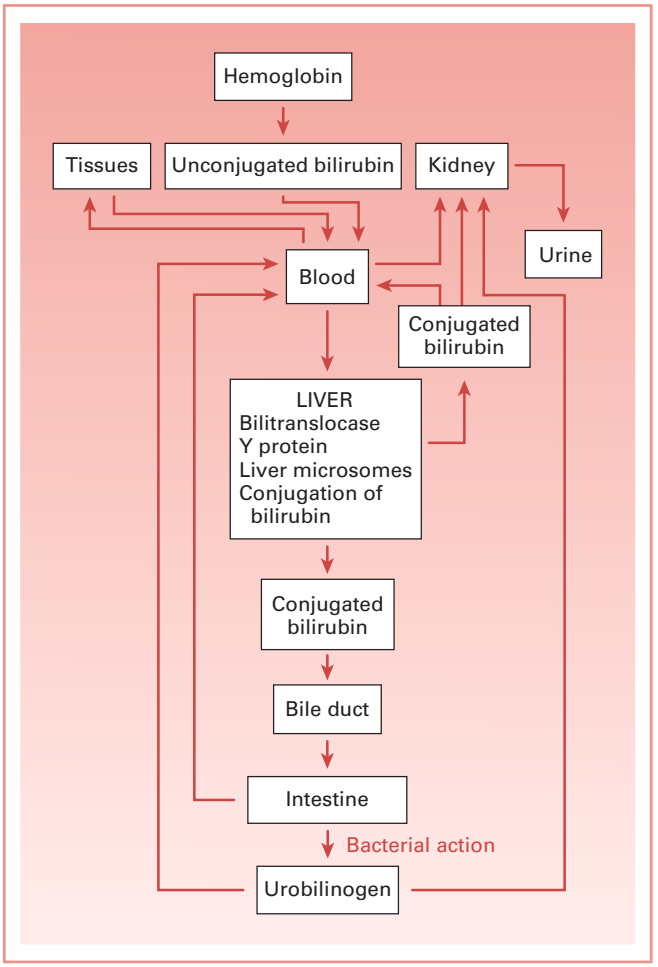

Figure 126.1. The bilirubin pathway.

In neonates, several factors contribute to physiologic jaundice. First, increased destruction of red blood cells occurs, because red blood cell survival in neonates is only 70 to 90 days, compared with 120 days in older children and adults. Second, hepatic uptake is lower, likely a result of decreased levels of hepatic proteins as well as decreased hepatic blood flow. Levels of glucuronosyltransferase do not reach adult values until the second week after birth; as a result, conjugation of bilirubin occurs at a slower rate. *Gilbert syndrome* is an autosomal recessive disorder characterized by low physiologic levels of glucuronosyltransferase; these individuals remain prone to jaundice at times of illness, stress, and starvation. Prolonged jaundice may occur in some breastfed newborns and infants and is likely related to poor caloric or fluid intake, weight loss and catabolism, slow passage of meconium, or immature intestinal microflora. Breast milk jaundice is different. It is an unconjugated hyperbilirubinemia and is thought to result from milk components such as pregnanetriol, which blocks glucuronosyltransferase. (See Chapter 29 for more information on breastfeeding.) In older children, similar mechanisms may act to cause an increase in the bilirubin level in disease states. Hemolytic anemias (eg, glucose-6-phosphate dehydrogenase [G6PD] deficiency, pyruvate kinase deficiency [PKD]) may result in increased red blood cell destruction. Inflammatory or infectious processes involving the liver, such as hepatitis, may impair the ability of the liver to excrete bilirubin. Pharmaceutical and toxicologic agents may also interfere with the ability of the liver to metabolize bilirubin.

Differential Diagnosis

The differential diagnosis of jaundice in children involves 3 criteria: age, the type of hyperbilirubinemia (conjugated or unconjugated), and, if the hyperbilirubinemia is conjugated, the nature of the obstruction (intrahepatic or extrahepatic). The latter 2 factors are particularly important in determining the etiology of jaundice in neonates and young infants. A diagrammatic representation of the differential diagnosis of jaundice in children is shown in Figures 126.2, 126.3, and 126.4.

Neonates and Infants Younger Than 8 Weeks

Unconjugated Hyperbilirubinemia

Jaundice occurs universally in all newborns; however, marked elevation of bilirubin levels (≥15 mg/dL) and the presence of jaundice in the first 24 hours after birth or beyond 2 weeks of age warrant

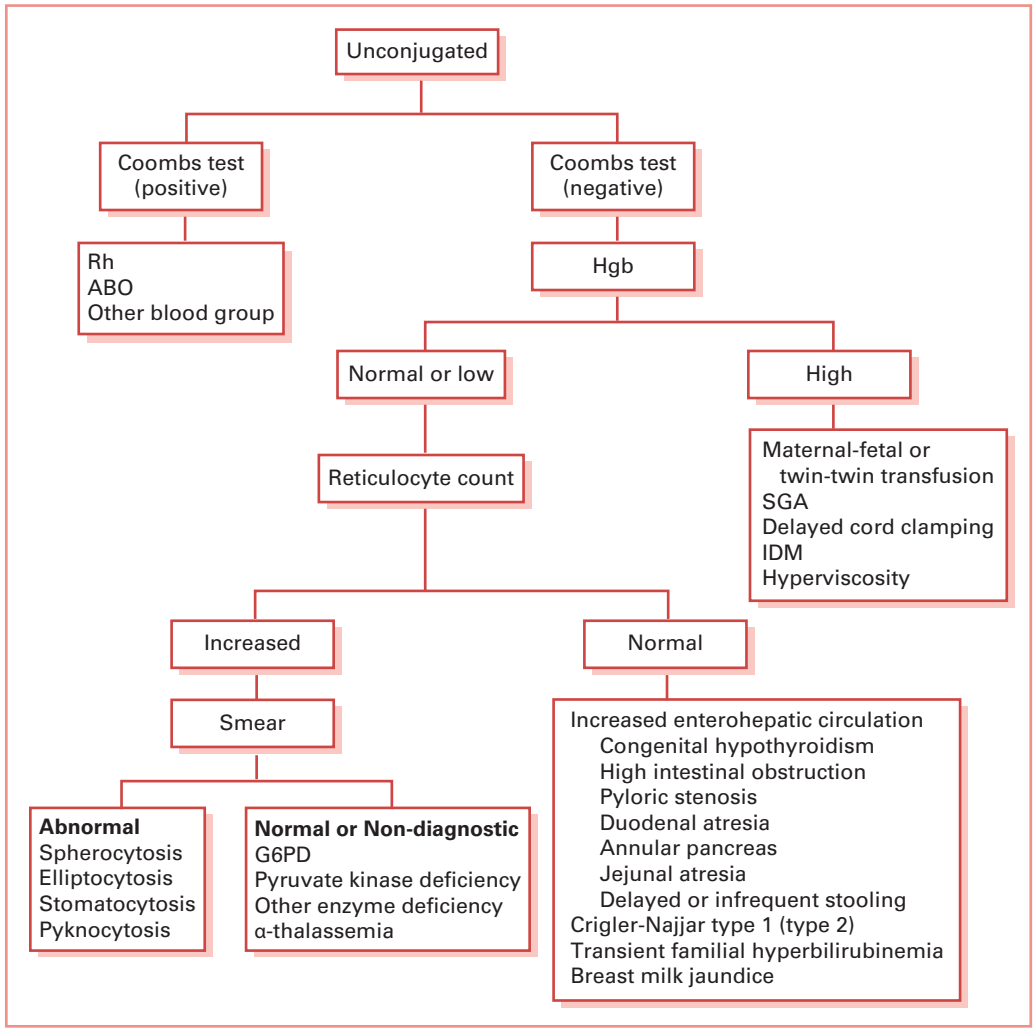

Figure 126.2. Differential diagnosis of jaundice (unconjugated hyperbilirubinemia) in neonates and infants through age 8 weeks.

assessment. When less than 15% of the total bilirubin is conjugated (direct hyperbilirubinemia), unconjugated hyperbilirubinemia is present. This is determined by measuring the levels of total and direct (ie, conjugated) bilirubin in the blood (bilirubin fractionation). Physiologic jaundice is associated with unconjugated hyperbilirubinemia and typically does not require an evaluation. The hematologic workup of affected newborns and infants is normal. *Breastfeeding jaundice* secondary to inadequate human milk intake may resemble physiologic jaundice and occurs during the first week after birth. With *breast milk jaundice,* bilirubin levels rise during the second week after birth when physiologic jaundice is improving. Breast milk jaundice usually peaks by age 4 weeks and can last up to 12 weeks. Levels may reach as high as 25 to 30 mg/dL, possibly posing a threat to the developing brain. In those cases, it may be necessary to stop breastfeeding and introduce formula or phototherapy.

Conditions associated with slow intestinal transit time and increased enterohepatic circulation, such as hypothyroidism, also may result in jaundice. High intestinal obstructions, such as pyloric stenosis, duodenal atresia, annular pancreas, and jejunal atresia, may cause jaundice, perhaps because of starvation and decreased levels of glucuronosyltransferase. Genetic and hematologic disorders should also be considered in the differential diagnosis.

Crigler-Najjar syndrome type 1 is an autosomal recessive disorder characterized by an absence of glucuronosyltransferase and, thus, severe unconjugated hyperbilirubinemia with bilirubin levels approaching 50 mg/dL soon after birth. *Crigler-Najjar syndrome type 2* is also autosomal recessive but is characterized by a reduced function of glucuronosyltransferase; bilirubin levels average 20 mg/dL and persist beyond 2 weeks in the absence of hemolysis. Because of very high bilirubin levels, type 1 disease may result in kernicterus unless managed with exchange transfusion. Phototherapy, cholestyramine resin, and eventual liver transplantation are additional therapies that may be necessary. Hematologic problems may also produce jaundice in the neonatal period. Such problems are most often associated with blood group (usually Rh or ABO) incompatibility

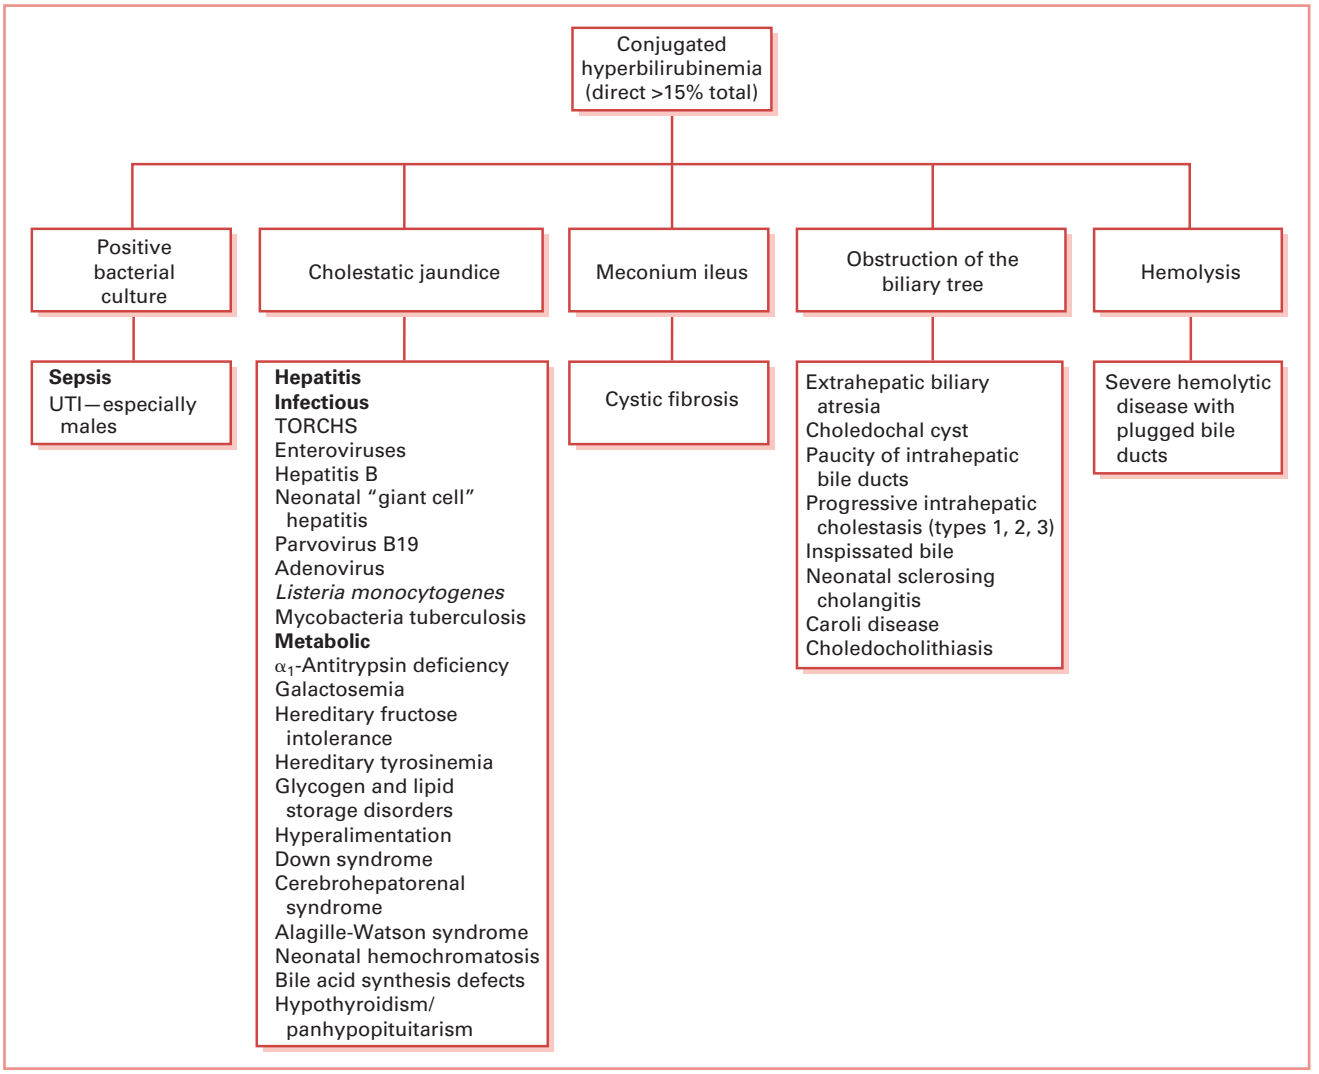

Figure 126.3. Differential diagnosis of jaundice (conjugated hyperbilirubinemia) in infants (during the first 8 weeks after birth).
Abbreviation: TORCHS, toxoplasmosis, other agents (syphilis, hepatitis B, varicellazoster virus, human immunodeficiency virus, parvovirus B19, enteroviruses, lymphocytic choriomeningitic virus), rubella, cytomegalovirus, and herpes simplex virus.

between mothers and newborns, but some minor blood group antigens can also precipitate jaundice. Jaundice occurs in affected newborns and infants because of the rapid destruction of red blood cells, which release hemoglobin that converts to bilirubin. Hemolytic anemias, such as spherocytosis, result in jaundice, as do conditions that result in polycythemia (ie, increased red blood cells in the circulation), such as maternal-neonate or twin-twin transfusions, neonates who are small for gestational age, delayed clamping of the umbilical cord, infants of diabetic mothers, and neonates with hyperviscosity syndrome.

Conjugated Hyperbilirubinemia

When more than 15% of the total bilirubin is direct, jaundice is categorized as conjugated (ie, direct) hyperbilirubinemia. This is always pathologic and warrants further investigation. Total parenteral nutrition is the most common cause of conjugated hyperbilirubinemia in the neonatal intensive care unit. It is most likely related to the lipid component of the total parenteral nutrition; however, it does not usually present a diagnostic dilemma. The institution of oral feedings helps reverse the process. In other cases, determining whether the problem is intrahepatic or extrahepatic is paramount. Intrahepatic involvement represents a spectrum of conditions from inflammation (ie, hepatitis), to inadequate formation of the bile ducts (ie, biliary hypoplasia, Alagille syndrome), to the destruction of the bile ducts (ie, BA).

Hepatitis is inflammation of the liver and usually is caused by an infection in the liver, although infection elsewhere in the body (eg, sepsis, urinary tract infection in neonates and young infants) may also cause jaundice. Urinary tract infections are usually caused by *Escherichia coli.* The hepatic involvement resolves with appropriate antibiotic therapy of the primary infection.

Primary liver infection in the neonatal period may be caused by a number of pathogens, collectively abbreviated as TORCHS (toxoplasmosis, other agents, rubella, cytomegalovirus [CMV], human herpesvirus, HIV, syphilis); the most common culprits are CMV and human herpesvirus. Neonates who are infected prenatally often have low birth weights, hepatosplenomegaly, petechial rashes, and ocular

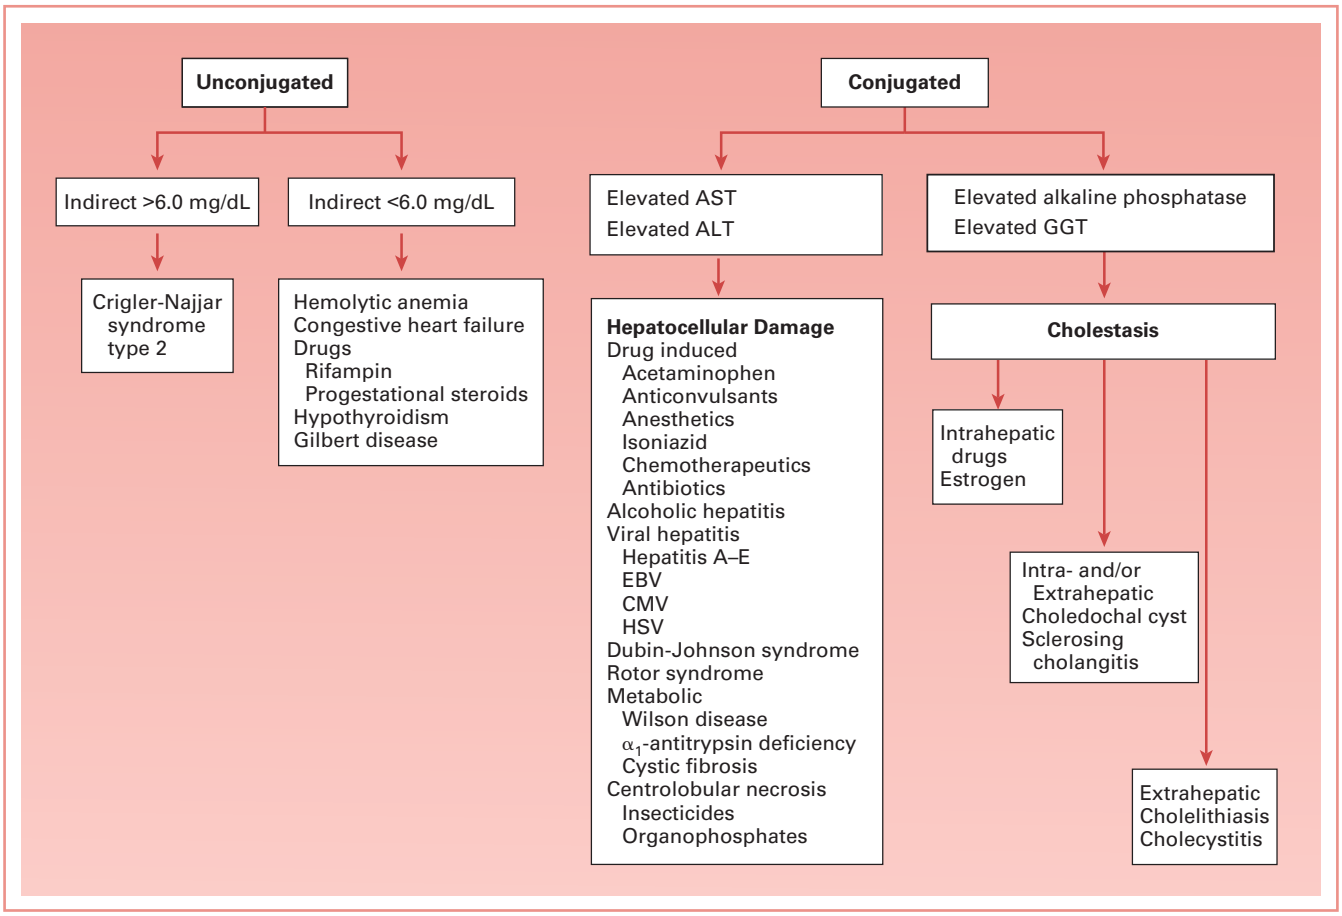

Figure 126.4. Differential diagnosis of jaundice in older infants, children, and adolescents.
Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GGT, γ-glutamyltransferase; HSV, herpes simplex virus.

findings, such as cataracts and chorioretinitis. Maternal transmission of hepatitis B is a possible etiology of neonatal cholestasis, but hepatitis C is usually asymptomatic in the neonate. Hepatitis A may cause an acute infection but rarely manifests as jaundice in neonates. Other infectious causes include enteroviruses, reovirus type 3, human parvovirus B19, human herpesvirus 6, human adenovirus 2, *Listeria monocytogenes*, and tuberculosis. Typically, these conditions are differentiated based on culture, polymerase chain reaction, or serology testing. Certain physical and epidemiologic findings may help distinguish these entities. For example, syphilis is more common in developing nations than in developed nations and jaundice may appear within the first 24 hours after birth or later on in infancy. Infection with *L monocytogenes* may be associated with the presence of focal granulomas on the posterior pharynx; similar granulomas may be evident in the liver.

Metabolic diseases and inborn errors of metabolism may also cause hepatitis. Most of these conditions are inherited in an autosomal recessive manner and are relatively rare. Newborns and infants may present with vomiting, irritability, lethargy, anorexia, hepatomegaly, hypoglycemia, failure to thrive, bleeding, or cataracts in addition to jaundice. Galactosemia may be detected through neonatal screening or may present as *E coli* sepsis. Newborns and infants with hereditary fructose intolerance present after exposure to fructose, sucrose, or sorbitol, usually past the neonatal period. Depending on the population, α_1-antitrypsin deficiency may account for 20% to 30% of cases of idiopathic neonatal liver disease and up to 10% of neonatal cholestatic disease. Inborn errors of metabolism (eg, glycogen storage disease, tyrosinemia) generally present with conjugated (direct) hyperbilirubinemia, whereas inborn errors of erythrocyte metabolism (eg, PKD or G6PD deficiency) present with unconjugated (indirect) hyperbilirubinemia.

Other genetic conditions that cause jaundice in newborns include lysosomal storage disease (eg, type 2 [infantile] Gaucher disease, Niemann-Pick disease, Wolman disease) and cystic fibrosis. The latter can cause cholestatic jaundice because of the presence of inspissated bile in the bile canaliculi. Approximately 50% of newborns and infants with cystic fibrosis have meconium ileus, meconium peritonitis, or intestinal atresia. "Plugged" bile ducts, resulting from bilirubin production overwhelming the drainage system, may occur with severe hemolytic anemia as well. Drugs may also induce intrahepatic cholestasis. Several syndromes are associated with persistent intrahepatic cholestasis. Alagille syndrome (ie, arteriohepatic dysplasia) is characterized by dysmorphic facies, skeletal and cardiovascular anomalies, and a paucity of intralobular bile ducts; the prevalence is 1 in 100,000 live births. Progressive familial intrahepatic cholestasis (which typically results from autosomal recessive defects

in bile acid transporters) and bile acid synthesis defect, together with Alagille syndrome (which is autosomal dominant), account for a total of approximately 10% of cases of neonatal cholestasis. Not surprisingly, as the etiologies for more of these cases are identified through genetic and metabolic testing, fewer cases are labeled "idiopathic neonatal hepatitis."

Extrahepatic BA accounts for approximately 25% of cases of cholestasis in newborns and is characterized by ascending obliteration of the biliary tree. Often, newborns and infants are well until 3 to 6 weeks of age, when they develop conjugated (direct) hyperbilirubinemia. The prevalence is 1 in 14,000 live births, and diagnosis must be prompt for long-term success of surgical correction. Surgery after 2 months of age is associated with liver failure and the future need for transplantation. It has been postulated that some primary insults, such as α_1-antitrypsin deficiency, metabolic disorders, or viral infections (eg, CMV, human herpesvirus), may be the inciting event resulting in BA. Choledochal cysts appear as dilatations of the biliary tree and obstruct the passage of bile. They usually present after the perinatal period with bilious emesis.

Older Infants, Children, and Adolescents

The approach to the differential diagnosis of jaundice in older infants and children is similar to that for neonates and young infants. The differential diagnosis is suggested by the total bilirubin level and the fractionated components. Unconjugated hyperbilirubinemia is usually caused by hemolysis, and the level of indirect bilirubin helps clarify the differential diagnosis. Patients with levels below 6 mg/dL may have hemolytic anemia; haptoglobin testing and a peripheral blood smear should help solidify the diagnosis. Patients with an indirect bilirubin level greater than 6 mg/dL may have Crigler-Najjar syndrome type 2; such patients respond favorably to phenobarbital. Congestive heart failure and hypothyroidism may also produce unconjugated hyperbilirubinemia to varying degrees. Gilbert disease is the most common inherited cause of unconjugated hyperbilirubinemia, with a prevalence of 5%; it is caused by reduced activity of the enzyme glucuronosyltransferase, which conjugates bilirubin. Bilirubin levels may rise to approximately 5 mg/dL in response to stress and starvation. Many different drugs, including rifampin and birth control pills, may also be associated with hyperbilirubinemia (usually indirect).

Conjugated (direct) hyperbilirubinemia may result from cholestasis and hepatocellular inflammation or injury. Cholestasis is characterized by high levels of alkaline phosphatase, mild to moderate elevation of transaminase levels, and increased levels of γ-glutamyltransferase. Intrahepatic cholestasis can occur in relation to drugs (ie, estrogens) and alcohol, as well as genetic disorders, such as progressive familial intrahepatic cholestasis (PFIC). This condition is divided into types 1, 2, and 3, depending on gene involvement. In PFIC, the capacity for liver cells to secrete bile is reduced. Extrahepatic cholestasis occurs with cholelithiasis or other obstructions of the biliary tree, such as a cyst. Cholelithiasis may occur in individuals with hemolytic anemia (black or brown pigment gallstones) and in adolescents who are overweight or postpartum (usually cholesterol gallstones). Hepatocellular injury most often results from hepatitis (see Chapter 127), including the infectious, alcoholic, nonalcoholic steatohepatitis, and drug-induced forms. Rarer disorders include Dubin-Johnson and Rotor syndromes. Metabolic diseases, such as Wilson disease, α_1-antitrypsin deficiency, and cystic fibrosis, should be considered in the differential diagnosis of every older child who presents with direct (conjugated) hyperbilirubinemia.

Evaluation

History

A careful history must be obtained, documenting the timing of the onset of jaundice, presence of fever (suggestive of infection), feeding intolerance, pale stools (suggestive of obstruction), and growth and development (Box 126.2).

Physical Examination

The patient should be evaluated for evidence of dysmorphism, organomegaly of the liver or spleen, ocular anomalies, developmental delay, abnormal heart sounds (eg, murmur), rash, hearing deficits, or lymphadenopathy. Unique facial features (eg, micrognathia, ocular anomalies) or a cardiac defect may be suggestive of a genetic disorder, such as PFIC or Alagille syndrome. Spleen enlargement is noted in hemolytic disorders and some inborn errors of metabolism, whereas isolated liver enlargement is suggestive of hepatitis. Rashes and lymphadenopathy are associated with certain infectious conditions, including congenital infections (eg, TORCHS) in newborns and infectious mononucleosis in adolescents.

Laboratory Tests

In the newborn nursery, noninvasive methods are used to measure the level of jaundice. The bilirubin meter uses reflectance spectrophotometry to determine the skin color and strongly correlates with serum bilirubin levels. Another noninvasive method is the

Box 126.2. What to Ask

Jaundice

- What associated symptoms are present?
- How long have the symptoms been present?
- Does the child have a fever?
- What is the color of the stools?
- Is there a family history of jaundice, hepatitis, or consanguinity?
- What is the child's diet? If a newborn or an infant, is the child fed mother's milk or formula?
- When did the parents or caregivers first notice the jaundice?
- Has the child been jaundiced previously?
- Has the child been vaccinated against hepatitis A and B?
- Is there a history of foreign travel or shellfish ingestion?
- Was newborn screening performed, and are the results known?

icterometer, which has an acrylic plastic color chart that is placed against the neonate's nose.

The aim of the laboratory assessment is to discover where bilirubin metabolism is abnormal. Total bilirubin as well as fractionated bilirubin levels should be determined. If the levels of direct (conjugated) bilirubin are elevated, consultation with a pediatric gastroenterologist should be considered. Demonstration of a yellow color to the foam of a shaken specimen of urine correlates with the presence of conjugated hyperbilirubinemia. Urine test strips also readily detect conjugated bilirubin in the urine.

In the child with unconjugated hyperbilirubinemia, hemolytic anemia is diagnosed based on a complete blood cell count with reticulocyte count and evaluation of the peripheral smear. Normal or low hemoglobin is typical in hemolytic anemia. An elevated reticulocyte count or an abnormal peripheral blood smear is indicative of hemolysis. Hemolytic anemias with abnormal peripheral smears include spherocytosis, elliptocytosis, stomatocytosis, and pyknocytosis (see Chapter 98). The levels of serum haptoglobin, which binds free hemoglobin, thereby decreasing its oxidative activity, are diminished in hemolytic disorders. In the neonate, a hemoglobin level should be obtained, an antiglobulin (ie, Coombs) test should be performed, and newborn and maternal blood types should be determined. In the child with conjugated hyperbilirubinemia, tests should be performed to determine if an infection such as bacteremia, urinary tract infection, congenital infection (eg, TORCHS), or hepatitis is present. Evaluation for metabolic diseases should also be obtained by assessing urine for the presence of reducing substances, organic acids, and bile acid metabolites. A sweat chloride test and assessment of α_1-antitrypsin level should be considered. The status of liver function can be determined by evaluating aspartate aminotransferase, alanine aminotransferase, γ-glutamyltransferase, and alkaline phosphatase. To assess synthetic liver function, the physician should test prothrombin time, total protein, albumin, glucose, cholesterol, and ammonia.

Imaging Studies

The anatomy of the biliary tree can be evaluated on ultrasonography, which usually is sufficiently sensitive to visualize a choledochal cyst. A "triangular cord sign" is a specific but not very sensitive sign seen on ultrasonography for the diagnosis of BA. A triangular-shaped echogenicity demonstrates the atretic ductal remnant in the area cephalad to the portal vein bifurcation. Other imaging tests, including excretion studies (eg, biliary scintigraphy by radioisotope [ie, hepatobiliary iminodiacetic acid scanning]) and cholangiography, can be used to help differentiate hepatitis from BA. Consultation with a pediatric gastroenterologist or pediatric surgeon may be appropriate.

Liver Biopsy

A histologic evaluation may be necessary if the etiology cannot be determined based on laboratory results. A detailed review by an experienced pathologist may be diagnostic and save the neonate from exploratory surgery.

Management

The management of jaundice depends on the cause of the condition. Physiologic jaundice and jaundice secondary to breastfeeding usually require no intervention. Breastfeeding jaundice is potentially preventable. The mother should be advised to initiate breastfeeding within 1 hour after birth with continuous rooming-in, continue to breastfeed every 2 to 3 hours, and promptly respond to hunger cues. Supplementation with water or sugar water should be discouraged. Neonatal urine output should be monitored. If bilirubin levels are greater than 20 mg/dL, interrupting breastfeeding for 24 to 48 hours will successfully lower bilirubin levels; however, support and counseling are mandatory to ensure that breastfeeding resumes. Studies suggest that the use of a casein hydrolysate formula (eg, Nutramigen, Alimentum) may result in a greater degree of reduction in the level of bilirubin than the use of a whey-predominant formula (eg, Enfamil, Similac). Some physicians use bilirubin-reducing lights to prevent kernicterus, but available data do not support imminent neurologic damage even when bilirubin levels climb as high as 25 to 30 mg/dL. Newer phototherapy techniques involve the use of woven fiber-optic pads that can be used in the home. Increasing the exposure of the neonate to phototherapy by using standard phototherapy above and a fiber-optic pad below is more effective than either modality alone. Clinical trials have demonstrated the efficacy of a single intramuscular dose of Sn-mesoporphyrin in managing and preventing neonatal hyperbilirubinemia. Sn-mesoporphyrin, a metalloporphyrin, blocks heme oxygenase, the first step in the production of bilirubin. Sn-mesoporphyrin may be especially helpful in situations in which blood transfusions are prohibited by parents or caregivers for religious reasons or known hemolytic disease puts the neonate at risk for kernicterus.

The preterm or ill neonate or the neonate with hemolysis may be at increased risk from elevated bilirubin levels. Exchange transfusion may be indicated in addition to phototherapy and hydration. The preterm neonate should receive exchange transfusions when the numeric value of the bilirubin measured in milligrams per deciliter reaches the newborn's weight (eg, 11 mg/dL for a newborn weighing 1,100 g [2 lb, 7 oz]). In babies with hemolysis resulting from blood group or Rh incompatibility, reducing hemolysis through the use of intravenous immunoglobulin may obviate the need for exchange transfusion.

Diet and nutrition can be integral to supporting a neonate with conjugated hyperbilirubinemia. Formulas that fortify with medium-chain triglycerides (eg, Neocate, Pregestimil, Similac Alimentum) allow for fat absorption independent of bile acids. Supplementation with fat-soluble vitamins A, D, E, and K is essential. 25-hydroxy (25-OH) vitamin D levels and prothrombin time are easy to assess and can act as a surrogate marker for the others. If galactosemia is suspected, a switch to soy formula is necessary pending results of the newborn screening.

Medications play a limited role in the management of jaundice. Phenobarbital may speed hepatic excretion of bilirubin, even in cases of hemolytic anemia. This drug is also useful in the management of jaundice caused by certain genetic conditions, such as Crigler-Najjar

syndrome. Appropriate antibiotics should be used to combat infections associated with jaundice (eg, cholangitis). For relief of pruritus, ursodeoxycholic acid (15–30 mg/kg/day), hydroxyzine, and rifampin are effective.

Infants with BA require surgery to reestablish bile flow from the liver to the intestinal tract, allowing for passage of bilirubin directly into the lumen of the small intestine (ie, portoenterostomy). Adolescents with gallbladder disease may also require surgical intervention (ie, cholecystectomy).

Prognosis

Most newborns and infants with elevated bilirubin levels have physiologic, breastfeeding, or breast milk jaundice. Prognosis is excellent in these conditions and usually does not require significant intervention. Recently, concern has arisen about a recrudescence of kernicterus, including cases in breastfed, healthy term neonates and infants. Early discharge from the nursery and late follow-up may have contributed to this debilitating complication. Physicians should pursue an appropriate assessment of hyperbilirubinemia in jaundiced newborns and infants and not simply ascribe the symptoms to breastfeeding. Other conditions may require further medical or surgical intervention. Children with metabolic abnormalities require lifelong therapies. Those with hepatic disease may succumb to their hepatic dysfunction or require a liver transplantation. Newborns and infants who undergo surgical correction of BA before 6 weeks of age have a better prognosis than those who undergo surgery after age 6 weeks. These children should be monitored for recurrent episodes of cholangitis, which promotes cirrhosis and the eventual need for liver transplantation.

Older infants, children, and adolescents who develop jaundice often have self-limited conditions that spontaneously resolve, most commonly viral syndromes that affect the liver (eg, Epstein-Barr virus, hepatitis A).

CASE RESOLUTION

Fractionation of the bilirubin revealed 7 mg/dL of conjugated and 3 mg/dL of unconjugated bilirubin; hemoglobin, peripheral blood smear, and haptoglobin were all normal, as was a neonatal genetic screen. Ultrasonography was positive for the triangular cord sign and could not detect a gallbladder. Nuclear scintigraphy showed decreased activity in the intestine, and liver biopsy showed bile duct hyperplasia and an inflammatory infiltrate. Biliary atresia was strongly suspected, and open cholangiography confirmed the condition; portoenterostomy was performed. The infant was started on fat-soluble vitamins (ie, A, D, E, K) and antibiotics for cholangitis prophylaxis.

CHAPTER 127

Viral Hepatitis

ChrisAnna M. Mink, MD, FAAP

CASE STUDY

A 15-year-old boy is brought to the office with a 1-week history of intermittent fever, vomiting, diarrhea, and diffuse abdominal pain. His mother reports the appearance of "yellow eyes and skin" on the day before the visit. Her son was previously in good health, and he has not seen a physician in several years. He is taking no medications and has no known ill contacts. He has no history of recent travel outside the United States and denies any unusual food ingestions. His mother reports that he frequently eats at a local fast-food restaurant with his soccer team, but his family does not eat there. He has 1 ear piercing and denies sexual activity, drug use, or tattoos.

The physical examination reveals a temperature of 38.6°C (101.4°F), pulse of 100 beats per minute, and blood pressure of 110/63 mm Hg. The teenager is a well-developed, well-nourished male with yellow skin and sclera. The abdomen is soft, with mild diffuse tenderness, most notably over the right upper quadrant, and normal bowel sounds. The liver edge is palpated 5 cm (2 in) below the right costal margin, and no splenomegaly is present. The rectal examination is normal, with negative fecal occult blood test results.

Questions

1. What are the most common causes of viral hepatitis in children and adolescents?
2. What is the appropriate evaluation for children and adolescents with suspected hepatitis?
3. What complications are associated with viral hepatitis?
4. What treatments are currently available for viral hepatitis, and how does treatment differ depending on the specific etiology?

Hepatitis is an inflammation of the liver that can occur as the result of an exposure to a toxin, such as a chemical or drug, or an infectious agent. In the United States, viruses are the most common cause of hepatitis in children and adolescents, including hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV). With the advent of routine immunization for pediatric age groups against HAV and HBV, the prevalence of both infections, as well as complications and long-term consequences, have dramatically decreased. All 3 of these unrelated viruses can produce an acute illness characterized by nausea, malaise, abdominal pain, and jaundice. Hepatitis B virus and HCV also can produce chronic infections, which are generally asymptomatic but are associated with an increased risk for chronic liver disease and hepatocellular carcinoma.

Other common viruses that can cause hepatitis in children in the United States are Epstein-Barr virus (EBV), cytomegalovirus (CMV), varicella-zoster virus (VZV), adenovirus, enteroviruses, and human herpesvirus; however, their contribution to the overall morbidity and mortality associated with infectious hepatitis is minimal. Hepatitis D (as coinfection with hepatitis B) and hepatitis E occur more commonly in other parts of the world.

Epidemiology

In 2017, more than 8,000 cases of viral hepatitis were passively reported from the 50 states and the District of Columbia to the Centers for Disease Control and Prevention (CDC). From 2011 to 2017, the number of HAV cases increased, primarily related to large, food-associated outbreaks and person-to-person transmission in communities of homeless individuals. In the past 10 years, the reported number of HBV cases has stayed relatively stable at approximately 3,000 annually. Over the same period, reported HCV cases increased more than 3-fold, with 3,186 new cases reported in 2017. The CDC notes under ascertainment and under-reporting and estimates that 44,300 acute hepatitis C cases occurred in 2017. The rise in HCV cases is related to an increase in injection-drug use, in part due to the opioid epidemic. There has also been an increase in case ascertainment of HCV, although most infections go undetected. Most new cases are reported in young adults, many with a history of drug use. The CDC states that the total number of acute and chronic hepatitis cases caused by these 3 viruses is probably underestimated because of under-recognition and underreporting but likely exceeds 50,000.

Since initiation of universal immunizations, the incidence of HAV and HBV infections in children and teenagers has significantly declined in the United States. For HAV, the rate of infections has declined from 12 per 100,000 in 1995 (before vaccinations) to a nadir of 0.4 per 100,000 in 2011, where it has remained, other than during outbreaks. Certain situations are associated with increased risk of HAV infection, including crowded living conditions, chronic care facilities, homelessness, military institutions, prisons, child care centers, traveling to endemic areas, outbreak exposure, use of illicit drugs, and high-risk sexual practices (eg, commercial sex workers, men who have sex with men). Poor personal hygiene and inadequate sanitation are also risk factors. In approximately 50% of

HAV cases, however, the source of infection is unknown. Hepatitis A is found worldwide, but specific locations have an increased incidence of infections, including Central and South America, Africa, the Mediterranean region, and Asia.

For HBV, groups at increased risk of infection include individuals who use illicit parenteral drugs, commercial sex workers, men who have sex with men or who have multiple sexual partners, health care workers, neonates born to infected mothers, recipients of hemodialysis, household contacts of carriers of HBV, and immigrants from HBV-endemic areas. Individuals who live in crowded environments with poor hygienic standards, such as institutions for the developmentally disabled or correctional facilities, are also at risk for HBV infection. However, no risk factors are identified in 40% of cases. Worldwide, approximately 5% of the population (ie, 350 million people) is chronically infected with HBV. Individuals with chronic hepatitis B are the primary reservoirs for infection. Areas with the highest incidence of hepatitis B include Southeast Asia, China, the Pacific Islands, most of Africa, and parts of the Middle East.

Approximately 10% to 15% of primary infections with HBV result in a chronic carrier state. The younger children are when they are infected with HBV, the more likely they are to become chronic carriers. Without preventive measures, 70% to 90% of neonates born to infected mothers become carriers, and at least 50% of children infected before the age of 5 years become carriers. Boys have a greater risk of becoming chronic carriers than girls, although the reason for this disparity is not known.

Hepatitis C virus accounts for 20% to 40% of all viral hepatitis in adults. The prevalence in the pediatric age group is estimated to be 0.1%. Individuals at high risk for HCV infection are those who use intravenous (IV) drugs, recipients of transfusions of blood or blood products (especially before 1992), recipients of organ or tissue transplants, health care workers with blood exposure, hemodialysis patients, and, infrequently, sexual or household contacts of infected persons. No identifiable source can be found in at least 35% of cases. In the pediatric population, dialysis patients, institutionalized children, and high-risk newborns (ie, maternal history of IV drug abuse, sexually transmitted infections [STIs], HIV coinfection) are more at risk.

Because hepatitis D only occurs as a coinfection with HBV, high-risk groups are the same, with the exception of health care workers and men who have sex with men. High prevalence rates occur in Eastern Europe, Central Africa, southern Italy, and the Middle East.

Hepatitis E virus (HEV) infection is endemic in low-income countries such as Mexico, Central and Southeast Asia, North Africa, China, and India. No cases of HEV infection acquired in the United States have been reported. In endemic regions, HEV is the most common cause of symptomatic hepatitis in children. Young and middle-aged adults are most commonly affected, and HEV infection is especially severe for pregnant women.

Clinical Presentation

Children with acute hepatitis generally present with symptoms suggestive of a flu-like illness, including fever, malaise, decreased appetite, nausea, and vomiting. They may also report diffuse abdominal pain. Unlike adults, in whom jaundice is a common finding, pediatric patients, particularly infants and young children, are frequently anicteric. Hepatomegaly is often found on physical examination, although not universally, and there may be varying degrees of right upper quadrant discomfort (Box 127.1). A nonspecific macular rash, papulovesicular acrodermatitis (Gianotti-Crosti syndrome), and arthralgia can also occur in the course of HBV infection.

Pathophysiology

Hepatitis A

Hepatitis A virus is a picornavirus composed of single-stranded RNA with only 1 serotype. The most common modes of transmission are through close personal contact and contaminated food and water. This generally occurs by fecal contamination and oral ingestion. Shellfish, such as raw oysters, clams, and mussels, are a frequent source of infection. Infected food handlers may also transmit the disease. With universal immunization of children, most cases now occur in adults 20 years and older.

The average incubation period for hepatitis A is 28 to 30 days (range: 15–50 days). Peak viral secretion occurs before the onset of jaundice. The virus is shed in the stool 2 to 3 weeks before the onset of jaundice and up to 1 week after its appearance. However, most young children with HAV infection are anicteric, so infections often go unnoticed during this highly contagious period (Figure 127.1). The duration of illness is usually 2 to 4 weeks. A prolonged course or relapse occurs in 10% to 20% of adult cases. A chronic carrier state for HAV does not exist, although fulminant infections can occur. Lifelong immunity is conferred after a single infection. Mortality is rare, especially in children.

Hepatitis B

Hepatitis B virus is a double-stranded DNA virus in the *Hepadnaviridae* family. The disease is usually spread by contact with infected blood or blood products, but it can also occur through close interpersonal contact. Although hepatitis B surface antigen (HBsAg) is found in numerous body secretions (eg, blood and blood products, feces, urine, tears, saliva, semen, human milk, vaginal secretions, cerebrospinal fluid, synovial fluid), only serum, semen, vaginal secretions, and saliva have been proven contagious. No fecal-oral transmission occurs. Transmission

Box 127.1. Diagnosis of Hepatitis in the Pediatric Patient

- Diffuse abdominal pain
- Nonspecific symptoms (eg, fever, malaise, anorexia, nausea, vomiting)
- Jaundice (not necessarily in all cases, especially infants and young children)
- Dark urine and light-colored stool
- Pain or tenderness over the liver area
- Hepatomegaly

is facilitated through percutaneous inoculation (eg, tattooing, IV drug use) and exposure of cuts in the skin and mucous membranes to HBV-infected fluids on objects such as razors. Sexual transmission occurs via semen, vaginal secretions, and saliva. Perinatal vertical transmission occurs in neonates whose mothers are acutely infected or chronic carriers and usually occurs from blood exposure perinatally. Postnatal infection from household exposure has been reported, although the exact mode of transmission is unclear. Hepatitis B virus can survive in the environment for longer than 7 days but can be inactivated with household disinfectants, such as bleach diluted 1:10 with water.

The average incubation period for HBV infection is 2 months (range: 1–6 months). Figure 127.2 depicts the typical course of acute hepatitis B infection, along with the course of the chronic carrier state.

Hepatitis C

Hepatitis C virus is a single-stranded RNA virus in the *Flavivirus* family; it is able to mutate rapidly, thus escaping detection by the host's immune system. Like HBV, HCV can be spread through contact with contaminated blood and blood products. Previously, children with frequent exposure to blood products had increased risk, but currently the risk of HCV infection after transfusion is less than 1 per 2 million units of blood transfused. Most acute cases reported to public health occur in individuals who use drugs who have shared needles or paraphernalia. About one-third of young adult (aged 18–30 years) individuals who engage in injection drug use in the United States have HCV infection. For children, maternal-fetal transmission is the most common route of infection, and the rate of vertical transmission is about 5% to 6%. Transmission of infection via household and sexual contact has been demonstrated but is uncommon.

The incubation period is variable, ranging from 2 weeks to 6 months, and averages 6 to 7 weeks. Most affected children are anicteric and asymptomatic. If symptomatic infection is present, it is usually mild, insidious, and indistinguishable from infections caused by HAV or HBV. Jaundice occurs in approximately 25% of patients. Fulminant hepatitis is extremely uncommon.

Hepatitis D

Acute hepatitis D infection is caused by a distinct single-stranded RNA virus that requires HBsAg for replication. The virus and a delta antigen are enclosed in an envelope of HBsAg. Transmission is similar to HBV, but vertical transmission is uncommon. Hepatitis D infection occurs as a coinfection with HBV or a superinfection in a chronic carrier of HBV. Acute disease is usually more severe and carries a higher risk of fulminant hepatitis than HBV infection alone.

Hepatitis E

Hepatitis E virus is caused by an enterically transmitted RNA virus. There are 7 genotypes in its genus, *Orthohepevirus*, and the viruses can infect humans and multiple animal species. Transmission is primarily through contaminated drinking water and fecal-oral spread, especially during rainy or monsoon seasons in endemic areas. Hepatitis E virus is the most common viral hepatitis worldwide, and sporadic infection is common in Africa and the Indian subcontinent. Nearly all HEV infections in the United States have been reported in travelers returning from endemic areas.

The incubation period ranges from 2 to 6 weeks, with most cases of acute infection being self-limited. Mortality is low in endemic populations, except in pregnant women. Mother-to-neonate transmission is common and contributes to fetal loss and perinatal mortality. Hepatitis E virus can cause chronic infection, but this usually occurs in individuals who are severely immunocompromised.

Differential Diagnosis

The differential diagnosis of hepatitis depends on the patient's demographics (eg, age), possible exposures, and immunization history. Possible infectious causes in neonates include overwhelming bacterial sepsis, VZV, and congenital infections (TORCHES [toxoplasmosis, other agents (syphilis, hepatitis B, varicellazoster virus [VZV], human immunodeficiency virus [HIV], parvovirus B19, enteroviruses, lymphocytic choriomeningitic virus), rubella, cytomegalovirus (CMV), and herpes simplex virus (HSV)]), in addition to HBV infection. Perinatal transmission of HAV is rare. Genetic disorders and anatomical abnormalities causing biliary obstruction (eg, biliary atresia) should also be considered (see Chapter 126).

In older infants and children, in addition to HAV, HBV, and HCV, other viral etiologies include EBV, CMV, enteroviruses (including coxsackieviruses), adenovirus, VZV, human herpesvirus, and, uncommonly, rubella, rubeola, and HIV. In the United States, bacterial, parasitic, and fungal causes of liver infections are uncommon. Bacterial processes include pyogenic abscesses and sepsis. Parasitic agents include *Plasmodium* species (causes of malaria), *Trypanosoma cruzi,* and amoebic abscesses, among others, and these should be considered in individuals from endemic areas and returning travelers. Acute or chronic anemias, such as sickle cell disease, can also cause hepatomegaly and jaundice. Noninfectious conditions to consider include drug-induced hepatitis (eg, prescribed medications such as isoniazid or phenytoin and illicit drugs), toxin ingestion (eg, acetaminophen, herbal remedies), and conditions such as cystic fibrosis, α_1-antitrypsin deficiency, Wilson disease, and other congenital disorders such as Caroli disease (dilatation of the intrahepatic bile ducts).

In adolescents, viral etiologies to consider are similar to those listed for children. Other infectious processes to consider in the adolescent age group include biliary tract infections, bacterial sepsis, and Fitz-Hugh–Curtis syndrome (ie, liver inflammation associated with pelvic infections, especially with *Chlamydia trachomatis* or *Neisseria gonorrhoeae*). The list of prescribed and illicit drugs that may cause liver toxicity is extensive and includes oral contraceptives, seizure medications, alcohol, inhalants, acetaminophen, and tetracycline.

Evaluation

History

A comprehensive history should be obtained in children of all ages (Box 127.2). A dietary and travel history is essential, especially when considering HAV and HEV infection.

For neonates and young infants, a complete maternal and obstetric history should be obtained and include the following questions: Does the mother have any history of IV drug use? Does the mother come from an area in which hepatitis is endemic, such as Southeast Asia? Did the mother receive prenatal care? Was hepatitis B screening performed prenatally or at delivery? Did the mother have any known STIs or sexual contacts with hepatitis B-infected individuals?

History in adolescents should also include queries about sexual activity, history or symptoms of STIs, the number of sexual partners, parenteral drug use, and tattoos.

Physical Examination

Most children with viral hepatitis are asymptomatic and generally do not present for medical evaluation. For symptomatic children, there are no clues on the examination to aid in differentiating the causes. However, a complete physical examination should be performed to help rule out other etiologies. All vital signs should be recorded, including temperature to monitor for fever. In children who are vomiting, signs of dehydration (eg, tachycardia, evidence of orthostatic hypotension, dry mucous membranes, tenting of the skin, sunken eyes, lethargy) should be noted. Growth parameters,

Box 127.2. What to Ask

Hepatitis

- Does the child have any history of fever, malaise, anorexia, or weight loss?
- Has the child experienced any vomiting or diarrhea?
- Is any abdominal pain or discomfort present? If so, in what location?
- Are yellow eyes or any changes in skin color apparent? If so, for how long?
- Is the color of the urine dark and the stool light?
- What is the child's recent travel history?
- Has the child ingested any shellfish in the previous 1 to 2 months?
- Has the child been in contact with any individuals with hepatitis or jaundice (including sexual contacts)?
- Is the child taking any medications (eg, isoniazid)?
- Does the child have a history of transfusion with blood or blood products?
- Is the adolescent sexually active, or has the adolescent had any known exposure to sexually transmitted infections (STIs)?
- Does the adolescent have a history of intravenous (IV) drug use or tattoos?
- Does the mother have a history of hepatitis, IV drug use, STIs, or multiple sexual partners?

particularly weight, should be obtained and compared with previous measurements, if available.

The skin should be examined for jaundice; evidence of pruritus (eg, excoriations), which may be associated with elevated bilirubin; or a nonspecific rash. Icterus of the sclera, tympanic membranes, and palate should also be noted. The abdomen should be palpated for tenderness and organomegaly, particularly hepatomegaly. The liver span should also be determined by percussion because it will help monitor the patient's progress. Splenomegaly, which is not typically found in hepatitis, indicates a different diagnosis, such as leukemia, or another infectious cause, such as EBV or CMV. A rectal examination should be performed to look for masses or blood in the stool, which may suggest a neoplastic etiology.

A neurologic examination is important to document any signs of encephalopathy from hyperammonemia, which occurs more commonly in chronic liver disease or fulminant hepatic failure.

Laboratory Tests

The initial laboratory tests needed are directed by the severity of illness in the child at presentation. At a minimum, these include liver function tests (LFTs), including alanine aminotransferase, aspartate aminotransferase, γ-glutamyltransferase, and total and direct bilirubin, and coagulation studies (ie, prothrombin time and partial thromboplastin time). Monitoring prothrombin time is particularly useful because of its rapid turnaround time and predictive utility; if the value is greater than 3 seconds above the upper reference range limit (international normalized ratio ≥1.5), prognosis is poor.

Serologic antibody testing for hepatitis A (HAV-immunoglobulin [Ig]M and HAV-IgG) and hepatitis B (HBsAg, anti-HBs, hepatitis B e antigen [HBeAg], anti-HBe, and hepatitis B core antibody) should also be performed. Nucleic acid amplification testing (NAAT), polymerase chain reaction, and hybridization assays to detect and quantify hepatitis B DNA in plasma and serum are also available. Diagnostic antibody patterns for HAV and HBV are shown in Figures 127.1 and 127.2. For HAV, positive HAV-IgM results are suggestive of acute infection, and positive HAV-IgG results may be seen after vaccination or prior to infection. Hepatitis B virus vaccine contains surface antigen, so only anti-HBs will be seen postvaccination. Of note, HBsAg may be detected for fewer than 3 weeks after vaccination.

Serum antibody to HCV (anti-HCV) should be sent, especially for individuals with risk factors for infection and if test results are negative for HAV and HBV. The current third-generation antibody testing has 97% sensitivity and 99% specificity, making results more reliable than previously available immunoassays. Within 3 to 6 weeks of onset of hepatitis, approximately 80% of individuals will have positive anti-HCV antibody test results. Hepatitis C virus NAAT can detect HCV RNA in serum before seroconversion. Nucleic acid amplification testing has generally replaced the immunoblot for confirmatory testing and can also be used in other situations (eg, an immunocompromised individual who may not make antibodies, in infants younger than 18 months who may have circulating maternal antibodies).

Serologic markers for hepatitis D (IgM and IgG anti-hepatitis D virus [anti-HDV]) can be sent when concurrent HBV infection is evident. Immunoglobulin M anti-HDV may be seen with acute or chronic infection. Hepatitis D virus RNA testing is available and should be performed if chronic HBV infection with superinfection with HDV is suspected.

Other serologic testing may be performed as indicated by history and physical examination, as discussed previously. A complete blood cell count and comprehensive metabolic panel may be needed in ill-appearing children, especially with signs of dehydration. A urinalysis for bilirubin should be done. In severe or complicated cases of viral hepatitis, additional testing, such as liver biopsy or ultrasonography, may be indicated. For these cases, consultations with specialists in infectious diseases and hepatology are needed.

Management

Most cases of acute HAV and HBV infections are uncomplicated, and therapy consists of supportive care. These illnesses are usually self-limited, and no specific therapy is available. Adequate nutrition and hydration are of primary importance. Therefore, the intake of sufficient calories and fluids should be ensured. A low-protein diet during the acute phase of the illness may be considered. The use of antipyretics such as acetaminophen or ibuprofen for fever usually does not pose a problem in patients with mild disease and acutely elevated LFTs. However, because it is metabolized by the liver, it is preferable to limit the use of acetaminophen. Physical activity should be limited until patients feel better and LFTs return to reference range. Children and adolescents can return to school when they are no longer jaundiced; they may also resume a typical diet at that time.

In children with more severe symptoms, IV hydration and an antiemetic may be indicated. Hospitalization is required for children who are moderately to severely dehydrated, are unable to tolerate fluids, or have evidence of fulminant liver failure. Treatment is aimed at correcting any metabolic abnormalities or electrolyte disturbances, including hypoglycemia. It may be necessary to correct coagulopathies with vitamin K, fresh frozen plasma, and cryoprecipitate. Total parenteral nutrition may be required to maintain caloric needs.

Consultation with a pediatric gastroenterologist is important for management of acute fulminant liver failure or chronic, active hepatitis in children. No specific treatments are available for fulminant acute HAV infection. However, a few treatment options are available for children with chronic infection with HBV and HCV. Treatment options for both infections include immunomodulators such as interferon-alfa, available as interferon alfa-2b and pegylated recombinant interferon alfa-2a. For HBV infection, 5 antiviral agents are available, including entecavir, lamivudine, telbivudine (nucleoside analogues), and tenofovir and adefovir (nucleotide analogues). For HCV infection, direct-acting anti-HCV medications are approved and are the standard of care for adults but not yet for children. Enrollment in a clinical trial should be considered for children with HCV infection. Information is available at www.hcvguidelines.org.

Children and adolescents with chronic HBV and HCV infection and their parents or guardians should be counseled to avoid hepatotoxic medications and alcohol. Parents or guardians should be informed of the possibility of transmission to others, and patients

should refrain from donating blood, organs, tissue, or semen. In addition, sexually active adolescents should be informed of the possible risk to sexual partners. Toothbrushes and razors should not be shared among household contacts. Most children with chronic HBV and HCV infection should not be excluded from child care centers because of their infection. Possible reasons for exclusion of children with HBV infection include biting behaviors, bleeding disorders, and generalized dermatitis. Because children with chronic HBV and HCV infection are at risk for the development of serious liver disease, they should be followed regularly by their primary care physician in conjunction with a pediatric gastroenterologist.

Prevention

All children should routinely receive immunizations for HBV (starting at birth) and HAV (starting at 12 months of age). For older children and adolescents, review of their immunization records should be performed, and catch-up doses of hepatitis A and B vaccine should be provided as needed. In the United States, 43 states and the District of Columbia require proof of hepatitis B vaccination for school enrollment.

Hepatitis A

Routine immunization for children starting at the age of 12 months has been recommended since late 2006. In 1995, target groups were given hepatitis A vaccine, which led to a more than 85% decline in disease incidence. Handwashing by food handlers, medical personnel, and child care workers is among the primary methods of preventing the spread of HAV. Contact precautions should be used for hospitalized patients for at least 1 week after onset of symptoms. Active immunization with HAV vaccine or passive immunization with immune globulin intramuscular (IGIM) is recommended as postexposure prophylaxis for all people who have had intimate exposure to infected individuals. Hepatitis A virus vaccine and IGIM may be administered at the same time in different sites. Postexposure IGIM is generally not indicated for contacts at school or work, but it is indicated for HAV-exposed infants younger than 12 months, because they are not candidates for vaccination. The dose of IGIM is 0.02 mL/kg within 48 hours of exposure but no later than 2 weeks after exposure. Immune globulin intramuscular is 80% to 90% effective in prevention of clinical HAV disease. Hepatitis A virus vaccine may be used for postexposure prophylaxis for most healthy individuals aged 1 to 40 years.

Pre-exposure prophylaxis with HAV vaccine is preferred for individuals who are eligible for vaccination. Infants younger than 12 months and individuals with contraindications are not vaccine candidates. Hepatitis A virus vaccine should be administered 2 weeks before expected exposure (eg, travel to endemic areas). Two inactivated HAV vaccines are licensed in the United States in pediatric formulation for children 12 months and older. Formulations for adults aged 19 years and older are also licensed. The vaccine efficacy is greater than 94% for preventing clinical HAV disease. Two doses of the vaccine are recommended and should be given initially and 6 to 12 months later. Combination vaccine against HAV and HBV is licensed for individuals older than 18 years. For IGIM given pre-exposure, the dose is 0.02 mL/kg if the planned stay is less than 3 months and 0.06 mL/kg every 5 months for longer stays.

In addition to routine childhood immunization, specific other groups for whom hepatitis A vaccine is recommended include travelers to endemic areas who are older than 12 months, close contacts of newly arriving international adoptees, individuals with chronic liver disease, men who have sex with men, users of injection and illicit drugs, people with clotting-factor disorders, and those at occupational risk of exposure (eg, food handlers, nonhuman primate handlers, health care workers, child care workers, HAV laboratory researchers).

Hepatitis B

Preventive strategies for hepatitis B include universal immunization of all neonates beginning at birth and catch-up immunizations for unimmunized older children and adolescents, as well as adults with increased risk of HBV. Postexposure prophylaxis with HBV vaccine is recommended to protect unimmunized individuals.

Use of hepatitis B immunoglobulin (HBIG) for postexposure prophylaxis is recommended in specific settings, including infants born to mothers who are known to be HBsAg positive or mothers with unknown status that cannot be determined within 12 hours of birth. Passive immunization with HBIG is also recommended for susceptible individuals with discreet, identifiable percutaneous, mucosal, or sexual exposure to blood or body fluids of a person known to be HBsAg positive or whose status cannot be determined. Simultaneous active immunization with HBV vaccine should also be initiated in these cases. Standard IV immunoglobulin does not contain sufficient antibodies to HBV and should not be used for prophylaxis.

Hepatitis B virus vaccine is recommended for all newborns, infants, children, and adolescents through age 18 years (see Chapter 37). The vaccines are produced using recombinant DNA technology and contain only HBsAg. In the United States, HBV vaccines are available as single component and combination formulations. They are generally well tolerated and provide long-term protection for immunocompetent recipients. Newborns should receive the first dose before discharge from the nursery, the second dose 1 to 2 months later, and the third dose at 6 to 18 months of age. Infants should not receive the third dose before 6 months of age. Dosing intervals for other individuals are similar, and for adolescents (11–15 years of age), a 2-dose regimen using hepatitis B vaccines (eg, Recombivax HB, Engerix-B) is approved by the US Food and Drug Administration. The CDC also recommends a 3-dose HBV vaccine series for adults who are at high risk of infection and those desiring protection against HBV.

Perinatal vertical transmission of HBV can be prevented by giving newborns HBIG (0.5 mL intramuscularly) within 12 hours after birth and HBV vaccine concurrently (at a different site). This practice prevents approximately 90% of chronic infections in neonates born

to mothers who are HBsAg and HBeAg positive. Postimmunization serologic screening is recommended for these infants at 9 to 12 months of age because approximately 5% of infants become carriers despite appropriate preventive vaccination. Special schedules for active and passive immunizations against HBV should be consulted for preterm neonates who weigh less than 2,000 g (4 lb, 6.5 oz) (see Chapter 37).

Hepatitis C

No vaccine exists for the prevention of HCV infection. Because IV immunoglobulin is manufactured from plasma that is HCV-antibody negative, it is not recommended for prophylaxis.

Current recommendations include screening individuals with risk factors of HCV infection (see the Pathophysiology section), including children born to women who are infected with HCV; people born between 1945 and 1965; individuals who use injection or illicit drugs; recipients of immunoglobulin between April 1993 and February 1994, blood transfusions or solid organ transplants before July 1992, or clotting factors before 1987; hemodialysis patients; patients with known exposure to HCV; patients who have HIV infection; incarcerated individuals; and individuals with clinical hepatitis found not to have hepatitis A or B.

Hepatitis D

Prevention of HBV infection through universal vaccination is the most important means of controlling HDV infection.

Hepatitis E

Availability of safe, clean drinking water is the most effective means of preventing HEV infections and their spread. No HEV vaccine is available in the United States, but a recombinant vaccine has been approved in China.

Prognosis

The prognosis for children with viral hepatitis depends on etiology, as well as the child's age and underlying health status. For HAV infection, the outcome is generally good, with an uneventful recovery for healthy children. Infants and children infected with HBV are at high risk of becoming chronic carriers, especially if infected at a young age. Approximately 25% of carriers develop chronic, active hepatitis, which often progresses to cirrhosis. In addition, the risk of developing hepatocellular carcinoma is 12 to 300 times higher in these patients compared with the general population.

Chronic hepatitis also occurs with HCV infection in 75% to 85% of adults, but it appears to occur less commonly in children. Autoimmune complications such as arthritis, serum sickness, and erythema multiforme are common with chronic disease. About 10% to 20% progress to cirrhosis and hepatic failure, and HCV infection is among the leading indications for liver transplant for adults in the United States. Hepatocellular carcinoma has also been described in a small proportion of patients.

Complications of hepatitis D, such as cirrhosis and portal hypertension, are not uncommon. They occur more frequently with HBV infection associated with HDV infection than with HBV infection alone and progress more rapidly. Infection with HEV infrequently results in chronic infection but is more likely to occur in individuals who are severely immunocompromised.

Fatal hepatitis A infection is a rare occurrence. The overall mortality associated with HBV, HCV, and HEV infections is also low (approximately 1%–2%), although HEV infection can be fatal in 20% of infected pregnant women. Mortality rate may increase to 30% for HBV infection with HDV coinfection.

CASE RESOLUTION

The teenager has a classic presentation of viral hepatitis despite no clear history of exposure, such as travel to an endemic area. Statistics point to probable infection with hepatitis A, and exposure possibly occurred at the fast-food restaurant. Because he does not appear to be dehydrated or seriously ill, he can be managed as an outpatient. Serologic testing for hepatitis A, B, and C should be performed, in addition to LFTs and coagulation tests. The parents should be informed of the probable diagnosis, and, if confirmed as hepatitis A infection, all household contacts should receive hepatitis A vaccine or prophylaxis with immunoglobulin. They should also be educated on the infectivity of the disease and counseled about supportive therapy. Public health officials should be consulted for management of other cases of individuals who were possibly exposed. The boy should have limited physical activity while symptomatic and should be scheduled for a follow-up visit in a few days for repeat LFTs and coagulation tests. The prognosis is good.

PART 12

Neuropsychiatric Disorders

CHAPTER 128

Hypotonia

Hanalise V. Huff, MD, MPH, and Kenneth R. Huff, MD

CASE STUDY

A 6-month-old girl is brought to the office because she no longer reaches for her toys. The pregnancy was full term, but the mother remembers that the fetal kicking was less than with an older brother. Delivery was uncomplicated, and the newborn fed well from birth. The girl began to show visual attention at 2 to 3 weeks, smiled socially at 1 month, and pushed up while prone at 2 months. Although she turned over at 4 months, she has not done this in the past month. She no longer reaches up to the mobile over her crib.

On physical examination, the girl lies quietly on the table and watches the examiner intently. Her growth parameters, including head circumference, are normal. After she has been undressed, it is apparent that she exhibits "see-saw" breathing (ie, abdomen rises with inspiration) and has a frog-leg posture (ie, batrachian position). The cranial nerve examination is normal except for head-turning strength. When she is pulled to a sitting position, her head lags far behind and her arms are straight at the elbows. She cannot raise her arms off the table. When a rattle is placed in her hands, she manipulates the toy, which she regards from the corner of her eye. Deep tendon reflexes are absent, but her pain sensation is intact.

Questions

1. What is meant by hypotonia?
2. How is the level of nervous system involvement determined in infants with hypotonia?
3. What is the significance of a loss of developmental milestones or abilities?
4. When are diagnostic tests appropriate for a child with hypotonia?
5. How are clinical management issues related to prognosis?

Infants with decreased tone are referred to as hypotonic or "floppy." *Hypotonia* is most simply defined as lower than normal resistance to passive motion across a joint but is also suggested by abnormal posture. Although the lack of resistance may have other components (eg, connective tissue abnormalities suggested by an unusual range of joint mobility and hyperelastic skin, features of Ehlers-Danlos syndrome, features of Down syndrome), muscle strength is a key component. Tone can be used as a surrogate indicator of strength in infants who cannot cooperate with resistance testing. Weakness can also be inferred from functional observations and the inability to sustain limbs against gravity or the lack of a withdrawal response of a limb to a painful stimulus. Identification of the affected central nervous system (CNS) level (eg, upper motor neurons, lower motor neurons, spinal cord, anterior horn cell, peripheral nerve components, myoneural junction, muscle fibers) is most important in determining the etiology of hypotonia in infants and children. Only after this localization is the likely pathology defined in most cases.

Epidemiology

Hypotonia is not unusual in neonates, and non-neuromuscular causes of hypotonia are more common than neuromuscular conditions. Non-neuromuscular causes include hypoxic-ischemic encephalopathy and brain lesions related to preterm birth, such as intraventricular hemorrhage and periventricular leukomalacia. Genetic abnormalities also are frequently present shortly after birth. Spinal muscular atrophy (SMA) is a common progressive genetic condition with a prevalence similar to that of cystic fibrosis (approximately 1 in 5,000). Duchenne muscular dystrophy (DMD), which manifests between ages 2 and 5 years, is the most common neuromuscular condition in childhood, with a prevalence of 1 in 1,700 to 1 in 3,500 male births. The *DMD* gene has been found to spontaneously mutate in approximately 50% of patients. Among non–genetically acquired disorders, the prevalence of acute postinfectious polyneuritis (ie, Guillain-Barré syndrome) is 2 to 8 per 100,000.

Clinical Presentation

Hypotonia in infants often presents with unusual posture, diminished resistance to passive movements of the limbs or trunk, or an excessive range of joint mobility. Infants with hypotonia have delayed motor milestones, decreased movements, and poor head and trunk control (Figure 128.1). Older children may have decreased ability to resist with strength testing of individual muscle groups as well as impaired functional strength in sitting, standing, walking, climbing, or running (Box 128.1). Swayback posture in standing may be indicative of hip girdle or proximal weakness. Pointed toes in the supine position may be indicative of an upper motor cause.

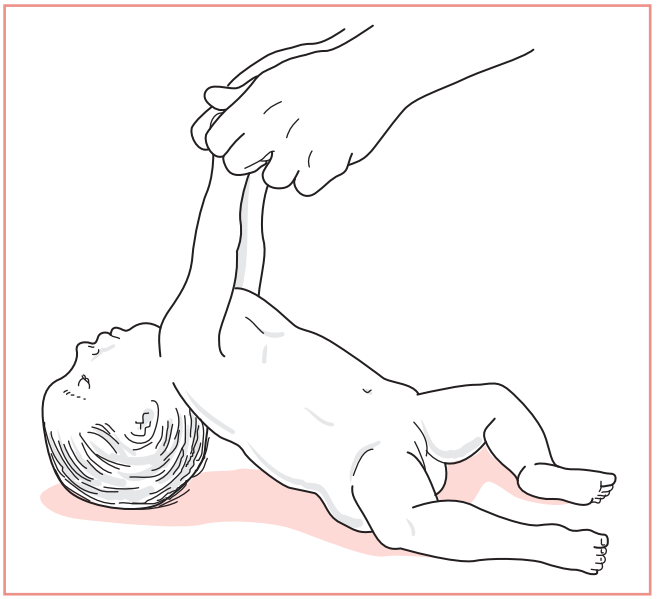

Figure 128.1. Traction maneuver. The arms are completely extended, head control is poor, and the legs are abducted at the hip.

Box 128.1. Diagnosis of Hypotonia in the Pediatric Patient

- Decreased resistance to passive movement of a joint
- Muscular weakness in older children
- Etiologic diagnosis related to the nervous system level of the lesion

Pathophysiology

Tone is a product of connective tissue structural elements, including ligaments, tendons, and joint capsules; muscle fiber number and integrity; and nerve fiber input to muscle. Nerve input to the muscle includes the number and myelination of axon fibers, trophic factors from the nerve, and frequency of action potentials depolarizing the muscle membrane. The control of tone through the anterior horn cells is complex and involves more than just the corticospinal tract (upper motor unit) but also other descending tract influences. Lesions of the neuromuscular apparatus (lower motor unit), which includes muscle, nerve, nerve sheaths, and anterior horn cells, can most directly decrease tone; however, lesions of any of the other structures at many levels of the nervous system also can affect tone. The final common pathway of upper or lower motor unit modification of tone is through the gamma loop, which is part of the fusimotor system. The fusimotor system consists of gamma motor neurons within the anterior horn of the spinal cord innervate the contractile muscle portions on each end of the intrafusal fiber and enhance the sensitivity of the sensory endings to stretch, which in turn transmit signals back to the alpha motoneurons in the anterior horn, thereby innervating the rest of the muscle. Different CNS levels (ie, motor cortex, thalamus, basal ganglia, vestibular nuclei, reticular formation, cerebellum) can modify tone through their effect on the gamma loop motor neuron.

The nature of the lesion at different levels of the nervous system may be quite variable. For example, ultrastructural abnormalities occur in congenital myopathies, including those related to respiratory chain defects; anterior horn cell apoptosis occurs in SMA and may also occur with ischemic insults; stripping of myelin by macrophages occurs with acute postinfectious polyneuritis; and muscle voltage-gated channels are involved in periodic paralyses.

Differential Diagnosis

Distinguishing clinical features in determining the level of the lesion in the nervous system includes pattern of weakness, activity of deep tendon reflexes, presence of fasciculations or sensory loss, cerebrospinal fluid findings, serum muscle enzyme levels, electromyography (EMG) pattern, nerve conduction studies, and histologic appearance or assays of the muscle or nerve biopsy. When assessing the child with hypotonia it is useful to separate first upper motor neuron or brain causes from neuromuscular causes (Table 128.1). The former includes perinatal hypoxia-ischemia, intracranial hemorrhage, and cerebral dysgenesis. These problems may present with hypotonia in infancy but later are evident as a static encephalopathy. A child with a CNS cause may have a below-normal level or range of attention and may lack age-appropriate social skills. Seizures or hemiparesis also signify a likely CNS cause. In an older child, fine motor coordination, quality and repertoire of movements, and language may be affected. The deep tendon reflexes may be brisk or easily elicited. The Babinski reflex may be dorsiflexor. In infants, fisting of the hands, scissoring of the extended legs on vertical suspension, and movement through postural reflexes, such as the asymmetric tonic neck reflex, are clues to an upper motor neuron process. In a patient with an upper motor neuron lesion, serum muscle enzymes, EMG, nerve conduction studies, and muscle biopsy are all normal. However, the child with 1 of the neuromuscular causes for hypotonia, including congenital myopathy, SMA, muscular dystrophy, and acute postinfectious polyneuritis, that does not also involve brain or facial nerves or muscles may have an interested and visually attentive facial appearance. This may be the case even in the presence of severe weakness that allows only sparse or nearly absent limb movements. With many of these neuromuscular lesions, deep tendon reflexes may be difficult to elicit or may be absent.

Older children may display a different pattern of weakness that is suggestive of the level of involvement. If the weakness is preferentially in the upper extremity extensor and lower extremity knee flexor, ankle dorsiflexor, and ankle evertor muscle groups (ie, antigravity muscles), the lesion likely involves the upper motor neuron. Static bilateral hemiparesis is suggestive of severe hypoxemic-ischemic insult, and in the child who was born preterm, diplegia is suggestive of periventricular leukomalacia. A differential weakness in opposing muscle groups resulting from CNS causes may be present and contribute to hypotonia for a long period before spasticity intervenes and increases tone. If the weakness involves agonist and antagonist muscles equally across a limb joint, however, it

Table 128.1. Exemplified Differential Diagnosis of Infantile Hypotonia by Nervous System Level

Level	*Specific Lesion*
Cerebral hemisphere	Static encephalopathy related to perinatal or prenatal insults Dysgenesis (eg, Down syndrome, Prader-Willi syndrome) Degenerative conditions (eg, storage disease)
Spinal cord	Traumatic transection Dysraphism or other malformation Epidural abscess
Anterior horn cell	Spinal muscular atrophy Enterovirus-associated myelitis Arthrogryposis multiplex congenita
Peripheral nerve	Leukodystrophy Hereditary sensorimotor neuropathy type 3 Acute polyneuritis (rarely occurs in infancy)
Myoneural junction	Myasthenia gravis (transient or congenital) Toxin (botulism or aminoglycoside antibiotics) Hypermagnesemia
Muscle	Congenital structural myopathy (ie, nemaline, central core, myotubular, multicore, congenital fiber-type disproportion) Congenital myotonic dystrophy Congenital muscular dystrophy (eg, Fukuyama type, Walker-Warburg syndrome, muscle eye brain disease, merosin-deficient myopathy) Mitochondrial myopathy (cytochrome-*c* oxidase deficiency)
Systemic	Aminoacidopathy and organic acidemia, hypercalcemia, renal tubular acidosis, rickets, celiac disease, hypothyroidism, collagen disease, congenital heart disease, glycogen storage disease (eg, Pompe disease), carnitine deficiency, peroxisomal disorders)

probably represents a neuromuscular process. It is also important to remember that hypotonia can result from disorders with combined lesions in levels above the lower motor neuron and in the motor unit. Examples include Krabbe disease, glycogen storage disease type 2 (ie, Pompe disease), congenital myotonic dystrophy, mitochondrial and peroxisomal disorders, and hypoxic-ischemic insults involving the upper motor neuron and anterior horn cell.

Evaluation

A methodical assessment using clinical and laboratory features in children to localize the lesion to a particular nervous system level can help anatomically narrow a wide differential diagnosis (Table 128.2).

History

Particular aspects of the history are especially important (Box 128.2). Strength of fetal movements relative to other pregnancies and ischemic, toxic, metabolic, or infectious fetal exposures should be ascertained. Relatively decreased fetal movements may signify an early degenerative condition. Polyhydramnios can signal prenatal weakness in swallowing. Birth events should be investigated for sources of possible insults to the neonatal nervous system, such as preterm status or birth asphyxia. The physician should determine whether any of the child's developmental skills have been lost. Any associated loss of tone or strength could signify a progressive condition rather than a static problem, such as would occur with a birth injury. The acuity of the developing

Box 128.2. What to Ask

Hypotonia

- Were the fetal movements of the child abnormal or less than those of previous pregnancies?
- Was the pregnancy full term? Was the delivery complicated?
- Does the mother, do any siblings, or do other family members suffer from a similar weakness?
- Has the child lost any developmental skills? Is the problem getting worse?

Table 128.2. Simplified Approach to Localization of the Lesion for the Diagnosis of Hypotonia

	Anatomic Site				
Clinical Feature	*Cerebrum*	*Spinal Cord*	*Anterior Horn Cell*	*Neuromuscular Junction*	*Muscle*
Alertness	Decreased	Normal	Normal	Normal	Normal
Cry	Decreased	Normal	Normal/weak	Weak	Normal/weak
Eye movements	Sometimes abnormal	Normal	Normal	Abnormal	Normal
Tongue fasciculations	Absent	Absent	Present	Absent	Absent
Muscle bulk	Normal	Normal	Decreased	Normal	Decreased
Deep tendon reflexes	Normal/increased	Decreased/increased	Absent	Normal	Normal/decreased

weakness is another important clue in the differential diagnosis. Rapid-onset hypotonia accompanied by constipation, poor feeding, and other bulbar involvement may be suggestive of botulism. Acute losses of tone and strength may also occur with enteroviral poliomyelitis, Guillain-Barré syndrome, myasthenia, and myositis. Relapsing-remitting courses of hypotonia may occur with myasthenia; metabolic myopathies, including mitochondrial disorders; and periodic paralysis in the older child. The child who has recently been hiking should be evaluated for tick paralysis. A parallel deterioration in intellectual functions or seizures may be indicative of leukodystrophy, storage disorder, or another degenerative disorder, including 1 of the several types of Leigh disease, particularly if ataxia, brain stem symptoms, and respiratory dysfunction subsequently occur.

Family history should be determined as well. The presence of weakness or hypotonia in other family members or prior unexplained neonatal or childhood deaths in the family may indicate a genetic or maternal basis for the patient's hypotonia.

Physical Examination

Dysmorphic features should be noted in children with developmental delay who exhibit hypotonia, because these features may be suggestive of cerebral dysgenesis as part of a multiple malformation syndrome or a chromosomal anomaly (eg, the characteristic stigmata of Down syndrome) or as part of a neuromuscular condition (eg, narrow face, hypoplastic mandible, high-arched palate, thin ribs with deformed rib cage, pectus excavatum). In the older child, characteristics of dermatomyositis, such as a rash on the hands and coloration of the eyelids, may be noted.

Poor feeding with small male genitalia in the neonate may be suggestive of Prader-Willi syndrome. A large tongue with decreased growth parameters may be indicative of hypothyroidism. Hepatomegaly may occur with Niemann disease and cerebrohepatorenal (ie, Zellweger) syndrome. Signs of brain dysfunction, such as lethargy, unresponsiveness to the environment, and lack of social skills, should be noted. Acute signs of sepsis along with generalized hypotonia in a neonate may be indicative of an inborn error of metabolism; these are signs of decompensation, and emergent intervention is required. Age-appropriate cognitive abilities should be assessed as a measure of cerebral function. This assessment may range from primarily observation of visual attention (eg, loss of visual following without loss of oculocephalic reflex) in the very young infant to evaluation of language and academic skills in the older child. Cranial nerve examination to assess eye movements, facial strength, and presence of tongue fasciculations is important, especially in the differential diagnosis of many neuromuscular conditions. Ocular muscle involvement may be part of mitochondrial myopathies, myotubular myopathy, and myotonic dystrophy. Blindness and hyperacusis responses may be suggestive of Tay-Sachs disease. Deafness may be part of a mitochondrial disorder. Facial muscle involvement is common in some congenital and mitochondrial myopathies and myotonic dystrophy but is not a part of SMA. Sucking and swallowing difficulty is a feature of SMA, congenital myotonic dystrophy, myotubular and nemaline myopathies, neonatal myasthenia, and Prader-Willi syndrome, in addition to birth asphyxia.

The degree of hypotonia and strength in the trunk and limbs should be examined carefully in the awake infant with the head in midline. Passive pronation, supination, flexion, extension, and gentle shaking of hands and feet may be signs of hypotonia. Additional maneuvers to assess hypotonia (Box 128.3) include the traction maneuver to assess head control (ie, neck tone; Figure 128.1), horizontal prone suspension to assess the trunk (Figure 128.2), the scarf sign and axillary suspension to assess the shoulder girdle (Figure 128.3 and Figure 128.4), and the popliteal angle to assess extremity tone (Figure 128.5). Preterm neonates normally exhibit a caudal-rostral progression of tone development, particularly flexor tone, correlated with age up to 40 weeks' term.

Individual joint movements should be observed, and agonist-antagonist strengths should be tested bilaterally to look for asymmetries and focal discrepancies. The infant may exhibit a paucity of spontaneous limb movements, and breathing may be paradoxical, with chest lowering and stomach rising as the result of primarily diaphragmatic strength. Severe respiratory compromise along with profound hypotonia may be features of neonatal spinal cord injury as well as congenital myopathies. A loss of pain sensation below the neck, as evidenced by the absence of facial grimace following a painful stimulation, is suggestive of spinal cord injury. Deep tendon reflexes and the presence of clonus should be assessed in all children and the plantar response elicited in the older child. The presence of contractures is common in congenital muscular dystrophy and congenital myotonic dystrophy. Some infants present with multiple joint contractures (ie, congenital multiple arthrogryposis) resulting from intrauterine anterior horn cell damage. The older child may have developed scoliosis from the effects of gravity on a weak spine. Important clues are the absence of deep tendon reflexes in neuropathies and SMA and the presence of percussion myotonia in myotonic dystrophy. Sensory testing is important in the patient with suspected neuropathy, including hereditary motor-sensory and sensory-autonomic neuropathies, radiculopathies, and myelopathies. The responses to be observed are latency, limb movement quality (more than stereotyped triple flexion), facial grimace and cry, and habituation. Muscle pain on palpation is suggestive of immune or

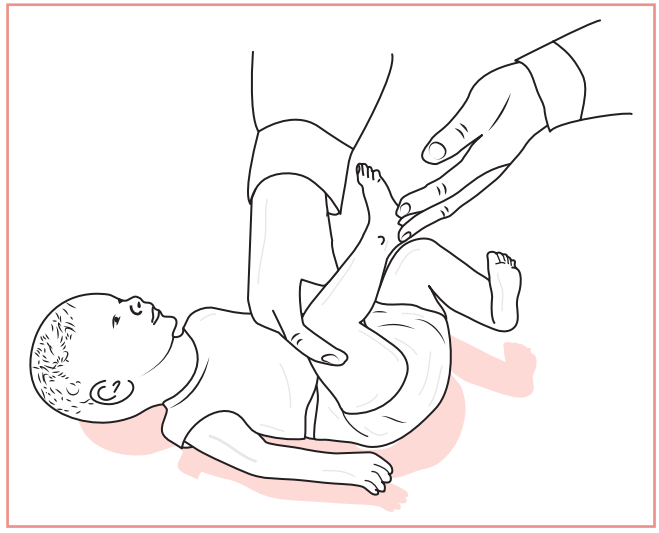

Figure 128.5. Popliteal angle. With the hip maximally flexed, the knee is gently extended maximally while resting on the infant's abdomen. In the infant with hypotonia, the angle of the knee joint is greater than 90° shortly after term birth and greater than 120° at 3 months of age.

infectious, viral, or parasitic myositis. In the neonate with hypotonia, it may also be necessary to examine the mother for the presence of signs of myotonic dystrophy or myasthenia gravis.

Observation rather than formal individual muscle testing is often easier and more revealing, particularly in infants and preschool-age children. Useful activities to observe include walking, running, climbing stairs or stepping onto a stool, lying on the floor and coming to a standing position unassisted, smiling, closing the eyes tightly, and speaking. The ambulatory child may have a waddling gait resulting from hip girdle weakness, genu recurvatum resulting from quadriceps weakness, or talipes planus resulting from foot weakness. Arising from a prone position on the floor, the child may demonstrate the Gowers sign by first getting to the hands and knees, then walking the feet forward to the hands, and finally "walking" the hands up the shins, the thighs, and the trunk to gain an upright position, rather than quickly rising from squatting without using the hands.

Laboratory Tests

Evaluation of the depressed neonate with hypotonia should include an evaluation for infection consisting of complete blood cell count and appropriate cultures as well as an assessment of pH, blood gas,

glucose, electrolytes, liver function tests, ammonia, and amino acids in the blood, and sugars, organic acids, and ketones in the urine. Spinal fluid examination is sometimes helpful in the setting of an increase in white blood cells related to possible infection or inflammation or in the setting of an increased level of protein, as in immune, storage, or necrotizing CNS conditions.

Screening blood or plasma tests can also be important for diagnosis of severe neonatal hypotonia, which can be a result of inborn errors of metabolism (Box 128.4). Serum creatine phosphokinase, a screening test for muscle fiber necrosis, should be requested when the history is suggestive of a degenerative condition or examination is indicative that the cause of hypotonia is in the neuromuscular unit. Creatine phosphokinase is 10 to 100 times higher than normal in children with muscular dystrophy, and it may also be mildly elevated in female carriers of the mutant dystrophin gene in their first 3 decades. The serum creatine phosphokinase level may be less markedly elevated in the child with an inflammatory myopathy, such as dermatomyositis and polymyositis, and to some extent after muscle trauma, unless there is rhabdomyolysis where serum creatinine phosphokinase levels are uniformly elevated.

One purpose of laboratory tests in the child with a neuromuscular condition is to confirm which nervous system level is involved (Table 128.3). Useful information about the presence of neuropathic, myopathic, and neuromuscular junction disorders can be obtained from the nerve conduction velocity and EMG. Demyelinating neuropathies slow nerve conduction or produce signs of a segmental conduction block. If the problem is a motor neuropathy, an axonal neuropathy may have depressed amplitude of the nerve action potential or fibrillation potentials on EMG. In some myopathies, small amplitude potentials and myotonia may be seen on EMG. Decremental response to stimulation and other abnormalities are evident with myasthenia gravis and neuromuscular junction blockade caused by the botulinum toxin. Serology and EMG tests can confirm diagnosis of myasthenia gravis in the child with variable weakness and easy fatigability by history and particularly eyelid or extraocular muscle fatigability on examination. Some neuromuscular conditions are associated with cardiomyopathies and, therefore, electrocardiography and echocardiography can help in diagnosis and identification of potentially critical problems that necessitate acute intervention, such as heart conduction block. Pulmonary function tests may be necessary in the setting of acute acquired myopathies and some severe congenital myopathies. Sleep studies are often helpful in the setting of chronic conditions, particularly myotonic dystrophy.

When done properly, muscle biopsy provides useful diagnostic information about neuromuscular disorders that may cause hypotonia. A large portion of the tissue should be frozen for histochemical studies. With histochemistry, neuropathic changes can be differentiated from myopathic changes related to fiber-type specificities and structural abnormalities that are indicative of dystrophy, glycogen storage disease, or congenital myopathy (eg, nemaline bodies, central cores, central nuclei) can be identified. Histochemical stains can also be informative about metabolic myopathic disorders, and immunohistochemical stains can be used to establish marker evidence for specific diagnoses. Another portion of the muscle should be fixed in glutaraldehyde for evaluation on electron microscopy to determine if ultrastructural abnormalities, such as those that occur in mitochondrial myopathies, are present. Tissue can be subjected to other specific expression analyses, such as dystrophin protein levels, glycolytic enzyme activity, cytochrome-*c* oxidase and other respiratory chain enzyme complex assays, free carnitine and acylcarnitine levels, or fatty acid transport and beta oxidation assays to confirm a diagnosis.

Metabolic and molecular genetic studies can sometimes be done on blood or urine samples, such as thyroid functions if clinical suspicion of hypothyroidism persists; white blood cell enzymatic assays; very long-chain fatty acid profiles for peroxisomal disorders, including neonatal adrenoleukodystrophy; lysosomal enzyme screening tests, such as acid maltase for glycogen storage disease type 2; plasma amino acid levels; and urine organic acid levels. Cytogenetic analysis may be useful when Down syndrome or other chromosomal aberrations are suspected, and DNA methylation analysis is done when Prader-Willi syndrome is suspected as a cause of nonparalytic

Table 128.3. Laboratory Tests Useful Early in the Diagnosis of Hypotonia Caused by Neuromuscular Lesions[a]

	Anatomic Site

- Vitamin D-dependent rickets type I
- Magnesium toxicity
- Creatine metabolism disorders
- Hyperammonemic encephalopathies

hypotonia. When examination and screening laboratory tests have narrowed the diagnostic possibilities to a level of the nervous system, molecular techniques, including use of specific nucleic acid probes, comparative genomic hybridization, copy number variance, gene panels, and exon sequencing screening tests, can sometimes be used to help make specific diagnoses for genetic disorders (eg, Duchenne or other X-linked muscular dystrophies, myotonic dystrophies, mitochondrial cytopathies, SMA). Increasingly, use of these blood tests has eliminated the need for painful EMG or muscle biopsy.

Imaging Studies

Brain magnetic resonance (MR) imaging is diagnostically helpful in at least 4 situations: when deficits in mental status, cognitive function, or attention are apparent in the child with hypotonia; when neurologic examination suggests an upper motor neuron component to the weakness or hypotonia, such as active deep tendon reflexes, persistent ankle clonus, or asymmetries in any sign that may be suggestive of a stroke or a space-occupying lesion; when a progressive congenital muscular dystrophy or a mitochondrial cytopathy, such as Leigh disease, is suggested based on myopathic and CNS signs; and when a child exhibits hypotonia as part of a multiorgan dysgenesis, such as with a chromosomal aberration, because of the high likelihood of a brain component to the dysgenesis. Brain computed tomography is rarely helpful except acutely in the setting of trauma or suspected trauma. Muscle MR imaging can be useful in selecting a muscle for biopsy in cases of suspected inflammatory myopathy. Spinal MR imaging may be necessary in the setting of focal weakness, sensory level, and back pain.

Management

Specific management is dependent on the diagnosis but ranges from supportive respiratory measures and anti-inflammatory therapies to physical and orthopedic therapy to improve function. Sometimes the potential for partial or full recovery is an important factor in determining the goals of clinical management and therapy for the child with a neuromuscular condition. An infant with a congenital myopathy may gradually increase in strength and should, therefore, receive intensive supportive care, including long-term ventilatory support and gastrostomy feeding. However, the family of an infant with a rapidly degenerative terminal condition with CNS damage, such as Walker-Warburg syndrome, the severe infantile type of pyruvate dehydrogenase deficiency, or Tay-Sachs disease, may elect not to undertake respiratory support after they understand the course of the disease and lack of curative therapy. Such families usually continue to benefit from the ongoing information provided by the physician and support of paramedical personnel and lay groups, and the affected child can benefit from palliative therapies and hospice care.

Spinal muscular atrophy is caused by mutations in the *SMN1* gene, which codes for the survival motor neuron protein. Nusinersen is an antisense oligonucleotide that modulates mRNA splicing of a closely related gene, *SMN2*, and converts it to a form that produces functional survival motor neuron protein. Another promising agent for treating spinal muscular atrophy uses an adeno-associated virus 9 viral capsid shell engineered to deliver an intracellularly functional survival motor neuron gene. This agent crosses the blood-brain barrier, so it can be administered intravenously.

Adjunctive corticosteroid therapy is useful in the child with Duchenne muscular dystrophy; however, the temporary beneficial effects must be weighed against steroid toxicity. New therapies for providing dystrophin expression are under active investigation, including "exon skipping" promoting drugs and dystrophin gene fragment-carrying viral vectors. Eteplirsen is an exon-skipping drug recently marketed for boys with a mutation in 1 of the most commonly mutated exons producing a stop codon. This drug allows production of sufficient dystrophin to arrest disease progression.

Suspected metabolic disorders can be managed with focused metabolic therapy, such as eliminating a toxic nutrient from feeding; using a high-energy alternative nutrient (ie, glucose or fatty acids); using the ketogenic diet for hypoglycemic or glucose transporter defects; frequent feedings and overnight continuous gastric formula infusions for fatty acid metabolism defects; managing hyperammonemia with benzoate, sodium phenylbutyrate, or arginine or using dialysis when the ammonia level becomes dangerously high; administering insulin to control hyperglycemia; reducing periods of catabolism during an infection; and supplementing vitamin cofactors and carnitine. Enzyme replacement therapy is available for a growing number of storage disorders. Metabolic myopathies are sometimes empirically managed with thiamine, riboflavin, nicotinamide, coenzyme Q10, biotin, L-carnitine, succinate, vitamin C or K, and medium-chain triglyceride oil. In some cases, use of these therapies may be based on tissue analysis.

The child with acquired acute hypotonic weakness may require therapy directed more at the underlying pathophysiologic process than at the weakness (Box 128.5). Acute postinfectious polyneuritis and variants necessitate careful, frequent monitoring of respiratory status and artificial ventilation when significant loss of vital capacity has occurred. Additionally, plasmapheresis or intravenous immunoglobulin should be considered, particularly for the small child whose condition rapidly worsens early in the course of the disorder. Specific antisera are used for botulinum intoxication. In the child with tick paralysis, removal of the tick from the skin results

Box 128.5. Common Neuromuscular Etiologies of Hypotonia Caused by Acute Generalized Weakness

- Acute postinfectious polyradiculoneuritis (ie, Guillain-Barré syndrome)
- Postinfectious myositis, with or without rhabdomyolysis
- Enteroviral poliomyelitis
- Acute myasthenia gravis
- Infantile botulism
- Tick paralysis
- Periodic paralysis (hyperkalemic, hypokalemic, and normokalemic)
- Metabolic myopathy

in recovery in 1 to 2 days. Dysimmune myasthenia resistant to immunosuppressive medication can be managed with anticholinesterase medication, intravenous immunoglobulin, or thymectomy. In addition to more acute disorders, chronic relapsing polyneuritis and myositis can be managed effectively with various anti-inflammatory agents, including prednisone and immunoglobulin, during periods of exacerbation.

The child with profound weakness easily succumbs to respiratory infections and has difficulty recovering from anesthesia; thus, vigilance on the part of the parent or caregiver as well as early intervention are required because the child may need intense respiratory support. Nutritional and gastrointestinal support may be necessary in the setting of a chronic condition. In some instances, the child with long-term neuromuscular weakness may benefit from orthopedic procedures for scoliosis stabilization to prevent respiratory compromise. Many conditions are genetically complex, and families benefit from genetic counseling and consultation.

Currently, treatment and care of the child with muscular dystrophy or another neuromuscular condition is focused individually on maintaining mobility and preventing contractures through physical therapy, bivalve casting, bracing, and surgical repair to improve limb function by joint stabilization or equalizing of muscle strengths across joints. Physical and occupational therapy can accelerate recovery after procedures and maximize function. Inactivity generally increases disability. Many new hardware technologies (eg, long leg brace, electric wheelchair, battery-operated ventilator, noninvasive positive-pressure ventilation for some cases of respiratory insufficiency) have allowed affected children to overcome previously insurmountable disabilities.

Prognosis

Forms of muscular dystrophy without available treatments progress over a variable number of years. Duchenne muscular dystrophy generally progresses to full-time artificial ventilation over the course of 15 to 20 years, but new gene therapies in development may eventually extend the age before full-time artificial ventilation is required. The course of many genetic conditions can be quite variable and related to different alleles at the disease gene locus or different positions of a critical base pair substitution or deletion. For example, SMA and dystrophinopathies involve genes with multiple abnormal modes of expression with widely different prognostic implications for disease course. The disease course of SMA is dependent on the number of copies of the rescue *SMN2* gene present. In DMD, the relentless disease course is produced by a stop codon mutation, whereas in Becker muscular dystrophy a different mutation allows some or partially functional protein to be manufactured. The severity of myotonic dystrophy is dependent on the length of the triple repeat mutation in the gene. Other loci may also have a modifying effect on disease gene expression or the pathophysiology of the disease.

The weakness associated with congenital myopathies, however, usually slowly improves. Acquired toxin and immune-mediated conditions, such as infant botulism and Guillain-Barré syndrome, generally have a good outcome (ie, in up to 85% of patients), although long-term supportive measures may be necessary.

CASE RESOLUTION

The infant was judged to have hypotonia caused by a neuromuscular condition, in part because of her alert appearance and absent deep tendon reflexes. Neuropathic abnormalities on EMG and muscle biopsy were also present. A blood test for the survival motor neuron genes did not detect any normal sequences, confirming the diagnosis of SMA type 1. She had both SMN1 alleles mutated and only 2 copies of the *SMN2* gene. She was begun on an oligonucleotide to support production of sufficient survival motor neuron protein. The family received genetic counseling and became involved in a support group, and the girl made slow motor developmental progress with normal intellectual function. The physician coordinated genetic and neurologic services for the family.

CHAPTER 129

Headaches

Hanalise V. Huff, MD, MPH, and Kenneth R. Huff, MD

CASE STUDY

A 12-year-old girl is brought in with a history of headaches. Although she has been sent home from school twice in the past 6 weeks, she has experienced headaches for at least 1 year. The last episode, 1 week prior to this office visit, was typical. The headache began as a dull feeling over both eyes, radiated up to the top of her head, and eventually became pounding. She had no preliminary visual symptoms or other warning signs prior to the head pain. The episode began during an afternoon class after she had been outside on a hot, sunny day for physical education. The headache worsened after she walked home from school. After she got home, she went to her room, drew the curtains, and lay down on her bed. She experienced some nausea and loss of appetite but no vomiting. She did not get up for dinner. She denied experiencing diplopia, vertigo, ataxia, and limb weakness, and her speech was observed to be articulate and coherent. She took 2 80-mg children's acetaminophen tablets without significant relief but eventually fell asleep. The following morning, she felt fine.

Between headaches, her behavior has not changed, and she has continued to make above-average grades. She has not experienced any major changes in her home environment. When initially questioned, her mother denied having migraines but did admit to needing to lie down because of headaches approximately once a month. A detailed neurologic examination of the girl is completely normal.

Questions

1. How do the symptoms and neurologic examination help differentiate headaches caused by an intracranial space-occupying lesion from headaches caused by a chronic migrainous condition?
2. How do the symptoms and neurologic examination help identify the etiology of the headache?
3. What are the characteristics of headaches caused by intracranial tumors and migraines?
4. How do lifestyle and environmental history help identify headache triggers and help in management of the headache?
5. What is the appropriate treatment plan for patients such as the one discussed in the case study?

Headaches, which are quite common in adolescents and older children particularly, frequently prompt parents or caregivers to have their child evaluated by a physician. The physician must differentiate headaches that are symptomatic of a progressive intracranial process from those that may possibly be intermittently disabling but do not necessitate surgery. The cornerstone of this determination is obtaining key historical information and determining whether abnormalities exist on examination of the nervous system. Decisions about management strategies are influenced mostly by etiology and the effect of the headaches on the child's life.

Epidemiology

The contribution of secondary headaches (ie, those related to tumors, vascular abnormalities, or meningitis) to the overall prevalence of headache is relatively small. Chronic nonprogressive headaches in children that are not related to a self-limited condition are frequently lumped together as "migraine," which includes migraine with and without aura. The prevalence of migraine that comes to the attention of a physician is approximately 3% to 10% for all children, although as many as 75% of all children and 85% of adolescents admit to having experienced a headache in the prior year. Although initial headache symptoms begin most often between ages 6 and 12 years, many patients come to medical attention initially during adolescence, especially girls, whose headache prevalence at that age is double that of boys. In adolescents, the prevalence of chronic migraine is 0.8% to 1.8%. Headaches are also commonly associated with trauma, including concussion, acute intercurrent infection, and other systemic illness.

Clinical Presentation

Parents and caregivers must interpret the nature and severity of their child's experience and symptoms, which may be difficult, especially in younger children. Younger children more rarely complain of head pain but more commonly complain of stomachache or present with nausea or vomiting. Later, as the child ages, the same episodic setting and behavior are associated with a headache complaint. The episodic syndromes of cyclic vomiting, benign paroxysmal vertigo, benign paroxysmal torticollis, and abdominal migraine are related presentations of childhood migraine. Adolescents, however, may report persistent, dull, aching, or pounding head pain, which can recur daily. As opposed to headaches that increase in intensity or frequency and are associated with neurologic signs, which may be suggestive

of an intracranial mass lesion, migraine episodes may be relatively stable in frequency over many weeks or months, accompanied by a normal neurologic and ophthalmologic examination, and similar to that experienced by other family members (Box 129.1). A multigenerational family history of "sick headaches" is a frequent finding in the child with migraine. This history must be specifically elicited by the physician, however, because its significance is often discounted by parents. Migraine with aura, which is relatively unusual in children, is distinguished by the presence of reversible specific sensory symptoms (usually visual) that precede the headache. The headaches may be associated with a prodrome of lethargy, irritability, slowness of movement and response, concentration problems, intolerance of intense sound or light, loss of appetite, and typically at least 1 facial autonomic manifestation (eg, conjunctival injection, sweating, periorbital swelling, ptosis, miosis). Migraine has a tremendous capacity to negatively affect a child's schooling, both in attendance and performance while present.

Pathophysiology

Pain fibers are carried in the trigeminal nerves from the scalp, skull, meninges, and vessel walls within the brain. These fibers experience traction or inflammation at their endings, thereby producing the pain that is associated with mass lesions or meningeal inflammation as well as mediating the pain from an internal (brain) pain generator or perhaps an external painfully tense scalp muscle (through a more circuitous route). The "migraine generator" likely resides in the brain stem and has input to the trigeminal nucleus, which both innervates intracranial blood vessels and receives nerve signals from them. "Cortical spreading depression of Leão," the neuronal and glial depolarization wave that may be the electrophysiologic correlate of the migraine aura, also activates trigeminal afferents. One likely pathogenically deficient neurotransmitter at the vascular nerve endings, serotonin, allows a cascade of release of local cytokines, substance P, calcitonin gene-related peptide, and histamine in and around the vessel walls. These substances in turn cause changes in vascular permeability, local extravascular space swelling, and painful inflammation.

The usual distinction between migraine and tension headache pathophysiology is more difficult to make in the child than the adult (and perhaps is less important from a management perspective) and may involve the types of factors that trigger headaches at different ages (Box 129.2). Several different mechanisms result in the triggering of pain nerves involving environmental or internal factors in genetically predisposed individuals. For example, bright sunlight, environmental stress, or a drop in menstrual hormones likely trigger migraines by different mechanisms within the brain. The rare condition of familial hemiplegic migraine has been related to mutations in 3 different genes thus far, illustrating a quite specific predisposition. Most pediatric patients have in their pedigree other individuals who have experienced migraine at some point in their life; however, the relative roles of genetic susceptibility and environmental trigger agents are subjects of much ongoing investigation.

Differential Diagnosis

Acute Headaches

Emergent causes should be considered if headaches have an abrupt onset, rapidly worsen, or are especially severe or if the child describes the headache as a "thunderclap" or "the worst of my life." Intracranial hemorrhage from a ruptured aneurysm or an arteriovenous malformation or, rarely, as a secondary effect of extreme hypertension, is foremost on the list of such causes. If a child has a condition that may potentially result in stroke, such as coagulopathy, hemoglobinopathy, or heart disease, the stroke may become hemorrhagic and produce such an acute, severe headache resulting from sudden traction of pain fibers from space-occupying extravascular blood.

Nonhemorrhagic meningeal irritation, such as the inflammation produced by bacterial or viral meningitis, may also cause acute headache. These conditions may render the patient confused and lethargic while still conscious and often are associated with fever. Both types of meningeal irritation produce nuchal rigidity and Kernig and Brudzinski signs. Less serious viral illnesses outside the nervous system also can produce headache acutely but show other reassuring signs, such as rhinitis, and lack meningeal signs or altered mental status.

Chronic Progressive Headaches

The child with brain tumor or brain abscess or with a gradual block in cerebrospinal fluid (CSF) flow producing hydrocephalus

Box 129.1. Diagnosis of Headaches (Migraine) in the Pediatric Patient

- Head pain of ≥2 hours' duration, often pounding in character, mostly bilateral, over the eyes, at the vertex, or in the temporal region
- Pain frequently accompanied by nausea, anorexia, photophobia, or phonophobia, and aversion to movement
- Pain sometimes preceded or accompanied by visual symptoms, such as scotomas or other sensory or dysphasic auras that fully reverse
- Frequent presence of trigger factors
- Positive family history of headaches

Box 129.2. Triggers of Migraine

- Glare, dazzle, bright sunlight, or fluorescent lighting
- Physical exertion, fatigue, lack of exercise, lack of adequate sleep, hunger or skipping meals
- Change in ambient temperature or humidity
- Allergic reactions involving sinuses, pungent odors
- Certain foods, alcoholic beverages, and cold foods or beverages
- Anxiety, stress, and worry
- Head trauma
- Menstruation and oral contraceptives
- Refractive errors if they produce squinting (unusual)

frequently has a "crescendo" history, usually of less than 6 months' duration, of increasing severity or frequency of headaches. The headache pain may be consistently localized, or it may awaken the patient from sleep, presumably related to relative shift in intracranial traction forces resulting from gravity and the horizontal position. Of note, many children with brain tumors do not complain of a localized headache and may present with persistent vomiting without headache as a prominent symptom. Between headaches children often experience new coordination problems, lethargy, loss of attained skills, personality change, or deterioration of schoolwork. Idiopathic intracranial hypertension (IIH), like intracranial venous sinus obstruction, presents with headaches of recent onset and associated papilledema. Hypervitaminosis A, steroid withdrawal, tetracycline treatment, and obesity have all been related etiologically to IIH, which most commonly occurs in adolescent females.

Chronic Recurrent Headaches

The pain of migraine headaches, the most common chronic headache type, is throbbing in character, and if headaches are severe, patients avoid intense sensory stimuli or even routine physical activity. Episodes may last 2 hours to 3 days but often resolve with sleep. Nausea or dizziness, anorexia, and visual blurring are often associated with migraine headache. The pain may be severe enough to curtail activities, or the child may participate under duress, particularly at school. Migraine with aura is preceded by 10 to 20 minutes of a sensory phenomenon, usually dark spots or visual patterns. The aura may be confused with a transient ischemic attack; however, aura proceeds more slowly and may exhibit positive sensations, such as scintillations or paresthesias.

Sinus infection may be confused with chronically recurring or acute headaches, especially if the pain is facial as well as cranial. Symptoms of chronic nasal congestion may be present with migraine, but allergies and postnasal drip may be associated with sinus headaches. In many cases the infection is a trigger for a migraine headache and the patient has primary migraine, not pain originating from the sinusitis as may have been previously assumed. Children with asthma also have recurring headaches that possibly are triggered by sinus involvement, generalized cytokine release, or other aspects of asthmatic pathophysiology, such as smooth muscle reactivity and susceptibility to medication side effects.

Other types of headache may recur without progression. In some cases, *chronic daily headaches* (ie, >15 headache days per month) may be "transformed migraine" or "rebound headache" resulting from abortive medication overuse. Adolescents may have frequently recurring headaches triggered by irregular lifestyles, such as not exercising enough, eating regularly, or getting adequate sleep, if they are susceptible individuals. In many individuals, symptomatology is more consistent with *tension-type headaches*, which are characterized by a feeling of a tightening band around the head rather than a throbbing pain, an occurrence late in the day, and an association with anxiety, depression, or a stressful environment. These "featureless" headaches are not worsened by routine physical activity or accompanied by nausea, vomiting, photophobia, or phonophobia. Overlap exists in this group with migraine headache symptoms and response to therapy. Posttraumatic headaches may be a significant problem as part of a concussion but should recur with gradually decreasing severity over several days to months.

Cluster headaches are quite different from the other types discussed. They are shorter (ie, ½–3 hours' duration); are associated with unilateral lancinating pain, tearing, nasal stuffiness, Horner syndrome, and nighttime pacing; and are unusual in children, almost never occurring in persons younger than 10 years.

Evaluation

History

Information should be obtained from patients, parents or guardians, and other caregivers concerning when headaches first began; the quality, intensity, and location of headaches; and other associated symptoms before and during headaches (Box 129.3). Duration, clinical course, and conditions that evoke, intensify, or alleviate the pain are also important. It is useful to have the child describe a typical episode—perhaps the most recent—including the circumstances

Box 129.3. What to Ask

Headaches

- Where is the child, what time of day is it, and what is the child doing when a typical headache begins or the last recalled headache began?
- Where is the pain located? How severe is the pain? How long does the pain last?
- Is nausea, vomiting, phonophobia, or photophobia associated with the headache?
- What does the child do after getting the headache? Does the episode require cessation of activities?
- Does the child take any medication for the pain? If so, was it successful? What else, if anything, allows the child to feel better?
- How long ago did the first headache occur? Are headaches becoming more frequent or severe?
- Does the child experience motion sickness?
- Have headaches ever awakened the child at night?
- Does the child have other chronic conditions? Does the child take medications or vitamins?
- Have there been any changes in weight, speech, vision, gait, school performance, or personality or any loss of skills or abilities between headaches? Do all the accompanying symptoms of the headache resolve after each headache episode?
- Does the child have any warning symptoms before the pain? Does unilateral visual loss, weakness or numbness, diplopia, confusion, or loss of consciousness occur with the headache?
- How often does the child miss school because of a headache?
- Are there stressful circumstances or major life changes? Has there been depression or anxiety?
- Do other members of the family have headaches? Do they ever need to lie down or take medicine for these headaches?

of when and where the headache began and how it affected activities at the time. The circumstances of the headache can help determine individual triggers, and the degree to which the headache problem affects the child's lifestyle strongly influences the management plan for chronic recurrent headaches.

Physical Examination

Blood pressure should be noted, even though primary hypertension is an unusual cause of headaches in children. Growth abnormalities and neurocutaneous findings or signs of trauma may be relevant. A thorough neurologic examination is needed to determine if findings suggest an emergent problem, such as meningitis, or a potential neurosurgical condition, such as intracranial hemorrhage or brain tumor. Examination should assess for the presence of sinus, teeth, or temporomandibular joint tenderness; nuchal rigidity; funduscopic abnormalities (eg, papilledema, hemorrhage); signs of trauma; and any focal neurologic signs. Ataxia and cranial nerve signs for a posterior fossa lesion may be indicative of a brain tumor or other space-occupying lesion; loss of visual fields or hypothalamic dysfunction (ie, endocrine abnormalities) may be indicative of a suprasellar or third ventricular region lesion; and hemiparesis, hemisensory deficit, or language dysfunction may be indicative of a cerebral hemispheric lesion. The physician should pay particular attention to personality changes or developmental regression. Increased intracranial pressure (ICP) may lead to papilledema, loss of upward gaze, general hypertonicity, leg weakness, positive Babinski sign, spastic gait, loss of continence, or confusion or stupor resulting from either blockage of CSF by the tumor or by blocking of blood drainage from intracranial sinus occlusion or by IIH. Because the presence of papilledema is so informative, all children with headaches should undergo a fundus examination.

Rarely, during a migraine headache a child may exhibit confusion, aphasia, unilateral numbness, or, less commonly, weakness, hemianopsia, or perceptual distortion (ie, "Alice in Wonderland" syndrome). In these circumstances, diagnosis of complications of a migraine or a migraine syndrome is reached only after diagnostic tests have eliminated other acute encephalopathies.

Laboratory Tests

If stiff neck and fever are present and focal or lateralized neurologic signs are absent, an immediate CSF examination is indicated to diagnose the cause of meningeal inflammation, particularly in the child with immunodeficiency. When hemorrhagic fluid is encountered, it is often useful to centrifuge a specimen to check for xanthochromia and to count cells in a subsequent sample to differentiate a traumatic spinal tap from subarachnoid hemorrhage. If papilledema is present and imaging studies are normal, a lumbar puncture should be done to measure CSF pressure.

A sleep study may be indicated if the child has a history of obstructive snoring or recurrent sleep disruption.

Imaging Studies

Recent trauma; persistent vomiting; depressed alertness; crescendo or change in pattern; or chronic conditions, such as sickle cell disease, coagulopathies, neoplasms, neurocutaneous syndromes, cyanotic heart disease; and even recent onset of headaches, all may be indications for an immediate head magnetic resonance (MR) imaging (preferable) or computed tomography (CT). The risk of missing an anatomic diagnosis should be weighed against the risk of anesthesia for the study and perhaps false reassurance from an inadequate study. Such decisions are also influenced by the reliability and ease of communication with the child's caregivers. The yield of imaging is low in the absence of neurologic signs. If signs or symptoms of increased ICP are apparent, CT or MR imaging must be obtained to help diagnose the etiology of the headaches. New focal or general neurologic signs or signs of meningeal irritation or encephalitis also indicate the need for CT or MR imaging. Computed tomography angiography or invasive cerebral angiography may be necessary in rare instances to locate a focal source of subarachnoid hemorrhage, and MR venography may help diagnose dural sinus thrombosis. Head imaging studies are also helpful with the diagnosis of chronic or recurrent sinus headaches and Chiari type 1 malformation.

Management

The presence of progressive symptoms, abnormal neurologic signs, or a hemorrhage or space-occupying lesion on an imaging study usually necessitates a neurologic or neurosurgical consultation. It may be necessary to urgently initiate measures for managing increased ICP. In the absence of a mass, increased ICP related to IIH also requires treatment. A serious sequela of IIH is eventual loss of vision if pressure is not relieved. This complication can be monitored with visual field testing and optical coherence tomography. Therapies include CSF withdrawal as a temporizing measure, diuretics (eg, acetazolamide), a weight loss program if obesity is present, and potentially surgical CSF diversion.

If a careful assessment has revealed no acute or progressive conditions, pain is not severe, frequency is low, duration is short, and effect on lifestyle or daily activities is minimal, reassurance is often the appropriate management. Frequently, parental or caregiver anxiety about a potential mass or hemorrhage far outweighs the morbidity produced by the headache symptom itself. Sometimes placing the child's headache problem in context with the parent's/guardian's or other family member's headaches will help with reassurance, and sometimes in milder cases, nonpharmacologic or nonprescription medication strategies can be agreed on as a management plan. Education and sometimes a headache diary or log helps patients and their families take control and own their own problem (ie, discern triggers and track intervention efficacy), particularly when they can correlate headaches with inadequate exercise, skipping meals, inadequate hydration, and inadequate sleep.

It may be apparent, however, that the headaches have produced significant discomfort or disruption of activities or lifestyle for the child and that more than reassurance is needed (Table 129.1). Nevertheless, with any intervention the physician always should weigh side effects against effectiveness of treatment and the possibility of medication overuse headache if the abortive treatment is taken more frequently than twice per week. A goal is a reduction in

Table 129.1. Drugs Useful in Managing Childhood Headaches

Drug Type	*Drug*	*Dosing*
Abortive (symptomatic)	Acetaminophen, PO	325–650 mg every 4 hours (15 mg/kg/dose); alternatively, if ≥12 years, 1,000 mg of long-acting every 6 hours Maximum: 5 doses regular/24 hours or 3,000 mg long-acting/24 hours
	Acetaminophen + acetylsalicylic acid + caffeine	1 dose every 4 hours if ≥12 years of age
	Ibuprofen, PO	200–800 mg every 6 hours (10 mg/kg/dose) Maximum: 40 mg/kg/24 hours
	Naproxen, PO	5–7 mg/kg/dose every 8–12 hours Maximum: 15 mg/kg/24 hours
	Sumatriptan succinate[a] PO, IN, or SC	25–100 mg PO[b] (25 mg PO for children age 6–10 years; may repeat after 2 hours); or 5–20 mg IN (may repeat after 2 hours); or 6 mg SC (may repeat after 1 hour) Maximum: 2 doses/24 hours
	Rizatriptan benzoate, PO	5–10 mg orally disintegrating or regular tablets; may repeat after 2 hours Maximum: 3 doses/24 hours
	Isometheptene mucate with dichloralphenazone and acetaminophen, PO	1–2 capsules at onset; may repeat every 1 hour up to a maximum of 3–5 capsules/day
Status migrainous	Prochlorperazine, IV	5–10 mg single dose (for children age 12 and older) 0.1–0.15 mg/kg/dose (for children less than 12 years)
	Dihydroergotamine mesylate, IV	Age 8 years or younger or weight <25 kg (<55 lb): Test dose of 0.25 mg. After waiting 30 minutes, administer 0.5 mg. Every 8 hours after that, infuse 0.5 mg over 3 minutes. Age 9 years or older or weight ≥25 kg (≥55 lb): Test dose of 0.5 mg. After waiting 30 minutes, administer 1.0 mg. Every 8 hours after that, infuse 1.0 mg over 3 minutes. (Give metoclopramide hydrochloride with initial dose.)
	Dexamethasone, IV	4–16 mg single dose (0.25 mg/kg) or rapidly tapering every 6 hours
Prophylactic	Propranolol	Weight ≤35 kg (≤77 lb): 10–40 mg 2–4 times/day Maximum: 40–80 mg/24 hours
		Weight >35 kg (>77 lb): 120–160 mg/24 hours Maximum: 320 mg/24 hours
	Cyproheptadine hydrochloride	1–4 mg 2–4 times/day (0.25–0.5 mg/kg/24 hours) Maximum: 16 mg/24 hours
	Amitriptyline hydrochloride	5 mg at bedtime for children age 6–12 years; 10 mg at bedtime for children older than 12 years. The dose may be increased by 5–10 mg every 2–3 weeks up to a maximum of 75 mg at bedtime until headaches improve or the child experiences persistent daytime sleepiness.
	Verapamil hydrochloride	Age 1–5 years: 40 mg every 8 hours Age ≥6 years: 40–80 mg every 8 hours
	Divalproex sodium (ie, valproic acid)	10–15 mg/kg/day initial dose, followed by 20–30 mg/kg/day maintenance dose, divided twice/day or administered once every day if extended release Maximum: 60 mg/kg/day (follow clinical signs of toxicity and serum level) Avoid use if pregnancy may occur
	Topiramate	50–200 mg/day divided twice/day after increasing from 25 mg once/day every 2 weeks
	Levetiracetam	20 mg/kg divided 2 times/day; may increase to 60 mg/kg/day
	Gabapentin	4 mg/kg/day divided twice/day, increasing to 8 mg/kg/day after 1 week Maximum: 20 mg/kg/day
	Vitamin B_2 (ie, riboflavin)	25–400 mg/day
	Melatonin	3 mg at bedtime

Abbreviations: IN, intranasally; IV, intravenously; PO, orally; SC, subcutaneously.

[a] Not approved for children less than 6 years.

[b] Only approved route in children 6-10 years.

headache frequency, severity, duration, or disability with improved quality of life. Typically, the initial trial should consist of acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs), unless prior use of these medications has been unsuccessful. Abortive treatment should be initiated as soon as possible after the onset of prodromal or headache symptoms. Many children who are allowed medication at school and may lie down for 30 minutes can finish the school day. Naproxen is beneficial, particularly in the child with head or neck muscle or scalp tenderness. Naproxen can be used prophylactically for premenstrual migraine, and indomethacin may be used in the management of unilateral continuous pain with autonomic symptoms (ie, hemicrania continua). Headache in adolescents is sometimes helped by isometheptene mucate. For severe, recurrent headaches, 5-hydroxytryptamine, serotonin$_{1B/1D}$ receptor agonists (ie, triptans) are useful. Sumatriptan succinate and other triptans, which decrease calcitonin gene-related peptide levels, sometimes have relatively tolerable but occasionally anxiety-provoking immediate side effects, including tingling and chest pressure, and patients must be informed of these side effects. The combination of acetaminophen, acetylsalicylic acid, and caffeine compared favorably with sumatriptan succinate in a clinical trial of adolescents. Sumatriptan succinate in combination with naproxen may have increased efficacy compared with either sumatriptan succinate or naproxen alone. Dihydroergotamine mesylate, zolmitriptan, or sumatriptan succinate given intranasally along with promethazine hydrochloride given rectally are also effective abortive treatments in vomiting patients and work faster than tablets; however, the nasal drugs may have a disagreeable taste should they enter the posterior oropharynx. Particularly severe refractory headaches may respond to intravenous (IV) diphenhydramine, ketorolac tromethamine, or prochlorperazine or IV dihydroergotamine mesylate (given after a test dose for hypersensitivity and with an antiemetic) or dexamethasone if IV prochlorperazine is unsuccessful.

The decision to begin a prophylactic medication should be based on the frequency and severity (eg, missing school time) of headaches and failure of abortive medications. Anticonvulsant agents, such as valproic acid, topiramate, levetiracetam, and gabapentin, have been found to be successful antimigraine agents. Valproate sodium has appetite-stimulating and teratogenic effects. The beta blockers, including propranolol, have demonstrated efficacy as prophylactic agents but should be avoided in patients with asthma or depression, and the antihistamine cyproheptadine hydrochloride has been used successfully in many younger patients but is also an appetite stimulant. Amitriptyline hydrochloride and nortriptyline hydrochloride are effective preventive treatments in older children and adolescents; initially, a single bedtime dose should be used. Amitriptyline hydrochloride can be combined with propranolol if necessary. Calcium channel blockers, such as verapamil hydrochloride, may also be useful in older children and adolescents. Isolated success has been achieved with riboflavin, magnesium, botulinum toxin injections, and greater occipital nerve block. With any of the prophylactic medications, a 2- to 4-week trial is necessary before concluding that the initial treatment has proved to be ineffective. With most agents, the dose can be slowly increased to efficacy according to patient tolerance. In patients undergoing prophylactic therapy, the medication should be periodically withdrawn to ascertain whether continuation of the therapy is necessary.

For many of the aforementioned agents, weak evidence that is either anecdotal or from small studies supports their use in childhood migraine. As a result, the Childhood and Adolescent Migraine Prevention (CHAMP) trial was begun in 2012. In this randomized double-blind study, children age 8 through 17 years were recruited and assigned to 1 of 3 arms: amitriptyline hydrochloride (goal dose of 1 mg/kg), topiramate (2 mg/kg), and placebo. Children with continuous headache, medication overuse headache, a very high Migraine Disability Assessment score, psychiatric disease, or who were presently taking 1 of several classes of medications were excluded. The trial was stopped prematurely for futility, because neither test agent was superior to placebo in reaching a positive outcome, which for all 3 arms was an approximately 60% rate of having a 50% reduction in headache days. The test agents had a greater rate of adverse events than placebo, so they could be judged inferior. Perhaps a learning point for the quite high placebo effect in this trial is that all participants received monthly lifestyle migraine management advice and optimal acute therapy, including NSAIDs and triptans and frequency guidance, which reduce the risk of progressing from episodic to chronic migraine and may have had a preventive role in this trial. Despite the potential negative conclusion about prophylactic medication from this trial, a utility for prophylactics may still exist in cases in which the acute treatment cannot practically be as optimal as in the trial, the side effect potential is quite low (such as with melatonin, riboflavin, or lower doses of prescription medications [eg, amitriptyline hydrochloride at a 10 mg dose]), or the patient has 1 of the first 3 trial exclusion criteria (ie, continuous headache, medication overuse headache, very high Migraine Disability Assessment score).

Chronic daily headaches may be successfully managed with education, use of prophylactic medication, and avoidance of abortive analgesics in the patient who experiences transformed migraine resulting from rebound effects. In fact, medication overuse headaches often benefit solely from abstinence for 1 to 2 weeks. Some children need assistance returning to a functional daily routine or a program for restoring school attendance. Healthy lifestyle changes and learning how to manage stress by relaxation training have been very beneficial, particularly in adolescents (as seen in the CHAMP trial); however, biofeedback-assisted guided imagery, hypnosis, meditation, and acupuncture have limited availability and high cost. If either severe environmental stressors or psychological trauma serve an ongoing headache trigger, the patient may benefit from psychotherapy.

Prognosis

Many children with headaches have a good prognosis and do not require ongoing intervention after families are reassured of the benign nature of the problem. For other children, appropriately used abortive medications alone are frequently effective. The prognosis

is less positive in children with headaches with psychiatric comorbidity. Pediatric patients, especially boys, frequently experience complete remission of their headaches by adolescence, and, by adulthood, the incidence of headaches has decreased in both sexes. A study of more than 100 children reported that chronic headaches persisted after 8 years in only 12%.

CASE RESOLUTION

The child's symptoms and circumstances of the headache suggest a diagnosis of migraine. No laboratory tests or imaging studies are necessary. The girl is begun on amitriptyline hydrochloride and instructed to keep a calendar of headache occurrences. She has 2 headaches in the first 2 weeks, which are aborted effectively with ibuprofen. She has no further recurrences, and the amitriptyline hydrochloride is withdrawn successfully after 3 months.

CHAPTER 130

Tics

Hanalise V. Huff, MD, MPH, and Kenneth R. Huff, MD

CASE STUDY

An 8-year-old boy has unusual recurring behaviors that began 2 to 3 months prior to this office visit. He stretches his neck or raises his eyebrows suddenly several times a day. Sometimes he can suppress these actions. The boy's parents report that in the past 2 years he has displayed several repetitive behaviors, including blinking, grimacing, rubbing his chin on his left shoulder, making a "gulping" sound, and sniffing. Originally, they thought the sniffing was related to hay fever, but the boy has no other allergic symptoms. He does not use profane words. In conversation, he sometimes repeats the last phrase of a sentence that was just uttered by himself or someone else. Additionally, he must touch each light switch in the hallway every time he leaves his room, and he must retie his shoelaces several times until they are exactly the same length. Although his schoolwork has not deteriorated, he has always had trouble completing tasks and finishing homework. His teacher and his best friend have asked about his strange behavior. His mother has a "psychological" problem with her son's gulping sounds (ie, they recur in her own mind), and she recalls that her father had a habit of frequently looking over 1 shoulder for no apparent reason.

Although during examination the boy does not exhibit any unusual behaviors, he raises his eyebrows twice and places his hand over his mouth several times while his parents are interviewed. Except for mild fine motor incoordination, the neurologic examination is normal.

Questions

1. What are the characteristics of tics?
2. What are some of the other challenges that children with Tourette syndrome may face?
3. What are the considerations in the management of tic disorders?
4. What other problems are associated with Tourette syndrome that also warrant intervention?

A *tic* is a brief, abrupt, nonpurposeful movement or utterance. Tics occur in a background of normal activity and are repetitive and involuntary but can be suppressed. Tourette syndrome (TS) is the most common etiology of tics in children. It is defined by multiple types of tic displayed over time, including motor tics and vocal tics. Tourette syndrome most frequently manifests solely as a nondisabling movement disorder but may also be associated with other neurobehavioral problems, which may include attention-deficit/hyperactivity disorder (ADHD), obsessive-compulsive disorder, mood and rage disorders, anxiety, personality and conduct difficulties, and sleep disorders.

Epidemiology

Tics are relatively common in children but often go unrecognized as a movement disorder. The onset of tics associated with TS is generally between 5 and 12 years of age but can be as late as 21 years of age. The prevalence of tics is 5 times higher in males than females. By various estimates, TS prevalence is between 0.1% and 3%, and many cases of TS are familial, with some features occurring in a parent in up to 25% of cases. Family members may have had such mild symptoms that they never sought medical attention. The risk of TS in a sibling is approximately 8%. Tics are more common in male family members, but other family members may have only non-tic manifestations of the syndrome, such as obsessive-compulsive symptoms, which occur most often in females. Tourette syndrome appears to be less common among sub-Saharan Africans and African-Americans.

Clinical Presentation

Children with tics display sudden repetitive movements of the face, neck, shoulders, or hands in the context of normal behaviors, and normal behaviors are sometimes used to mask the tics. Sometimes tics can be suppressed when they would be embarrassing or during a time of intense physical activity, concentration, or performance, but they also may be worsened by stress or strong emotions. Tics associated with TS vary in their manifestations over periods of weeks to months. Some examples of tics are blinking, eye rolling, grimacing, neck stretching, head turning or shaking, shoulder shrugging, stomach tensing, and wrist flicking. Many affected children describe a brief premonitory sensation, which is an indescribable, uncomfortable feeling that is subsequently relieved by the motor tic. Tics may bizarrely mimic normal, sometimes complex, movements or postures or involve a series of orchestrated simple movements, such as sequential finger flexing, wrist bending, and arm stretching. Tics may include sudden repetitive sounds from the vocal apparatus (Box 130.1), which may be produced by a sudden

Box 130.1. Diagnosis of Tics

- Sudden, brief uncontrolled movements
- Repetitive sounds from the vocal apparatus
- Behaviors occurring in the context of or mimicking normal behaviors but having no purpose

movement of air or saliva within the larynx or pharynx or a clicking of the tongue or teeth. Sounds may include throat clearing, sniffing, grunting, squeaking, sucking, or blowing. Additionally, children with TS may also have socially inappropriate words or gestures or repeat a new word or phrase or a word or phrase they have just said or heard.

Children with TS may have learning problems, including easy distractibility and inability to finish schoolwork. Less frequently, they also have intrusive or repetitive thoughts, unfounded fears, or ritualistic actions that may involve touching, cleanliness or neatness, counting and exactness, symmetry or evenness, or irrational checking. Sleep disturbances are not unusual.

Classifications of tics according to the nature of the action can be helpful in understanding apparently widely different movements as being part of the same disorder because of ultimately shared central nervous system chemistry or circuitry (Box 130.2). Clonic tics are brief, and dystonic tics are more sustained movements. In addition to simple tics, patients may rarely have other unusual behaviors (ie, complex tics) including echopraxia (ie, repetitive gestures), copropraxia (ie, obscene gestures), and coprographia (ie, obscene writing). Unusual speech patterns include irrelevant or nonsense words, palinphrasia (ie, repeating one's own words), echolalia (ie, repeating another's words), and coprolalia (ie, obscene speech). Diagnosis is often delayed because of misunderstandings about the common and uncommon manifestations of TS (Box 130.3).

Box 130.2. Types of Tic in Children With Tourette Syndrome

Simple

- Clonic
- Dystonic

Complex

- Series of different or similar simple tics
- More complicated coordinated movement
- Copropraxia and coprographia

Vocal

- Oropharyngeal, nasopharyngeal, or laryngeal sounds
- Consonants or syllables
- Meaningless or nonsense words or phrases
- Coprolalia
- Palinphrasia and echolalia

Box 130.3. Misconceptions in Diagnosing Tourette Syndrome

- Attributing the unusual tic symptom to attention-getting or emotionally based behavior
- Diagnosing the episodic behavior as a seizure based on inadequate historical information
- Attributing a vocal tic to an upper airway, sinus, or allergic condition
- Attributing an ocular tic to an ophthalmologic problem
- Requiring observation of the tics in the office before making the diagnosis
- Waiting for coprolalia to be present before making the diagnosis
- Assuming severe tics are necessary for the diagnosis, or assuming mild tics are a normal developmental phase

Pathophysiology

Tics are thought to be generated from a functional abnormality of circuitry in deep brain nuclei that might include the striate nuclei, globus pallidus, subthalamic nuclei, and substantia nigra. The prefrontal cortex, thalamus, and limbic systems may also be involved. Tourette syndrome, including the generation of the tic movement disorder, must result from several brain-expressed genes with a developmentally influenced expression interacting in a complex manner with psychosocial and other environmental factors and thus making it a true neuropsychiatric condition.

Dopaminergic disinhibition within the circuitry is likely to be part of the abnormal function because of 1 class of medication (eg, stimulants) worsening the symptoms and another class (eg, dopamine antagonists) effective as a treatment. In patients with TS, the cerebrospinal fluid contains low baseline levels of homovanillic acid, a dopamine metabolite, which could result, as has been hypothesized, from a hypersensitive dopamine receptor. Additionally, amphetamines and methylphenidate hydrochloride increase dopamine release, and in some instances, these agents precipitate tic symptoms. Haloperidol, an effective tic-suppressing medication, blocks dopamine receptors and, therefore, may block a potentially hypersensitive Tourette dopamine receptor. The observation of a good clinical response with relatively low doses of dopamine blockers (eg, haloperidol) and the finding of increased homovanillic acid levels resulting from receptor desensitization long after disappearance of the drug support this hypothesis. The physiology is undoubtedly more complex, because medications involving other transmitters also are effective. Rare genetic causes of TS are mutations in the *SLITRK1* gene, which is involved in dendrite growth, and the gene for histidine decarboxylase, *HDC*. Histamine decarboxylase converts histidine to histamine in histaminergic neurons found in the posterior hypothalamus but connecting widely in basal ganglia and other brain regions. It is unknown how either of these genes causes symptoms, and the genetic basis of TS remains elusive.

An observed association of the sudden onset or exacerbation of obsessive-compulsive or tic symptoms with preceding group A

streptococcal infections of the pharynx has been termed pediatric autoimmune neuropsychiatric disease associated with streptococcus (PANDAS). Although for some time it has been known that a clear relationship exists between the same bacteria and another movement problem, Sydenham chorea, the evidence for causality or any role of the bacteria or of related autoimmunity is conflicting and unconfirmed by large studies involving TS or obsessive-compulsive disorder; therefore, routine screening or prophylaxis has not been recommended when these diagnoses or PANDAS are being considered.

Differential Diagnosis

The duration, frequency, and appearance of the movement, the premonitory sensation, and circumstances of occurrence of tics help distinguish them from several other episodic movement disorders. *Myoclonus* is a lightning-like, nonsuppressible jerk of a small group of muscles, and *chorea* involves nearly constant, small amplitude movements of the fingers, hands, and feet that are often accompanied by grimacing movements of the face. *Tremor* is an oscillatory movement of an extremity or the head. *Hemiballismus* is an uncontrollable episodic throwing movement of an extremity. *Hyperekplexia* is a hyperactive startle response provoked by touch or sudden noise. *Torticollis*, or neck writhing, may be paroxysmal but is generally part of a benign transient disorder or a chronic degenerative disorder, such as familial dystonia. *Paroxysmal kinesigenic choreoathetosis*, an unusual episodic condition precipitated by a sudden movement, is characterized by a twisted trunk and limb posture lasting a few seconds (longer than tics, generally) and not accompanied by loss of consciousness. Hypnagogic jerks and bruxism are persistent normal variant behaviors that occur in sleep.

Other repetitive behaviors are sometimes confused with tics. A *compulsion* is a complex action that is done against an individual's will or better judgment. A *stereotypy* is a persistent repetitive senseless movement. A *perseverative behavior* involves continued activity after the cause of it has ceased. The most common self-injurious behaviors are biting or banging of a body part during periods of agitation. An *addictive behavior* occurs with psychological dependence caused by a reward system. A *habit* is a fixed practice established by repetition. A *mannerism* is a stereotyped movement or habit peculiar to an individual and part of that individual's personality. An *anger outburst* is a sudden emotion-generated behavior occurring with relatively little provocation.

Tic disorders are sometimes divided into 3 groups: *simple transient tics*, which are monomorphic (ie, always the same appearance over a period of months), last less than 12 months, and may be caused by particular environmental situations or psychological states; *chronic tics*, which last longer than 12 months but are of a single type; and the tics of TS (Box 130.4). All 3 types of tic disorders may occur in the same family. Tics can also be seen in association with Huntington disease, neuroacanthocytosis, Sydenham chorea, infectious encephalitis, carbon monoxide poisoning, stroke, schizophrenia, head trauma, static developmental encephalopathies, and drug reactions, particularly stimulants, anticonvulsant agents, and antipsychotic agents.

Box 130.4. Conditions Necessary for Diagnosis of Tourette Syndrome

- Multiple motor and vocal tics variably manifested over time
- Tics present for ≥1 year
- Onset of tics before 21 years of age
- Tics not caused by another known condition or substance

Evaluation

History

A thorough history should be taken when evaluating a child with potential tic disorder. The physician should learn as much as possible about the duration, circumstances of occurrence, and frequency of the movements (Box 130.5). Parents or guardians may imitate the behavior or, if possible, bring in a video recording of the child's behavior. This may give the physician more telling information than verbal descriptions. The physician should suggest an array of tic behaviors, because the parent or guardian may not be aware that these behaviors could be tics.

Physical Examination

Frequently, tics are not seen by the physician when observing the child during the examination because the child is able to suppress them; however, the physician may be able to observe the child unobtrusively while still in the waiting room or during the course of the parent/guardian interview. As part of the examination, screening of cognitive abilities and fine-motor coordination should be included because of the comorbidity of ADHD, learning disabilities, and associated fine motor dysmaturity.

Laboratory Tests

No definitive diagnostic or supportive laboratory tests exist for tics generally or TS specifically. Any child with atypical or ambiguous

Box 130.5. What to Ask

Tics

- For how long and how often has the child been displaying the unusual behaviors?
- In what circumstances do the unusual behaviors occur? For example, do the behaviors occur when the child is eating or sleeping, engrossed in an activity, or excited? Or do they occur when attention is on the child or after a startle or other triggering behavior?
- Can the parents or other caregivers imitate or show a video recording of the child's unusual behavior?
- Can the child suppress the behavior?
- Does the child have an uncomfortable premonitory sensation just before the motor tic that is relieved by the tic?
- Is the child having difficulty at school, whether cognitive or social?

movement disorders should be screened for potential metabolic abnormalities, including routine determinations of calcium, magnesium, glucose, liver function enzymes, and ceruloplasmin levels (for Wilson disease). Thyroid function tests may also be requested in the setting of other signs or symptoms of thyroid dysfunction.

Imaging Studies

Research studies of patients with TS have demonstrated volumetric increases in left frontal grey matter thickness and the anterior parts of the corpus callosum and decreases in the caudate nuclei in magnetic resonance imaging studies, as well as increased premotor and cerebellar and reduced resting basal ganglia and orbitofrontal cortex activity in positron emission tomography studies. These imaging modalities have not yet proven clinically useful in the care of individual patients, however.

Management

Goals of management should include reduction in the frequency of tics, especially during critical circumstances, with a minimum of medication side effects and attention to other coexisting learning or behavioral disabilities. Before physicians prescribe drug treatment, they must consider the severity of the tic disorder; the local pain it might be producing from muscle, tendon, or joint stress—forceful neck tics have been associated with cervical spine, vertebral artery, and myelopathic injuries; and its potential for production of psychosocial disability, including family, peer, and school relationships. Some children do not need medication for the movement disorder, and they and their families can be reassured by an understanding of the problem. Other children may experience bullying, recess altercations, or incorrect teacher judgments. Successfully treated patients may also experience remission of their disorder for weeks or months, during which time it is appropriate to reduce or discontinue their medications. Several classes of drugs are useful in the management of tic disorders. Clonidine is indicated for mild cases because of its fair efficacy, good side-effect profile, and convenience. This α_2-adrenergic agonist is available in tablet form and as a transdermal skin patch. Dosage is titrated by effective tablet strength or size and strength of the patch. Guanfacine hydrochloride, an oral formulation in the same class, is also effective and may be less sedating than clonidine tablets. The most direct therapy for the troublesome tics but one that produces more sedative side effects is the dopamine-depleting tetrabenazine. Dopamine blockers, such as pimozide and fluphenazine, can produce tardive dyskinesia, and electrocardiography is recommended before beginning these medications because they have been associated with long QT syndrome; additionally, concomitant use of inhibitors of CYP3A liver metabolism is not recommended. Atypical antipsychotic agents, particularly risperidone, have also been effective, with reduced sedation and potential for extrapyramidal side effects but with increased propensity to cause weight gain and glucose intolerance. Haloperidol has long been used in divided doses starting as low as 0.5 mg per day up to 2 to 6 mg per day but also carries a small risk for tardive dyskinesia. With any of these medications, the child should begin with a low dose that is titrated up to efficacy or the development of intolerable side effects. Botulinum toxin type A injections may be useful for isolated persistent tics involving muscles that are needle accessible. Habit reversal training or comprehensive behavioral intervention for tics has a growing body of supportive evidence; however, such treatment involves a time commitment of child and parents/guardians, the proximity of a trained professional to teach the technique, and an expense that may not be covered by insurance. Nevertheless, the absence of medication side effects has resulted in growing interest in such treatment.

Treatment of the child with TS should be multimodal and prioritize, address, and monitor all problematic aspects of the syndrome (Box 130.6). Up to 60% of children with TS have learning disabilities, including ADHD, and learning disabilities may be a bigger problem for the child than the tics. An assessment is necessary when school performance is suboptimal. Interventions may include organizational aids, homework time management, reduction in potential environmental distractions, and more individualized instruction. Pharmacologic therapy may include clonidine, a tricyclic antidepressant, atomoxetine hydrochloride, or a stimulant. Long-acting methylphenidate hydrochloride or mixed amphetamine salt preparations are not necessarily contraindicated in children with TS; these drugs do not worsen tics in all patients. Children with TS

Box 130.6. Therapies Useful in Managing Tourette Syndrome

Tics

- Clonidine (tablet or transdermal patch): α_2-adrenergic agonist
- Risperidone (low dose): serotonin dopamine receptor antagonist
- Haloperidol (low dose): dopamine receptor blocker
- Pimozide (Orap): dopamine receptor blocker
- Fluphenazine: dopamine receptor blocker
- Guanfacine hydrochloride (Tenex): α_2-adrenergic agonist
- Habit reversal training

Attention-Deficit/Hyperactivity Disorder and Learning Disability

- Clonidine (tablet or transdermal patch): α_2-adrenergic agonist
- Methylphenidate hydrochloride: if tics are not worsened
- Atomoxetine hydrochloride: norepinephrine transporter inhibitor
- Desipramine hydrochloride: tricyclic antidepressant
- Education interventions: individualized or small-group instruction or "504 plan" of accommodations

Obsessive-Compulsive Disorder

- Fluoxetine hydrochloride (Prozac): serotonin uptake inhibitor (nontricyclic)
- Clomipramine hydrochloride (Anafranil): tricyclic antidepressant

Depression and Adjustment Problems

- Psychotherapy (individual and family)
- Imipramine: tricyclic antidepressant
- Support group

also may exhibit symptoms of obsessive-compulsive disorder, although this finding is much less common than learning disabilities. Fluoxetine hydrochloride, sertraline hydrochloride, and clomipramine hydrochloride are useful in managing this comorbidity.

In its severe form, TS may be socially devastating and provoke secondary frustrations, low self-esteem, depression, and other emotional problems as well as the primary psychobehavioral difficulties that may be part of the syndrome. Children with TS and their families frequently benefit from lay educational materials about TS, support groups composed of other families that have children with the syndrome, and local chapters of the Tourette Association of America (https://tourette.org). Referral for psychological or psychiatric counseling for patients and their families may also be necessary, however.

Prognosis

In most children, the prognosis for waning of the tics by adolescence is good, with 50% of tics disappearing by then. Of children who are symptomatic in grade school, less than 20% continue to exhibit clinically significant tic symptoms in older childhood and adulthood. Some children whose tics are exacerbated by psychosocial stressors, however, may have ongoing problems with school success and developing solid peer relationships. If present, these issues should be addressed early in childhood; as with other neuropsychiatric conditions, educational and social problems may be harder to reverse later in life, and the psychological adjustments become important in the long-term prognosis.

CASE RESOLUTION

The boy is diagnosed as having TS. After a discussion with his family about the syndrome, he is treated with Catapres patches. A questionnaire is sent to his teacher concerning ADHD symptoms at school. At a 6-week follow-up visit, he has fewer tics and is doing better in school, having been placed in a classroom with only 15 other students for most of the day.

CHAPTER 131

Seizures and Epilepsy

Hanalise V. Huff, MD, MPH, and Kenneth R. Huff, MD

CASE STUDY

A 6-year-old boy is evaluated for unusual episodic behaviors. The previous week his mother was awakened by the boy's brother and found her son lying in bed unresponsive and drooling, with his head and eyes averted to the right, his right arm slightly raised, and his body stiff. His face was jerking intermittently. When the paramedics arrived, the boy's posturing and movements had stopped. After the event, he could speak but was somewhat incoherent. He was taken to the local emergency department, where his examination and mental status were normal. Screening blood and urine tests were normal, and he was discharged with instructions to see his pediatrician for further recommendations.

His father remembers 2 or 3 other episodes of a somewhat different nature in the past month. These occurred as the boy was being put to bed. They involved some body stiffening and facial grimacing, with the mouth slightly open and the tongue twisted and deviated to one side. The child could not speak but appeared to be trying to talk. Each episode lasted 20 to 30 seconds. Afterward the boy was his usual self and could tell his father what had been said to him.

The child has had no intercurrent illnesses or abnormal behavior apart from these "spells," and he has lost no abilities. A paternal cousin and grandfather had seizures during childhood but "grew out of them." The examination is completely normal.

Questions

1. What history would suggest that a child had a seizure?
2. How does the physician determine if a child has a seizure disorder (eg, epilepsy)?
3. How do electroencephalography and other tests help in classifying the type of seizure disorder?
4. How does the physician determine the best course of short- and/or long-term management?

Seizures are a common medical problem in children. Diagnosing an episode that does not contain generalized convulsing movements as a seizure is sometimes problematic, however. Seizure is an episodic, stereotypical behavior syndrome of abrupt onset with loss of voluntary control, resulting in loss of responsiveness and rarely provoked by external stimuli. Frequently, the occurrence of this behavior correlates with interictal brain electrical discharges on electroencephalography (EEG), and the behavioral ictus (ie, seizures) should match temporally with a period of electrical hypersynchrony if it occurs during the EEG recording.

A detailed history of the nature of the episodic behavior from an eyewitness or a video recording is paramount in making the diagnosis of a seizure disorder and elucidating the type of seizure problem. The EEG is most often an adjunct to diagnosis. It is abnormal in many individuals who do not have clinical seizures, and it may be normal interictally in many patients with clinical seizures because of its sampling limitations. Special techniques can sometimes help alleviate these limitations.

Epilepsy is a seizure problem that implies recurrence of seizures. Identifying the type of seizure problem is important in devising the management plan. Seizures can simply be classified as primary generalized seizures, that is, involving the whole cerebrum from the outset, or partial seizures. Some partial seizures can secondarily generalize, however, thereby clinically mimicking primary generalized seizures after their onset. Distinguishing these entities illustrates the importance of eyewitness information. Many treatment options are available, but the therapeutic plan must be individualized to the child's seizure type or clinical syndrome to optimize seizure control and minimize side effects. With appropriate treatment, most children with seizure disorders are not handicapped scholastically or socially and can enjoy normal lives.

Epidemiology

Fifty million people worldwide have epilepsy, with 3 to 4 million of those in the United States (1.2% of the US population). Approximately 0.5% to 1.0% of all children experience at least 1 afebrile seizure. In children younger than 18 years, the new onset epilepsy incidence rate per year is approximately 0.05%. Recurrent seizures can occur as a component of a static encephalopathy after brain malformation or dysgenesis, encephalitis or meningitis, metabolic disorder, hypoxic-ischemic injury, or severe head trauma. Such secondary or symptomatic seizures make up approximately one-third of childhood epilepsies. The remaining two-thirds of epileptic seizures occur presumably as part of a genetic epileptic syndrome. As genetic knowledge increases, eventually the specific cause or association of seizures in most children will be diagnosed.

Clinical Presentation

Children present with a history given by observers of an episode of abrupt onset characterized by a loss of ability to respond to external stimuli (Box 131.1). The child may experience various difficult-to-describe sensory, emotional, or psychic phenomena (ie, aura) before losing consciousness. Observers then see convulsive muscle activity, after which the patient may be sleepy. With some seizures, observers may note only an akinetic or staring spell; however, other seizures present with dramatic, rhythmic spasms of the face, extremities, or torso. Major motor seizures are frequently also associated with systemic autonomic changes, including changes in skin vascular supply causing color change, sweating, saliva production, and loss of sphincter control. Approximately 10% of children have a headache before or after their seizure. With the exception of the common provocative factors of fever, intercurrent illness, and sleep deprivation and the much rarer provocative factors of the reflex epilepsies, most seizure episodes are neither provoked nor attenuated by environmental factors. Between episodes, a child's general physical and neurologic examination may be entirely normal.

Pathophysiology

A seizure represents a sudden, synchronous depolarizing change in the electrical activity of a network of neurons that becomes widely propagated over the cortex, affecting awareness, responsiveness to external stimuli, and motor control. The propagation may be enhanced by defects in cell ion channels. Focal seizure disorders may result from a focal cortical lesion, such as a glial scar caused by a remote insult (eg, trauma, infarct), or a dysgenesis or primary cortical dysplasia that disrupts the electrical circuitry. The focal abnormality also could contain hamartomatous immature cells and abnormal synaptic properties and allow for periodic, abnormal transmission of impulses.

Exactly what initiates the change in dynamic between excitatory and inhibitory influences on the neuron, the synchronous depolarization of the neurons, and the widespread network propagation is not well understood, and a rigorous analysis of abnormal neuronal and cerebral neurophysiology is beyond the scope of this chapter. Several different physiologic mechanisms, including disrupted neuronal circuitry; voltage- and ligand-gated membrane ion channel abnormalities; abnormal excitatory or inhibitory neurotransmitter or receptor production, degradation, or uptake, including a critical protein interaction involving the γ-aminobutyric acid (GABA) type A α-2 subunit of its inhibitory receptor; and perhaps glial support mechanisms, could each be involved depending on the type of epilepsy or epilepsy syndrome. One example is familial childhood absence epilepsy, which results from abnormal thalamocortical circuitry that is in some way developmentally vulnerable. Another example is cryptogenic West syndrome (ie, infantile spasms), an "inter-neuronopathy" that has been associated with several genes, including *LIS1, DCX,* and *ARX* (sometimes resulting in agyria), which are important in GABAergic inhibitory interneuron development. A third example is the neuronal voltage-gated sodium channel subunit gene, *SCN1A*, which is mutated in the mild phenotype of "generalized epilepsy with febrile convulsions plus" and also mutated but in different regions of the gene sequence in the much worse phenotype of Dravet syndrome, which was previously known as severe myoclonic epilepsy of infancy. Neonates are more susceptible because of a paradoxical excitatory effect of GABA receptors in immature neurons, a relative abundance of *N*-methyl-D-aspartate receptors, and a peak in dendritic spines and synapse numbers. Further understanding of the mechanism involved in familial epilepsy syndromes awaits the definition of relevant genes, their expression and product functions, as well as the effects of changes in exon base pair sequence, regulatory regions of the genome, or epigenetic mechanisms on membrane polarization, synaptic function, and circuitry physiology.

Box 131.1. Diagnosis of Seizure in the Pediatric Patient

- Abrupt loss of responsiveness
- Rhythmic clonic movements
- Sustained changes in posture or tone
- Simple automatic movements
- Drooling or bubbles of saliva present on the lips
- Completely unresponsive
- Staring without change in tone or posture
- Simultaneous change in cerebral electrical activity (eg, repetitive discharges)

Seizure Types

Seizures can be simply classified by their ictal appearance as either primary generalized seizures, which include grand mal seizures, generalized tonic-clonic convulsions, and petit mal (absence) seizures (so named because of the child's complete loss of awareness at the outset of the episode), or focal (ie, localization-related) seizures, which include focal motor, psychomotor, and other partial disorders (Box 131.2). Epilepsy syndromes are also a useful means of

Box 131.2. Simplified Classification of Epileptic Seizures by Ictal Appearance

Partial Seizures (Seizures Beginning Locally)

- Elementary symptoms: focal seizures
- Complex symptoms: psychomotor seizures
- Partial seizures evolving secondarily to generalized seizures

Generalized Seizures (Bilaterally Symmetric; Onset not Local)

- Absence seizures (ie, petit mal): typical and atypical
- Tonic-clonic seizures
- Tonic seizures
- Myoclonic seizures (eg, minor motor)
- Atonic seizures (ie, drop attacks)
- Infantile spasms

Unclassified Seizures (Includes Neonatal "Subtle" Seizures)

classifying seizures by their clinical patterns (ie, diagnosis, therapy, and prognosis). Even with a known genetic cause, the same gene can produce more than 1 epileptic syndrome (Box 131.3). The examples presented here are not an exhaustive list of seizure syndromes; rather, they are among the more important types encountered in practice.

Box 131.3. Epilepsy Syndromes by Age of Onset

Neonatal

- Benign (idiopathic) neonatal seizures, historically termed "fifth day fits"
- Benign familial neonatal epilepsy
- Early infantile epileptic encephalopathy (eg, Ohtahara syndrome)
- Early myoclonic encephalopathy

Infantile

- Myoclonic epilepsy in infancy, which is a benign Dravet syndrome variant
- Benign epilepsy of infancy
- Benign familial infantile epilepsy
- Epilepsy of infancy with migrating focal seizures
- Hemiconvulsion-hemiplegia-epilepsy syndrome
- West syndrome (eg, infantile spasms, hypsarrhythmia; infantile spasms are to be distinguished from benign myoclonus of early infancy, which is not an epilepsy)
- Severe myoclonic epilepsy of infancy (as in classic Dravet syndrome)
- Myoclonic encephalopathies in nonprogressive disorders

Childhood

- Genetic epilepsy with febrile seizures plus (can begin in infancy)
- Panayiotopoulos syndrome (ie, early-onset benign childhood occipital epilepsy)
- Myoclonic-atonic (formerly astatic) epilepsy (ie, Doose syndrome)
- Benign epilepsy with centrotemporal spikes (ie, benign rolandic epilepsy)
- Late-onset childhood occipital epilepsy (ie, Gastaut type)
- Epilepsy with myoclonic absences (ie, Tassinari syndrome)
- Lennox-Gastaut syndrome
- Epileptic encephalopathy with continuous spike and waves during slow wave sleep
- Acquired epileptic aphasia (ie, Landau-Kleffner syndrome)
- Childhood absence epilepsy (ie, pyknolepsy)
- Generalized epilepsy with eyelid myoclonus (ie, Jeavons syndrome)

Adolescence to Adult

- Juvenile absence epilepsy
- Juvenile myoclonic epilepsy
- Epilepsy with generalized tonic-clonic seizures alone
- Progressive myoclonus epilepsy
- Mesial temporal lobe epilepsy with hippocampal sclerosis
- Autosomal dominant focal epilepsy with auditory features
- Autosomal dominant nocturnal frontal lobe epilepsy

Syndromes with Less Specific Age Relationship

- Familial focal epilepsy with variable foci (childhood to adult)
- Reflex epilepsy

Two-thirds of nonfebrile seizures in children result from a focal seizure disorder. *Psychomotor seizures* are focal seizures that usually are preceded by a sensory aura or sometimes emotional behavioral manifestations and have a wide range of ictal behaviors, including focal clonic jerking, aversive or asymmetric hypertonic posturing, and more complex stereotypic fumbling or fingering behaviors. Seizures may be followed by postictal confusion or drowsiness. In some instances, children have partial sensory awareness but are unable to respond during seizures. In other cases, however, they are completely unconscious. The initial partial motor manifestations may not be seen by the observer before the movements rapidly generalize. Partial seizures are more often associated with focal brain pathologic processes, including traumatic lesions, infarcts, malformations, infections (eg, viral encephalitis, cerebral cysticercosis), and hippocampal sclerosis. The latter is rare in children but has been associated with a distant history of a prolonged febrile seizure. A few of these etiologies may be found with a characteristic appearance on magnetic resonance (MR) imaging; however, in most cases the etiology and its location are not apparent on MR imaging alone and require a combination of techniques to find the source of the resistant seizures.

Benign epilepsy syndromes occur in children with normal developmental history, respond well to therapy, and remit without sequelae. Rolandic seizures, or benign epilepsy with central temporal spikes, is a relatively common partial seizure syndrome that sometimes is familial and has a good prognosis for resolving by adolescence. These episodes commonly occur when children are falling asleep, during sleep, or on awaking. Motor manifestations involve the tongue, mouth, or face but can sometimes generalize to the rest of the body. The clinical syndrome is accompanied by a characteristic focal EEG discharge over the central temporal region of the scalp. Other benign syndromes include benign familial infantile seizures; benign infantile seizures with mild gastroenteritis; childhood occipital epilepsy characterized by visual symptoms and EEG occipital spike-wave discharges; and Panayiotopoulos syndrome, which is characterized by paroxysmal autonomic dysfunctions such as vomiting and other gastrointestinal motility problems, pallor, mydriasis, and cardiorespiratory and thermoregulatory abnormalities (lasting up to 30 minutes), often ending in generalized convulsing and largely occurring in sleep.

An absence seizure may sometimes be difficult to distinguish from a partial seizure (Table 131.1). The absence spell is a brief (2–15 seconds) loss of consciousness without loss of tone. Staring into space and minor movements, such as lip smacking or semi-purposeful-appearing movements of the hands are often the only observed behaviors. There is no postictal period. Because absence seizures occur multiple times per day and children are often unaware of them, parents or guardians may dismiss the subtle behavior change as selective attention or daydreaming; however, these seizures may adversely affect learning and carry a risk of injury. Hyperventilation, a useful diagnostic test that can be performed in the office, may provoke absence seizures. The EEG is generally confirmatory and may also distinguish classic petit mal seizures with 3-per-second

Table 131.1. Partial Complex Versus Absence Seizures

Characteristic	*Partial Complex*	*Absence*
Aura	Frequent	None
Loss of consciousness	Sometimes partial	Complete
Motor movements	Sometimes complex	Blinking or none
Postictal state	Frequent	None
Duration	>30 seconds	<15 seconds
Frequency	A few per month to a few per day	Many per hour or day
Hyperventilation provoked	No	Yes
Findings on electroencephalography	Variably localized discharge or normal	3-per-second spike-wave generalized
Prognosis past adolescence	Frequently persists	Rarely occurs

spike-wave discharges from variant syndromes. The classic petit mal is more often familial with dominant inheritance, age-specific occurrence between 4 and 16 years as childhood or juvenile absence, and sensitivity to ethosuximide treatment, whereas the atypical variant has a poorer prognosis for early resolution and is more resistant to anticonvulsant therapy. Juvenile myoclonic epilepsy begins during adolescence, but even if symptoms abate, treatment is often necessary into adulthood and is characterized by upper extremity myoclonus (ie, dropping or flinging behaviors) and convulsive seizures in the morning.

Neonatal seizures may be tonic, focal clonic, or multifocal clonic. The seizure problem is less often primary, and a vigorous search for an etiology of the seizure is more often successful than with older children. Problems commonly resulting in neonatal seizures include hemorrhage (eg, germinal matrix hemorrhage in the preterm neonate, subarachnoid or subdural hemorrhage from birth trauma in older neonates); hypoxic-ischemic damage from asphyxia; infections producing postnatal sepsis or meningitis or prenatal encephalitis; drug withdrawal in the newborn exposed to illicit drugs in utero; metabolic problems, including hypoglycemia, hypocalcemia, or hypomagnesemia in the neonate of a diabetic mother; amino or organic acidopathies occurring a few days after feedings have begun; congenital brain malformations; and genetic syndromes, including benign neonatal familial epilepsy, benign familial infantile epilepsy, and pyridoxine-dependent epilepsy.

Several more malignant seizure syndromes exist that have onset at typical ages, perhaps related to more widespread maturational events in brain circuitry or ion channels. Although the appearance of the seizures within each of these syndromes is stereotypical and ultimately interictal cognition is commonly affected, resulting in their designation as an "epileptic encephalopathy," in fact a wide variety of etiologic diagnoses may produce these syndromes.

West syndrome is an age-related seizure syndrome that involves typical but sometimes subtle movements of flexion contraction of the trunk with the head bowed or sudden raising of the arms, sometimes accompanied by a cry. These behaviors, infantile spasms, occur stereotypically several times in succession in a series. This syndrome, which includes a characteristic EEG and a period of developmental arrest, occurs in infants and children between 3 and 24 months of age. Another, perhaps related, but rarer syndrome of frequent tonic spasms, *Ohtahara syndrome*, occurs during the neonatal period and is associated with tonic seizures, an abnormal neurologic examination, and often structural brain abnormalities. It is characterized by a different burst-suppression EEG pattern but carries a similar dismal prognosis for impaired intellectual development. *Dravet syndrome* arises out of typical febrile seizures that then occur without fever and subsequently manifest as staring spells and myoclonic seizures accompanied by delayed cognition. As many as 50% of these children may experience sudden unexplained death in epilepsy (SUDEP) by age 10 years. Landau-Kleffner syndrome involves loss of language abilities at age 3 to 5 years in the context of epileptic seizures and a very abnormal EEG pattern in sleep. It is related to continuous spike and waves during slow wave sleep, which is associated with a more general cognitive decline. A fifth syndrome in older children that is also associated with a different but characteristic EEG pattern, Lennox-Gastaut syndrome, has the same poor prognosis for seizure control and cognitive development but produces several different behavioral seizure types, including tonic, absence, and drop attacks. Different types of brain lesion in these age groups (including focal lesions) can result in the same generalized seizure syndromes. Examples include tuberous sclerosis; neonatal ischemia, hemorrhage, or meningitis; and major central nervous system malformations. Other epileptic encephalopathies include early myoclonic encephalopathy, malignant migrating partial seizures of infancy, Rasmussen encephalitis, and Doose syndrome.

Differential Diagnosis

Seizures are distinguished from nonepileptic paroxysmal disorders based on patient history. The circumstances of place and time as well as details about the symptoms and nature of the behavior are important pieces of data. Syncope may be misdiagnosed as a seizure. Unlike seizure, however, the syncopal episode is frequently situational. It occurs when children are in hot or stuffy environments; when they have been standing in 1 place for a long time, such as during a ceremony or physical education class; or when they see or experience a painful event, such as an injection or phlebotomy. Boys may experience micturition syncope standing in the bathroom shortly after arising in early morning. Syncope often is preceded by symptoms of light-headedness, nausea, tinnitus, and eventually a gradual darkening of vision, sometimes without total loss of auditory perception. Observers may note pale skin color and cool damp skin.

Breath-holding spells are characterized by apnea and loss of responsiveness accompanied by cyanosis or pallid skin color. Breath-holding spells are also situational. Infants or children are often upset or crying just before such spells. They may be frightened

by a seemingly minor injury or angry after a toy is taken away or they are disciplined. Children may then throw themselves backward and stiffen while closing their glottis in expiration, and they may even have a few clonic jerks after losing consciousness (see Chapter 52).

Selective attention is frequently mistaken for absence seizure. Selective attention often occurs when children are involved in relatively passive activities (eg, watching television, playing a video game, daydreaming) and do not respond to verbal stimuli, such as hearing their own name called. Generally, the attention lapses do not occur during talking or eating; seizures will occur, however, even during these activities.

Epileptic seizures must also be differentiated from pseudoseizures (ie, psychogenic nonepileptic seizures), which occur most often in patients who have true seizures. Such episodes may include ictal eye closure and pelvic thrusting but also may resemble true seizures accurately, the psychodynamics of secondary gain or other motivation for the behavior may not be readily apparent, and the "need" for attention may be legitimate. The finding that the standard EEG is normal does not exclude a true seizure and thus is not helpful. Pseudoseizures should be suspected in children who may have witnessed seizures in relatives or close friends, who have seizures that consistently recur in the same situations, whose seizure frequency is not decreased with therapeutic levels of anticonvulsants, and whose seizures appear suggestible. Often, diagnosis can be supported in complicated cases by simultaneous video EEG monitoring, which shows a lack of correlation of electrical abnormalities with the behavior in question. Immediate postictal serum prolactin level also may be normal, and psychological assessment may detect underlying emotional problems related to prior trauma (eg, sexual abuse, other major psychological trauma). The prognosis of pseudoseizures in children generally is better than in adults and relates to the more acute psychosocial genesis of the problem in most children.

Infants and older children have several behaviors that mimic seizures. Infantile gastroesophageal reflux (ie, Sandifer syndrome) may have the appearance of brief epileptic tonic spasms but has a consistent temporal relationship to feeding. Benign paroxysmal vertigo occurs in the infant or toddler and presages migraine later in childhood. *Infantile shuddering* consists of brief, rapid side-to-side shaking of the head and trunk. Older children can experience a paroxysmal dystonia, which is provoked externally and produces a change in truncal tone and posture and a brief cessation of movement. *Tics* are sudden, brief stereotypical movements preceded by an urge and are partially suppressible. *Stereotypies* are recurrent movements that are often self-stimulatory and frequently occur with severe autism. None of these entities produces a loss of responsiveness of the child.

Sleep myoclonus is a normal nonepileptic variant that is common in infants; however, in older children accurate diagnosis of paroxysmal events in sleep may be a challenge because the motor behaviors of nonrapid eye movement sleep or other parasomnias may mimic nocturnal frontal lobe epileptic seizures. Video EEG polysomnography is also helpful in distinguishing between frontal lobe epileptic seizures and nocturnal parasomnias, which are not associated with ictal discharges.

Evaluation

History

The history should determine the exact events surrounding the seizure episode. A detailed history of the nature of the behavior from an eyewitness is extremely important (Boxes 131.4 and 131.5). The observer can be asked to video record a subsequent event. The physician must determine whether the child experienced any loss of the child's normal level of responsiveness. Typically, this change in mental status is abrupt, although a warning behavior or aura that lasts for a few seconds may precede complete loss of responsiveness. The warning behavior or aura for a seizure may be a cry, an expression

Box 131.4. Initial Evaluation of Seizure Patients

- Eyewitness account of the episode and/or video recording
- Description of the child's own experiences before, during, and after the episode if the child is sufficiently articulate
- History from caregiver concerning remote injuries to the nervous system, progressive neurologic symptoms, or intercurrent illness
- Careful neurologic examination for signs of cerebral hemisphere lateralization
- Brain magnetic resonance imaging, particularly for the patient in whom a partial seizure is observed, a crescendo history of neurologic symptoms is obtained, focal neurologic signs are noted on interictal examination, or postictal encephalopathy persists too long
- Waking and sleep electroencephalography with hyperventilation (if the patient can cooperate)

Box 131.5. What to Ask

Seizures

- Where was the child, and what was the child doing when the episode began?
- Did the child experience a loss of responsiveness?
- Did the child show any warning behavior or aura (eg, a cry, a facial expression of fear, irritability)?
- Did any part of the child's body become stiff? Was any shaking or jerking apparent?
- What did the child's eyes do, and was saliva produced at the mouth?
- Did the child's skin change color?
- Did the child experience a loss of sphincter control?
- How long did the episode last?
- Has the child been well recently?
- Did the child have a complicated birth, head trauma, meningitis, or other previous brain damage?
- Have episodes of a similar nature occurred previously? If so, when did they begin and how frequently do they occur?
- Has the child's development and school experience progressed normally?
- Does the child have any relatives who have had seizures?

of fear or anxiety, or nonspecific irritability. The child who is articulate may be able to describe a discrete sensory phenomenon or relate a less distinct or even indescribable sensation.

A change in muscle tone and activity is frequently associated with the abrupt change in mental status, unless the spell is an absence seizure. Most often, the tone is increased with general extensor posturing, more focal hypertonicity, or more complex torsion or aversive upper-body posturing. The patient may fall if not supported. Rhythmic jerking or clonic movements (focal or general), including the trunk, limbs, face, and eyes, may occur concomitantly. Respirations may involve gagging sounds, rhythmic grunting, or silent, nearly imperceptible movements. Swallowing may not occur, so that saliva pools or forms bubbles at the lips. Autonomic changes, including skin color change (ie, circumoral cyanosis), increased pulse, and loss of sphincter control, frequently occur with major motor spells. The ictal period generally lasts 30 to 120 seconds, although observers frequently overestimate this time. Postictal periods of sleepiness or lethargy may occur. The length of these periods often is correlated with the length or intensity of the seizure.

Children and those around them are sometimes unaware of the occurrence of absence seizures. Often, an observant teacher brings the child's problem to a physician's attention. During a spell, a child has no change in tone or clonic movements and may have only subtle facial or hand movements. The episode lasts only a few seconds, and there are no preictal or postictal behaviors.

Historical information can also help determine potential etiologies of the seizure problem. A known distant brain insult or a hereditary disposition or consanguinity may be related to the cause. The patient with progressive loss of skills should be evaluated for a degenerative disease. Many degenerative conditions can masquerade as epilepsy, and the physician must be continuously aware of progressive loss of vision, hearing, coordination, strength, or cognition as clues to initiate a more comprehensive workup.

Physical Examination

Children should be examined carefully for focal neurologic signs, particularly cerebral hemisphere-related asymmetries in strength, tone, or tendon reflexes. The examination should include a developmental assessment and mental status examination. The physician should evaluate for signs of potential genetic problems, such as dysmorphic features, microcephaly, or organ malformations, which often correlate with cerebral dysgenesis; abnormal skin pigmentation or vessels, which are suggestive of a neurocutaneous disorder; and organomegaly or bony abnormalities, which may be indicative of a storage disorder. A careful eye examination or ophthalmologic consultation might also reveal evidence of a neurocutaneous, neurodegenerative, or dysgenic disorder. The child who is old enough to cooperate should be asked to hyperventilate, which might provoke an absence spell if the history is suggestive of this type of seizure.

Laboratory Tests

An EEG should be requested to aid in the diagnosis of the type of seizure disorder, although the diagnosis should not rest on the EEG alone. In the child with partial seizure disorder, the interictal discharge is helpful in localizing the initial site of abnormal electrical activity. A sleep record is often essential for observing the most useful abnormalities; 40% of children with epilepsy have a normal EEG. If a normal waking EEG is obtained and seizures continue to recur, it is sometimes useful to help promote sleep during the recording by prior sleep deprivation carried out by the parents or caregivers. Patient anxiety about the test and setting as well as the discomfort of all the wires may make sleep elusive even after sleep deprivation. Special techniques (eg, prolonged monitoring with telemetry, special anatomic electrode placements) can sometimes help overcome the standard EEG limitations of sample time and inaccessible areas of cerebral cortex. It should be noted, however, that even the standard EEG is rarely normal in petit mal disorders.

Historical information can frequently guide the need for metabolic tests. A blood sugar determination should be done acutely; however, electrolytes are rarely abnormal in older children who have been well prior to the seizure. Urine toxicology should be done in a teenager with possible illicit drug use. Neonates and infants with recurrent unexplained seizures should undergo metabolic screening, including urine organic acid and amino acid levels, ammonia level, and acyl and free carnitine levels. If seizures persist, with resulting mental status changes, the physician should consider screening for cerebrospinal fluid glucose, lactate, and amino acid levels; conducting lysosomal and peroxisomal screening; and a diagnostic or therapeutic trial of pyridoxine. Tissue biopsy histologic analysis and specific assays may be indicated when physical signs are suggestive of possible storage or other metabolic etiologies. Dysmorphic features may indicate the need for chromosome analysis, a gene copy number variant screening array, or exome sequencing unless together they suggest the need for a specific diagnostic gene test. Epilepsy gene panels are available to assess for genes associated with epilepsy.

Imaging Studies

Magnetic resonance imaging is particularly helpful if a progression in neurologic symptoms or signs has occurred, the patient has a history of prior neurologic insult, an asymmetry of strength or tone is noted on examination, or signs of dysgenesis are present in other parts of the body. Even in the absence of these factors, partial or focal seizures have a higher yield of abnormal imaging results than do febrile seizures or petit mal disorders, which have a low yield. Finding a structural abnormality can obviate the need for expensive metabolic testing and can help narrow gene testing. In the acute period, intravenous contrast should generally be given because the cause of the seizure may be indicated by the loss of focal blood-brain barrier with an inflammatory or neoplastic lesion. The child with recurrent or resistant focal seizures should undergo MR imaging, particularly when surgical treatment is under consideration. Coronal MR imaging can detect mesial temporal sclerosis, a lesion in the hippocampus that occurs in chronic temporal lobe epilepsy, and 20% of children with this finding will have had febrile seizures. Helpful additional modalities in studying surgical candidates in a phased evaluation program include ictal positron emission tomography using fludeoxyglucose F 18, interictal positron emission tomography using α-methyl-L-tryptophan, single-photon emission computed tomography, functional

MR imaging, magnetoencephalography, and electrocorticography after craniotomy. These studies help define the nature of damaged or epileptic cortex and differentiate it from normal cortex.

Management

When an episode of abrupt loss of consciousness or tone with a potential for recurrence has occurred, families must be cautioned about the risks of drowning, falls from high places, burns, and accidents with operating machinery, including motorized vehicles.

Anticonvulsants are the mainstay of management of seizure disorders (Table 131.2). However, the physician must realize that both seizures and antiepileptic drugs affect brain development and could have long-term consequences, such as altered cognition. This observation may be especially true in the case of neonatal seizures, in which the seizures themselves may contribute to adverse outcomes and the standard treatment of phenobarbital has been shown in some long-term studies to inhibit learning. One-half of first-time seizures in otherwise neurologically normal children do not recur.

Table 131.2. Drugs Useful for Managing Seizures

Seizure Type	*Anticonvulsant*	*Dose*	*Toxic Symptoms/Side Effects*
Focal (narrow spectrum)	Carbamazepine	Approximately 15 mg/kg/day	Gastrointestinal distress, headache
	Phenytoin	4–8 mg/kg/day	Ataxia, nystagmus, bone changes
	Primidone	12–25 mg/kg/day	Drowsiness, ataxia
	Oxcarbazepine	30 mg/kg/day	Drowsiness, rare sodium depletion
	Lamotrigine	4–7 mg/kg/day	Dizziness, sedation, rash (eg, Stevens-Johnson syndrome)
	Gabapentin	4–8 mg/kg/day	Somnolence, ataxia
	Vigabatrin	15–50 mg/kg/day	Drowsiness, visual field defects
	Zonisamide	4–6 mg/kg/day	Sedation, metabolic acidosis
	Levetiracetam	10–60 mg/kg/day	Behavior or personality change
	Rufinamide	10–45 mg/kg/day	Sedation, headache
	Lacosamide	1.5–6 mg/kg/day	Dizziness, ataxia, caution with cardiac disease
Neonatal	Phenobarbital	5–6 mg/kg/day	Lethargy, irritability, osteopenia
	Topiramate	6–10 mg/kg/day	Sedation
	Levetiracetam	10–60 mg/kg/day	Sedation
	Pyridoxine	5–10 mg/kg/day divided 3 times a day for at least 3 days	None
Generalized (broad spectrum)	Valproic acid	20–60 mg/kg/day	Tremors, hair loss, thrombocytopenia, weight gain, pancreatitis
	Felbamate	45 mg/kg/day	Insomnia, anorexia, bone marrow aplasia
	Lamotrigine	4–7 mg/kg/day	Dizziness, sedation, rash (eg, Stevens-Johnson syndrome)
	Zonisamide	4–6 mg/kg/day	Sedation, metabolic acidosis
	Levitiracetam	10–60 mg/kg/day	Behavior or personality change
	Rufinamide	10–45 mg/kg/day	Sedation, headache
	Topiramate	6–10 mg/kg/day	Weight loss, sedation, speech disturbance, metabolic acidosis
	Clorazepate dipotassium	0.3–1.5 mg/kg/day	Drowsiness
	Clonazepam	0.01–0.2 mg/kg/day	Drowsiness, ataxia
	Clobazam	0.15–0.5 mg/kg/day	Drowsiness
	Perampanel	0.05–0.2 mg/kg/day	Weight gain, fatigue, nausea, rarely hostility or aggression
Absence	Ethosuximide	30 mg/kg/day	Nausea, hiccups
	Valproic acid	20–60 mg/kg/day	Tremors, hair loss, thrombocytopenia, weight gain
Infantile spasms	Adrenocorticotropic hormone	40 units/m^2/day	Increased appetite, irritability, acne, immunosuppression
	Prednisolone	0.14–2 mg/kg/day or 40–60 mg/day	Increased appetite, irritability, acne, immunosuppression
	Valproic acid	20–60 mg/kg/day	Tremors, hair loss, thrombocytopenia, weight gain
	Vigabatrin	15–50 mg/kg/day	Drowsiness, visual field defects

Anticonvulsants are prescribed based on seizure classification and individual factors. Consideration is given to the risk of recurrence of seizures, particularly prolonged seizures and the physical danger of recurrence. The social stigma of having a seizure at school is significant and outweighs the potential medication side effects. A known structural lesion on imaging or physiologic lesion demonstrated on EEG may also be suggestive of a higher risk for recurrence. The choice of anticonvulsant depends on age, sex, neurologic diagnosis, seizure type or epilepsy syndrome, other conditions or medications, and social factors. The doses and combination of anticonvulsants prescribed for children also depend on a balance of seizure resistance, risk of recurrence, and potential toxicity of medication. The initial goal in an otherwise neurologically intact child might be complete control with a single medication and the minimum toxicity possible. When this goal is not achieved, doses are advanced to an individualized optimal balance of seizure control and tolerated toxicity. In a very disabled nonambulatory child, a goal might be to prevent status epilepticus but tolerate some brief seizures to have reduced medication toxicity.

Levetiracetam has a broad spectrum of efficacy in seizure types, wide dosing range, intravenous availability, and little organ toxicity or interaction with other medications; however, it can cause mild irritable personality changes. Oxcarbazepine and carbamazepine are often recommended for focal seizures. Toxicity of these is generally mild, but adverse events can include gastrointestinal upset, dizziness, and headache. Carbamazepine can cause a flushing syndrome in Asian populations and has been known to aggravate idiopathic generalized and myoclonic epilepsies, including Lennox-Gastaut syndrome, however. Phenytoin is also effective for partial seizure types and can be given intravenously for status epilepticus, but it can worsen absence seizures. Phenobarbital is effective in neonatal seizures but may have deleterious effects on behavior and learning in older children. Pyridoxine, folinic acid, and pyridoxal 5′-phosphate may be successful in resistant neonatal seizures because of cofactor dependencies. Ethosuximide is used for petit mal seizures. Valproic acid is used for more common atypical petit mal seizures but is broadly effective in other seizure disorders that are resistant to other anticonvulsants because it works by several mechanisms. It should be used with caution in females who might conceive because of an increased risk of fetal neural tube defects and offspring learning disabilities and used with caution in infants younger than 2 years who are at higher risk of metabolic disorders. Felbamate is also effective in many epilepsy syndromes that are difficult to manage, although its use has been limited because of the quite small but nevertheless frightening incidence of irreversible severe bone marrow suppression and liver toxicity. Other anticonvulsants, including lamotrigine, vigabatrin, topiramate, lacosamide, zonisamide, rufinamide, clonazepam, clorazepate dipotassium, clobazam, and gabapentin have proven effective. Lamotrigine is useful in partial and primary generalized seizure disorders but may worsen seizures in patients with Dravet syndrome and reduces hormonal birth control efficacy. All sodium channel blocking agents as well as vigabatrin and tiagabine hydrochloride should be avoided in patients with Dravet syndrome. Vigabatrin is useful for managing infantile spasms caused by tuberous sclerosis. Topiramate is effective in the management of partial seizures, generalized seizures, and Lennox-Gastaut syndrome. Rufinamide and clobazam are particularly effective in patients with Lennox-Gastaut syndrome. Cannabidiol has shown promise for use in patients with Dravet and Lennox-Gastaut syndromes. Zonisamide is effective in the management of partial and generalized seizure disorders, and lacosamide is effective in the management of partial seizure disorders. Lacosamide may be used intravenously as well. Clonazepam, clorazepate dipotassium, and clobazam are adjunctive benzodiazepines that are effective in the management of several seizure types. Gabapentin can be useful as an adjunctive agent because of its lack of interaction with other anticonvulsants. Rectal diazepam, a universal antidote for status epilepticus, empowers the family to begin treatment at home before paramedic arrival for a long (>5 minutes) seizure or cluster of seizures.

Periodic monitoring of efficacy and side effects is essential in children who take medication daily on a long-term basis. A log of seizure frequency helps assess medication efficacy. Neurologic symptoms such as sedation and ataxia are the most common side effects, but many others are possible. The perception of symptoms being related to the medication as well as the actual presence of side effects or toxicity contribute to the complex issue of compliance. Serum drug levels are available for some medications and are useful in monitoring compliance, dosage, and the likelihood that symptoms are the result of drug side effects. Compliance is improved if a medication formulation with less frequent dosing can be used. Organ toxicity (ie, bone mineralization, bone marrow blood cell production, liver function, pancreas function) must be considered and monitored with many medications, although routine laboratory testing after a few months on stable doses is rarely necessary. Hypersensitivity reactions and Stevens-Johnson syndrome usually occur within 2 months of beginning the medication. Ethnic variability in drug metabolism and drug interactions can be important and involve the liver cytochrome P-450 system. This variability of the liver cytochrome P-450 system effect includes inducing potential of barbiturates, inhibiting potential of other medications such as erythromycin, and inhibiting detoxification systems that involve carbamazepine metabolism, resulting in acutely high levels and clinical toxicity. New educational problems in a child with epilepsy deserve aggressive evaluation to determine a common etiology of the underlying seizure condition and alternatively for assessing medication toxicity or long-term detrimental effects.

Nonpharmacologic therapeutic options are available for managing refractory epilepsy. Use of the ketogenic diet or the less intense modified Atkins diet has demonstrated success in approximately 50% of cases but requires considerable dietetic knowledge and family commitment. The vagal nerve stimulator delivers a regular electrical stimulus afferently to the central nervous system and allows for an abortive intervention by the caregiver with an external magnet. It is effective in approximately 50% of cases, enabling use of less medication in those patients and allowing a better overall quality of

life. Consideration of intracranial resection is warranted in select patients with epilepsy in childhood. Children with hemispheric seizure-associated syndromes, including Sturge-Weber syndrome, Rasmussen encephalitis, hemimegalencephaly, perinatal hemispheric infarction, catastrophic seizure disorders of early childhood (eg, infantile spasms related to a localized zone of epileptogenic cerebral tissue), and hamartomatous cortex-producing seizures, have benefitted the most often from surgical resection, but patients with refractory partial seizure disorders, including temporal lobe epilepsy, may also be candidates for such treatment. Extensive staged preoperative imaging and physiologic monitoring are necessary for these patients.

With the possible exception of rock climbing, sports participation is generally allowed for children with epilepsy. Swimmers must have individual supervision. Extra supervision is necessary around hot appliances and cooking equipment. Showers are preferable to baths. Attention-deficit/hyperactivity disorder is common in children with epilepsy, and the use of concomitant therapy, including stimulants, should be considered. Because of frequent behavioral and learning disability comorbidities, as well as social stigmatization, patients and their families often benefit from psychological and social therapy as well as support groups. Managing epilepsy often requires much more than just treating seizures.

Prognosis

Approximately two-thirds of children with a tendency for seizure recurrence have a good prognosis for prevention of further recurrence and few or no problems with side effects of medication. They can lead normal lives without handicap. Some of the seizure syndromes with a familial tendency, such as rolandic seizures and typical petit mal seizures, have a good prognosis for control by medication and complete resolution by the teenage years. The etiologic diagnosis is the most important prognostic factor. The type of epilepsy, EEG findings, child's age, difficulty of initial seizure control, and time since the last seizure are also important factors. Compared to seizure syndromes with a familial tendency and typical petit mal seizures, partial complex disorders sometimes have a poorer prognosis for early resolution and may be more resistant to treatment with anticonvulsants. Some seizure types have intrinsically poor prognoses. For example, infantile spasms are prognostically ominous because even in the absence of a metabolic diagnosis, children frequently suffer temporary brain growth and developmental arrest unless the seizures are controlled with medication. Approximately 10% to 25% of children, most often those with generalized symptomatic types of epilepsy, frequent seizures, high anticonvulsant use, and early onset of epilepsy, exhibit some intellectual decline. A small percentage of these patients develop an epileptic encephalopathy and are significantly handicapped. Children with seizures that are resistant to 2 concomitant medications have a much lower chance of responding to a third medication or other drug combinations. Regardless of age, 36% of patients fully respond to the initial antiepileptic drug, 22% respond to the addition of a second drug, only 3% respond to a third drug, and 38% become multidrug resistant. By parental report, 80% of children with active or uncontrolled epilepsy are restricted in their activities because of concern about a seizure occurring during the activity (eg, swimming). These children also are at increased risk for death, with an annual risk of 0.84% (of which 30% are the result of SUDEP), particularly if they have secondary epilepsy.

The individualized decision of when to discontinue medication after successful treatment is often complex. Generally, withdrawal of medications should be considered in most children after 2 years of seizure freedom. The prognosis for recurrence of seizures, parental/caregiver and children's reactions to seizures and the prospect of their recurrence, and social factors (eg, school participation) may all contribute to the decision. In older adolescents, it may be necessary to consider discontinuing driving for a time if medication is to be stopped. Children and parents/caregivers must be aware that none of the prognostic factors, whether considered individually or in combination, is an absolute predictor of seizure recurrence or nonrecurrence in a given child.

CASE RESOLUTION

On evaluation at the emergency department, the seizure was deemed to be a generalized seizure. The previous episodes recalled by the father have characteristics of partial seizures. The tonic-clonic seizure was likely a secondary generalized rather than a primary generalized seizure. The possibility of rolandic seizures is suggested by the circumstances of the prior episodes, drowsiness, facial or oral symptomatology, and family history. This diagnosis was confirmed on EEG. Oxcarbazepine was prescribed. The boy experienced no side effects or seizure recurrences and was able to successfully discontinue the medication 3 years later.

CHAPTER 132

Autism Spectrum Disorder

Robin Steinberg-Epstein, MD

CASE STUDY

The mother of 18-month-old twin boys is concerned because 1 twin is not talking as much as his twin sibling. Both twins are quite active. The mother feels that even though the child is quiet, he is very smart. He likes to figure out how things work. He seems very sensitive to sounds and covers his ears around loud noises. He loves music and even knows which CD his favorite song is on. He will interact with his sibling but does not seem interested in other children.

During the office visit, both boys are quite active. It is difficult to perform an adequate examination because the twin with limited language is crying the entire time. He does not seem to seek out his mother for comfort. Although both children have stranger anxiety, the twin about whom the mother is concerned seems to have extreme stranger anxiety. He appears well otherwise.

Questions

1. What is autism spectrum disorder?
2. How does autism spectrum disorder differ from language delay?
3. How does the physician evaluate a child for autism spectrum disorder?
4. Where can a physician refer a patient with autism spectrum disorder?
5. What types of treatment are available?
6. Should a child suspected of having autism spectrum disorder receive further immunizations?

Autism spectrum disorder (ASD) is characterized by impairments in social communication as well as restrictive, repetitive, and stereotypic behaviors or interests. According to the *Diagnostic and Statistical Manual of Mental Disorders,* 5th Edition (*DSM-5*), a person with ASD must display persistent communication, interaction, and behavioral challenges across multiple contexts. These disturbances must be present early on but may not be apparent until social demand exceeds the limitation. These characteristics must cause significant impairment and cannot be caused by cognitive impairment (Box 132.1). Cognitive impairment is often a comorbidity, however.

This new term, ASD, includes the previous terminology of autistic disorder, Asperger syndrome, and pervasive developmental disorder–not otherwise specified; the term ASD no longer includes Rett syndrome. Although criteria differ somewhat, all these disorders had in common an impairment in social communication and repetitive or unusual interests of varying degrees. These disorders require similar management and treatment, and assessing the level of impairment is somewhat subjective. Therefore, a single term—ASD—best incorporates all those individuals who are significantly affected by its symptomatology.

Box 132.1. Diagnostic Criteria for Autism Spectrum Disorder

- Deficits in social communication and interactions
  - — Social-emotional reciprocity
  - — Nonverbal communication
  - — Developing, maintaining, and understanding relationships
- Preferred patterns of behavior, interests, or activities
  - — Repetitive, stereotypic motor movements, use of objects, or speech
  - — Need for sameness, routines, and patterns of verbal or nonverbal behavior
  - — Fixated interests of abnormal intensity or focus
  - — Increased or decreased reactivity to sensory input or sensory aspects of the environment

Derived from *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition.

Epidemiology

As recently as 1999, the prevalence of ASD was thought to be 1 in 2,500. More recent numbers from the Centers for Disease Control and Prevention published in 2014 cite a prevalence of 1 in 59 children in the United States. The prevalence in Europe, Asia, and North America averages between 1% and 2% of the overall population. Boys are affected approximately 4 times as often as girls, which equates to 1 in every 38 boys. Affected girls are often more impaired than boys, however. Autism is considered the fastest-growing developmental disability. This increase is, in part, the result of an understanding of a broader phenotype.

Clinical Presentation

Autism spectrum disorder is truly a spectrum of social communication deficits. Although a certain set of behaviors defines the disorder, any child may have any combination of the symptoms that result in the same outcome—severe and incapacitating social deficits. Furthermore, the challenges experienced by this population are more than just developmental delays; the behaviors of these individuals are aberrant and odd.

Many children with an ASD have difficulty with eye contact and body posture. Even those who have some eye contact often do not use their eyes to convey a social message. They may look out of the corner of their eyes, focus only on the lips of the speaker, or look only infrequently. In other words, they may make eye contact but at the wrong time. They may talk to others with their bodies facing away from them. They may not gesture to help clarify intention.

Whereas some children have limited communication, some offer too much information. They may be quick to talk to others about things they are interested in but be unable to talk to their conversational partner about that person's own interests. They seem socially insensitive. As younger children, they are often entertained by their own interests for long periods. Some have limited need for relationships, but others desire interaction but do not understand how to initiate or maintain interactions. Although some of these children are nonverbal, some repeat or echo what they hear from movies, television, or nearby conversation. Others seem able to converse but have trouble with social banter. It is important not to be deceived by a child who interacts with others or even gives hugs but only on the child's own terms.

Children with ASD often have a fascination with patterns. The pattern may be in the form of household routines or within a particular subject area. This may manifest in an obsession for sameness and resistance to change or an obsessive need to know everything about a certain topic. Many know all there is to know about such favorite topics as Thomas the Tank Engine or dinosaurs from the Jurassic Period but cannot answer a question such as, "How are you?" or "What is your name?" They may be upset by a road detour or a furniture rearrangement. Some of these children, because of an incredible ability to recognize patterns, can read as early as 2 years of age, even though they can neither speak functionally nor comprehend what they read.

A significant portion of children have difficulty with sensory processing. This takes the form of problems with smells, tastes, sounds, sights, and touch. This symptom may be manifest in the need to taste everything, including nonfood items; covering ears in loud situations; or an inability to tolerate tags in clothing.

A huge variation exists in cognitive ability. The severity of ASD is independent of cognitive ability. Although approximately 25% of those with ASD have intellectual disabilities, many are of normal intelligence and some are gifted.

Parents or caregivers often raise behavioral concerns. It is important to recognize red flags and behaviors that demand further evaluation (Boxes 132.2 and 132.3). That is, certain classic symptoms exist, but the physician must be mindful of the child who is simply unable to connect with others. Physicians should rely on their own instincts. Inconsistent symptoms are the hallmark of this disorder. Some parents or guardians of children with an ASD describe a phenomenon whereby the children are developing normally until 12 to 15 months of age and then suddenly lose skills or stop progressing. This finding is particularly concerning.

Box 132.2. Common Aberrant Behaviors Associated With Autism Spectrum Disorder (ie, Red Flags)

- Decreased eye contact (common but *not* universal)
- Only wants to be cuddled on the child's terms
- Areas of unusual knowledge—recognizes entire alphabet by 2 years of age, all types of dinosaurs by 4 years, names of all Thomas trains, interest in fans or spinning items
- More interested in how things work than with playing
- Unusual sensitivities—oversensitive to hearing, bright lights, shirt tags, new foods, new places
- Smelling or licking nonfood items
- Repeating words instead of answering questions, or answering off topic
- Difficulty interacting with other children
- Plays amongst children, not with them
- Resistance to change, "very independent"
- "In his/her/their own world"
- Lines things up
- Unusual hand movements or jumping when emotional
- Things have to be a certain way
- Odd tone of voice (ie, prosody)
- Increased pain tolerance

Box 132.3. Indications for Referral for Evaluation

- 12 months of age: Not babbling or gesturing (pointing, waving)
- 16 months of age: No single words
- 24 months of age: Absence of 2-word phrases
- Loss of language or social skills at any age

Derived from Filipek PA, Accardo PJ, Baranek GT, et al. The screening and diagnosis of autism spectrum disorders. *J Autism Dev Disord.* 1999;29(6):439–484.

Pathophysiology

Numerous proposed etiologic possibilities for the origins of ASD exist, from the inbreeding of computer "whizzes" to exposure to microwaves. However, no consistent explanation or pattern has emerged. It is known that the structure of the brain is different, but the reason why remains unknown.

Up to 10% of those with ASD have another medical condition that might have led to this disorder (Box 132.4). This leaves 90% of patients without an etiology, however.

Genetics seem to play an important role in the development of ASD. A risk of the disorder among siblings of up to 20% has been reported, which is more than 10 times the risk in the normal population. Family members are more likely to exhibit social deficits, anxiety, or depression than are family members who do not have a relative with the disorder. Several candidate chromosomes have been suggested as being associated with this disorder, but no 1 locus is responsible for this disorder.

It is also important to realize that up to 30% of children with ASD have abnormalities on electroencephalography (EEG). This finding may point to the structural abnormalities in an autistic brain but does not seem to account for the disease itself. The epileptiform changes should be evaluated by a neurologist to determine if

Box 132.4. Medical Conditions Associated With Autism Spectrum Disorder

- Epilepsy
- Fragile X syndrome
- Tuberous sclerosis
- Prader-Willi syndrome
- Visual or auditory impairment syndrome
- Down syndrome (ie, trisomy 21)
- Cerebral palsy
- Neurofibromatosis
- Congenital rubella

medication is indicated. Without an outward expression of seizures, however, many patients do not opt for treatment.

Several environmental markers have also been suggested as being linked to ASD, but most have not proved credible. Major epidemiologic studies within the United States and internationally have examined the roles of vaccinations, diet, and thimerosal preservative in the development of this disorder. None of these studies has found proof to support these theories. Known associations include older paternal age, preterm birth, and jaundice. Several studies have suggested that pollution may play an epigenetic role.

Much of the newer research suggests a fundamental neurobiologic difference in the prefrontal cortex, which likely occurs as the result of abnormal neuronal overgrowth in the first 20 weeks of gestation. This suggests a genetic or epigenetic etiology before birth in 90% of patients with autism.

Children with ASD should undergo routine health maintenance, including all recommended immunizations. No evidence exists linking ASD with immunizations.

Differential Diagnosis

Few entities present with impairment in the same 2 domains as those that are affected by ASD. A limited number of disorders mimic ASD (Box 132.5). However, several disorders exist that commonly occur with ASD that, if not identified, make treatment more difficult (Box 132.6).

Box 132.5. Disorders That May Mimic Autism Spectrum Disorder

- Hearing impairment
- Global developmental delay
- Tourette syndrome and comorbidities
- Selective mutism
- Reactive attachment disorder
- Lead ingestion
- Sensorimotor integration dysfunction
- Severe auditory processing/language deficit
- Severe anxiety
- Severe attention-deficit/hyperactivity disorder
- Brain trauma
- Childhood-onset schizophrenia

Box 132.6. Disorders That Can Occur With Autism Spectrum Disorder

- Tuberous sclerosis
- Congenital blindness
- Global developmental delay
- Chromosomal abnormalities (eg, Down syndrome, fragile X syndrome, Prader-Willi syndrome)
- Phenylketonuria
- Epilepsy
- Elevated lead level
- Congenital infections
- Brain trauma
- Bipolar disorder
- Neurofibromatosis
- Congenital profound hearing loss
- Tourette syndrome
- Landau-Kleffner syndrome
- Inborn errors of metabolism
- Anemia
- In utero exposure to drugs and/or alcohol
- Depression and/or anxiety
- Attention-deficit/hyperactivity disorder

Evaluation

No single diagnostic test, blood or otherwise, can confirm the diagnosis of ASD. Diagnosis is based on history, interaction with the child, and meeting *DSM-5* criteria.

History

Regular developmental surveillance and screening should be part of every well-child evaluation, especially between ages 9 and 30 months. In 2019, the American Academy of Pediatrics recommended that pediatricians conduct developmental and behavioral surveillance during all well child visits, developmental screening at the 9-, 18-, and 30-month visits, and standardized screenings of patients for ASD at 18 and 24 month. Special attention should be given to a child who has a sibling with ASD or a child whose parent or caregiver has expressed concern. Several standardized screening tools can be used, including the Parents' Evaluation of Developmental Status or the Ages and Stages Questionnaire, to identify developmental and social competency skills and concerns. The Modified Checklist for Autism in Toddlers, Revised, with Follow-Up (M-CHAT-R/F) is an excellent autism-specific screening tool with moderate sensitivity and high specificity for use at the 18- and 24-month visits to identify individuals at high risk for ASD. A positive M-CHAT-R/F screening is associated with ASD in 50% of patients and with developmental delay in 90% of patients. These screening tools are quick and easy and can be completed by the parent or caregiver in the waiting area or with minor assistance from office personnel.

For the child with suspected developmental difference, the physician must gather as much information as possible. Thorough birth and medical histories are important in helping to understand if early experiences may have predisposed the child to any deficits. For example, children born preterm are at increased risk for ASD. Monozygotic and dizygotic twins have high concordance. Older fathers or infertility treatments may have a role as well.

Family history is also important, because ASD is presumed to have a genetic contribution and it may be helpful in identifying other etiologies. Understanding family structure is helpful in determining whether abuse, neglect, or maternal depression play a role in the child's delay. It is important to remember, however, that ASD is not caused by poor parenting.

Developmental history is a critically important part of the history. The physician must probe all 4 areas of development: fine motor, gross motor, language, and social development (see Chapter 32). As stated previously, it is expected that the most significant delays will be in language and social interaction; however, delays may be noted in all components of development. Additionally, probing for abnormal behaviors specific to ASD helps distinguish this disorder from others. Box 132.7 contains some suggestions that may help elicit information relevant to a diagnosis of ASD in a toddler; the history should be adjusted based on the age of the child. The physician should always include early language milestones. Children with ASD tend to have *splinter skills*, that is, skills that may be normal or above developmental level for age. The physician should not let these skills distract from probing areas of suspected delay.

Finally, parents/caregivers and physicians often fall victim to common myths and excuses about development because it is not easy for many parents to discuss or admit delays (Box 132.8). These myths, although they may seem plausible, are not substantiated and only serve to further delay onset of intervention.

Physical Examination

A thorough physical examination with special attention directed to the growth parameters, neurologic examination, dysmorphic features, and neurocutaneous stigmata are essential to a complete evaluation. Height, weight, and head circumference should be plotted. Twenty-five percent of children with ASD have a head circumference greater than the 97th percentile. That is not to say that everyone with a large head has ASD, only that it is an associated feature. In utero infections may predispose to a small occipitofrontal circumference, but both a large and a small head circumference have developmental implications for ASD.

Detecting subtle physical signs, such as clinodactyly, simian crease, or a high-arched palate, although not diagnostic, is somewhat helpful in raising suspicion for neurodevelopmental delays. A Wood lamp evaluation may be helpful in uncovering neurocutaneous stigmata.

A series of dysmorphic features, such as a thin upper lip, flat philtrum, and upturned nose, may be suggestive of a syndrome, such as fetal alcohol syndrome. Hypotonia is a common finding among children with ASD but may be suggestive of an inborn error of metabolism. The physician must also check reflexes, because degenerative

Box 132.7. What to Ask

Autism Spectrum Disorder

Questions to Ask Parents/Caregivers

- Does your child seem to hear you? Did your child undergo a hearing test in the neonatal period?
- Does your child make noises? If so, what kind?
- When did your child say his, her, or their first word after "mama" and/or "dada"? Does your child have 2-word phrases?
- Are there any other behaviors that concern you?
- Can your child scribble? Has your child lost any skills? Does your child line things up?
- When did your child first walk? What does your child like to play with?
- Do tags on the back of clothes bother your child?
- Is your child interested in other children? What does your child do upon seeing another child in a park?
- When do you first remember your child pointing with 1 finger?
- Does your child play peekaboo? Will your child try to engage you?
- Does your child talk into a play telephone?
- Does your child eat a variety of foods?
- Does your child turn when you call him, her, or them?

Questions for the Physician to Ask Oneself

- What does this child's autism specific screener show?
- Do any complicating historical factors exist that may predispose this child to a developmental problem?
- Is this merely personality variation, or does this represent delays and aberrant behavior?
- Is this a language delay, or does concern exist for more social or odd behaviors?
- What should be done to evaluate?
- What types of intervention would be helpful?

Box 132.8. Common Excuses for Unusual Behaviors in Children With Suspected Autism Spectrum Disorder[a]

1. We speak 2 languages at home. (By age 3 years in a bilingual home, language should follow a normal progression. Social and unusual behaviors should always follow a normal trajectory.)
2. He is a boy. (This is accounted for in the range of normal.)
3. She is a twin. (If 1 twin has autism spectrum disorder [ASD], the other twin has an increased risk of having ASD or being delayed developmentally.)
4. He is the first child. (There is no evidence that firstborn children speak late.)
5. She is the baby. (There is no evidence that children born last speak late.)
6. He is having a bad day.
7. She watches too much television. (Neglect can result in delays, but these children still need intervention.)

[a] These are *not* reasons to delay evaluation.

disorders (eg, muscular dystrophy) can present with *language delay*, that is, isolated delay in the acquisition and expression of language.

One of the most useful examinations in the office is to simply have a conversation with an older child or play with a younger child. The physician can bring out bubbles and engage in a popping game, watching the child's eyes and observing the child's interaction with the physician and the parent or caregiver. The physician can pretend that the otoscope is a telephone that is ringing and then pick it up, talk briefly, and pass it to the child. The physician should watch the child's response. Does the child play with you, with only the bubbles, or with neither? Does the child display repetitive flapping when excited?

Laboratory Tests

No single laboratory or radiologic evaluation is diagnostic for ASD. The real keys to diagnosis are developmental surveillance, screening, and observation. Some tests are helpful to rule out comorbid conditions, however. If the child has not undergone an audiologic evaluation, that should be done first. However, the physician should not wait for audiology results before referring the patient for help. From a medical perspective, a tiered approach to the workup often is helpful. The first tier includes laboratory studies, such as a chromosomal microarray analysis (eg, comparative genomic hybridization) and a DNA test for fragile X syndrome. A lead level, carnitine profile, plasma homocysteine levels, serum amino acids, urine organic acids, thyroid evaluation, and vision evaluation should be assessed in children with global developmental delay, loss of developmental milestones, or other findings concerning for neurological or developmental disorders. If the symptoms are severe, ammonia, lactate, and pyruvate levels should also be measured. An EEG is appropriate if concern for seizures exists. The results of the newborn screening should also be reviewed. In the absence of specific clinical findings, the yield of these diagnostic studies is anticipated to be low (approximately 7%) but, if positive, may aid in the recognition of a specific comorbidity.

The second tier of tests, if necessary, includes an evaluation for specific rare diseases. Some consideration might be given to chromosomal 15 methylation, methyl CpG-binding protein 2 (in males and females), phosphatase and tensin homolog deleted on chromosome 10, fibroblast karyotype if pigmentary abnormalities are noted, sterol profile, guanidinoacetate urine analysis (only in males), or other associated genetic evaluations. According to current literature, laboratory evaluation for ASD yields an etiology in 15% of patients.

Imaging Studies

Magnetic resonance imaging should be considered for the patient with a history of regression or microcephaly, or in the presence of focal findings suggestive of central nervous system malformations; otherwise, it is considered low yield for detecting any abnormality of diagnostic significance. The child with regression, more significant involvement, or behavior suspicious of a seizure should undergo EEG. Although positron emission tomography and single-photon emission computed tomography show abnormalities, these studies are not sufficiently specific for diagnosis or to direct care. These studies are not warranted in a child with ASD; they are used primarily in the research setting.

Management

Diagnosis of ASD is sometimes challenging, but early diagnosis is critical in changing ultimate outcomes. Waitlists to see specialists and a limit on the number of specialists in this field makes it imperative for the primary care physician to be able to make the diagnosis of significant autism. The primary care physician who makes the diagnosis of ASD in a child who is older than 2 months of age with significant symptoms is correct more than 90% of the time. Because early intervention can have such a vital effect on patient outcomes, the American Academy of Pediatrics has made early diagnosis and intervention, which can reduce the cost of lifelong care by two-thirds, a priority. The diagnosis of ASD is based on the *DSM-5*.

Because children 3 years and older receive services through the local public school district, children younger than 3 years should be referred to other local governmental agencies. Most states have a government-sponsored early intervention program for children up to 3 years of age that is responsible for the evaluation of as well as the behavioral, educational, and therapeutic interventions for children with suspected delays. Such agencies offer comprehensive diagnostic evaluation and placement of eligible children in an intensive intervention program. Therefore, after a hearing test has been completed, referral to such an agency is the next step. On average, it takes 6 months from the time a child is seen in a physician's office to the attainment of such services. Thus, it is important to identify eligible children before age 30 months. Furthermore, such services are covered by private insurance in many states. It is important for primary care physicians to make such referrals.

For children older than 3 years with moderate to severe impairment, the responsibility for evaluation and treatment lies with the local school system, medical insurance, and government-sponsored agency. Even before a child is of school age, the child's local school district is responsible for the evaluation and interventions necessary to implement appropriate remediation. Physicians should verify with local agencies to determine whether such a system exists in their respective state, however. Between ages 3 and 21 years, each child is entitled to a free and appropriate education guaranteed under the federal mandate known as the Individuals with Disabilities Education Act. By law, educational programs should be comprehensive and individualized to the needs of each child. Following the assessment, teachers and other school personnel meet with parents to develop an Individualized Education Program (IEP) for the child.

Most children with ASD require, at minimum, speech and language services, occupational therapy, and social skills training. Many require a 1:1 aide in a mainstream class, and others benefit from special education services in the form of pullout or a special day class. Additional services to augment those provided in school can be given privately. Some states have mandated that medical insurance support these additional necessary services; however, in other states these additional services are the sole responsibility of the parent or caregiver.

Interventions

Autism spectrum disorder is a neurologic condition that can improve with intensive multimodality interventions. This improvement is

slow. No quick solutions, magic medications, or diets exist to "cure" ASD. Behaviors such as impulsive aggression, repetition, resistance to change, and obsession are frequently targeted by systematic interventions. Furthermore, some basic social learning behaviors can be shaped by different types of intervention. Several different techniques based on different psychological principles exist that may be used to help improve the difficulties associated with ASD (Box 132.9). The best studied therapy is known as *applied behavior analysis*, in which a child's behavior is scrutinized by a trained behaviorist and goals and trials are developed to slowly shape appropriate responses. The parent or caregiver is then taught the skills necessary for the desired outcome.

Speech and language services are vital to intervention. The initial goal is to help establish communication. In higher-functioning children who already have established language, this service is vital to the establishment and development of prosocial language, such as eye contact, inferences, understanding jokes, and the more subtle aspects of language. Social skills groups are often used to teach appropriate social responses in a seminaturalistic environment.

Occupational therapy is often necessary to help with fine motor skills and the processing of sensory information. Such therapy can be helpful in easing transitions. Although not much has been published to support the use of occupational therapy for sensory concerns, it is a widely accepted premise that sensory exposure helps children with an over- or undersensitive sensory system.

Special education in the form of an aide, classroom pullout, or special day class often is necessary to help with commonly associated learning difficulties. A child with an ASD may have a full array of learning difficulties. Commonly associated learning difficulties are in reading comprehension, written expression, and auditory comprehension; additionally, a child may have specific math disability.

Under the law, these services should occur in the least restrictive and most appropriate environment.

Box 132.9. Techniques Used in the Management of Autism Spectrum Disorder

Floortime

This intervention uses personal relationships and play in the child's area of interest to draw the child through increasingly complex developmental tasks.

Applied Behavior Analysis

Applied behavior analysis strives to achieve pre-academic skills, such as eye contact, imitation, sitting, and following simple directions using the principles of conditioning and behavioral psychology. In a 1:1 fashion, a child is trained to respond in a predetermined way using a specific curriculum and reinforcers.

Behavior Analysis

This method uses close study of behaviors to determine antecedent triggers and consequences, such as a tantrum. The goal is to substitute acceptable responses, such as using words, and increase rewards for substituted behaviors.

Pivotal Response Treatment

This strategy uses principles of behavior analysis as well as the child's interests and internal drives to motivate with the aim of generalizing the skills from a therapy room to a variety of environments. Children with an autism spectrum disorder often have difficulty performing a previously mastered skill in a new setting.

Picture Exchange Communication System

The Picture Exchange Communication System uses pictures that the nonverbal child can use to show a caregiver what the child wants.

Treatment and Education of Autistic and Related Communication Handicapped Children

The Treatment and Education of Autistic and Related Communication Handicapped Children is a complete program that incorporates the child into a large autism spectrum disorder community. The goal is to promote autonomy; the program uses many methods based on cognitive therapeutic principles.

Social Stories

These are often used as a complementary strategy. These stories describe in detail basic social skills in different scenarios.

Pharmacotherapy

The mainstay for treatment of ASD remains behavioral. Although medications do not seem to help the core symptoms of ASD, almost 2 in 3 children with ASD receive medications for behaviors that, despite intensive behavioral intervention, continue to obstruct progress or become dangerous.

Only 2 drugs have been approved by the US Food and Drug Administration for use in children with ASD. Risperidone and aripiprazole are approved for the agitation associated with this disorder. Other medications may be prescribed for other behaviors seen in children with ASD. The choice to use medication is not simple. The purpose of the medication should be to address emotional or psychological function causing the symptom. The most common medications include selective serotonin reuptake inhibitors and stimulants. However, research and clinical experience indicate that children with ASD are more sensitive to side effects and at lower doses. Therefore, the choice and direction of medication management in this population is often best guided by a developmental-behavioral pediatrician, neurologist, or child psychiatrist (see Chapter 134).

Alternative Treatments

A variety of alternative treatments have been suggested. Secretin injections, dietary restrictions, chelation, high-dose vitamins, antifungal agents, and neuron injections are just some of the interventions considered as part of alternative treatments. Anecdotal improvement has been reported with some of these methods; however, others are dangerous and have resulted in death. None of these methods is considered traditional or the standard of care, because minimal empiric data exist to support their use.

Prognosis

While many children show dramatic improvements with early intervention, others show minimal improvement. Therefore, all children need both early and ongoing intensive interventions to ensure the best possible outcome. Some prognostic indicators, such as IQ, early and intensive interventions, and a supportive family, bode

well. Obtaining an accurate IQ is often challenging. The major determinant of ultimate outcome seems to be progress in a comprehensive, early intervention program for a duration of 2 years before the child reaches age 5 years. Having little or no language by age 6 years is a poor prognostic indicator. Therefore, the goal remains focused on early identification, intensive treatment, and advocacy for children to receive such interventions with ongoing support throughout their preschool and school years.

Intensive early intervention programs have been available only since approximately 1995. Since that time, children with ASD have moved into the mainstream. Despite receiving early intervention, these children continue to have problems with transitions, more complex social interactions, and higher-level organization tasks. Thus, physicians must continue to advocate for and support these families in an ongoing longitudinal manner.

Many adults with ASD continue to require significant support. They may require sheltered living and work environments, safety monitoring, and ongoing medical support. Persons with severe ASD may receive care in group homes.

Another significant proportion of children with ASD attend college, marry, and have children. It is difficult to quantify the number of persons with ASD who achieve these milestones, because the numbers change rapidly, and the true number of children with ASD remains unknown.

CASE RESOLUTION

The child's parent completed an M-CHAT-R/F, and the child scored a 4 (ie, intermediate risk). A follow-up interview confirmed that the risk for ASD was significant, and the child was evaluated by a developmental-behavioral pediatrician and the local governmental agency, where he underwent a comprehensive assessment by a multidisciplinary team. The diagnosis of autism was confirmed, and his brother was noted to have a language delay. Both children were placed in an early intervention program. The primary patient was placed in a 1:1 structured teaching environment for 4 months. After exhibiting significant improvement, he was moved to a therapeutic preschool setting that emphasized generalization of his newly acquired skills, speech therapy, occupational therapy, and social skills. His brother received speech therapy 2 times per week. Both are due to start a regular kindergarten class in the fall, with ongoing speech and social support. The primary patient has been placed on a stimulant medication to control hyperactivity and problems with attention.

CHAPTER 133

Attention-Deficit/ Hyperactivity Disorder

Andrew J. Barnes, MD, MPH, FAAP, and Iris Wagman Borowsky, MD, PhD, FAAP

CASE STUDY

Cody, a 10-year-old boy, has visited a primary care clinic annually for well-child care, seeing a different pediatrician each time. After falling behind his peers in all academic subjects during the first half of fourth grade, his teacher asks his mother to see if Cody's doctor can do anything to help him at school. When the appointment is made, the clinic obtains standardized attention-deficit/hyperactivity disorder (ADHD)–specific behavioral rating scales from Cody's parents and teachers. Before the visit, the pediatrician reviews these rating scales and Cody's medical history. She discovers that at Cody's 6-year well-child visit, a colleague documented, "Likely has ADHD, medication is indicated." The medical records indicate that the family deferred starting stimulant medication and were told to follow up as needed. No further mention of ADHD exists in the record. Cody also has a history of several urgent care and emergency department visits for minor unintentional injuries.

Questions

1. What are the primary symptoms of attention-deficit/hyperactivity disorder? What other conditions should be considered in the differential diagnosis of attention-deficit/hyperactivity disorder?
2. What psychiatric disorders or other neurodevelopmental disabilities commonly coexist with or mimic attention-deficit/hyperactivity disorder?
3. What is the appropriate evaluation of the child with suspected attention-deficit/hyperactivity disorder?
4. What treatment modalities are useful in the management of attention-deficit/hyperactivity disorder?
5. What is the role of primary care in the long-term management of attention-deficit/hyperactivity disorder?

Physicians should initiate a thorough evaluation for attention-deficit/hyperactivity disorder (ADHD) in any child aged 4 to 18 years who exhibits social, academic, or behavioral problems associated with inattention, impulsivity, and hyperactivity. Three types of ADHD are described in the *Diagnostic and Statistical Manual of Mental Disorders,* 5th Edition (*DSM-5*): predominantly inattentive presentation, predominantly hyperactive/impulsive presentation, and combined hyperactive-inattentive presentation. Most children and adolescents with the disorder exhibit symptoms of the combined type. A growing body of evidence suggests that differentiating such subtypes has little bearing on prognosis or management.

The diagnosis of ADHD is based solely on clinical judgment, requiring documentation of sufficiently impairing criteria from the inattentive and/or hyperactive/impulsive domains (Box 133.1). Some symptoms of ADHD must be present before 12 years of age, and several symptoms must persist in at least 2 major contexts of the child's life (eg, home and school) for at least 6 months. These symptoms must be more frequent and severe than those typical in someone of the same developmental age and must impair the child's developmental competence, learning, or social interactions. The symptoms should not be better explained by another condition (eg, anxiety). If impairing symptoms occur at sub-diagnostic levels or are associated with a *DSM-5* exclusionary condition, a diagnosis of ADHD, not otherwise specified, should be made. Treatment, however, is symptomatic and not specific to subtype.

Transient behavioral variations, challenging temperamental features, and problem-level ADHD-like symptoms that are not frankly disordered or sufficiently impairing are better classified using the framework of *The Classification of Child and Adolescent Mental Diagnoses in Primary Care: Diagnostic and Statistical Manual for Primary Care* (DSM-PC). *Child and Adolescent Version* instead of *DSM-5* (eg, "Hyperactive/Impulsive Developmental Variation—Middle Childhood: The child plays active games for long periods. The child may occasionally do things impulsively, particularly when excited"). One advantage of the *DSM-PC* is that it takes into account specific environmental and psychosocial contexts, stressors, and developmental factors that influence children's behavior.

Epidemiology

Attention-deficit/hyperactivity disorder is the most common neurobehavioral disorder in children. An estimated 4% to 12% of school-age children have ADHD, and there exists a 3:1 predominance of boys in community samples. Over the past 2 decades, ADHD diagnoses have increased; it remains unclear whether this represents a true increase in incidence, secular changes in diagnostic criteria and practices, sociocultural bias, or effects of unspecified environmental factors.

Box 133.1. Criteria for Attention-Deficit/ Hyperactivity Disorder

Inattention[a]

- Inadequate attention to detail, makes careless mistakes
- Poor attention
- Poor or inadequate listening
- Does not follow instructions or complete assignments at school, home, or work
- Poor organizational skills
- Dislikes/avoids activities that require concentration
- Loses necessary objects (eg, homework, keys, eyeglasses, mobile telephones)
- Distractable
- Forgetful

Hyperactivity[a]

- Fidgety
- Gets out of seat (cannot sit still)
- Runs about or climbs when not appropriate
- Cannot participate in quiet activity
- Constant motion
- Excessive talking

Impulsivity

- Blurts out answer before question fully posed
- Difficulty taking turns
- Interrupts others

[a] Presence of 6 symptoms for patients age 16 years or younger or presence of 5 symptoms for patients age 17 years or older.

Derived from *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition.

Clinical Presentation

Children with ADHD have problems with selective attention and mental stamina for nonrewarding or nonpreferred activities. They often make careless mistakes or fail to pay attention to details. They may be easily distracted and have difficulty starting tasks and concentrating on tasks long enough to complete them. Stopping a preferred activity also can be problematic, and caregivers often note that their children with ADHD overfocus or "get lost" in their favorite activities, such as video games, drawing, or reading. Difficulties following instructions and organizing tasks and activities are also characteristic of ADHD. Poor impulse control manifests as difficulty waiting one's turn, frequently blurting out responses at inappropriate times, and interrupting or intruding on others. Symptoms of hyperactivity include fidgetiness, excessive talking at inappropriate times, difficulty remaining seated or playing quietly, and subjective feelings of restlessness or impatience in older children and adolescents. Difficulties with social relationships and low frustration tolerance are also common among children with ADHD.

Pathophysiology

The etiology of ADHD is unknown. Interacting genetic, prenatal/perinatal, environmental/psychosocial, and neurologic factors all play a role. Family studies indicate that first-degree relatives of children with ADHD have a risk of ADHD that is 5 times greater than the risk in the general population. Additionally, measures of behavior and attention are more alike in monozygotic twins than in dizygotic twins of the same sex. The most widely confirmed gene association with ADHD is the 7-repeat allele of the D_4 dopamine receptor gene that, although found in approximately 30% of the general population, is found in 50% to 60% of individuals with ADHD. Prenatal and perinatal risk factors that have been associated with ADHD include in utero exposure to alcohol or cigarettes; extreme preterm birth; brain injury or stroke; and severe early deprivation, neglect, and maltreatment.

Currently, ADHD is conceptualized as a chronic neurodevelopmental-behavioral condition. Patients with frontal lobe lesions have long been known to exhibit severe and intractable inattention, hyperactivity, behavioral disinhibition, and impulsivity. Recent neurodevelopmental research suggests that ADHD is associated with developmental differences in specific frontal and prefrontal regions of the brain involved in executive functions, including organizing, planning, sequencing, selective attention, impulse inhibition, the ability to stick to a plan yet change it as needed (ie, set maintenance), the ability to self-talk through internal rules, and working memory. Several recent studies, some longitudinal, show delayed maturation (ie, myelination delayed) and abnormal activation/inactivation of critical prefrontal circuits and frontostriatal reward-motivation circuits in children and adolescents with ADHD compared with control subjects. Dopamine and norepinephrine are involved in neurotransmission within these brain pathways, and the prefrontal cortex is rich in catecholamine receptors. Psychostimulants can improve ADHD symptoms by increasing the availability of these neurotransmitters in the brain, thereby improving efficiency in attention and motivation circuits. Stimulants seem to primarily increase activity in key areas of the striatum, such as the ventral tegmental area, in turn activating the prefrontal cortex and executive functions.

Differential Diagnosis

The symptoms of ADHD (eg, hyperactivity, inattention, distractibility) can be seen in a variety of other conditions (Box 133.2). Sensory deficits, especially hearing impairment, can imitate attention deficits. Attention-deficit/hyperactivity disorder symptoms are often a component of autism spectrum disorder and other neurodevelopmental conditions, such as neurofibromatosis 1 or Tourette syndrome, co-occurring with typical features of the respective diagnoses, such as impaired social communication in children with autism spectrum disorder. Lead and other heavy metals have dose-related detrimental effects on behavior and development; likewise, chronic iron deficiency can result in or mimic ADHD. Seizure disorders, such as petit mal (ie, absence) or partial complex seizures, may cause altered attention or behavioral changes that can mimic ADHD. Other neurologic disorders that can present with symptoms of ADHD include Wilson disease and adrenoleukodystrophy; however, focal and often progressive neurologic deficits of acute to subacute onset are the hallmarks of these rare conditions, as opposed to the more soft and static neurologic signs of ADHD. Certain medications, such as high-dose

Box 133.2. Differential Diagnosis of Attention-Deficit/Hyperactivity Disorder

- Developmental delay or intellectual disorder
- Specific learning disorder
- Speech and language disorder
- Sleep disorder/apnea
- Sensory deficiencies (eg, hearing or vision impairment)
- Autism spectrum disorder
- Seizure disorder
- Neurogenetic syndromes (eg, neurofibromatosis 1)
- White matter disorder (eg, Wilson disease)
- Iron deficiency
- Environmental toxins (eg, lead)
- Side effects of medication (eg, phenobarbital)
- Hyperthyroidism
- Congenital infection
- In utero exposure to drugs or alcohol
- Previous brain insult (eg, stroke, trauma, infection)
- Severe family or social stresses
- Temperamental variation
- Psychiatric disorders
  - — Conduct disorder
  - — Oppositional disorder
  - — Anxiety disorders
  - — Affective disorders (eg, depression, bipolar illness)
  - — Personality disorders (eg, aggression, antisocial behavior)
  - — Substance abuse

corticosteroids, phenobarbital, and theophylline, may cause ADHD-like mental status effects, as can recreational drugs of abuse, including inhalants and marijuana. Hyperthyroidism can cause the hyperactive symptoms of ADHD, but other signs of increased metabolism, such as elevated heart rate, tremors, or weight loss, should be apparent. Exposure to alcohol or drugs in utero has been associated with subtle difficulties with learning and attention as the child develops. Congenital infections, central nervous system infections in early childhood, and traumatic brain injuries may produce behaviors similar to those that occur with ADHD. Sleep disorders, especially sleep apnea, can cause severe behavioral problems that often resolve after definitive treatment of the underlying sleep condition. Severe or chronic psychosocial-environmental stressors, such as bullying, marital discord, unemployment, poverty, homelessness, trauma/maltreatment, substance abuse, and ineffective parenting (eg, overly permissive, overly harsh), can also masquerade as, co-occur with, or exacerbate ADHD.

Children with ADHD have an increased prevalence of co-occurring pathology, which can magnify or overshadow the core symptoms of the disorder. Such pathology includes oppositional defiant disorder (35%), conduct disorder (26%), depressive disorders (18%), anxiety disorders (26%), Tourette syndrome and tics, sleep disorders (especially insomnia), fine motor delay or developmental coordination disorder, speech and language disorders, and specific learning disorders of reading, mathematics, and/or written expression. In adolescents and young adults, aggression, delinquency, and other antisocial behaviors, as well as substance abuse, often are seen together with untreated or undertreated ADHD. Children with ADHD and co-occurring conditions are well served by primary care physicians working within a multidisciplinary context, which may include developmental-behavioral or neurodevelopmental pediatricians, child and adolescent psychiatrists, child neurologists, psychologists, and therapists.

Evaluation

Children and adolescents with symptoms of inattention, hyperactivity, academic or social underachievement, or impulsivity should be evaluated first by a primary care physician, ideally one with whom the child has enjoyed continuity of care, rapport, and a strong therapeutic alliance. A complete evaluation of this nature is best accomplished with plenty of time for face-to-face review of records and a comprehensive history and physical examination; 90 to 120 minutes is a suggested minimum amount of time to do this effectively and correctly. Typically, it is necessary to schedule several appointments over the course of days or weeks.

History

The diagnostic evaluation of ADHD should begin with multiple informants (eg, caregiver[s], child, sibling[s]) giving a comprehensive medical history that includes details of the child's problem behaviors, antecedents, and outcomes and consequences (Box 133.3). The physician should learn how these informants perceive and cope with the child's behavioral problems and, in turn, how the child responds. Social/family stresses and the home and school environments should be described and evaluated and school reports and report cards reviewed. Interviewing the child alone provides an opportunity to better understand the child's own thoughts, feelings, insight, judgment, self-image, and developmental status; however, children generally have poor insight into their ADHD symptoms and generally are not considered reliable informants for *DSM-5* ADHD symptoms. Interviewing caregivers alone and talking with teachers by telephone before or after the visit can be quite helpful and alleviate some of the burden on the child of what is often initially a problem-oriented discussion about him, her, or them. The physician should inquire about the child's difficulties, developmental strengths and competencies, adaptive strategies, stress management skills, self-regulation, protective factors, and adjustment. Other important information includes developmental history (and for older children academic history, which might include school report cards or other formal assessments), family history, and sleep and diet history.

The history should cover all *DSM-5* criteria (Box 133.1). Parents/caregivers and teachers may report the child's behaviors using an ADHD-specific questionnaire or rating scale (eg, *National Institute for Children's Health Quality [NICHQ] Vanderbilt Assessment Scales*), which can be found in the American Academy of Pediatrics (AAP) publication *Caring for Children with ADHD: A Resource Toolkit for Clinicians.* Non–ADHD-specific developmental screening tools do

Box 133.3. What to Ask

Screening for Attention-Deficit/Hyperactivity Disorder

- History of presenting complaint (from multiple informants)
  - What concerns do you have about the child's development, behavior, or learning?
  - How is the child doing in school academically and socially?
  - Is the child happy in school?
  - Has the child been held back in any grade, suspended, dropped out, or considered dropping out?
  - How often does the child have problems completing home chores, class work, or homework?
  - How often does the child have major problems controlling his or her behavior at home, in school, or with friends?
  - How often is behavior management, self-regulation, or discipline difficult at home or school?
  - What are the antecedents and consequences for problem behaviors at home and school? What discipline techniques have been tried, and what effects did each have?
- Perinatal, developmental, academic, and medical history
- Psychological history and previous treatments
- Social and environmental history
- Family history, with particular focus on immediate family attention-deficit/hyperactivity disorder, school problems, developmental delays, conduct problems, and cardiac, musculoskeletal, neurologic, or psychiatric conditions

not replace this type of comprehensive ADHD assessment because their sensitivity and specificity for ADHD are inadequate. For younger children (aged 4–7 years), few validated screening tools exist (eg, *Conners Comprehensive Behavior Rating Scales*, *ADHD Rating Scale-IV*). Questionnaires can suggest a diagnosis but are insufficient to confirm a diagnosis; only clinical interview and observation can definitively confirm or rule out ADHD.

The physician should evaluate for coexisting conditions that would warrant further investigation. Broad screening tools, such as the Child Behavior Checklist; Behavior Assessment System for Children, 2nd Edition; Strengths & Difficulties Questionnaires; or Pediatric Symptom Checklist, can be useful in this endeavor. For example, frequent sadness or isolation is suggestive of depression, and persistent negative, hostile, and defiant behavior toward authority is suggestive of oppositional defiant disorder. The AAP toolkit for clinicians includes a scale specific to ADHD behaviors and a broader scale for possible coexisting conditions.

Physical Examination

The child's weight, height, and head circumference should be plotted on a growth curve and the pattern of growth evaluated; pubertal status should be recorded. The child should be examined for congenital anomalies, syndromic stigmata, or dysmorphic features, such as fetal alcohol facies or café au lait skin macules. A cardiac examination should document pulses and heart sounds. A musculoskeletal evaluation should document bulk, strength, tone, gait, station, and fine and gross motor coordination; a neurologic examination should include assessment of the cranial nerves; sensation, including hearing and vision; balance and proprioception; and repetitive movements, tics, or tremors. The psychiatric and behavioral status examination should include an assessment of parent/caregiver-child interactions and the child's temperament, mental status, affect, mood, insight, judgment, social-emotional reciprocity, joint attention, speech/language and communication, memory, fund of knowledge, and thought content and processes.

Observing the child's behavior during the office visit is crucial, with the caveat that many children with ADHD do not appear grossly hyperactive or inattentive in the office. Nevertheless, interaction between the child and the parents or caregivers should be observed and documented. The physician should note how the child deals with complex parental and examiner instructions, directives, and questions and how parents or caregivers respond to any misbehavior. Does the child cooperate and comply with the examination, and does the child seem motivated to change? How well does the child relate to adults? The physician should observe the child playing (eg, drawing, playing with toys) and note the child's organization of activities, attention span, distractibility, impulse control, and motor activity.

Laboratory Tests

Diagnostic tests, such as specific neuropsychological or psychiatric metrics (eg, IQ tests), are not indicated for initial ADHD evaluations and should be guided by selected findings on the history and physical examination. Psychometric testing or standardized school district tests may show that a discrepancy exists between the child's raw abilities (eg, IQ) and academic progress in 1 or more areas (eg, achievement scores, grades); in such a case, a referral for psychoeducational testing to rule out specific learning disabilities is indicated. If indicated, the child should be referred for further evaluation of speech, hearing, and vision. Similarly, blood tests, such as hematocrit, lead level, and thyroid hormone are indicated only in the setting of relevant signs or symptoms. Additionally, computerized continuous performance tasks designed to measure vigilance or distractibility have low sensitivity and specificity and do not adequately differentiate children with ADHD from control subjects.

Currently, brain imaging (eg, magnetic resonance imaging, positron emission tomography) has no role in the evaluation of ADHD. Despite the utility of such measures in population-level studies, they cannot yet accurately differentiate between the brains of individuals with and without ADHD. Electroencephalography or neurologic consultation is indicated only if absence or partial complex seizures are suspected based on the history or physical examination.

Management

Attention-deficit/hyperactivity disorder is a chronic condition; thus, management of it must be multimodal, continuous, and longitudinal. Because of its chronicity, ADHD is a special health care need that should be managed within a medical home model. Frequent

follow-up—at least quarterly—and consistent management is the key to sustaining the benefits of behavioral and pharmacologic treatments for ADHD. Family education should emphasize the strengths of children and families and address parental/caregiver concerns; additionally, physicians should foster a close working relationship between families and their children's school systems. Families should be aware that children with untreated or undertreated ADHD often experience functional impairments in academic achievement, self-esteem, social skills, peer status, and family relationships; more unintentional injuries; and above-average use of emergency departments. The physician can ease parents' or caregivers' guilt by explaining the neurodevelopmental basis of ADHD and assuring that ADHD is not the result of insufficient parenting. Children who discover that their problems are explained by a medical condition may feel that a heavy burden has been lifted from their shoulders. However, parents/caregivers and children may find it difficult to accept that the child has a chronic disorder. Support groups and parent/caregiver training through organizations such as Children and Adults with Attention-Deficit/Hyperactivity Disorder (www.chadd.org) may be helpful for families. Physicians should work together with the child, family, and school personnel to specify appropriate target outcomes. Parents and school personnel should then monitor the child for target behaviors and adverse effects. If target outcomes are not met, the physician should reevaluate the initial diagnosis, the use of available treatments, adherence to the plan, and the potential for coexisting conditions.

Behavior Management

Behavior management should be the first-line treatment for preschool-age children with ADHD. Behavioral treatment may also be effective for older children, particularly those with anxiety or disruptive or oppositional problems. Recent studies suggest that initial treatment with behavioral modification therapy (also known as behavioral parent training) is generally more beneficial and more cost-effective than beginning with medication therapy for children ages 5 through 12 years. The goals of behavior management are to modify the child's physical and social environment at home and school to influence positive behavioral change. Behavioral modification techniques include rewards for the target outcome behaviors (eg, verbal praise; hugs; points or stars on a chart that can be traded for material objects or a desired activity, such as a game or special time with a parent or caregiver) and punishments for unacceptable behaviors (eg, time-out, loss of a privilege, extra chores, reduction in allowance). Acceptable and unacceptable behaviors should be clearly defined and measurable, and rewards and punishments should be spelled out in a contract drawn up with input from the child. The strongest behavioral interventions follow immediately after a behavior (eg, immediate praise when a child follows a command after the first time it was given). If rewards or punishments are used over time, parents/caregivers and teachers must be creative in periodically varying the rewards and penalties. Management of overactive children who have difficulty focusing attention, following rules, and controlling impulses can be challenging for parents/caregivers and teachers. The best results come from praising and reinforcing positive behaviors and ignoring negative behaviors unless the latter are dangerous or intolerable. Using praising and ignoring in combination can be quite successful. Parent or caregiver commands should be clear and countable, such as, "You need to go upstairs to brush your teeth before the egg timer goes off in 3 minutes." Because children with ADHD can have difficulty carrying out multistep commands, it is best to set them up for success by giving clear, doable, single-step commands. Behavior management in combination with medication management can be extremely effective. Potential benefits of behavioral therapy when used concurrently with medication include improved scores on some academic measures, improved behavior, and decreased anxiety symptoms. Approaches that target executive function training and cognitive-emotional self-regulation may also be useful adjuncts. Interventions such as play therapy, psychotherapy, and cognitive therapy have no documented efficacy in managing core ADHD symptoms; however, they may be indicated for common co-occurring conditions, such as anxiety, conduct disorder, and depression.

Educational Interventions

The pediatrician can improve the child's educational experience by contacting the child's teachers and even attending school conferences and special education meetings. Although most children with ADHD can be accommodated in the regular classroom, special education in a smaller, more focused setting may be indicated for the child with behavioral or academic difficulties.

Teachers can use specific strategies to help children with ADHD focus their attention and follow directions in the classroom (Box 133.4). Behavioral therapy should be integrated into the classroom, focusing on a child's strengths and minimizing stigma. Teachers and caregivers who are most successful in working with children with ADHD are able to set firm limits and discipline children without anger or frustration, while at the same time remaining flexible enough to recognize when a change in tactics or even "rolling with it" is necessary. Caregivers of children with ADHD can request needed classroom accommodations through Section 504 of the Americans with Disabilities Act of 1990, and children whose ADHD symptoms cause significant learning deficits may qualify for an Individual Education Program through the Individuals with Disabilities Education Act. A letter from a primary care physician documenting a child's health impairments, developmental risks, and academic limitations attributable to ADHD can have a considerable effect in helping to ease this process for families and schools. Preschool-age children with ADHD should be referred to early intervention services in their school district to see if they qualify for educational services that would help prepare them for kindergarten entry.

Because children with ADHD are easily provoked into misbehavior and are prone to clashes with peers, they can also benefit from closer supervision in unstructured school areas, such as the playground, cafeteria, halls, and school bus. Programs designed to improve social competence and peer relationships (eg, group social skills training, therapeutic recreational activities) may also be helpful.

Box 133.4. Strategies for Managing the Behaviors of Children with Attention-Deficit/Hyperactivity Disorder in the Classroom

- Seat children where distractions are minimized and where teachers can see how and when children are paying attention.
- Cue children discretely or nonverbally to remind them to refocus their attention.
- Give clear, succinct, 1- to 2-step directions, and repeat them frequently and patiently.
- Break up work periods by allowing children to get up and move around (eg, handing out papers, cleaning blackboard or whiteboard).

Box 133.5. Stimulant Medications for Use in Managing Attention-Deficit/Hyperactivity Disorder[a]

Methylphenidate Hydrochloride

- Short-acting
  - — Pill: Ritalin, Methylin, Focalin
  - — Chewable: methylphenidate hydrochloride chewable
  - — Liquid: Methylin solution
- Intermediate-acting
  - — Pill: Ritalin SR, Metadate ER, Methylin ER
  - — Chewable: QuilliChew ER
- Long-acting/extended release
  - — Pill: Apetensio XR, Concerta, Metadate CD, Ritalin LA, Focalin XR
  - — Chewable or dissolvable: Cotempla XR-ODT
  - — Liquid: Quillivant XR
  - — Transdermal: Daytrana

Amphetamine

- Short-acting
  - — Pill: Dexedrine, Dextrostat, Desoxyn, Evekeo, Zenzedi
  - — Liquid: ProCentra
- Intermediate-acting
  - — Pill: Adderall, Dexedrine Spansule
- Long-acting/extended release
  - — Pill: Adderall XR, Vyvanse
  - — Liquid: Dyanavel XR
  - — Dissolvable: Adzenys XR-ODT

[a] Short-acting (3–6 hours), intermediate-acting (6–8 hours), and long-acting (10–12+ hours).

Pharmacotherapy

Research has shown that psychostimulant medication with and without behavioral therapy is efficacious in reducing the core symptoms of ADHD. Furthermore, some evidence exists that these effects translate into an increased ability to follow rules as well as improved classroom behavior and improved relationships with peers and parents or caregivers; the effects on higher-order executive functions are less predictable, however. The effects of stimulant medication on learning are not well studied. Caution should be used when treating children younger than 5 years or weighing less than 20 kg (<44.1 lb) with stimulant medication, because many pharmaceutical stimulant preparations have narrower therapeutic windows and more adverse effects on a per-kilogram basis for children of smaller stature. However, for preschool-age children without access to behavioral treatment or with frequent dangerous impulsive behaviors, methylphenidate hydrochloride has been well-studied in randomized controlled trials and can be considered first-line treatment if the physician believes that the benefits outweigh the risks.

Psychostimulant medications are the most commonly used agents for ADHD and have by far the most evidence-based research to support their use. Currently available stimulants include short-acting (3–6 hours), intermediate-acting (6–8 hours), and long-acting (10–12+ hours) formulations of methylphenidate hydrochloride and amphetamines (Box 133.5). Studies have found few, if any, differences between the efficacy of methylphenidate hydrochloride and amphetamine, but some children will respond better to, or have fewer side effects with, 1 or the other.

Stimulants affect behaviors within 30 to 60 minutes and affect attention (eg, for a school subject such as math) within 1.5 hours after administration. There is little evidence of tolerance to stimulants over time, but short-term tolerance occurs so that blood levels must remain therapeutic during the day to maintain efficacy. Therefore, it is best to use long-acting stimulants that eliminate the need to take medication at school. In addition, the effect of long-acting stimulants may persist during after-school homework time. A transdermal delivery system and liquid formulations are available for some stimulants.

The most common side effects of stimulant medications are decreased appetite, stomachache, headache, delayed sleep onset, and jitteriness; side effects occur in 4% to 10% of children. Less common side effects include severe emotional lability/sadness or agitation, transient rebound irritability or hyperactivity (as the medication wears off), delusions or mania, and hallucinations (especially somatic creepy-crawly feelings). Transient motor tics may occur while on the medication, or an existing chronic tic or Tourette syndrome may be exacerbated or unmasked. At higher doses, stimulants can negatively influence height velocity and may slightly decrease predicted adult height. Although dosing of stimulant medication is based on individual variation in response, researchers have found that children generally do better on a maximized tolerable dose of stimulant medications, which is body-weight dependent, rather than the lowest dose that shows a clinical effect. Thus, the best stimulant dose for an individual child is the dose that produces near-complete symptom remission while producing acceptable side effects (eg, appetite suppression is usually tolerable, whereas growth suppression is not). For this reason, it is recommended that physicians do a controlled open-label titration trial of multiple dosages of a single agent using a systematic method. For example, a physician might use either long-acting methylphenidate hydrochloride in 18-, 36-, and 54-mg dosages or long-acting amphetamine in 10-, 20-, and 30-mg dosages in 1-week blocks, with teacher- and parent-/caregiver-completed *DSM-PC* based rating scales (eg, *NICHQ Vanderbilt Assessment Scales*) at the end of each week. The physician can then use these scales to develop a medication management plan with the family. Published guidelines and algorithms, such as those from the AAP, can aid the physician in this regard.

After the medication dosage is stable and helpful, often after 2 to 4 visits over 1 to 2 months, follow-up should occur at least every 3 to 4 months, with particular attention to emerging developmental competencies, self-mastery, and improvement in targeted goal behaviors. Such visits should minimally include an interim history, weight, height, blood pressure, and scales of clinical response from caregivers and teachers.

If a particular stimulant does not produce symptom remission at all or does so only with severe or intolerable adverse effects, the physician should systematically try 1 or 2 other stimulants, because 70% to 80% of children achieve complete remission of symptoms in this manner. If 2 or 3 psychostimulants are not effective or produce unacceptable or intolerable side effects, other medications can be used. Atomoxetine hydrochloride (Strattera) is a nonstimulant medication that selectively inhibits the norepinephrine transporter. It is approved for children older than 6 years, has once-daily dosing, should be titrated to an effective weight-based dose, and often takes 1 to 6 weeks to produce effects; adverse effects can include gastrointestinal upset and mood irritability. Alpha$_2$-agonists, such as clonidine hydrochloride (Catapres, Kapvay) and guanfacine hydrochloride (Tenex, Intuniv), are often useful as adjuncts for children with poorly controlled hyperactivity/impulsivity or comorbid tics, although few children with ADHD achieve adequate symptom remission on α_2-agonist monotherapy. Tricyclic antidepressants, selective norepinephrine reuptake inhibitors, or bupropion hydrochloride can have positive effects on ADHD symptoms for some children, although these medications are rarely used as monotherapy and are typically fourth-line agents. Pemoline (eg, Cylert) is generally not used because of the potential for fatal hepatotoxicity and is no longer manufactured as of 2005. Similarly, generic pemoline is no longer being manufactured. Modafinil, mood stabilizers, antiepileptic agents, and atypical antipsychotic agents are generally not indicated in the management of ADHD in the primary care setting.

Complementary and alternative medicines, such as vitamins, dietary restrictions, and occupational therapy or sensory integration, are used by 54% of parents/caregivers, but only 11% discuss these with their child's clinician. Primary care physicians are challenged to help families safely navigate the limited evidence available on the risks and benefits of such therapies. For example, melatonin is safe and often helpful for comorbid sleep disorders prevalent in children with ADHD, and eliminating artificial colors from the diet may help children who are sensitive to the effects of those artificial colors on their activity level. Some popular holistic approaches, such as behavioral optometry and the Feingold elimination diet, have either no evidence to support them or have evidence indicating that they should not be used. Finally, although neurobehavioral toxicity may be associated with low doses of various environmental toxins, particularly in young children, pediatricians are encouraged to emphasize primary prevention; chelation has no role in this context.

Prognosis

Attention-deficit/hyperactivity disorder is a chronic condition, persisting into adolescence and adulthood in approximately two-thirds of affected children. Children and adolescents with ADHD can succeed in school, at home, and with their peers when provided longitudinal, comprehensive care within a medical home. Biweekly to monthly visits are recommended during the initial phase of assessment and management as well as whenever medications or therapies are changed. Thereafter, quarterly visits (or more frequently as indicated) are ideal because more frequent follow-up is associated with improved long-term outcomes. Gathering information in an ongoing fashion from multiple informants is a critical part of such follow-up (eg, periodic ADHD symptoms checklists from teachers). Primary care for children and youth with ADHD and their families can be enhanced through clinical systems improvements, such as integrated behavioral health, care coordination, and rapid access for patients with behavioral crises.

Overall, adults whose childhood ADHD went untreated or undertreated complete less schooling, hold lower-ranking occupations, have lower self-esteem and more social-skill deficits, and exhibit more antisocial behavior and alcohol and drug abuse. High-quality health care can improve and possibly reduce sociodemographic disparities in these outcomes for youth with ADHD. Having ADHD does not preclude attaining high educational and vocational goals, and some adults who had childhood ADHD no longer meet full *DSM-5* criteria. Typically, hyperactivity greatly diminishes or resolves in high school or early adulthood; some young adults experience a bothersome sense of inner restlessness. Attention problems and impulsivity may continue or worsen, to varying degrees. Adults with ADHD may choose occupations that match their strengths and minimize limitations (eg, on-the-road salesperson vs desk-job accountant). Although up to 50% of adults with ADHD choose to continue medication, others function well without medication; many continue to engage in psychological therapies to help manage daily life tasks, such as money management, and/or for co-occurring conditions, such as anxiety.

CASE RESOLUTION

Cody's primary care clinic reorganized its system of care to leverage the core concepts of the medical home to improve care for children with chronic conditions, including ADHD. One of the clinic's nurses, Karen, has been trained to coordinate referrals to behavioral health and other specialists as indicated, communicate and coordinate care with schools and community services, and monitor adherence and response to treatments.

During Cody's visit, the pediatrician confirms the diagnosis of ADHD and probable comorbid anxiety using AAP clinical practice guidelines and standardized criteria. She educates Cody and his family about multimodal evidence-based interventions for these conditions and introduces the family to Karen and the medical home model of care. Karen follows up with the family by telephone 1 week later as planned and learns that they are reluctant to start Cody on any medicine. She guides Cody's parents to voice their preferences and cultural perspectives on possible interventions and assists them in making another appointment with the same pediatrician, thereby ensuring continuity of care. At the next visit, the pediatrician uses motivational interviewing to help the family find agreement on a watchful waiting approach with close, continuous school and home follow-up by Karen and at least quarterly visits with the same pediatrician. One month later, after a behavioral crisis at school, Cody's parents request an urgent appointment with same-day access. The pediatrician reviews recent parent and teacher behavioral rating scales at the point of care (gathered by Karen the week prior) and reiterates the available first-line treatment options. The family agrees to pursue an open titration trial of stimulant medication for ADHD symptoms and referral to a therapist who is familiar with behavioral parent training, for evaluation and possible treatment of the anxiety symptoms. Another clinic visit is scheduled in 1 month, and meanwhile, Karen continues to follow up weekly with Cody's parents, teachers, and therapists.

CHAPTER 134

Psychopharmacology in Children

Robin Steinberg-Epstein, MD, and Nisha Warikoo, MD

CASE STUDY

An 8-year-old girl has been diagnosed with high-functioning autism spectrum disorder. The local developmental-behavioral pediatrician has recommended treating her anxiety and inattention with atomoxetine hydrochloride. The girl's mother is quite hesitant to do so. She trusts you, however, and wants your opinion.

Questions

1. What is the means by which the safety and appropriateness of psychotropic medications is assessed?
2. What type blood tests are used to maximize safe administration and how often are they performed?
3. What factors should be considered when placing a child on psychotropic medications?
4. What are the usual side effects of commonly used psychotropic medications?

Psychopharmacologic agents are being used with increased frequency in the pediatric population. Approximately 50% of children and adolescents will, at some point before age 18 years, meet criteria for a psychiatric diagnosis. Almost 25% of children will have substantial impairment as a result of those symptoms. Unlike antibiotics or other medications used in children, psychopharmacologic agents are used daily and for extended periods. Furthermore, it is important to recognize the dearth of evidence-based information supporting the use of many medications in children, including psychotropic medications. Therefore, many of these medications are used in an off-label fashion. The medical community must rely on published data (often in adult subjects), clinical experience, and expert consensus to guide medication choice, dose, and management. This often provokes parental anxiety and sparks numerous concerns from families who do not understand that the US Food and Drug Administration (FDA) label limits the claims a manufacturer can make but does not limit a physician's use of medications. Furthermore, families are often anxious, because physicians rely almost exclusively on history and structured behavioral observation, which is the most important "test" for most of these disorders. Unfortunately, the United States has a shortage of pediatric subspecialists trained to choose, monitor, and manage these medications for children. Pediatricians often serve as the first point of contact with families. In most cases, many months may elapse before families are able to see a child and adolescent psychiatrist for diagnostic evaluation and medication management. It is, therefore, necessary for pediatricians to be familiar with the common psychiatric conditions, different classes of psychotropic medications, and controversies facing families of affected children.

Pediatricians need to understand the principles guiding the use of these medications and become familiar with some of the more frequently used psychopharmacologic agents. The most used classes of medication in children include stimulants, selective serotonin reuptake inhibitors (SSRIs), selective norepinephrine reuptake inhibitors (SNRIs) and atypical antipsychotics, also known as serotonin-dopamine antagonists (SDAs). This information can also be useful in helping families navigate this confusing maze.

The decision to use psychopharmacologic agents should be made only after obtaining a comprehensive history as well as a physical and mental status examination and making an accurate diagnosis. It is imperative to obtain collateral information from parents or caregivers, school, and/or therapists. Rating scales can be used as screening tools, as tools for establishing a baseline, and for monitoring progress and treatment response. For common psychiatric conditions, such as depression and anxiety, referral to therapy is indicated. If the symptoms and associated impairments are moderate or severe, however, medication management is necessary, often in addition to therapy. Medications should be an integral part of a comprehensive treatment program that addresses the academic, behavioral, medical, and developmental needs of the child. The decision to place a child on any agent should be based on significant dysfunction as well as discussion and full disclosure of potential risks and benefits with the parents or caregivers and the child. A medication trial, once undertaken, should be carefully monitored, methodically addressing adverse events and effectiveness. Generally, it is best to change 1 agent or dose at a time, followed by structured observation (eg, rating scale[s]) to determine the effect of the change. Therefore, a physician usually begins with monotherapy, optimizes the dose over

the recommended period of time, and assesses risks and benefits before developing a more complex regimen. Such a trial necessitates frequent visits and discussion with the administering physician. Current scientific information and clinical experience indicate that the use of psychopharmacologic agents in young children (<5 years) should be reserved for extraordinary circumstances.

Children are not little adults. Pharmacokinetics in children is affected by increased rates of metabolism in their relatively larger livers, a faster glomerular filtration rate, and variable fatty tissues. Some children, therefore, require a dose larger than that used in adults. Conversely, perhaps because of size, fat distribution, and other explanations, a much smaller, and seemingly ineffective, dose may be sufficient. In general, it is recommended to start low and go slow to prevent adverse effects of medication. For most agents, little correlation exists between blood level and treatment response. Furthermore, some medications have a duration of effect that well exceeds the half-life (eg, atomoxetine hydrochloride); however, with other medications (eg, stimulants) the effect diminishes despite a significant level of the agent in the blood. Additionally, for most agents (eg, stimulants, SDAs), no correlation with milligrams per kilogram exists. Frequent clinical monitoring and communication with parents/caregivers and family and often with teachers and therapists as well are vital to understanding response to medication, tolerance, and treatment adherence.

Psychostimulants

Psychostimulants are the most studied psychotropic medications used in pediatrics (see Chapter 133). These medications are used to manage the hyperactivity, inattention, and impulsivity that occur with attention-deficit/hyperactivity disorder (ADHD) and disturbances of attention that occur in other disorders (eg, autism spectrum disorder [ASD], traumatic brain injury, depression). Stimulants are also used in the management of narcolepsy. During the past decade, many new delivery systems have been developed with differing durations of action, which help to cater to the specific lifestyle needs of the patient. Much work has been done to determine optimal blood level delivery resulting in the most consistent effect. Overall, the duration of action and clinical efficacy are more relevant than the blood level in this class of medication.

The mechanism of action of psychostimulants is to increase dopamine and norepinephrine in the synapse. Overall, this enhances activity in the prefrontal cortex of the brain responsible for attention, focus, and executive function (ie, organization and planning).

Substantial evidence exists in multisite, double-blind, placebo-controlled studies (eg, Multimodal Treatment Study of Children With Attention-Deficit/Hyperactivity Disorder) to support the first-line use of these medications in the treatment of school-age children and adolescents with ADHD. Evolving evidence exists (Preschool Attention-Deficit/Hyperactivity Disorder Treatment Study) to support the use of these drugs in preschool-age children. Medications may be helpful for preschool-age children for whom an adequate trial of behavior therapy has been unsuccessful. A growing body of evidence supports their use in ASD, albeit at lower doses because of the lower threshold for side effects.

Parents and caregivers have varied concerns related to stimulants, many of which are propagated by the media; however, leaving ADHD untreated results in significant comorbidities and risks for negative outcomes. Attention-deficit/hyperactivity disorder in children and adolescents has been associated with academic underachievement, grade retention, and ultimately, school dropout in several studies as well as an increased risk for substance use disorders. Nonetheless, several areas of controversy exist and often become a primary focus for hesitant parents or caregivers. Understanding the facts can help demystify these medications for parents or caregivers. For example, a risk of substance abuse has long been linked with stimulant medication. A substantial body of evidence shows that the use of stimulant medication does not result in an increased risk of later substance abuse. In fact, it is untreated ADHD and the resultant development of maladaptive behaviors that places adolescents at increased risk for substance use disorders. The hypothesis is that management of ADHD with stimulant medication in fact reduces substance use and many other potential negative outcomes, such as early tobacco use, undesired pregnancy, and motor vehicle crashes. Because stimulants often are prescribed for extended periods of time, however, additional long-term studies are needed.

Another frequently raised concern is the association between stimulants and an increase in sudden unexpected deaths. This would raise concern for any parent or caregiver. However, FDA scrutiny of these statistics revealed a lower incidence of sudden unexpected deaths in individuals on stimulants compared with the unmedicated population. Persons who died tended to have an underlying cardiac defect. Based on the current evidence, the American Academy of Pediatrics and the American Heart Association recommend a detailed cardiovascular history, a family history, and a physical examination followed by the initiation or continuation of pharmacotherapy with ADHD medications without further assessment in patients whose history and examination are not suggestive of cardiac disease. In individuals with a positive personal or family history and/or physical examination for cardiac disease, further evaluation is necessary, consisting of electrocardiography (ECG) and/or consultation with a pediatric cardiologist. After treatment is initiated, children and adolescents must be monitored for changes in heart rate, blood pressure, and cardiovascular symptoms during treatment.

Historically, height suppression has been raised as a concern with these medications. Numerous studies have tried to answer this question. A recent longitudinal study of more than 10 years' duration supports an initial growth suppression emphasized in the first 3 years of treatment that appears to resolve over the remaining 7 years. Parents or caregivers can be further reassured that if height suppression does occur, it seems to be minimal (eg, a median loss of <0.2 standard deviations over 2–3 years) and tends to attenuate with increasing time on treatment for both methylphenidate hydrochloride and amphetamine formulations. It is preferable for patients to graduate from high school even if their final adult height is slightly lower than that predicted by parental stature. Another 10- to 11-year longitudinal study that assessed the effect of ADHD and its treatment on growth outcomes in children followed into adulthood did

not support an association between deficits in growth outcomes and ADHD or psychostimulant treatment for ADHD. However, it is important to monitor growth in routine follow-up visits.

Finally, many parents and caregivers are concerned that their children will be "zombies" on medication. Children who are overmedicated can appear glassy-eyed and overly passive; however, good communication and interaction between families and doctors will quickly alleviate this problem. Families who often want to try alternative therapies are routinely encountered in clinical practice. Families should be educated about the potential risks of alternative therapies and continually encouraged to use evidence-based pharmacotherapeutic and/or psychotherapeutic measures simultaneously. Additionally, families may have concern about worsening tics with use of stimulant medications. A recent meta-analysis concluded that most patients with ADHD and a tic disorder benefit from moderate doses of stimulant treatment without worsening of tics and that the addition of α_2 agonists was especially useful because they were therapeutic for both ADHD and the tic disorder. Additional information about these medications may be found in Chapter 133.

Selective Norepinephrine Reuptake Inhibitors

Currently, the SNRIs include 1 medication that is frequently used in children: atomoxetine hydrochloride (eg, Strattera). Atomoxetine hydrochloride is used in the management of ADHD and for the inattention and anxiety associated with ASD.

The mechanism of action for atomoxetine hydrochloride is to block the reuptake of norepinephrine in the synapse. This may have a direct effect on enhancing the signal-to-noise ratio in the brain and may also ultimately result in an increase in dopamine in the prefrontal cortex of the brain. Unlike stimulant medications, atomoxetine hydrochloride avoids the nucleus accumbens so that it has no abuse liability.

Atomoxetine hydrochloride was originally studied as an antidepressant agent, but early investigation did not yield robust antidepressant effects. Marketed as providing "continuous symptom relief," a careful duration of action study shows little effect on core ADHD symptoms after 9 hours; however, some possible other small effects (eg, compliance) may last slightly longer. The attractiveness of atomexitine hydrochloride stems from its identity as an FDA-approved non-stimulant. Although usually less effective than stimulants, it has a different side-effect profile and may be associated with slight mood and anxiety benefits.

Research shows that atomoxetine hydrochloride, which is FDA approved for use in patients with ADHD, is effective in managing symptoms of this disorder for a given individual but has been found in studies of groups of people to be less effective than stimulant medications. Atomoxetine hydrochloride generally has a 60% response rate (measured by 25% reduction in ADHD ratings), compared with a 70% to 80% response rate (measured by 30% reduction in ADHD ratings) with stimulant medications. Furthermore, 3 different studies in which atomoxetine hydrochloride was directly compared with stimulants have demonstrated atomoxetine hydrochloride to be less effective on average, even though, as stated previously, some individual patients do well with this medication. Atomoxetine hydrochloride should especially be considered for patients in whom use of a stimulant was unsuccessful (eg, poor tolerance or poor effect of a trial on a methylphenidate hydrochloride preparation and a trial on an amphetamine preparation), significant history of substance use and diversion, exacerbation of tic disorder with stimulants, and the presence of comorbid anxiety disorder.

The side effects of atomoxetine hydrochloride are quite similar to those of traditional stimulants, with the added concerns of drowsiness, dizziness, and cough. Furthermore, similar to SSRIs, atomoxetine hydrochloride carries a warning citing a slightly increased risk of suicidal ideation. It is important for physicians to monitor for changes in mood, irritability, agitation and suicidality, especially during first 4 to 5 months of therapy. Atomoxetine hydrochloride is not associated with tic exacerbation. Response to this medicine is more like that of an antidepressant in that it may take 4 to 6 weeks to see the full effect of a particular dose. Drug holidays are not an option with this medication. The dosage range is 0.5 mg/kg to 1.8 mg/kg. Individuals on the autism spectrum tend to respond at lower doses and with a lower threshold for adverse side effects.

A few patients have reportedly experienced a serious idiosyncratic reaction suggestive of liver failure. These patients were on FDA-approved doses of atomoxetine hydrochloride for several months. They experienced vomiting, jaundice, and elevated liver enzymes. These findings resolved when the medication was discontinued and returned with reexposure to the drug. This finding resulted in an FDA warning to consider potential liver failure in a vomiting patient on atomoxetine hydrochloride. If the patient develops jaundice or laboratory signs of hepatic injury, the medication should be discontinued.

The American Academy of Pediatrics and American Academy of Child and Adolescent Psychiatry recommend stimulants as first-line treatment for ADHD. Neither blood nor urine test monitoring is necessary for either stimulants or SNRIs. The physician should regularly monitor improvement, adverse events, and adherence using rating scales; this should be done at least every 3 months after both dose and agent have been optimized.

Parents and caregivers often want to know if these medications can be used intermittently and stopped as soon as possible. With stimulants and SNRIs, results are optimized when these medications are administered 7 days a week and without large breaks. Longitudinal studies suggest that although some symptoms may resolve over time, significant impairment from even a small number of symptoms persists into adulthood for 60% to 70% of those diagnosed with ADHD. Inattention is more likely to persist into adulthood. Therefore, many people may continue on medication for several years. To assess for continued benefit, a break from medication may be attempted annually. As children grow larger, they often need higher doses. However, as compensatory mechanisms develop and some symptoms subside, some patients may require less medication. It is beneficial to re-optimize doses and agents throughout

the length of treatment. Drug holidays have no established intrinsic value on their own and should be recommended only for children with significant medication side effects, such as substantial weight loss. If a parent or caregiver is requesting a drug holiday, it is a signal that the parent or caregiver may need to review the value of the medication. A discussion should ensue as to whether the parent/caregiver and child continue to see benefit, the patient is having troubling side effects, or the medication at any dose is not helpful and is associated with concerning symptoms. The physician must take into consideration the knowledge that atomoxetine hydrochloride, once stopped and restarted, needs time to reachieve a therapeutic level.

Box 134.1. Disorders Managed With Selective Serotonin Reuptake Inhibitors

- Depression
- Obsessive-compulsive disorder
- Generalized anxiety disorder
- Separation anxiety disorder
- Panic disorder
- Selective mutism
- Posttraumatic stress disorder
- Autism spectrum disorder
- Bulimia

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors are frequently used in children and adolescents to manage a variety of depression- and anxiety-based symptoms (Table 134.1) (Box 134.1). Similar to SNRIs, SSRIs block presynaptic reuptake of serotonin after it is released into the synapse, thereby enhancing serotonin activity in the synapse. Empirical evidence has established the benefit of SSRIs in the management of depressive and anxiety disorders.

Medication is not a substitute for therapeutic support. In fact, most clinical guidelines recommend psychotherapy as first-line treatment for mild and moderate anxiety and depressive disorders in children. Medication management should be undertaken only if psychotherapy progress is minimal or symptom severity and impairment are moderate to severe. Most studies have proved that combination treatment of medication and therapy is more effective than either treatment modality alone. Obsessive-compulsive disorder is a unique anxiety disorder that typically requires higher doses of SSRIs than do anxiety or depressive disorders. The chronicity of the condition with the possibility of frequent exacerbations necessitates the use of a specific type of cognitive behavioral therapy, namely, exposure and response prevention.

Medications are chosen based on side-effect profile and half-life. Because of a significant placebo effect and a lack of multiple, large, highly powered studies in children, only a few medications have received FDA approval for use in children (Table 134.1). Numerous studies exist that may not meet strict scientific criteria but, taken together with vast clinical experience and consensus, imply reasonably well-tolerated and beneficial effects of these medications. Studies have consistently found SSRIs to be more effective and safer than tricyclic antidepressants as a treatment for depression.

Selective serotonin reuptake inhibitors are metabolized via the liver through the cytochrome P-450 system. Individual enzyme variations exist that result in variable metabolism of any of the many medications that travel through these pathways. Overwhelming this system may cause inhibition and buildup of medications or facilitated rapid metabolism of others. Thus, monitoring of all medications

Table 134.1. Selective Serotonin Reuptake Inhibitors

Generic	*Trade Name*	*FDA Pediatric Approval*	*Suggested Pediatric Dose, mg*	*Half-life*	*Increase Increment (After 4 Weeks)*	*Time Steady State, days*
Fluoxetine	Prozac	Depression/OCD	5–60[a]	4–6 days	5–20 mg[b]	28–35
Sertraline hydrochloride	Zoloft	OCD	25–200[a]	26 hours	25–50 mg[b]	5–7
Fluvoxamine	Luvox	OCD	50–200 twice a day[a] Maximum: 200 mg/day up to 11 years and 300 mg/day >11 years	15 hours	25–50 mg[b]	5–7
Paroxetine hydrochloride	Paxil	None	10–40[a]	21 hours	5–10 mg[b]	5–10
Citalopram hydrobromide	Celexa	None	10–40[a]	36 hours	10–20 mg[b]	7
Escitalopram oxalate	Lexapro	Depression	5–20[a]	27–32 hours	5–10 mg[b]	7

Abbreviations: FDA, US Food and Drug Administration; OCD, obsessive-compulsive disorder.

[a] Recommend decreasing the maximum dosage by approximately one-third for prepubertal children.

[b] Recommend using lower dose but in increased increments for younger children.

metabolized via this pathway is necessary. Reduced metabolism of SSRIs may result in *serotonin syndrome*, a relatively rare response to a flood of serotonin, presenting with confusion, restlessness, diaphoresis, shivering, tremor, hyperreflexia, and diarrhea. This syndrome often goes unrecognized, and affected patients may find their way to a pediatrician's office or emergency department. Occasionally, the combination of an SSRI with other prescribed or over-the-counter serotonin-enhancing agents may precipitate such a response. It is important for the prescribing physician to inquire into the use of additional prescribed or over-the-counter medications and be aware of the potential interactions between all agents.

No specific recommendations exist on dose other than to start low and go slow. It is important to use the full dose range for the medication and wait at least 4 to 6 weeks with each increase in dose. Typically, effects may be noted between 1 and 4 weeks, although often it takes up to 8 to 12 weeks to note effects for anxiety disorders. If an adequate trial of 1 SSRI is unsuccessful, a cross-titration to another SSRI is indicated. Suggested dosage ranges are provided in Table 134.1.

Many children with anxiety or depression go on to experience intermittent exacerbations throughout life. This does not mean that they should remain on these medications forever. It is recommended that physcians periodically discuss the length of trial of medication with patients and their families. Current recommendations support an initial 9- to 12-month treatment period with the SSRI that provided response at the same dose that resulted in remission of symptoms. Generally, taper should be avoided around the time of major transitions or stressors and should take place over months, with close follow-up. Finally, re-recurrence of symptoms may indicate the need for longer-term treatment. Patients with chronic depression and/or with multiple episodes of major depression usually require longer-term therapy.

Selective serotonin reuptake inhibitors are generally well tolerated, with mild transient side effects such as gastrointestinal symptoms, headache, increased motor activity, and insomnia. It is important to monitor patients for less common side effects, such as disinhibition, a phenomenon of increased impulsive behaviors in association with SSRIs that is usually dose related. Individuals with ASD as well as younger children are particularly susceptible to this particular side effect.

A withdrawal phenomenon can occur, especially with sudden discontinuation of SSRIs. This risk is inversely proportional to the drug half-life. For example, paroxetine hydrochloride, which has a short half-life, tends to be associated with a far greater risk of withdrawal symptoms than an agent with a longer half-life, such as fluoxetine. Antidepressant discontinuation syndrome may present as flu-like symptoms, including vomiting, diarrhea, and body aches. Simply readministering the skipped dose and tapering off over the course of 1 or 2 weeks alleviates symptomatology.

These medications are controversial. In 2004, the FDA created a black box warning advising that children and adolescents on SSRIs should be monitored for worsening depression, agitation, and suicidality, particularly in the early stages of treatment. This warning arose from an FDA meta-analysis that showed an increased risk of suicidal ideation in depressed teenagers soon after starting the medications. No completed suicides occurred. This prompted an FDA recommendation that children placed on SSRIs be seen weekly for 1 month, then semimonthly for 1 month, then monthly, and, ultimately, at longer regular intervals. The FDA subsequently acknowledged that untreated depression also carries an increased risk of suicide. The potential for benefit usually outweighs the risks, and concerns about suicidal ideation should not detract from the importance of these medications or their judicial use.

The FDA warning led to a decrease in prescriptions of SSRIs, which resulted in the first increase in the suicide rate since the FDA SSRI approval. The FDA warnings should serve only to increase awareness, not serve as a contraindication. An increase in suicidality has not been noted in adolescents with isolated anxiety or ASD. Selective serotonin reuptake inhibitors serve a vital role in helping children paralyzed by anxiety, obsession, and depression to lead more normal lives.

Atypical Antipsychotics (Serotonin-Dopamine Antagonists)

Atypical antipsychotics or second-generation antipsychotics, also known as SDAs, are medications with dopamine D2 and 5-hydroxytryptamine (serotonin) type 2 antagonism (Table 134.2). Compared with conventional antipsychotics, these newer medications offer a reducecd risk of extrapyramidal effects, such as dystonia; *akathisia*, a subjective feeling of restlessness; tremor; tardive dyskinesia; and hyperprolactinemia. These medications carry significant cardiometabolic risks, however. Although initially billed as a safer alternative to traditional antipsychotics, some experts have suggested that these newer medications merely substitute 1 set of severe side effects for another. These medications offer benefits for severe behaviors that are not responsive to other intervention.

Although often used off-label, second-generation antipsychotics are incorporated into best practice clinical guidelines for psychotic depression, schizophrenia, bipolar disorder, agitation in intellectual disability, Tourette syndrome, stuttering, and ASD. The only diagnoses for which an atypical antipsychotic has pediatric approval are schizophrenia, bipolar disorder, mania, and agitation associated with ASD. Therefore, although these medications often lack sufficient empiric evidence to be validated for all the indications mentioned, clinical consensus by experts recommends judicious use in treating children with serious mental illness after other forms of intervention have been unsuccessful or in cases of psychosis or severe aggression. These medications should not be used to promote weight gain, as a sedative or sleep aid, or as a treatment for ADHD.

Medications are chosen based on clinical experience and side-effect profile. Atypical antipsychotics are not innocuous; they must be used with full disclosure to parents. The most common side effects are listed in Box 134.2. The severity of some of the side

Table 134.2. Serotonin-Dopamine Antagonists (Atypical Antipsychotics)

Generic	*Trade Name*	*FDA Pediatric Approval*	*Usual Starting Dose*	*Dose*
Risperidone	Risperdal	Agitation with ASD, schizophrenia, mania, and bipolar disorder	0.25 mg nightly at bedtime	0.25–6 mg/day
Olanzapine	Zyprexa	Bipolar mania and schizophrenia	2.5 mg nightly at bedtime	2.5–20 mg/day
Quetiapine fumarate	Seroquel	Bipolar mania	25 mg twice a day	12.5–400 mg twice a day
Ziprasidone hydrochloride	Geodon	None	20 mg twice a day	20–160 mg/day
Aripiprazole	Abilify	Agitation with ASD, schizophrenia, mania, and bipolar disorder	2 mg once a day	0.5–30 mg/day
Lurasidone	Latuda	Bipolar depression	20 mg once a day	20–80 mg/day

Abbreviations: ASD, autism spectrum disorder; FDA, US Food and Drug Administration.

effects deserves discussion with the parents and patient. With the possible exception of aripiprazole, the SDAs have caused significant increases in weight, glucose, and lipids and decreases in sensitivity to insulin, otherwise known as *metabolic syndrome.*

Transient elevations of prolactin have occurred among recipients of these medications, most commonly with risperidone. The clinical significance of this increase is unclear. Prolonged QT syndrome on ECG is rarely noted, with the exception of ziprasidone hydrochloride. Prolonged QT syndrome on ECG has not been associated with death but remains a clinical concern.

Risperidone is the best studied medication of its class for children. The studies on which its FDA approvals hinged exposed side effects, however, most notably weight gain. Therefore, anticipatory counseling on diet management is routinely recommended. Another important finding indicated that a small but significant number of children with agitation and ASD were successfully able to stop treatment after 6 months, which suggests that a trial off medication may be warranted in those patients with agitation and ASD successfully treated for 6 months.

Box 134.2. Serotonin-Dopamine Antagonists: Potential Side Effects

- Weight gain
- Sedation
- Dizziness
- Hypotension
- Long QT syndrome
- Metabolic syndrome (hyperglycemia and increased lipids)
- Constipation
- Reduced blood cell count
- Dry mouth
- Headache
- Increased liver function tests
- Decreased triiodothyronine, thyroxine
- Extrapyramidal effects
- Akathisia (ie, sense of restlessness)
- Cataracts (in dogs)
- Neuroleptic malignant syndrome
- Tardive dyskinesia

Neuroleptic malignant syndrome is a rare, potentially life-threatening complication of neuroleptic agents that is extremely unlikely with the newer generation of medication. It is important to review the risk of neuroleptic malignant syndrome before starting medication. *Neuroleptic malignant syndrome* is characterized by hyperthermia, autonomic instability, diaphoresis, lead pipe rigidity, increased creatine phosphokinase caused by rhabdomyolysis, and delirium. It may occur at any point during treatment with these medications. Another important side effect to discuss is the risk of tardive dyskinesia with these agents. Although the condition is rare, monitoring is recommended using the abnormal involuntary movement scale (AIMS) at baseline and every 6 months. Risk of tardive dyskinesia increases with duration of use, and after it manifests it may be irreversible in 50% of patients. It is also necessary to explain the risk of dystonia to the families and the use of diphenhydramine as an antidote.

It is important to monitor side effects following the initiation of treatment with an atypical antipsychotic. Recommendations include following body mass index at each visit, after 6 weeks, and again every 9 to 12 months thereafter, as well as checking the following blood chemistries every 6 months: complete blood cell count, a comprehensive chemistry including hemoglobin A_{1c}, prolactin level, fasting blood glucose, and lipid levels. Complete blood cell count with differential can be obtained after a few months after initiation to identify suppression, if any, following treatment. An ECG before starting medications, 1 month after baseline, and biannually are necessary only for children on ziprasidone hydrochloride to monitor the QT interval.

As with any medication, psychotropic agents sometimes are incorrectly prescribed. Generally, however, psychopharmacologic agents remain underused in the management of many disorders. Incorporation for routine screening procedures, such as rating scales for depression and anxiety, can help in early identification of psychiatric conditions, which can result in early intervention for these chronic and disabling disorders. It is hoped that new and ongoing research will help physicians recognize mental illness in children and substantiate and refine the use of such medications in their care.

Careful thought and discussion of target symptoms as well as side effects will help physicians choose the best medication and treatment plan. It will also prepare parents or caregivers to observe the positive and negative responses to medication.

Although this chapter provides substantial detail on side effects, it is critical to understand that the diseases being managed often are incapacitating. Informed consent and parent/caregiver and child involvement are vital in medication choice. Pediatricians have an extremely influential voice in supporting compliance. Therefore, knowledgeable guidance is crucial in helping parents and caregivers make an uncomfortable and difficult decision that may ultimately result in dramatic improvements in their and their child's quality of life.

CASE RESOLUTION

You empathize with the mother about this decision but explain that this medication is a reasonable and safe one to try. The patient starts the medication and experiences some nausea in the first few days. With your reassurance, this resolves. The patient's mother calls a few weeks later to thank you for your advice and to let you know that although her daughter still has difficulties related to the ASD, she seems to be somewhat less anxious and is functioning better at school.

PART 13

Dermatologic Disorders

CHAPTER 135

Acne

Samantha Snider, MD

CASE STUDY

A 15-year-old boy comes to your office for a sports preparticipation physical evaluation. He is healthy and has no questions, complaints, or concerns.

The adolescent is well developed and well nourished, with normal vital signs, including blood pressure. The physical examination is entirely normal except for the skin. Multiple closed comedones are noted along the hairline. Erythematous papules and pustules are present across the forehead and over both cheeks. Scattered open comedones are located over the nose and cheeks as well. The chest and back are clear, with no lesions.

Questions

1. Who gets acne?
2. What are some contributing factors in the development of acne?
3. What is the pathogenesis of acne vulgaris?
4. What are the different types of acne lesions?
5. What management options are available for the treatment of mild, moderate, and severe acne?
6. What are the indications for the use of isotretinoin?
7. What is the prognosis for adolescent patients with acne?

Acne vulgaris is a common chronic inflammatory skin disease that most frequently occurs in adolescents. The spectrum of disease can vary widely, but regardless of type and severity, acne can be severely distressing for patients. The psychological burden and negative effect on quality of life can be comparable to those with asthma, arthritis, or epilepsy. Primary care physicians should, therefore, acknowledge acne as a significant chronic medical problem and treat the condition early and aggressively to prevent permanent sequelae, such as scarring.

Epidemiology

Estimates indicate that more than 85% of people in the United States have been affected by acne and that more than $2 billion is spent annually on acne treatments. Acne most commonly occurs in individuals 9 to 24 years of age, with peak prevalence and severity during puberty. However, the condition can also affect neonates, young infants, and older adults (up to 26% of women and 12% of men). Preteens are more likely to experience comedonal lesions, with progression to more inflammatory lesions during the teenage years. The condition is usually more severe in males but typically lasts longer in females. Certain individuals may be genetically susceptible to acne. White teenagers are more likely to have acne than black, Hispanic, or Asian teenagers. However, patients with darker skin tones often have more issues with post-inflammatory discoloration and scarring.

Etiology

Acne has a complex, multifactorial etiology with many overlapping influences that are endogenous and exogenous (Box 135.1).

Internal (host) factors include hormones (eg, androgen excess, changes in estrogen or progesterone during menses, stress-induced cortisol release), skin microflora balance (especially with *Cutibacterium* [previously *Propionibacterium*] *acnes*), sebum overproduction, skin hyperkeratinization, and stimulation of internal inflammatory pathways.

External factors include medications and drugs (ie, progestin-only contraceptives, isoniazid, phenytoin, corticosteroids, anabolic steroids, and lithium-containing compounds), chemicals (ie, petroleum), oil- or wax-containing hair care products and cosmetics, overzealous facial cleansing, local skin occlusion from sports gear and excessive perspiration, and diet. While specific foods such as chocolate, caffeinated drinks, and fried or greasy foods have not been shown to directly cause or worsen acne, emerging research suggests that diets with high-glycemic indices or high dairy intake

Box 135.1. Factors Contributing to Acne

Endogenous (Internal [Host]) Factors

- Skin microflora imbalance
- Sebum overproduction
- Hyperkeratinization
- Pro-inflammation pathways
- Hormonal imbalances

Exogenous (External) Factors

- Medications/drugs
- Oily/waxy hair products and cosmetics
- Excessive face washing/scrubbing
- Excessive sweating
- Occlusion (eg, hats, headbands, sports gear)
- Diet (eg, high glycemic load, high diary intake)

may contribute to inflammation and the development of acne lesions.

Pathophysiology

The pathogenesis of acne involves 4 major interrelated processes that naturally occur within the pilosebaceous unit: hyperkeratinization of follicular infundibulum, sebaceous gland overproduction and alteration of sebum composition, proliferation of *C acnes*, and immune response and inflammation (Box 135.2). Alteration or imbalance of any of these 4 normal processes can lead to formation of acne lesions.

Hyperkeratinization of Follicular Infundibulum

Keratinocytes constitute 90% of the cells of the epidermis and function to produce a keratin barrier that protects against environmental damage. Activation of the innate immune system by internal or external factors will initiate pro-inflammatory biochemical cascades. One important pathway includes activation of toll-like receptors (TLR-2/4) and ensuing release of defensin and interleukin. Interleukin-1α specifically has been linked to increased keratinocyte proliferation, which, in turn, leads to overproduction of keratin and reduced desquamation and remodeling within the pilosebaceous unit. This results in the formation of a keratin plug within the follicular infundibulum. Keratin plugging leads to retention of sebum and cellular debris and subsequent development of the microcomedo, the earliest precursor lesion of acne.

Sebaceous Gland Overproduction and Alteration of Sebum Composition

Sebum is a complex mixture of oils that includes triglyceride and fatty acid breakdown products, wax esters, squalene, and cholesterol. Any alteration to the composition of these different lipids can contribute to acne lesion formation. A common cause of alteration is antioxidant and free radical imbalance. Exposure to pollution and UV radiation decrease skin antioxidants, such as vitamin E, and can lead to formation of reactive oxygen species. Increases in reactive oxygen species lead to subsequent oxidization of sebum lipids and inflammation that contribute to acne.

The amount of sebum produced is also important, because overproduction can contribute to inflammation and comedo formation. The sebaceous gland is highly sensitive to hormonal stimulation, especially the increase in androgens during puberty and corticotrophin-releasing hormone spikes during stress. Hormonal activation causes sebaceous glands to undergo hypertrophy, leading to an overall increase in sebum production. Diet can also lead to increase in sebum production via activation of insulinlike growth factor 1, leptin, and peroxisome proliferator-activated receptors (PPARα, β, and γ). Alternatively, activated retinoic acid and retinoid-X receptors have an antiproliferative effect on keratinocytes and inhibit lipid synthesis.

Box 135.2. Acne Pathogenesis

- Hyperkeratinization leads to pilosebaceous follicle plugging and microcomedo formation.
- Hormones induce sebum overproduction and lead to over-proliferation of *Cutibacterium acnes*.
- *C acnes* leads to increased inflammation and innate immune response.
- Ongoing innate immune responses attract inflammatory cells and damage the dermal matrix.

Proliferation of *Cutibacterium Acnes*

Cutibacterium acnes is a gram-positive anaerobic diphtheroid bacterium that plays a major role in acne pathogenesis. *Cutibacterium acnes* normally exists in balance alongside *Staphylococcus epidermidis* as the predominant cutaneous microflora of the sebaceous follicle. In the setting of normal microflora balance, *C acnes* limits proliferation of *Staphylococcus aureus* and *Streptococcus* species, whereas *S epidermidis* helps limit proliferation of *C acnes*. When left unchecked, *C acnes* releases hyaluronate lyase and CAMP (Christie Atkins Munch Petersen, the researchers who discovered the factor) factors that cause extracellular matrix degradation and porphyrins that oxidize sebum, and can form a strong antibiotic resistant biofilm—all of which lead to inflammation that can cause acne.

Immune Response and Inflammation

The innate immune system also plays a key role in acne lesion formation and subsequent scarring. Innate immune responses release inflammatory mediators that activate the hyperkeratinization that causes keratin plugging, which, in turn, leads to the rupture of the pilosebaceous follicle and expulsion of follicular contents into the dermal layer of skin. This spillage of sebum, keratin, and bacteria leads to further inflammation and the development of inflammatory acne lesions. In addition, specific cytokines such as interleukin-8/10 also attract circulating inflammatory cells into the tissue and promote pustular acne lesions. Many inflammatory cytokines can also induce matrix metalloproteinases (eg, MMP-9) that cause dermal matrix destruction and subsequent scar formation.

Clinical Presentation

The lesions of acne primarily affect the face, especially central facial areas, or the T-zone, which includes the forehead, nose, and chin. Lesions can also be found on other areas of the body that are dense in sebaceous glands, including the neck, chest, shoulders, and back.

There are a number of different types of acne lesions (Box 135.3). Lesions are typically described as comedonal (non-inflamed) or inflammatory. Comedones can be open or closed to the environment. *Closed comedones*, or *whiteheads*, are small, flesh-colored bumps with no surrounding erythema that are caused by plugging of the sebaceous follicle and resultant dilation that is closed to the surface of the skin. *Open comedones*, or *blackheads*, are small, dome-shaped papules with an open orifice that contains central dark material. These also occur as a result of dilatation of the follicular orifice but are open to the outside environment. The dark-colored material at the surface of the skin within open comedones is not dirt;

Box 135.3. Acne Characteristics

- Located on face, chest, back, and shoulders.
- Comedones are non-inflamed, open (blackheads), or closed (whiteheads).
- Inflammatory lesions—papules, pustules, or nodules.
- Nodules can be large, deep, and cystic.

therefore, patients should not attempt to scrub off or pick out the lesion. The dark color is actually caused by a number of processes, including melanin deposition in the horny cells, interference with the transmission of light through compacted epithelial cells, and oxidation of keratin and sebum.

Pustules and papules are inflammatory lesions. Pustules lie in the superficial epidermal layer of the skin, and papules form in the lower dermal layer. Because of their deeper location, papules are often accompanied by a more severe inflammatory reaction, and scarring may result. Nodules or cysts are suppurative inflammatory lesions located deep within the dermis. Associated with the most severe form of acne, nodules are the result of deep papules that suppurate and rupture, and then subsequently become lined with epithelium to form cysts.

Evaluation

History

A detailed history investigating the medical and psychosocial aspects of acne is key (Box 135.4). It is often helpful to start with the psychological effects first. How do patients feel about their acne and how does it affect their life? Do they desire treatment at this time, and if so, what are their expectations about treatment and recovery? From a medical standpoint, the health professional should determine how long the acne has been present, the types of lesions that are present, if and how the condition has ever been treated, and what has or has not worked in the past. A general review of systems is important to exclude symptoms associated with androgen excess or other metabolic disorders that may be contributing to acne breakouts.

Physical Examination

The physical examination should focus on the primary sites of acne—face, chest, back, and shoulders—although the entire skin should be inspected closely at the first visit. Currently no universally accepted grading scale for acne severity exists. However, American Academy of Dermatology guidelines currently use the number of lesions and extent of inflammation as the main factors to determine severity (Table 135.1). The presence of nodular lesions is of particular importance, because this indicates more severe acne even in the absence of other lesions and typically requires systemic treatment. The presence and extent of scarring should also be assessed as a possible predictor of outcome.

A complete physical examination at the initial visit is important to assess for signs of hormonal imbalance that may be contributing to symptoms. Androgen excess can present with hirsutism, male pattern baldness, obesity, and acanthosis nigricans. Indications of virilization, such as congenital adrenal hyperplasia or androgen-producing tumors, have more severe effects, such as clitoromegaly, loss of female body contour, and deepening of the voice. Signs of steroid use or cortisol excess include central obesity, moon facies, stretch marks, buffalo hump, and decreased testicular volume in males. Acne in prepubescent children older than 1 year is never normal and is cause for concern for precocious puberty and hormone-secreting tumors. Signs include axillary and pubic hair, breast development in females, and testicular enlargement in males.

Box 135.4. What to Ask

Acne

Psychological Aspects

- Is the patient bothered or embarrassed by the lesions?
- Do the patient's feelings about the acne prevent him from participating in certain activities?
- Is the patient bullied by the patient's peers because of the acne?
- Does the patient desire treatment at this time?
- What are the patient's expectations for treatment and resolution?
- Is there any past history of psychiatric conditions, such as depression or anxiety?

Personal Acne History

- How long have the lesions been present?
- Where on the patient's face or body do breakouts usually occur?
- What types of acne lesions does the patient usually have?
- Does the patient pick at or try to pop the lesions?
- Do specific activities, medications, or environmental factors seem to make the acne worse?
- Are timing factors, such as menses or stress, related to breakouts?

Acne Treatment History

- Has the adolescent ever received treatment for acne in the past?
- Did the patient try self-treatment only with over-the-counter products, or was therapy prescribed by a physician?
- What specific treatments were used?
- How long did treatment continue?
- What treatments seem to help or worsen the acne?
- If the patient stopped any treatments, what were the reasons the therapy was discontinued?

Related History

- Does the adolescent have any other medical conditions?
- Is the adolescent taking any medications? Any history of steroid use? If female, any use of hormonal contraception?
- Is there a family history of acne with or without scarring?

Reactive Oxygen Species Screening

- Full 10-system review of systems at the initial encounter with subsequent focused check-ins.
- If female, are menses regular? Is there a history of hirsutism, male pattern baldness, or voice deepening?
- If prepubescent, are there any signs of precocious puberty?

Laboratory Tests

In general, no laboratory studies are needed at the time of the initial evaluation. However, targeted testing is warranted if there is concerning

Table 135.1. Classification of Acne	
Category	*Physical Findings*
Grade 1 Mild comedonal	A few non-inflammatory lesions (ie, open and closed comedones) with no more than 1 small inflammatory lesion
Grade 2 Mild inflammatory	Some non-inflammatory lesions with no more than a few inflammatory lesions
Grade 3 Moderate	Many non-inflammatory lesions and/or some inflammatory lesions, with no more than 1 small nodular lesion
Grade 4 Severe	Many non-inflammatory lesions and/or inflammatory lesions, with no more than a few nodular lesions
Grade 5 Very severe	More than a few nodular lesions regardless of number of non-nodular lesions

history or examination findings that are suggestive of a hormonal abnormality. In females with signs of androgen excess, initial studies should include testosterone, dehydroepiandrosterone sulfate, androstenedione, follicle-stimulating hormone, and luteinizing hormone levels. Additional supplemental testing for prolactin, estradiol, and sex-hormone-binding globulin levels may be included. Screening for Cushing syndrome should begin with corticotropin and early morning cortisol levels. Any evidence of precocious puberty should prompt bone-age imaging and testing for follicle-stimulating hormone, luteinizing hormone, testosterone, dehydroepiandrosterone sulfate, insulinlike growth factor 1, and thyrotropin levels. If any abnormality is found, prompt referral to an endocrinologist is needed.

When isotretinoin is indicated, several pretreatment studies are necessary, including a complete blood cell count, liver function tests, and a fasting lipid profile. In addition, 2 negative pregnancy tests 1 month apart are required prior to and within 2 weeks of starting isotretinoin in female adolescents. These studies should be obtained in consultation with a dermatologist, who is generally responsible for prescribing isotretinoin through the iPLEDGE program (see the Isotretinoin Therapy section).

Management

The general management of acne begins with counseling. The health professional should start by providing a general, nontechnical overview of the pathophysiology of acne and eliciting any related questions. Common therapy options should be discussed while exploring possible barriers to treatment to individualize therapy for optimized adherence and efficacy (Box 135.5). Common barriers include patient motivation and maturity, unrealistic expectations of therapy duration and likely outcome, complexity of treatment regimen, medication-related side effects, and overall cost to families. Increased parental involvement can help mitigate some of these barriers, particularly when the patient is young or has severe acne requiring a more complex treatment regimen.

Prior to starting treatment for acne, physicians should counsel the patient and family that acne often appears to worsen with treatment for the first 2 to 4 weeks. Noticeable improvement of acne from any treatment regimen usually takes at least 4 to 8 weeks. Patients should be reminded that treatment is long-term, because medications only control the acne but do not cure it.

The specific therapies prescribed depend on the severity of the acne, the type of lesions present, and the patient's ability to adhere to the proposed treatment (Table 135.2). The most common regimens

Box 135.5. General Management Recommendations

- Wash skin with a mild soap-free cleanser and water no more than 1–2 times per day.
- Avoid antibacterial washes (other than benzoyl peroxide) because they may lead to bacterial resistance.
- Use cosmetics and moisturizers that are oil free and noncomedogenic.
- Use sunscreen daily; most acne medications are photosensitizing and increase UV damage.
- Avoid picking at lesions and excessive scrubbing, especially with abrasive cleansers or exfoliators.
- Maintain a healthy diet; a low-fat, low-glycemic diet may be more helpful for patients who have obesity.
- Follow the prescribed regimen carefully, because adherence is key to treatment success.
- Manage medication-related side effects, such as increased redness and dryness of the skin.
- Understand that long-term treatment is often required.

Table 135.2. Treatment of Acne	
Classification	*Recommended Treatment Regimen*
Grade 1 Mild comedonal	First-line: topical retinoid monotherapy, starting every other day. Second-line: increase to daily use and/or add benzoyl peroxide.
Grade 2 Mild inflammatory	First-line: topical retinoid or benzoyl peroxide monotherapy, starting every other day. Second-line: increase to daily use and/or add benzoyl peroxide/topical retinoid. Third-line: add topical antibiotic once or twice daily.
Grade 3 Moderate	First-line: topical retinoid and benzoyl peroxide double therapy daily. Second-line: add topical antibiotic once or twice daily. Third-line: trial of oral antibiotics (especially if body acne present). Adjuncts: if female, can add oral contraceptives or spironolactone. Recalcitrant: isotretinoin.
Grade 4 Severe	First-line: topical retinoid, benzoyl peroxide, and topical antibiotic triple therapy daily. Second-line: isotretinoin. Adjuncts: trial of oral antibiotics; if female, oral contraceptives or spironolactone.
Grade 5 Very severe	First-line: isotretinoin (and oral contraceptives, if female). Adjuncts: intralesional steroids or oral steroid taper, oral antibiotics.

include topical products such as retinoids and benzoyl peroxide, which can be used alone or in combination with each other as well as with topical or oral antibiotics, hormonal agents, and isotretinoin. Regardless of regimen selection, close follow-up is needed for subsequent titration or modification of the treatment regimen according to the patient's clinical response, adverse effects experienced, and overall adherence to treatment.

The patient's skin type should also be taken into consideration when selecting the appropriate vehicle for the active ingredient. Most topical medication comes in a variety of forms, including creams, gels, ointments, foams, and lotions. Oily skin types tend to respond better to gels, foams, or solutions, whereas lotions, creams, and ointments are better suited for dry skin.

Topical Therapy

Topical retinoids are vitamin A derivatives that treat existing acne lesions (comedolytic) and prevent the formation of new microcomedones. The mechanisms of action include normalizing follicular keratinization, decreasing the adhesiveness of horny cells shed into the follicular lumen, and reducing inflammation.

Topical retinoids are now recommended as first-line treatment for comedonal and inflammatory acne. They can be used alone as monotherapy for mild acne or as part of a combination regimen for moderate and severe acne. Several different formulations of topical retinoids are available in a wide variety of concentrations and vehicles.

- Tretinoin (eg, Retin-A, Avita, Atralin) is the most widely used topical retinoid and is available only by prescription. It comes as a gel, cream, or liquid in concentrations varying from 0.025% to 0.1%. Newer microsphere vehicle technology (eg, Retin-A Micro) is less irritating and allows delivery of the medication more slowly over time to decrease side effects without compromising effectiveness.
- Adapalene (eg, Differin) is a newer third-generation retinoid that is less irritating and more photostable than other topical retinoids. It is also the only topical retinoid that is currently available without a prescription. The 0.1% gel is available for purchase over the counter, whereas the 0.1% cream/lotion and 0.3% gel are still prescription only. It is not approved for children younger than 12 years.
- Tazarotene (eg, Tazorac) is another newer third-generation topical retinoid that was originally created for the treatment of psoriasis. It is the most effective of the topical retinoids; however, it is also significantly more expensive and has a higher adverse effect profile than other topical retinoids, including teratogenicity (pregnancy category X). For these reasons it is not widely used in the treatment of acne.

Retinoids are frequently used as part of combination therapy with benzoyl peroxide, but they cannot be applied simultaneously. Benzoyl peroxide causes inactivation of the topical retinoid when they are applied together. Most health professionals recommend applying benzoyl peroxide in the morning and topical retinoids at night. Another reason for nightly usage is that retinoids are photolabile and degrade quickly when exposed to sunlight, thus significantly decreasing their effectiveness.

Common dose-dependent side effects are redness, dryness, peeling, stinging, and burning of the skin. To minimize these effects, only the lowest concentration clinically indicated should be used. Skin type should also be considered, and a history of sensitive or dry skin may necessitate initial use only every 2 to 3 days. Correct application and use of moisturizers can also help prevent side effects and should be discussed when initially prescribed. Application should ideally occur 20 to 30 minutes after the skin is cleansed and completely dried. A pea-sized amount should be gently spread as a thin, even layer over the entire face, followed by a noncomedogenic moisturizer. Retinoids also cause significant photosensitivity of the skin; therefore, use of sun protection factor 30 or higher sunscreen should be strongly recommended, and excessive sun exposure or tanning should be strongly discouraged.

Benzoyl peroxide is another commonly used topical medication that helps to treat acne in several ways. Similar to topical retinoids, benzoyl peroxide is also comedolytic and anti-inflammatory. What makes it unique from other treatment options is that it is the only medication with antibacterial properties against *C acnes* with no reported resistance. In fact, it is recommended to use benzoyl peroxide when traditional antibiotics are used as part of an acne treatment regimen to prevent the development of antibiotic resistance.

Benzoyl peroxide can be used as first-line monotherapy for mild inflammatory acne and is often used in combination regimens for comedonal acne and more severe acne cases. It is typically available in concentrations of 2.5%, 5%, and 10% as cream, gel, or body wash. All strengths are available over the counter and are relatively inexpensive.

The health professional should keep in mind when choosing a benzoyl peroxide concentration that a higher concentration does not always equate to higher efficacy and may only result in a higher level of adverse effects. Common side effects of benzoyl peroxide are generally the same as those of topical retinoids and additive when used in combinations and higher strengths. It is, therefore, recommended to start with the lowest concentration of benzoyl peroxide indicated (2.5%–5% for the face; 5%–10% for the body) and to initiate gradually over time. Initially, a thin application should be used once every other day, and the frequency and/or strength can be increased as tolerated.

A serious adverse effect is allergic contact dermatitis. This manifests as an erythematous and very pruritic papular-vesicular eruption on areas of application. While it rarely develops, its presence necessitates immediate discontinuation of all benzoyl peroxide-containing medications.

One additional issue to be aware of is that benzoyl peroxide has a significant bleaching effect on textiles. This can lead to splotchy, orange-yellow discoloration of towels, bed linens, and clothing if patients are not appropriately counseled. There are linens that are specifically marked as benzoyl peroxide resistant.

Salicylic acid is a compound originally produced from willow tree bark (like aspirin) and has comedolytic effects when applied to skin. It is available in concentrations ranging from 0.5% to 2% and comes in a variety of vehicles. It is the main active ingredient in many over-the-counter facial cleansers and "spot-treatment" serums marketed for the treatment of acne. However, there are limited data to support its effectiveness. It is, therefore, not included in most acne treatment

algorithms or physician-prescribed regimens. Patients should be advised to check labels on over-the-counter products, because concurrent use of salicylic acid-containing products with other topical medications can cause worsening of redness, dryness, burning, and peeling.

Antibiotic Therapy

Antibiotics can be used as adjuncts in the treatment of inflammatory acne of all severities. The choices of topical versus oral and which specific antibiotic to use typically depend on the extent of skin involvement and severity of inflammation. However, any antibiotics chosen (whether topical or oral) should not be used as monotherapy or first-line therapy, or for continuous periods longer than 3 to 4 months, because of the risk of inducing bacterial resistance. It is recommended to use benzoyl peroxide alongside any antibiotics and to begin tapering usage after 6 to 8 weeks of treatment to help prevent development of resistance.

Topical antibiotics are often helpful as second-line therapy for mild to moderate inflammatory acne that is unresponsive to topical retinoids and/or benzoyl peroxide. Local side effects are generally similar to other topical acne medications, and systemic adverse effects are significantly less frequent than with oral counterparts because of minimal systemic absorption. Allergic reactions to topical antibiotics are rare and are typically limited to localized dermatitis.

- Clindamycin and erythromycin are the most popular topical antibiotics. Clindamycin is available by prescription as a 1% gel and is now is the preferred first-choice topical antibiotic because of its superior efficacy. Erythromycin is available as a 2% gel by prescription. Both are also available as fixed-strength combination preparations with benzoyl peroxide. Although these combination preparations are generally more costly, overall adherence often improves due to reduced regimen complexity. Topical antibiotics and combination preparations can be used once or twice daily.
- Dapsone (eg, Aczone) is a sulfa-containing antibiotic that is typically used in its oral formulation to treat leprosy. However, the topical form of the drug can be used in combination regimens to treat severe or nodulocystic acne or as second- or third-line therapy for resistant mild to moderate acne. It is available by prescription as a 5% gel that can be used once or twice daily. Dapsone gel should not be co-applied with benzoyl peroxide because this will cause orange-brown discoloration over the skin (however, this discoloration can be washed off). It should also not be used in patients who are taking oral dapsone or antimalarial drugs because of the potential for severe hemolytic reactions. However, hemolytic reactions in patients with glucose-6-phosphate dehydrogenase deficiency have *not* been reported when using topical dapsone alone; therefore, glucose-6-phosphate dehydrogenase testing is *not* required prior to starting treatment. More common side effects include redness, dryness, and peeling of the skin.

Systemic oral antibiotics are most often used for inflammatory acne that is severe refractory or that covers large areas of the trunk. It should be noted that oral antibiotics have not been shown to be effective against comedonal acne. Oral antimicrobial therapies help inhibit over-proliferation of *C acnes*, which, in turn, limits sebum oxidation and additional cellular matrix damage. As a result, lesser amounts of free fatty acids and other by-products are released, leading to decreased levels of inflammation.

The ultimate goal of oral antibiotic therapy is use of the lowest dose indicated to control lesions and minimize side effects. However, most patients require prolonged or frequent intermittent courses of oral antibiotics before remission occurs. Once new inflammatory lesions have stopped emerging (usually after 6–8 weeks), the dose of the oral antibiotic may be gradually tapered over 1 to 2 months and topical antibiotic treatment may be substituted.

- Tetracycline and its derivatives (ie, minocycline, doxycycline, and sarecycline) have been found to be the most effective and should be considered the first-line choices among the systemic antibiotics. Currently, extended-release minocycline and sarecycline are US Food and Drug Administration (FDA) approved for treatment of moderate to severe inflammatory acne in children 12 years and older and 9 years and older, respectively.
- Azithromycin, trimethoprim-sulfamethoxazole, amoxicillin, and cephalexin are significantly less effective and generally are not useful choices unless patients have contraindications to tetracyclines. Common contraindications to tetracyclines include age younger than 8 years and active pregnancy.
- Erythromycin is not recommended because of rising bacterial resistance.
- Clindamycin is not recommended because of the associated risk of pseudomembranous *Clostridium difficile* colitis with the extended use needed for acne treatment.

The most common side effects of oral antibiotics include candidal vaginitis, especially in females who also take oral contraceptives; gastrointestinal (GI) upset; and photosensitivity. Phototoxicity and pill esophagitis occur most commonly with oral doxycycline; therefore, patients must be instructed to use sunscreen liberally and remain upright for at least 1 hour after taking the medication. Significant rare but serious potential adverse effects associated with the first-line tetracycline class include cholestatic hepatitis (especially if liver dysfunction is already present), hypotension, cardiac arrhythmias (eg, torsades de pointes, ventricular tachycardia), and severe neurologic effects (ie, confusion, psychosis, seizures, and hearing loss).

Hormonal Therapy

Hormonal therapies are very helpful adjunct treatments for menstruating females with moderate to severe acne and signs of androgen excess. They work via a variety of mechanisms to decrease or inhibit androgen overproduction, which often contributes to acne. Several different medications with antiandrogen effects are available.

Oral contraceptives treat hyperandrogenism by blocking androgen synthesis and activity. They decrease androgen production through negative feedback inhibition of pituitary gonadotropin secretion and direct suppression of 5a-reductase. They decrease the effect of androgens directly, by blocking the testosterone receptor, as well as indirectly, by increasing sex-hormone-binding globulin to limit active free testosterone. In general, oral contraceptives must be taken for 3 to 4 months before improvement is seen, with relapses occurring if treatment is discontinued. Maximum effects are usually seen by 6 months of usage. It should also be noted that a

Papanicolaou test and a bimanual pelvic examination are *no longer indicated* before initiating the use of an oral contraceptive.

There are currently 4 FDA-approved combined oral contraceptives specifically for the treatment of acne:

- Ethinyl estradiol and norgestimate (eg, Ortho Tri-Cyclen)
- Ethinyl estradiol and norethindrone acetate with ferrous fumarate (eg, Loestrin)
- Ethinyl estradiol and drospirenone (eg, Yaz, Yasmin, Ocella)
- Ethinyl estradiol and drospirenone with levomefolate (eg, Beyaz, Safyral)

When choosing an oral contraceptive for acne treatment, a low-dose combination estrogen-progestin formulation is recommended to help limit possible adverse effects. Unopposed progestin, especially medroxyprogesterone injections (eg, Depo-Provera), can worsen acne and lead to hirsutism. Localized slow-release progestin implants (eg, Nexplanon, Implanon) and intrauterine devices (eg, Mirena, Skyla) are less likely to have these adverse effects. High levels of estrogen may cause nausea, vomiting, bloating, decreased libido, systemic hypertension, and idiopathic intracranial hypertension and increase the risk of deep vein thrombosis and breast or cervical cancer. Alternatively, very low doses of estrogen may not be sufficient for normal bone mass accrual that is critical during adolescence.

Contraindications to oral contraceptives include pregnancy, breastfeeding, significant hypertension (ie, systolic blood pressure >160 mm Hg or diastolic blood pressure >100 mm Hg), migraine with aura, heavy smoking, prior deep vein thrombosis or pulmonary embolism, history of stroke or myocardial infarction, or a diagnosis of breast or cervical cancer. Patients should also be warned that efficacy of the oral contraceptive may be affected by other medications, especially rifampin and griseofulvin.

Spironolactone is an aldosterone receptor antagonist normally used as an antihypertensive. However, it also competitively binds the testosterone receptor, thus blocking activity of testosterone and dihydrotestosterone. The combined antihypertensive and antiandrogen effects make it especially helpful for young women with metabolic syndrome and obesity. It should be avoided in young men because of a high likelihood of causing gynecomastia. It is typically dosed from 50 to 200 mg daily and can be tapered once acne improvement is noted. Common side effects include polyuria, hypotension, dizziness, fatigue, headache, and menstrual irregularities. Serious adverse effects are related to hyperkalemia caused by aldosterone blockade. However, potassium levels *do not* need to be checked prior to initiation for most healthy young patients. There are also no data showing increased risk of hyperkalemia when drospirenone oral contraceptives and spironolactone are used together.

Steroid therapy can be useful for the treatment of severe inflammatory acne in boys and girls, especially for those with nodular acne. Deep nodular lesions often respond quickly to the anti-inflammatory effects of intralesional injections of triamcinolone acetonide (eg, Kenalog; 10 mg/mL) and oral prednisone tapers (5–30 mg per day over 5–7 days, with maximum 0.5–1 mg/kg/day over several weeks). However, steroids should never be used topically because they will cause acne to significantly worsen secondary to *C acnes* overgrowth. Long-term use is discouraged given the risks of serious long-term adverse effects.

Isotretinoin Therapy

Isotretinoin (eg, Absorica, Zenatane, Claravis, Amnesteem, Myorisan) is a systemic oral analog of vitamin A and influences nearly all aspects of acne formation: sebum secretion, follicular keratinization, and inflammatory responses. It is the strongest and most effective acne treatment available and is among the few treatments to provide long-term remission. Currently, it is the recommended first-line therapy for very severe (nodulocystic) acne and can be used as second- or third-line therapy for resistant moderate to severe acne. However, given the high incidence of side effects and potential for serious adverse reactions, referral to a dermatologist is strongly recommended for patients who require isotretinoin therapy.

Common side effects include intense dryness of the skin and mucous membranes, myalgias and joint pain, GI upset, fatigue, headache, hematuria, hematologic abnormalities (eg, anemia, neutropenia, thrombocytopenia, thrombocytosis), and elevation of triglycerides and transaminases. Therefore, baseline blood cell counts, liver function tests, and lipid panel tests should be obtained prior to initiation of isotretinoin and monitored regularly for the duration of treatment.

Severe adverse effects include GI hemorrhage, pancreatitis, hepatitis, inflammatory bowel disease, agranulocytosis, allergic vasculitis, stroke, bronchospasm, decreased bone mineral density, rhabdomyolysis, glomerulonephritis, pseudotumor cerebri, optic neuritis, and seizures. Neuropsychiatric effects including depression and suicidal ideation have long been attributed to isotretinoin because of their association to hypervitaminosis A and have led to related black box warnings by the FDA. However, data to support this correlation are limited to case reports and related database reviews. Regardless, given the high likelihood of depressive symptoms in an adolescent with recalcitrant acne, health professionals are advised to be aware of the possible coexistence of a mental health disorder when prescribing isotretinoin and are urged to monitor patients closely for indication for psychiatric referral.

Teratogenicity is also a significant concern for adolescent and adult women taking isotretinoin. To minimize fetal exposure to isotretinoin, the FDA implemented a mandated distribution program called iPLEDGE in 2007 to register all patients and their prescribing physicians, along with distributing pharmacies and manufacturers. iPLEDGE is a computer-based risk management program that requires prescribers to read and sign designated policies and procedures and patients to read educational material and sign an informed consent. Additionally, documentation of 2 negative pregnancy tests separated by 1 month and 2 forms of active birth control are required prior to dispensing the medication to patients. An identifying qualification sticker must be affixed to all isotretinoin prescriptions indicating the prescribing physician is appropriately registered with the iPLEDGE distribution program. Monthly follow-up and pregnancy testing by the prescribing dermatologist are mandatory.

Prognosis

Most uncomplicated cases of acne (approximately 90%) resolve by the third decade after birth. Hyperpigmentation and scarring are the most common sequelae of acne and affect 40% to 50% of patients.

While they can be more severe and widespread for patients who are severely affected, they can occur even with mild to moderate acne. Therefore, prompt treatment is crucial.

Post-inflammatory hyperpigmentation is a common problem once acne resolves and can sometimes be more upsetting to patients than the acne itself. It is triggered by inflammation within the skin that activates melanocytes to produce excess melanin, thus leading to dark spots. Darker-skinned patients are more commonly affected because of higher baseline melanin production. The most effective preventions are early acne treatment, sunscreen, and avoidance of irritant such as abrasives and exfoliants. One possible treatment for lighter-skinned patients is azelaic acid (eg, Azelex, Azelike), a naturally occurring wheat derivative that treats acne and lightens skin. It is available by prescription as a 20% cream and can be applied once or twice daily.

Atrophic scars develop in areas where there is loss of tissue. The 2 common types of atrophic scars are ice pick and boxcar scars. Ice pick scars are prominent pinpoint holes in the skin. Boxcar scars are depressed rounded areas with steeply angled sides, similar to the punched-out appearance of chickenpox scars. These scars can be treated in a number of ways; however, all treatments are very expensive, may only provide temporary improvement, and come with a risk of infection, worsening hyperpigmentation, prolonged redness, and poor healing—all of which increase with darker skin tones.

Resurfacing involves purposeful injury to the epidermis and superficial dermis to stimulate neocollagenesis and scar repair. Methods include chemical peels, dermabrasion, and laser resurfacing.

Lifting is an attempt to elevate the scar base to match the surrounding tissues. Techniques include injection fillers, subcision, and punch elevation.

Excisional treatments are reserved for deep, sclerotic, or severely hypopigmented scars and include punch or elliptical excision and punch grafting.

Keloid scars are hypertrophic masses of raised tissue on the surface of the skin that form as a result of increased collagen production as acne wounds heal. These scars are incredibly difficult to treat because manipulation of the scar tissue often triggers additional keloid formation and leads to scarring that is often worse than that experienced prior to treatment. The most effective treatment currently available includes cryotherapy followed by intralesional steroid injection to remove scar tissue and attempt to prevent new keloid formation. Additional adjunct therapies are also available but are less effective.

CASE RESOLUTION

The adolescent should be offered treatment for his mild to moderate comedonal and inflammatory acne. This may include benzoyl peroxide, retinoic acid, and topical antibiotics. The common side effects of the medications (eg, dry skin, peeling) should be reviewed, and the teenager should be instructed to use a noncomedogenic sunscreen. A follow-up appointment should be arranged for 4 to 6 weeks after the initiation of treatment to assess adherence to and tolerance of the prescribed treatment regimen and to address any questions or concerns.

CHAPTER 136

Disorders of the Hair and Scalp

Janice Ma, MD; Delphine J. Lee, MD, PhD, FAAD; and Ki-Young Yoo, MD

CASE STUDY

A 6-year-old girl presents with a 1-month history of swelling on the right side of her scalp that is associated with hair loss. She has previously been in good health, and she has no history of fever. On examination, she is afebrile, has normal vital signs, and appears well. A 2- × 2-cm (0.8- × 0.8-in) area of nontender, boggy swelling with associated alopecia is apparent over the scalp in the right temporal area. Small pustular lesions are scattered over the involved area. Generalized scaling of the scalp and occipital adenopathy are evident.

Questions

1. What are the common causes of circumscribed hair loss in children?
2. What are the common causes of diffuse hair loss in children?
3. What are the common causes of scalp scaling in children?
4. What features distinguish tinea capitis from alopecia areata?
5. What is the treatment for tinea capitis? Is there a role for topical antifungal agents?

Disorders of the scalp may be congenital or acquired during childhood or adolescence. Conditions may be further classified according to the presence or absence of hair loss (alopecia), whether the hair loss is diffuse or circumscribed, and whether the hair loss results in scarring of the scalp.

Epidemiology

Scalp Disorders Without Associated Hair Loss

Among the congenital scalp disorders, caput succedaneum and cephalohematoma occur in an estimated of 1% of caesarean sections and 2% of vaginal deliveries via a cephalic position. Neonatal scalp abscess has an prevalence of 0.1% to 5.2%. Meanwhile, 85% of neonatal human herpesvirus infections occur at time of delivery and the scalp usually has the longest contact with the cervix, one of the sites for transmission of infection.

Among acquired scalp disorders, seborrheic dermatitis is most frequently seen in infants; however, it can occur in children and even adults, with an estimated prevalence of 5% across all groups (see Chapter 138). Atopic dermatitis is a common condition, affecting between 10% and 20% of school-age children in the United States (see Chapter 138). The prevalence of head lice (pediculosis capitis) is highest among children aged 3 to 11 years, with a propensity for affecting females and blacks more commonly. Scabies disproportionately affects resource-limited and crowded areas, with an estimated prevalence of 100 million people worldwide.

Scalp Disorders Associated With Hair Loss

Congenital scalp disorders leading to hair loss are uncommon compared with acquired scalp conditions. *Nevus sebaceus* is a congenital hairless lesion that mainly occurs on the face and scalp, occurring in about 3 of 1,000 neonates and affecting males and female newborns equally. *Aplasia cutis congenita*, the congenital absence of skin, presents in approximately 1 in 10,000 births.

Tinea capitis is a common acquired scalp disorder that can be associated with hair loss. Tinea capitis is a fungal infection of the scalp most often caused by the dermatophytes *Microsporum canis* or *Trichophyton tonsurans.* Tinea capitis affects primarily school-age children between the ages of 3 and 7 years and is less common in infants and postpubertal adolescents. Prevalence varies geographically but is estimated to be between 3% and 13% in the pediatric population. Boys are affected more often than girls with *M canis,* although both are affected equally in epidemics caused by *T tonsurans.* Black children have the highest rates of infection, although the reasons for this are unclear. Up to 60% of affected children are asymptomatic.

Alopecia areata is considered an autoimmune disorder targeting the hair follicles, with a prevalence of 0.1% to 0.2% in the United States, occurring equally in males and females. Although alopecia areata may develop at any age, it is rare before the age of 1 year, and 40% to 50% of cases of alopecia areata develop before the age of 21 years.

Traction alopecia is more commonly seen in females whose hair-grooming practices (eg, certain hairstyles, use of chemical relaxers combined with any pulling forces on the hair) result in excessive tension and trauma to the hair. *Trichotillomania*, or compulsive hair-pulling, may be seen at any age; however, onset is typically between the ages of 5 and 12 years (see Chapter 54). It affects females more often than males and children more than adults.

Pediatric discoid lupus erythematosus is rare, with a female predominance. Epidemiology data on the incidence of secondary

syphilis in the pediatric population are limited. Meanwhile, the prevalence of Menkes disease (kinky hair syndrome) is estimated to be about 1 in 100,000 live births. Among the causes of diffuse hair loss in children (ie, telogen effluvium, anagen effluvium, and loose anagen syndrome), telogen effluvium is the most common.

Clinical Presentation

Children may present with specific symptoms, including localized baldness, pruritus, scaling, or inflammation (Box 136.1). Occasionally, lymphadenopathy, particularly in the occipital area, is the major presenting symptom.

Pathophysiology

An understanding of the physiology of the typical hair growth cycle helps in the evaluation of hair and scalp disorders. The average human scalp contains approximately 100,000 hairs. Individuals with blonde hair generally have 10% more hairs; those with red hair have 10% fewer. Healthy terminal hair grows an average of 0.3 mm (0.01 in) per day, or 1 cm (0.4 in) per month. Typical hair growth is a cyclic process composed of 3 stages. The *anagen phase,* the period of active hair growth, lasts for an average of 3 years (range: 2–6 years). Normally, about 85% to 90% of scalp hair is in this phase at any 1 time. The *catagen phase,* the transition period, lasts for about 10 to 14 days. The *telogen phase,* the final resting phase, lasts for about 3 to 4 months. About 13% of scalp hairs are in this phase at 1 time. The average individual loses about 100 to 150 telogen hairs per day. The typical hair cycle results in replacement of each scalp hair every 3 to 5 years.

Scalp Disorders Without Associated Hair Loss

Among the scalp disorders affecting newborns that are not associated with hair loss, both caput succedaneum and cephalohematoma are caused by birth trauma. Meanwhile, scalp abscess and herpesvirus are neonatal infections caused by rectovaginal bacterial flora and herpes simplex virus, respectively. The pathophysiology for atopic and seborrheic dermatitis is described in detail in Chapter 138. Head lice and scabies are infestations caused by *Pediculus humanus capitis* and *Sarcoptes scabiei*, respectively.

Box 136.1. Diagnosis of Disorders of the Hair and Scalp in Pediatric Patients

- Circumscribed or generalized hair loss (alopecia)
- Scaling
- Pruritus
- Erythema of the scalp
- Localized or generalized swelling of the scalp
- Occipital adenopathy

Scalp Disorders Associated With Hair Loss

Nevus sebaceus, a congenital scalp disorder that presents as a hairless plaque, is thought to be caused by noninherited mutations associated with a defect in the ectoderm, consequently resulting in hyperplasia of the epidermis and sebaceous glands. Aplasia cutis congenita occurs sporadically; however, familial cases have been reported. Aplasia cutis congenita is thought to be a result of many possible etiologies, including exposure to teratogens and trauma, and it can be an isolated defect or occur in association with other congenital defects such as cleft lip or palate, syndactyly, or multiple other genetic anomalies.

Tinea capitis is a communicable fungal infection and can be acquired via interpersonal contact, contact with infected animals, and fomites. There are 3 patterns of hair invasion. In endothrix infections (eg, *T tonsurans*), the fungus produces chains of spores within the hair shaft. In ectothrix infections (eg, *M canis*), spores are present around the exterior of the hair shaft. Favus, the most severe form of tinea capitis, demonstrates hyphae and air spaces within the hair shaft. This is usually caused by *Trichophyton schoenleinii,* a less common etiologic organism. Although dermatophytes have a relatively short incubation period (up to 3 weeks), they are viable in fomites for months. On close examination with dermoscopy, hairs may have a comma or zigzag appearance, with endothrix and ectothrix infections, respectively. Subcutaneous invasion in conjunction with an exaggerated host response can result in kerion, a boggy swelling of the scalp. Kerions are more commonly caused by a zoophilic dermatophyte, namely, *M canis.*

Pathophysiologic mechanisms of alopecia areata are not clearly known. One possible contributing factor is the aberrant expression of class 1 human leukocyte antigens on early anagen follicles, resulting in T lymphocyte recognition of these hairs, which are normally not recognized as foreign. There follows an immunologic attack causing premature transition to the telogen stage. The hairs then break easily at the surface of the scalp.

Traction alopecia and trichotillomania are caused by trauma to the hair. Discoid lupus erythematosus is an autoimmune condition thought to be multifactorial in etiology; the interplay of factors including genetic predisposition, sun exposure, and environmental toxins may lead to development of this condition. Secondary syphilis is caused by the bacterium *Treponema pallidum,* which can be transmitted during pregnancy through transplacental transmission, or through sexual contact. *Treponema pallidum* is not transmitted through human milk. Menkes disease is a congenital genetic disorder affecting copper uptake from the intestine, consequently resulting in copper deficiency. It is characterized by sparse kinky hair, failure to thrive, and neurodevelopmental deterioration. Telogen and anagen effluvium are 2 types of temporary hair shedding that occur at different growth stages of the hair cycle.

Differential Diagnosis

While some hair and scalp disorders can be easily recognized clinically, the differential diagnosis can be challenging at times.

Scalp Disorders Without Associated Hair Loss

These conditions are divided into those disorders seen most often in neonates and young infants and those seen more frequently in children and adolescents (Box 136.2).

Caput succedaneum, a generalized edema involving the soft tissues of the scalp, and cephalohematoma, a subperiosteal hematoma, are 2 of the most common lesions of the scalp that occur during the neonatal period, often caused by birth trauma. A cephalohematoma does not extend beyond the suture lines of the affected bone, which distinguishes it from caput succedaneum.

Other neonatal scalp conditions include infections such as scalp abscess and human herpesvirus infection. Scalp abscess occurs most commonly as a complication of scalp electrode placement. The infectious agents are usually flora of the cervix and vagina. Although most cases are self-limited, the abscess can be complicated by intracranial infection and/or sepsis. Patients who appear ill or have unstable vital signs may warrant additional workup, including blood cultures and/or neuroimaging based on clinical impression. Human herpesvirus infections of the scalp are not uncommon in neonates. Herpes lesions are typically vesicular, but petechial, purpuric, or bullous lesions may also be apparent. Skin lesions typically develop at 1 week after birth but may be present at birth or develop as late as 3 weeks later.

Seborrheic dermatitis and atopic dermatitis are the 2 most common diagnoses of scalp scaling among infants and children younger than 10 years. *Seborrheic dermatitis* is a red, scaly eruption that occurs mainly on the scalp (also known as cradle cap), face, and postauricular and intertriginous areas (see Chapter 138). It is often seen in infants and children younger than 2 years. Additionally, the scale, often termed *dandruff* in children 2 to 10 years of age, is usually associated with seborrheic dermatitis, and this is seen more in black children. Unlike atopic dermatitis, seborrheic dermatitis is generally non-pruritic. Occasionally, the inflammatory process is severe enough to result in diffuse hair loss. Psoriasis and Langerhans cell histiocytosis presenting on the scalp can mimic seborrheic dermatitis. Skin biopsy may be required for definitive diagnosis. Seborrheic dermatitis is often seen in conjunction with adenopathy of the head and neck without associated tinea infection.

Atopic dermatitis on the scalp is also characterized by erythema and scaling of the scalp, and it can overlap with seborrheic dermatitis. Atopic dermatitis on the scalp can be associated with significant pruritus with rubbing and scratching that result in the secondary effects of crusting and lichenification. Severe atopic and seborrheic dermatitis, as well as psoriasis, can result in pityriasis amiantacea (also known as tinea amiantacea, although it is not a fungal infection). *Pityriasis amiantacea* is a scalp condition that usually presents as localized, thick, adherent, and white or gray scale.

Head lice (pediculosis capitis) is an extremely common childhood infestation that affects girls more often than boys and is most common in children aged 3 to 11 years. Lice are spread by direct contact with infected individuals or infested clothing, combs, or other hair accessories. Pruritus is the primary symptom along with erythema and scaling, with secondary impetigo being common. The viable ova or nits may be visible as small, oval, tan to brown specks found most commonly attached to the hair above the ears and the nape of the neck. Hatched eggs are clear to white. Generally, only the ova closest to the scalp are viable. They are difficult to remove. Scabies, a pruritic infestation commonly seen in children, generally does not affect the scalp, except in infants, the elderly, and those who are immunocompromised. On the scalp of infants, 2- to 3-mm (0.08- to 0.1-in) erythematous papules are seen, with overlying excoriations and, often, secondary bacterial infection.

Box 136.2. Common Disorders of the Scalp Without Associated Hair Loss

Neonatal Period and Early Infancy

- Birth trauma to the scalp (eg, caput succedaneum, cephalohematoma)
- Scalp abscess (at fetal scalp electrode site)
- Herpes simplex infection
- Cradle cap/seborrheic dermatitis
- Atopic dermatitis[a]
- Scabies

Childhood and Adolescence

- Seborrheic dermatitis[a]
- Atopic dermatitis[a]
- Head lice (pediculosis capitis)
- Psoriasis[a]

[a] May occur with or without associated hair loss.

Scalp Disorders Associated With Hair Loss

Box 136.3 lists the common scalp disorders associated with hair loss. When evaluating hair loss in children, it is important to determine whether the loss is diffuse or circumscribed.

Nevus sebaceus is a benign, congenital growth characteristically presenting on the face or scalp. These lesions are characteristically hairless. In addition, they are usually solitary, well-circumscribed plaques on the scalp, yellow-orange in color, and ovoid to linear in shape. Nevus sebaceus can be associated with a small risk of malignant transformation, namely basal cell carcinoma, at a rate of less than 1% before the age of 18 years. Other benign growths within nevus sebaceus may also occur at a rate of approximately 1%. Therefore, regular monitoring or consideration of excision should be part of the management. Because of the relatively low risk and low metastatic potential, it is reasonable to postpone excision until later in life. Aplasia cutis congenita is a congenital skin defect with localized areas of epidermal, dermal, or subcutaneous tissue loss. Lesions can occur anywhere on the body, but most are found along the midline of the scalp. At birth, the lesions usually appear as punched out, round or oval defects that may have an overlying thin, glistening membrane. Erosion, ulceration, or a scar due to healing in utero can also be seen. A hair collar sign, or ring of long and coarse hair, may surround the lesion.

Box 136.3. Common Disorders of the Scalp With Associated Hair Loss

Circumscribed Hair Loss

Congenital

- Aplasia cutis congenita
- Nevus sebaceus
- Epidermal nevus

Acquired

- Tinea capitis
- Alopecia areata
- Traction alopecia
- Trichotillomania
- Discoid lupus erythematosus
- Secondary syphilis
- Human herpesvirus
- Lichen planus

Diffuse Alopecia

Congenital

- Congenital hypothyroidism
- Hair shaft defects (eg, Menkes syndrome, monilethrix)
- Ectodermal dysplasia and other genetic syndromes

Acquired

- Seborrheic dermatitis
- Psoriasis
- Telogen effluvium
- Anagen effluvium (secondary to toxins or chemicals)
- Endocrine (eg, diabetes mellitus)
- Hypothyroidism-hypoparathyroidism-hypopituitarism
- Medication-induced (isotretinoin)
- Androgenic alopecia (eg, male pattern baldness)
- Loose anagen syndrome

Other

- Nutritional (eg, acrodermatitis enteropathica, malnutrition, iron deficiency, rickets)
- Systemic lupus erythematosus

Tinea capitis, a fungal infection of the scalp, is among the most common causes of acquired hair loss in children. This condition is characterized by patchy alopecia with broken-off hairs and scaling of the scalp and may lead to scarring if the infection becomes inflammatory. *Trichophyton tonsurans* currently accounts for most cases in the United States, but in a given geographic area, the etiologic fungus may change over time. *Trichophyton tonsurans* infection sometimes appears as a series of black dots within the affected area because of the presence of fragmented hairs. Human-to-human transmission is more common with *T tonsurans,* an anthropophilic fungus. Children who handle dogs or cats, which harbor *M canis,* a zoophilic fungus, are susceptible to infection. Carriers are most commonly adults exposed to affected children, and carriers are potentially contagious and warrant screening and consideration of treatment. The diagnosis of tinea capitis can be difficult in children with diffuse scalp scaling or a diffuse pustular eruption without significant alopecia. Patients with tinea capitis may have palpable cervical lymphadenopathy on examination. Occasionally, an intense hypersensitivity response may result in a boggy swelling of the scalp known as a kerion. The surface of the kerion may be smooth or covered with small pustules, mimicking a bacterial infection. Tinea capitis lesions can present with scale and localized patches of hair loss and may lead to scarring if the infection becomes inflammatory. Uncomplicated tinea capitis leaves no scars, but kerion or favus may result in permanent, scarring hair loss.

Alopecia areata, which frequently leads to hair loss, is characterized by well-defined areas of complete hair loss without associated scaling, irritation, or inflammation of the scalp. The hairs at the margins of alopecia are easily plucked and have an "exclamation mark" appearance with the proximal end thinner than the distal end. The most common presentation is that of 1 or more round or oval bald patches. A less common subtype is the ophiasis pattern, in which hair loss is present in a band along the periphery of the temporal and occipital scalp. With alopecia areata, spontaneous regrowth with nonpigmented, white or gray hairs may initially be seen. However, patients may develop a new bald patch at another site despite regrowth at the initial location. Associated nail defects, including nail pitting (most common) and ridging, may occur. Occasionally, alopecia totalis (loss of all scalp hair) or alopecia universalis (loss of all body and scalp hair) may result. It may be seen in association with atopic dermatitis, Down syndrome, and other autoimmune diseases (eg, thyroid disease, vitiligo, inflammatory bowel disease). Family history is positive in 10% to 50% of affected patients.

Common traumatic causes of alopecia in children are traction alopecia and trichotillomania. Traction alopecia often occurs along the margins of the hairline secondary to having the hair pulled back in tight ponytails or braids. Short, broken hairs with patchy hair loss and follicular papules may be seen. Chronic, prolonged traction can result in permanent, scarring alopecia. Obtaining a history of hair care habits, including use of styling tools, headgear, and chemicals (eg, relaxants, dyes), is crucial. Trichotillomania is a self-induced form of traction alopecia in which children twist or pull out their hair either consciously or subconsciously and may be seen in association with other impulse disorders such as thumb-sucking and nail-biting (see Chapter 54). It results in hair loss caused by self-induced trauma. Usually scalp hair is involved, but any hair-bearing areas, including eyebrows or eyelashes, may also be affected. Hairpulling is generally believed to occur in a younger population and usually resolves with minimal or no intervention needed. Trichotillomania is classified in *Diagnostic and Statistical Manual of Mental Disorders,* 5th Edition, in the Habit and Impulse Disorders category. Hair is generally plucked in a wavelike fashion across the scalp or centrifugally from a starting point. The occiput is generally spared. Trichotillomania may mimic other types of alopecia, but the diagnosis can usually be made on the basis of the bizarre patterns of hair loss with hairs broken at differing lengths. Children occasionally eat the hairs as they are pulled out, resulting in the formation of a trichobezoar (hair ball) in the stomach.

Discoid lupus erythematosus, lichen planus, and secondary syphilis are uncommon causes of localized hair loss from the scalp in children. The patches of alopecia in discoid lupus erythematosus often appear hypopigmented with hyperpigmentation at the periphery, the latter representing older lesions. Because adnexal structures are involved in discoid lupus, scarring alopecia is commonly seen. Lichen planus, an idiopathic inflammatory disease of skin and mucous membranes, can result in scarring and non-scarring alopecia. Secondary syphilis lesions appear as diffuse, "moth-eaten" patches of alopecia often affecting the occipital or bitemporal scalp regions that are non-scarring. In addition to the scalp, other areas, including the eyebrows, eyelashes, and body hair, may also be affected.

A variety of structural defects, endocrine and metabolic disorders, and toxins may be associated with diffuse loss of scalp hair (Box 136.3). Intrinsic structural defects of the hair may cause hairs to break, thus resulting in failure of hair growth. In some forms of ectodermal dysplasia, the number of hair follicles is reduced or the follicles are altogether absent, giving the appearance of sparse or thinning hair. Many of the ectodermal dysplasias have abnormalities of the teeth, nails, and sweat glands. Monilethrix is an autosomal-dominant condition that can appear in isolation or in association with other anomalies. Microscopic evaluation of hairs shows a "beads on a string" appearance due to alternating nodes and internodes resulting in fractures between the nodes. Pili torti can be seen in several syndromes, including Menkes disease (kinky hair syndrome). Affected patients have twisted hair leading to premature breakage and, thus, chronically short hair. There is often baldness at sites of friction.

Causes of diffuse hair loss in childhood include telogen effluvium, anagen effluvium, and loose anagen syndrome. Telogen effluvium is a common cause of diffuse, non-scarring hair loss that may occur 2 to 4 months after a variety of events, including pregnancy, discontinuation of oral contraceptives, severe febrile illness, medications, severe diets, or significant emotional stress. Hair loss results from the abrupt conversion of numerous scalp hairs from the anagen (growth) phase to the telogen (resting) phase. Loss of more than 150 hairs per day is considered atypical. Patients may report losing several hundred hairs a day, but the occurrence of clinically significant baldness is rare. Estimates indicate that individuals must lose about 25% of their hair before thinning becomes clinically apparent. The hair loss may continue for several weeks, but complete regrowth usually occurs within 6 to 12 months, or after reversal of the inciting trigger. *Anagen effluvium* results in the loss of growing hairs due to a sudden cessation of the growing phase. It occurs most commonly after systemic chemotherapy but can also occur with exposure to radiation or toxins. *Loose anagen syndrome* is a disorder in which the anagen hair follicle is anchored improperly, resulting in easy, painless plucking of the hairs. This can result in patchy diffuse hair loss or focal areas of alopecia without increased hair fragility. This is a familial condition, with fair-haired females more commonly affected. Often, these children will not need a haircut through early childhood. The hair is expected to spontaneously become normal by the teenage years without treatment. Thyroid disorders, particularly hypothyroidism, can also result in diffuse congenital or acquired hair loss.

Evaluation

History

The age of the child guides the differential diagnosis because some lesions are more common at one age than another. Box 136.4 reviews pertinent history that may be helpful in diagnosis.

Physical Examination

The scalp should be examined to see if hair loss is diffuse or circumscribed and whether scalp hairs can be plucked easily. Signs of irritation, inflammation, or scaling of the scalp should also be noted, as well as the presence of adenopathy, nail changes, or hair loss elsewhere on the body.

Wood light examination of the scalp for fungus is helpful if the result is positive. A negative examination does not rule out the possibility of fungal infection, however, because *T tonsurans,* the most common cause of tinea capitis in the United States, does not fluoresce. *Microsporum canis* fluoresces yellow-green under the Wood light.

Laboratory Tests

Laboratory assessment is useful in some cases. If fungal infection is suspected, a potassium hydroxide examination should be performed by the primary care physician. Scales and broken hairs can be obtained from involved areas by brushing, scraping (eg, with a No. 15 scalpel blade), plucking, or rubbing a moistened 10- × 10-cm (3.9- × 3.9-in) gauze over affected areas and then removing broken hairs and scale from the gauze with forceps. The scrapings should be placed on a glass slide, dissolved in potassium hydroxide solution, heated gently, and examined under the microscope. Hyphae and spores within the hair shaft (eg, *T tonsurans* infection) or surrounding the hair shaft (eg, *M canis* infection) should be noted.

Box 136.4. What to Ask

Disorders of the Hair and Scalp

- Is the child losing any hair?
- If so, is the child losing hair from all over the scalp or only from localized areas on the scalp?
- Has the child lost any body hair (eg, eyebrows, eyelashes) in addition to the scalp hair?
- How long has the child been losing hair?
- Is the scalp pruritic or scaling?
- Have the parents noticed the child twisting or pulling the hair?
- Is the child's hair often in ponytails or braids?
- Has there recently been any significant stress in the child's life?
- Do any pets live in the home?
- Is the child taking any medications?
- Is anyone else in the home or anyone in close contact with the child having similar symptoms?

In addition to microscopic examination, fungal cultures are recommended in all cases of suspected tinea capitis. Brushings using a moistened sterile cotton swab or a sterile brush as used in Papanicolaou tests will yield the most reliable results. Hair or scalp scrapings are inoculated onto Sabouraud agar or dermatophyte test medium. Within 5 to 14 days, a distinctive growth seen on the Sabouraud agar or a color change from yellow to red in the dermatophyte test medium confirms the diagnosis. Negative potassium hydroxide examination and fungal culture results, in addition to a lack of inflammation and scaling, may be required for differentiating trichotillomania or alopecia areata from tinea capitis.

The diagnosis of telogen effluvium is usually suggested by the history and counting the number of hairs lost each day. If the diagnosis is in question, the patient may be referred to a dermatologist for examination of the involved hair roots via biopsy and determination of the anagen to telogen ratio, which is usually about 85:15. A telogen count of more than 25% is considered to be diagnostic of telogen effluvium. The ratio of anagen to telogen hairs is normal in trichotillomania. For cases in which the trigger for suspected telogen effluvium is unknown, additional laboratory workup (ie, chemistry panel, thyroid function tests, hematocrit, ferritin, and sedimentation rate) should be performed. In persistent cases, a scalp biopsy may be obtained.

A more extensive laboratory workup may be required if the hair loss is persistent or the history or physical examination is suggestive of systemic disease (Box 136.3). Studies that may be considered include liver function tests, thyroid function studies, a serum VDRL test, antinuclear antibodies, and serum electrolytes. Routine thyroid function studies should be reserved for patients with alopecia areata with a personal history of atopy or Down syndrome, family history of thyroid disease, or clinical findings suggestive of thyroid disease. Low vitamin D has been linked with alopecia areata, with one study finding deficient levels of 25(OH) vitamin D in the serum of patients with alopecia areata, and an inverse relationship between serum vitamin D and disease severity.

Management

Scalp Disorders Without Associated Hair Loss

Management depends on the diagnosis. Cephalohematoma and caput succedaneum result from birth trauma and generally resolve spontaneously within a few weeks to months without further complications. Meanwhile, management of scalp abscesses includes incision and drainage alone for uncomplicated cases and consideration of systemic antibiotics depending on the severity of the infection (eg, associated cellulitis, signs of systemic involvement). Herpetic infection in a newborn requires immediate attention and systemic antiviral therapy because the risk of systemic infection is significant. Scalp electrodes and vacuum-assisted vaginal deliveries should be avoided in neonates with mothers known to have human herpesvirus infections because these can increase the rate of infection transmission. Currently, cesarean section remains the standard of care, although most cases of herpes simplex in neonates are in those born to mothers without known infection at time of delivery.

Seborrheic dermatitis can persist into the pubertal years, contrary to previously held beliefs. Cradle cap, which refers to seborrheic dermatitis seen during infancy, can be treated with simple skin care measures such as bathing and the use of moisturizing emollients. Gentle shampoos, low-potency corticosteroids, and, if needed, 2% ketoconazole cream can resolve most cases. Past infancy, seborrheic dermatitis may be treated with shampoos containing tar, zinc pyrithione, ketoconazole, or selenium in rotation. Topical, mild corticosteroid solutions can be used if pruritus is significant. As with the management of atopic dermatitis elsewhere in the body, the goals of treatment for atopic dermatitis involving the scalp include reducing environmental triggers and minimizing inflammation and pruritus of the skin. Treatment modalities typically include topical corticosteroids, topical calcineurin inhibitors, and phototherapy (see Chapter 138).

Head lice may be treated with pyrethrin products, such as permethrin 1% cream rinse (Nix) or the prescription 5% cream typically used for scabies. Other medications can also be effective. Topical ivermectin (Sklice Lotion) was approved by the US Food and Drug Administration in 2012 for use in patients 6 months and older with head lice. Topical malathion (Ovide Lotion) is another option, although it is flammable given its high concentration of isopropyl alcohol. Lindane shampoo may be considered in patients who have head lice refractory to treatment. Of note, lindane shampoo has a US Food and Drug Administration black box warning given the possible risks of neurologic toxicity. All topical medications should be used twice, 1 week apart, regardless of package insert information. A fine-toothed comb or tweezers may be required after rinsing to remove the ova or nits of head lice. Other alternative treatments have been unsubstantiated, such as using mayonnaise or petroleum jelly. Heat, such as that associated with blow-drying the hair, also kills a large percentage of the lice. The timing of when children infested with head lice can return to school is controversial. Some school authorities recommend a no-nit policy that prohibits children with nits from returning to school, even if the nits are not viable. Groups including the Centers for Disease Control and Prevention (CDC) and American Academy of Pediatrics do not support adherence to the no-nit policy once children are treated. Per the CDC, many of the nits are 0.6 cm (0.25 in) or more from the scalp and typically not viable. In addition, the disadvantages of unnecessary absences from school outweigh the low probability of transmission.

For treatment of scabies, permethrin 5% cream is the preferred scabicide. It should be applied from head to toe in infants and children younger than 2 years and from neck to toe for those older than 2 years, for 8 to 12 hours, washed off, and repeated in 1 week. Permethrin 5% cream can be used in infants as young as 2 months and pregnant women. For these patients, sulfur 6% ointment can also be used. For scabies and lice, the treatment of fomites is also important. Clothing, bed linens, and towels should be washed in hot water

and machine-dried in high heat. Fomites that cannot be laundered should be sealed in plastic for 48 to 72 hours.

Scalp Disorders Associated With Hair Loss

Children suspected of nevus sebaceus should be referred to a dermatologist. Excision may be considered not only because of the risk, albeit low, of secondary neoplastic changes but also because these lesions can become more prominent and warty in appearance and friable during puberty and adulthood. In cases of aplasia cutis congenita, small defects generally heal well with conservative management, whereas larger defects may require surgical excision and eventual skin grafting. Preoperative imaging studies may be required for extensive, severe cases.

Both oral griseofulvin and terbinafine hydrochloride are effective treatment options for children with tinea capitis. Terbinafine appears to be more effective for individuals with *T tonsurans* infection, while griseofulvin is preferred for those with *M canis* infection. Oral griseofulvin administered for at least 6 to 12 weeks has been the long-held treatment of choice for tinea capitis. Although griseofulvin can have many side effects, including gastrointestinal disturbances, hepatotoxicity, and leukopenia, it is generally well tolerated by children and is available in suspension form. Care should be taken to use proper dosing when using micronized (20–25 mg/kg) or ultra-micronized (10–15 mg/kg) griseofulvin. Terbinafine, available in tablets or granules, has been effective at shorter treatment times than griseofulvin. Newer antifungal agents are also being used with great success, often for shorter durations than griseofulvin, which can increase compliance. Itraconazole and fluconazole are alternative treatments, specifically for those infected with *Trichophyton* species. Itraconazole can be given as continuous or pulse therapy and is available as a solution. Fluconazole, also available as solution, is usually administered for 3 to 6 weeks or at a higher dose once weekly for 8 to 12 weeks. Ketoconazole is contraindicated because of its potential for adverse effects, including liver toxicity and adrenal insufficiency, especially in light of other available agents. Generally, longer courses of treatment are needed for *M canis* infection. Topical antifungal agents are not effective on the scalp for treatment of tinea capitis because the hair follicle must be penetrated, requiring the use of systemic therapy. Twice-a-week shampooing with ketoconazole or selenium sulfide shampoos has been shown to reduce carriage of spores and reduce infectivity.

A course of oral prednisone may be required in conjunction with an oral antifungal if a kerion is present to minimize discomfort and permanent, scarring hair loss. Children with kerion are often misdiagnosed as having a bacterial infection of the scalp and treated with oral antibiotics. However, the pustules in kerion are generally sterile, and even when secondary bacterial infection is present (ie, about 30%–50% of patients), antibiotics do not alter the course of the condition.

Children believed to have alopecia areata should be referred to a dermatologist. Therapy for alopecia areata consists of topical and intralesional corticosteroids, topical anthralin, or minoxidil. Topical immunotherapy with a sensitizer such as squaric acid has also been used for the treatment of extensive alopecia areata. Occasionally, oral steroids can be tried for extensive or rapidly progressing disease. Tofacitinib, a Janus kinase inhibitor, has recently been proposed as a well-tolerated therapy for patients with alopecia areata, including adolescents. Many psychosocial factors should be considered when treating children with this condition. Children with severe forms of the disease may benefit psychologically from wearing a wig. The National Alopecia Areata Foundation (www.naaf.org) is available as a support group for affected children and their families.

Prevention and management of traction alopecia includes modifying hairstyling practices to minimize tension on the hair and scalp. No treatment has been demonstrated to be consistently effective for children with trichotillomania, although cognitive behavioral therapy and the use of antidepressants, including clomipramine hydrochloride, have been reported to have some success. Cessation of the inciting triggers of telogen and anagen effluvium (eg, drugs, toxins, stress) should lead to regrowth of hair.

Diligent sun protection is crucial in the management of discoid lupus erythematosus. Topical medications are the first-line therapy, with corticosteroids preferred over calcineurin inhibitors. Menkes disease has no cure. Given that it is a copper deficiency condition, some individuals with this disease may achieve benefits with copper injections. Children with Menkes disease often benefit from a multidisciplinary team, including physical and occupational therapists, nutritionists, gastroenterologists, and urologists, given the systemic nature of this condition.

The recommended regimen for infants and children with secondary syphilis is a single dose of intramuscular benzathine penicillin G (50,000 units/kg, up to adult dose of 2.4 million units). The CDC advises that all infants (>1 month of age) and children diagnosed with syphilis should be evaluated by a pediatric infectious disease specialist and evaluated for sexual abuse. Additionally, individuals diagnosed with syphilis should also be tested for HIV.

Prognosis

Common disorders of the scalp, such as seborrheic dermatitis, head lice, and tinea capitis, generally respond well to treatment and rarely result in long-term sequelae. The course and prognosis of alopecia areata are quite variable and may be difficult to predict. Generally, prognosis for regrowth is good if hair loss has occurred in only a few patches. Prognosis is usually poorer with younger age at onset, positive family history, nail involvement, and an ophiasis (band-like) pattern of hair loss. It is important to pursue further workup if a condition does not respond to therapy because it is critical that a condition such as Langerhans cell histiocytosis, which mimics seborrheic dermatitis, not be missed. Many of the hair disorders are a result of syndromes that will not respond to therapy; thus, education for patients and their families is important.

CASE RESOLUTION

The child exhibits physical findings of a kerion. Diagnosis can be made clinically on the basis of the appearance of the lesion. The diagnosis is established by microscopic evidence of hyphae and culture confirmation. Treatment with oral antifungals and possibly oral steroids should be initiated. Carriers should also be identified and treated. The child should be examined in 4 weeks to ascertain the response to therapy and check for any adverse reactions.

CHAPTER 137

Diaper Dermatitis

Houmin Li, MD, PhD; Delphine J. Lee, MD, PhD, FAAD; and Ki-Young Yoo, MD

CASE STUDY

A 6-month-old boy has a 3-day history of a rash in the diaper area. The mother has been applying cornstarch, but the rash has worsened and spread to the inner thighs and abdomen. The infant has no history of fever, upper respiratory tract symptoms, vomiting, or diarrhea. He was seen in the emergency department 1 week prior to this office visit for acute gastroenteritis, which has since resolved. On examination, a poorly demarcated, shiny, erythematous rash is noted over the convex surface of the buttocks, lower abdomen, and genitalia, with relative sparing of the intertriginous folds. The rest of the physical examination is within normal limits.

Questions

1. What are the common causes of rashes in the diaper area (ie, diaper dermatitis)?
2. What features distinguish the various types of diaper dermatitis?
3. What systemic diseases may present with diaper dermatitis?
4. What are complications that may affect dermatitis in the diaper area?
5. What are some common treatments for diaper dermatitis?

Diaper dermatitis (DD) is a nonspecific term used to describe the various inflammatory reactions of the skin within the diaper area. Diapered skin is exposed to friction, excessive hydration, and varying pH; additionally, it is in constant contact with urine and stool, both of which are highly irritating to the skin. Management of DD focuses on acceleration of healing of the damaged skin and prevention of a recurring rash. More importantly, the key to efficient DD management is prevention.

Epidemiology

Diaper dermatitis is the most common dermatologic disorder in infancy, with a peak incidence at 9 to 12 months of age, although some reports have shown a high incidence in the first month after birth. The prevalence of reported DD in infants varies greatly, from 7% to 50%. This disorder is not limited to infants and small children; it may occur in any individual who wears diapers, although the prevalence in adults is unknown.

Clinical Presentation

Diaper dermatitis primarily affects the skin of the buttocks, gluteal cleft, lower abdomen, genitalia, perineum, and proximal thighs. The 3 most common types of DD are chafing dermatitis, irritant contact dermatitis, and diaper candidiasis. The different types of DD have distinct clinical presentations. *Chafing dermatitis* is quite common in infants and appears in areas in which friction from the diaper is most severe. It appears as mild redness in the affected area and improves quickly on its own with frequent diaper changes and/or decreased friction. The most common type of DD, *irritant contact dermatitis*, appears as scaly erythematous papules and plaques or poorly demarcated, glistening erythema over the convex surfaces, with relative sparing of the intertriginous folds (Figure 137.1A). *Diaper candidiasis* is another common form of DD and presents as well-defined red plaques with satellite papules and superficial pustules along the margin. Candidal infections may be primarily concentrated within the skin folds (Box 137.1) (Figure 137.1B).

Pathophysiology

The development of all 3 main subtypes of DD is the result of multifactorial interaction, of which the most important is prolonged contact of the skin with urine and stool. Other factors characteristic of the diaper area are excessive moisture, elevated pH, high enzymatic activity, and friction, all of which to some extent compromise the skin barrier function and induce a skin inflammatory reaction.

Prolonged wetness in the diaper area results in maceration of the stratum corneum. Weakening of its physical integrity makes the stratum corneum more susceptible to mechanical friction generated as the diapered infant tries to move, local irritation resulting from chemicals or enzymes, and microbial infections. Urine and stool can elevate the local pH to more alkaline values and in turn cause increased activity of fecal proteases, lipases, and ureases, all of which are highly irritating to the skin. Furthermore, fecal ureases produced by a variety of fecal bacteria catalyze the breakdown of urea to ammonia, which in turn contributes to increased skin pH level. Friction generated as the infant tries to move about may further aggravate the condition and result in maceration of the skin. A damaged skin barrier can also result in microbial imbalance on the skin surface. *Candida albicans* and *Staphylococcus aureus* are typically isolated from the affected area and may further aggravate skin inflammation.

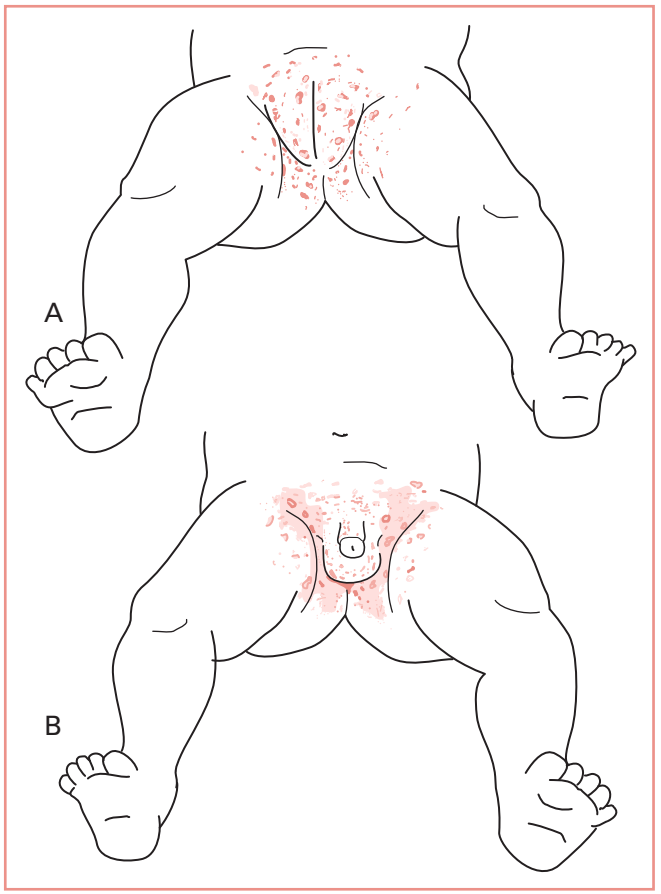

Figure 137.1. Diaper dermatitis. A, Diaper dermatitis secondary to irritant contact. Convex surface areas are affected. B, Diaper dermatitis secondary to *Candida*. Intertriginous areas are affected, and satellite lesions are present.

Box 137.1. Differential Diagnosis of Diaper Dermatitis

Most Common Causes

- Irritant contact dermatitis
- Candidiasis
- Seborrheic dermatitis

Less Common Causes

- Allergic contact dermatitis
- Impetigo
- Perianal streptococcal or staphylococcal disease
- Atopic dermatitis
- Psoriasis
- Zinc deficiency, including acrodermatitis enteropathica
- Biotin deficiency
- Langerhans cell histiocytosis
- Congenital syphilis

Differential Diagnosis

Although most cases of DD can be easily recognized clinically, it is important to consider other etiologies beyond the common types mentioned previously, especially when the condition is not responsive to therapy. Familiarity with the difference in appearance of these conditions is critical. The internet can be valuable by providing access to images of many dermatologic conditions. Some websites display a pictorial representation and allow for searching by features such as rash morphologies, symptoms, exposures, skin color, body location, and many other factors.

The differential diagnosis of DD is presented in Box 137.1.

Granuloma gluteale infantum is a possible complication of irritant DD that presents with violaceous nodules and plaques on the buttocks, vulva, scrotum, and perineum. Although these nodules and plaques are alarming in appearance, they are benign and will resolve after the dermatitis is cleared; scarring can occur, however. The development of granuloma gluteale infantum does not necessarily correlate with the severity of the preexisting irritant dermatitis. Jacquet erosive dermatitisis another potential complication in which the irritant dermatitis is severe. This form of dermatitis is characterized by small, well-demarcated erosions or ulcers that can also feature elevated borders. With chronic irritant dermatitis, a child may develop *perianal pseudoverrucous papules and nodules*, which are small bumps characterized by a flat-topped, moist, smooth, shiny surface. All 3 types—granuloma gluteale infantum, Jacquet erosive dermatitis, and perianal pseudoverrucous papules and nodules—are considered to be less common manifestations of irritant contact dermatitis.

Candidiasis, which is the result of infection with *C albicans,* typically begins in the folds (ie, intertriginous areas) and then spreads to other surfaces. Sometimes associated with oral thrush, candidiasis is also a common sequela of systemic antibiotic therapy. The rash appears as bright, beefy red plaques with sharp, raised borders and many small satellite papules, vesicles, and pustules along its margins, often with desquamation. *Candida albicans* can be a cause of secondary infection of already inflamed skin as well as a primary causative factor in some cases of DD. Recurrent diaper candidiasis can be associated with candidal colonization of the gut and oral cavity. Persistent diaper candidiasis in young children may be a sign of type 1 diabetes mellitus, chronic mucocutaneous candidiasis, or an underlying immune deficiency.

Seborrheic DD, like candidal DD, also primarily affects the intertriginous areas of the groin. The rash has a characteristic salmon-colored appearance with soft, yellowish scale. Satellite lesions can be seen. Seborrheic dermatitis of the face, scalp (including postauricular areas), neck, trunk, and proximal extremities usually is seen in association with seborrheic dermatitis of the diaper area.

Allergic contact dermatitis is a less common cause of DD but should be considered in patients who do not respond to standard therapeutic interventions. Possible allergens include the chemical makeup of the diaper itself or topical preparations such as soaps, emollients, and baby wipes that are applied to the diaper area. For example, rubber additives (eg, 2-mercaptobenzothiazole) found in the elastics of disposable diapers have been shown to cause allergic DD on the hips and outer buttocks. This distribution is reminiscent of a cowboy's gun holster, which has earned the condition the moniker "Lucky Luke" dermatitis. Methylchloroisothiazolinone, also known as methylisothiazolinone, is a combination preservative used in personal care and household products and is a common cause of

allergic contact dermatitis. Allergic contact dermatitis in the diaper area has been reported with increased frequency in babies on whom wet wipes containing methylisothiazolinone are used. Other allergens to consider are emulsifiers in topical preparations, fragrances, disperse dye, and preservatives.

Bacterial infections can exacerbate DD. Impetigo, especially bullous impetigo, is a not uncommon eruption in the diaper area. Bullous impetigo is caused by *S aureus* and is toxin mediated. The rash presents as vesicles that may enlarge into 3- to 5-cm (1.2- to 2-in) bullae that easily rupture, leaving superficial erosions with thick, honey-colored crusts. The associated systemic symptoms of fever and diarrhea may be present. Perianal bacterial disease can result from group A β-hemolytic streptococcus or *S aureus.* Classically, perianal streptococcal dermatitis manifests as well-demarcated, bright red, tender patches. Rectal bleeding and painful defecation may also be noted.

In 30% to 60% of infants born with congenital syphilis, the symptoms are the same as those of DD. Initially, there usually exists a bright erythematous morbilliform eruption that fades to a coppery color, often with scaling. Pustules can develop later. The buttocks, face, extremities, palms, and soles generally are affected.

Diaper rashes that persist despite seemingly adequate therapy should raise suspicion for other systemic diseases as the underlying cause. Though less common than irritant and seborrheic dermatitis and candidiasis, these conditions include psoriasis, atopic dermatitis, zinc deficiency, biotin deficiency, and Langerhans cell histiocytosis. Psoriasis may occur anywhere on the body, but lesions typically occur on the scalp, face, elbows, and knees. In infants, generally between 2 and 8 months of age, psoriasis may involve the diaper area. Lesions elsewhere on the body typically are well-circumscribed, erythematous plaques with a thick, silvery scale. Psoriatic lesions in the diaper area, however, may be difficult to differentiate from seborrheic dermatitis or candidal infection. Plaques are brightly erythematous and sharply demarcated but without obvious scale because of the moisture from the occluded diaper area. Skin biopsy, family history of psoriasis, or nail involvement may help confirm the diagnosis.

Atopic dermatitis typically spares the diaper area, even in infants who have lesions elsewhere on the body. The relative sparing of the diaper area may be a result of the increased moisture of the skin in this area. (See Chapter 138 for a discussion of atopic dermatitis.)

Zinc deficiency can cause dermatitis in a characteristic periorificial distribution (ie, mouth, nose, ears, eyes, and anogenital area) and in the distal extremities. Zinc deficiency may result from the inherited defect acrodermatitis enteropathica or may manifest secondary to insufficient intake or malabsorption, such as in patients with cystic fibrosis. *Acrodermatitis enteropathica* is a rare, autosomal recessive inherited disorder with mutations in *SLC39A* resulting in defective zinc transporters in the small intestine. In breastfed infants, the disease manifests shortly after weaning, whereas in bottle-fed infants, signs and symptoms appear days to weeks after birth. Afflicted infants are irritable and listless and present with diarrhea, failure to thrive, and skin lesions in the previously mentioned distribution, featuring erythematous bullous and pustular lesions as well as dry, red, scaly plaques. Candidal and *S aureus* superinfection can occur. Treatment consists of oral zinc supplementation. Biotin deficiency, as well as several other nutritional deficiencies, can present with identical skin findings, and treatment is with supplementation of the deficient nutrient.

Langerhans cell histiocytosis refers to a group of disorders characterized by proliferation of macrophages, a progenitor cell in the bone marrow. Members of this group include Letterer-Siwe disease, Hand-Schüller-Christian disease, eosinophilic granuloma, and congenital self-healing reticulohistiocytosis. Skin lesions may involve the scalp and flexural areas of the perineum, axilla, and neck. The lesions appear as small, pink to tan scaling papules and pustules that can coalesce; associated purpura or ulceration may be apparent in the inguinal fold with secondary impetiginization (ie, honey-colored crusting caused by *S aureus* superinfection). The rash is most often confused with seborrheic dermatitis. Diagnosis can be confirmed by skin biopsy.

Evaluation

History

A thorough review of the medical history is crucial for efficient diagnosis and management, including duration of the presenting rash, frequency of urination and defecation, other symptoms (eg, pain, itchiness), hygiene practices, and previously used therapies (Box 137.2). Diaper candidiasis should be suspected if oral antibiotic therapy has recently been administered.

Physical Examination

On physical examination, DD presents as an erythematous eruption with varying patterns as described previously. Based on the physical examination of the diaper area and presence of skin lesions elsewhere on the body, potential etiologies should be considered. This is particularly important in the case of a persistent, resistant, or recurrent diaper rash in which a generalized skin disorder, such as psoriasis, must be considered. The distribution of the rash within the diaper area itself may provide clues to the diagnosis. Candidiasis and seborrheic dermatitis occur primarily in the folds, whereas irritant contact dermatitis usually affects the convex areas of the skin with relative sparing of the intertriginous areas. Streptococcal disease manifests primarily as marked perianal erythema.

Box 137.2. What to Ask

Diaper Dermatitis

- When did the rash begin?
- Does the rash resolve and then recur?
- Is the rash pruritic?
- Is the infant feeding and sleeping? Is the infant irritable?
- Have any home remedies or previous treatments been used? If so, which ones?
- Does the infant have a family history of atopic dermatitis or psoriasis?
- Is the infant taking antibiotics now, or has the infant used them recently?
- What type diaper is used?
- How frequently are the diapers changed?

Laboratory Tests

Laboratory tests are rarely necessary in the evaluation of DD; however, they can be useful in confirming the etiology of atypical cases. Although the diagnosis of diaper candidiasis is usually evident clinically, microscopic examination of skin scrapings with potassium hydroxide may be performed to establish the diagnosis. Typically, budding yeast with hyphae or pseudohyphae is seen. The diagnosis of perianal streptococcal disease or bullous impetigo may be confirmed by bacterial cultures from the perianal area or bullous lesions, respectively. Biopsies may be warranted for the patient with recalcitrant DD. Other laboratory tests, such as viral culture, polymerase chain reaction, direct fluorescent antibody, or Tzanck, may be performed to exclude other suspected skin diseases.

Management

Management of DD is based on 2 major objectives: accelerating healing of the damaged skin and preventing recurrence. The key to efficient DD management, however, lies in prevention of the initial eruption.

Skin Care

The mainstay of DD prevention and management involves keeping the diaper area clean and dry. General skin care measures are needed for maintaining a healthy skin barrier. Gentle but thorough cleansing of the diaper area is necessary when stool is present and can be done with water alone or with water and mild cleanser. The area should then be patted dry and allowed to air-dry completely if possible; alternatively, cotton balls can be used to dry the area. Cleansing frequently with harsh soaps or scrubbing too vigorously can further irritate skin that is already damaged and inflamed.

Additionally, the diaper should be changed frequently. Cloth and standard disposable diapers are less effective than superabsorbent gel diapers in decreasing moisture. Dusting powders, such as cornstarch and talc, minimize friction. Unlike cornstarch, talc does not enhance the growth of yeast on skin. Concerns about the pulmonary effects from inhalation of cornstarch and talc precludes their routine use in the absence of any skin inflammation, however. Moisture-resistant barrier ointments or creams, such as zinc oxide and petrolatum, are quite helpful in reducing irritation. The role of hygiene in preventing and managing all forms of DD cannot be overemphasized. Topical application of medicated creams and ointments is not effective in the presence of poor hygiene.

Parent and caregiver education with clear explanation of DD etiology and general skin care measures in the diaper area are key to ensuring compliance and adherence.

Management of Diaper Dermatitis

In mild to moderate DD, the use of a topical barrier preparation as the first-line therapy is usually sufficient. More severe forms of DD with clinical signs of secondary infections require greater medical attention with careful diagnosis and therapeutic treatment.

Candidal infection is quite common in more severe cases of DD, and antifungal creams, such as nystatin, miconazole, ketoconazole, and sertaconazole, can be applied to the diaper area with every diaper change. Additionally, low-potency topical corticosteroids, such as 0.5% or 1% hydrocortisone ointment or cream may be required if inflammation is severe. Oral antifungal therapy is usually not indicated, although it may be necessary in cases of recurrent candidiasis.

If a secondary bacterial infection is present, topical or oral antibiotics may be necessary. If the bacterial infection is localized and mild, topical mupirocin applied twice a day for 5 to 7 days may be sufficient to treat a staphylococcal infection. Oral antibiotics (eg, cephalexin) may be required for more extensive bacterial infections, especially if the infant is febrile and/or ill-appearing.

A short duration of low-potency topical corticosteroid can reduce inflammation in DD that persists despite skin care measures and use of barrier preparations. Nothing stronger than 1% hydrocortisone should be considered. Additionally, as per the recommendation of most specialists, this should be applied only until the eruption has cleared and for no longer than 2 weeks. Combination topical medications containing a corticosteroid and an antifungal agent are not recommended routinely because they usually contain high-potency corticosteroids. When topical steroids and antifungal agents are used in conjunction with barrier ointment, the medication should be applied before the barrier ointment.

When the more common causes of DD, such as irritant contact dermatitis and *Candida,* do not respond to conventional therapy, further workup must be initiated because of the possibility for an underlying systemic disease manifesting as DD.

Prognosis

Although recurrence of DD is common, most patients respond well to topical medications and measures undertaken to keep the diaper area clean and dry.

CASE RESOLUTION

The infant has irritant contact dermatitis. He has a recent history of gastroenteritis, and stool is known to be particularly irritating to the skin. Treatment includes keeping the diaper area clean and dry with frequent diaper changes and use of superabsorbent diapers as well as topical application of a low-potency corticosteroid ointment or cream and a barrier ointment (eg, petroleum ointment).

CHAPTER 138

Papulosquamous Eruptions

Janice Ma, MD; Delphine J. Lee, MD, PhD, FAAD; and Ki-Young Yoo, MD

CASE STUDY

A 6-month-old girl presents with an erythematous, confluent, slightly raised and scaly rash on the cheeks. The extremities are also covered with a fine papular rash. The infant has had some scaling behind the ears and on the scalp since early infancy, but the symptoms have recently increased. The mother has been applying baby oil to the scalp to relieve the scaliness. Except for some intermittent rhinorrhea, the infant has otherwise been well. Immunizations are deficient; she received only the first set when she was 2 months old. The family history is positive for bronchitis. The infant's weight is at the 75th percentile and height is at the 50th percentile. Vital signs are normal. The physical examination is normal except for the presence of the rash.

Questions

1. What are the characteristics of papulosquamous eruptions?
2. What are the common conditions associated with papulosquamous eruptions in children?
3. What are the appropriate treatments for common papulosquamous eruptions?
4. When should children with papulosquamous eruptions be referred to a dermatologist?

Rashes, a common problem in children, can be classified in ways that help to establish a diagnostic approach. First, rashes are assessed in terms of appearance: macular (flat), papular (raised), squamous (scaly), vesicular (fluid filled), or bullous (large, fluid filled). Next, the extent of the rash is determined. Rashes may be described as generalized or localized. Location is also important. The site of a localized rash may be consistent with certain diagnoses (eg, diaper dermatitis). Pruritus is an important distinguishing feature. Other systemic symptoms must also be taken into consideration. Rashes may be a primary skin condition or a manifestation of an underlying infection or reaction to a precipitating agent.

Papulosquamous eruptions are rashes characterized by scaly papules and plaques. Eczema is a broad group of skin disorders characterized clinically by scale and histologically by spongiosis and makes up a large component of the papulosquamous disorders. The etiology of many papulosquamous eruptions is unknown, and the clinical appearance of lesions is the reason they are classified together.

Epidemiology

Although a large number of conditions may cause papulosquamous eruptions in children, a select number of diagnoses account for most problems and are the focus of this chapter. One of the most common types of papulosquamous eruptions in children is atopic dermatitis. Atopic dermatitis has become increasingly more common, and the prevalence in school-age children in the United States is estimated to be between 10% and 20%. Positive family history is often elicited. The severity of atopic dermatitis generally improves with age; however, lifelong dry, itchy skin, in varying degrees of severity, is not uncommon. Seborrheic dermatitis is another common papulosquamous rash seen in the pediatric population. Although most commonly described in infants younger than 3 or 4 months, it can occur in all pediatric age groups. It is estimated to have a prevalence of up to 5%, encompassing pediatric and adult populations.

Scabies occurs worldwide and is frequently encountered in general pediatric and dermatologic settings. The prevalence is much greater in developing countries and in situations in which populations are forced into close proximity (eg, during wars, incarceration, in refugee camps). Scabies is transmitted through direct contact; thus, family members and close contacts are at greatest risk of infection.

Clinical Presentation

Papulosquamous eruptions consist of skin-colored to erythematous, scaly papules and plaques that may involve the face, trunk, or extremities. The lesions can be pruritic, and scratching may lead to crusting or secondary infection. Sometimes multiple family members are affected (Box 138.1). Chronicity and repeated manipulation may lead to lichenification (thickening) of involved skin.

Pathophysiology

The pathophysiology of atopic dermatitis has not been definitively established. Evidence suggests that mutations in the *FLG* gene, encoding a protein important for skin barrier function, may play a large role in atopic dermatitis. It is also important to keep in mind that atopic dermatitis is a multifactorial disease with variable expression, influenced by environmental factors. Inheritance of this disease

Box 138.1. Diagnosis of Papulosquamous Eruptions in Pediatric Patients

- Raised, scaly papules and plaques
- Pruritus
- Afebrile, unless secondary infection is present
- Personal or family history of allergies
- Intertriginous rash

is associated with atopy, made up of the triad of atopic dermatitis, allergic rhinitis, and asthma. The disorder is attributed largely to skin barrier function; however, immune dysfunction and reactivity of nerves and blood vessels may also be involved. Initially, the disease is characterized by Th1 cytokine predominance, but later in chronic disease, there is activation of the Th2 immune pathway with a resultant synthesis of cytokines, including interleukin (IL)-4 and IL-5, causing elevated immunoglobulin (Ig) E levels, eosinophilia, and diminished cell-mediated immunity. Elevated IgE is reported in up to 80% of patients with atopic dermatitis.

Like atopic dermatitis, the etiology of seborrheic dermatitis remains unclear. There may be an association with the yeast *Malassezia*, including the *Malassezia furfur* species (formerly known as *Pityrosporum ovale*), although whether this organism is causative is unclear. It is widely accepted that this yeast has some role in seborrheic dermatitis, which is further supported by the improvement observed with topical antifungal medications. Individuals with seborrheic dermatitis that is severe or extensive may have immune dysfunction, such as uncontrolled HIV/AIDS.

The inflammatory response in scabies is triggered by an infestation with the mite, *Sarcoptes scabiei.* The adult female burrows under the skin and lays 60 to 90 eggs. After 2 weeks, the eggs become adults. Affected individuals may be asymptomatic on first exposure. Up to 2 to 6 weeks after infestation, the host's immune system becomes sensitized to mites or scybala (mite feces), resulting in systemic pruritus and rash. In most individuals, the rash associated with scabies is an allergic phenomenon; each eruptive papule may not actually contain mites.

Differential Diagnosis

While many papulosquamous eruptions are clinically distinguishable, the differential diagnosis may be challenging at times. Familiarity with the appearance of these conditions and their differentiating features is critical.

Conditions that present as papulosquamous eruptions in children include atopic dermatitis and seborrheic dermatitis, as described previously; however, the differential diagnosis is vast and includes other conditions, such as contact dermatitis, psoriasis, pityriasis rosea, lichen planus, lichen striatus, scabies, and fungal infections of the skin.

Eczema is a general term used to describe a type of papulosquamous eruption. The most common eczematous conditions seen in children are atopic dermatitis, seborrheic dermatitis, and contact dermatitis. Atopic dermatitis is a disorder of infancy and childhood and may persist into adulthood. More than half of affected individuals are symptomatic by 1 year of age, and in 90% of cases onset occurs by 5 years of age. The area of involvement changes with age. In infancy, the face, scalp, and extensor surfaces are involved, often areas where the infant can relieve itching by rubbing, and the diaper area is often spared (Figure 138.1A). By childhood, the more typical pattern seen in adults becomes more common: involvement of flexural surfaces such as the neck and antecubital and popliteal fossae. Adults tend to have greater extremity involvement, along with the head and neck. The itching is typically worse at night and can be exacerbated by multiple triggers, including extreme temperatures, sweating, clothing with rough textures, and infections. Clinically, xeroderma (abnormally dry; also called xerosis), erythema, and a pruritic papular eruption are common. Scratching and rubbing lead to crusting and weeping. Eventually, the irritation and inflammation of the skin leads to thickening of the skin, known as *lichenification*. Changes in color, including hypopigmentation and hyperpigmentation, may also occur. *Pityriasis alba*, considered to be the mildest form of atopic dermatitis, presents as hypopigmented areas with fine scale, most commonly observed on the face. Xeroderma is a frequent coexisting condition. *Ichthyosis vulgaris*, characterized by dirty-appearing excessive scaling and hyperlinear palms, is present in up to one-half of patients affected with atopic dermatitis. Lesions around mucosa (Morgan folds in the infraorbital fold under the eye and cheilitis around the mouth) may also be seen. Symptoms of other atopic conditions, such as allergic rhinitis, asthma, or food-related allergies, may also affect these patients.

Seborrheic dermatitis, which frequently develops during the first 3 months after birth, is characterized by scaly papules or confluent waxy, scaly plaques, particularly of the scalp. Scalp eruptions in infancy are referred to as *cradle cap.* Seborrheic dermatitis has a predilection for areas with a high density of sebaceous glands, such as the scalp, face, ears, presternal chest, penis, and intertriginous areas, including the folds of the diaper region (Figure 138.1B). The red or pink papules and plaques may have a greasy quality. Secondary infections may occur with *Candida,* particularly in the intertriginous areas. Seborrheic dermatitis is usually not exceedingly pruritic, in contrast with atopic dermatitis. The intertriginous involvement and the onset shortly after birth may help to differentiate between these 2 dermatitides. Severe seborrheic dermatitis may be associated with an immune deficiency, such as HIV.

Irritant or *allergic contact dermatitis* occurs when individuals come into physical contact with an irritant or a specific allergen, respectively. Irritant dermatitis is caused by direct cytotoxic effect, while allergic contact dermatitis is a delayed type of hypersensitivity (ie, type IV hypersensitivity reaction) in response to an allergen. Although their etiologies are different, the 2 typically have a similar clinical appearance, with well-defined erythematous vesicles, papules, or plaques, often with scale, oozing, and subsequent lichenification. Diaper dermatitis is among the most common types of irritant dermatitis in the pediatric population (see Chapter 137).

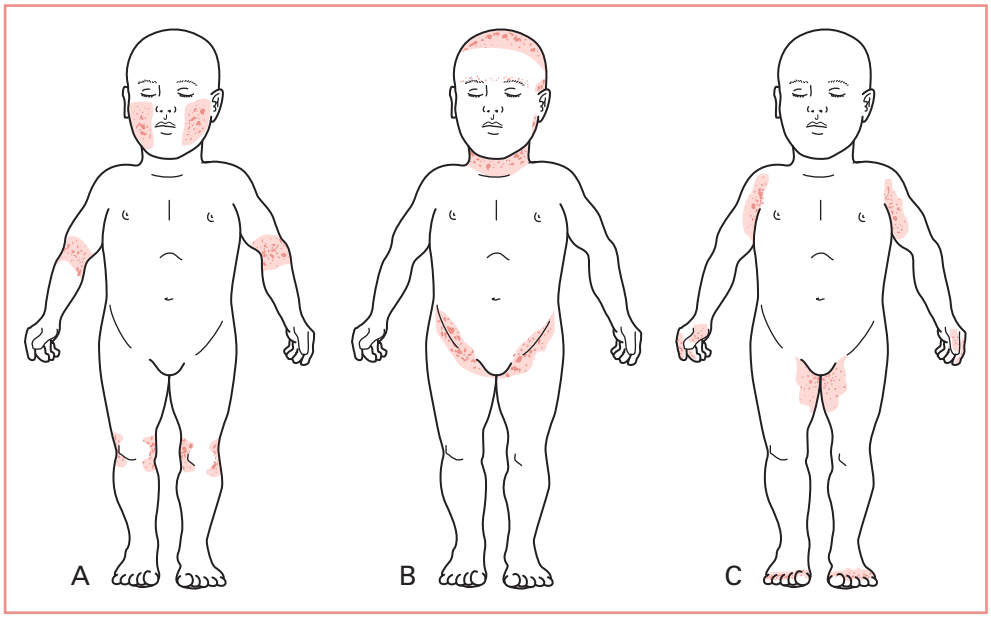

Figure 138.1. Typical distribution of papulosquamous eruptions in children. A, Atopic dermatitis: usually located on cheeks, creases of elbows, and knees. B, Seborrheic dermatitis: usually located on scalp, behind ears, in thigh creases, and behind eyebrows. C, Scabies: usually located on axillae, webs of fingers and toes, and intragluteal area.

Rhus dermatitis (poison ivy/oak), nickel, and fragrance allergy are among the common types of allergic contact dermatitis seen in older children and adolescents. Sensitization to allergens can begin by around 6 months of age. It remains controversial whether atopic dermatitis is a risk factor for allergic contact dermatitis. However, children with atopic dermatitis may have more exposure to sensitizers, in conjunction with a damaged epithelial barrier, putting them at risk.

Plaque-type psoriasis, a chronic papulosquamous skin condition manifested most commonly as well-defined erythematous papules and plaques with silvery scale, is not uncommon in childhood. About 40% of adult patients with psoriasis report having had the disease in childhood. It most commonly affects the scalp in the pediatric population as well as the face and intertriginous areas. Infrequently, a young infant may develop psoriasis in the diaper area. Guttate psoriasis features smaller scaly papules and is usually precipitated by group A streptococcal infection in the pharynx or perianal area. Pruritus is variable but not prominent. Classically, psoriatic lesions can develop at sites of trauma (scratches and cuts), known as the Koebner phenomenon. Given that psoriasis is an inflammatory skin condition, clinicians should screen pediatric patients with psoriasis for associated comorbidities, including metabolic and lipid abnormalities, in addition to signs and symptoms of arthritis, depression, and anxiety.

Pityriasis rosea is a self-limited papulosquamous eruption that is frequently seen in adolescents. The lesions tend to be round or ovoid and classically have a symmetric distribution on the trunk extending downward from the midline at a 45° angle, a pattern resembling a pine tree on the back. Classically, there is a larger herald patch preceding the eruption by a few days to weeks. However, the presentation is not always classic; many patients cannot recall a herald patch, and the pattern over the trunk may be haphazard. Pityriasis rosea is generally self-limited and resolves in 1 to 2 months. It is pruritic in about one-quarter of those affected. The etiology is unknown, although some report an association with human herpesvirus 6 or 7 infection.

Lichen planus is an uncommon papulosquamous eruption in the pediatric population, most frequently afflicting children of Arab and Afro-Caribbean backgrounds. It is characterized by pruritic, polygonal, pink to purplish flat-topped papules, sometimes with an overlying network of delicate white lines called Wickham striae. Etiology is also unknown, although viruses, including hepatitis C, and medications can occasionally be associated. Flexor surfaces are usually affected, and these lesions can koebnerize. Lichen planus affecting the skin typically resolves within 1 to 2 years; meanwhile, lichen planus involving the mucous membranes and nails, albeit rare in children, may persist.

Lichen striatus is an asymptomatic eruption consisting of flat-topped papules that are skin colored to slightly hyperpigmented. The lesions develop along the Blaschko lines and may be arranged in a curvilinear distribution. This eruption spontaneously resolves over months to years. It is most commonly seen between 9 months and 9 years of age. The etiology is unknown, although up to 85% of individuals with lichen striatus report a personal or family history of atopy.

Scabies may resemble atopic or seborrheic dermatitis in infants and young children. The lesions may be papules, pustules, or vesicles. The characteristic burrow, which is only 3- to 10-mm (0.1- to 0.4-in) long, is often difficult to appreciate unless certain diagnostic maneuvers are undertaken. The lesions are most often noted on the skin of the hands and feet, including the palms and soles in infants and young

children. Intertriginous areas, such as the intragluteal region, groin, and finger webs, are commonly infected (Figure 138.1C). In infants and those who are immunocompromised, all skin surfaces, including the face and head, may be involved. Scratching and secondary infection may alter the appearance of the rash. Reddish-brown nodules may be characteristic of more chronic infection. In individuals who are institutionalized or immunosuppressed, extensive mite infection can occur, resulting in thick, greasy-appearing, yellowish scale and crusts over the extremities and trunk, a condition referred to as *crusted scabies.* The use of long-term topical corticosteroid use has been reported to induce crusted scabies.

Fungal infections (eg, tinea corporis, tinea pedis) commonly appear as papulosquamous eruptions. The lesions usually assume a characteristic morphology, with scaly papules grouped in a circle or coalesced into an annular plaque with central clearing.

Evaluation

History

A thorough history should be obtained (Box 138.2). The presence of a rash in other family members is suggestive of a contagious condition such as scabies or a familial disorder such as atopic dermatitis or psoriasis. An onset in the first few weeks after birth is consistent with seborrheic dermatitis. It is important to determine if any medications have been used because these may modify the appearance of the rash. In addition, certain medications can cause a rash themselves, although these tend to be more morbilliform in appearance (see Chapter 139). Pruritus should be noted. Asking about lesions developing at sites of previous trauma can aid in diagnosing eruptions that koebnerize, such as psoriasis and lichen planus.

Physical Examination

The physical examination helps define the exact nature of the eruption and its distribution, which is often the clue to its etiology. The entire body should be examined, and particular attention should be paid to the intragluteal region and web spaces between fingers and toes. Certain rashes have characteristic appearances. For example, a circular cluster of scaly papules with central clearing signifies tinea corporis, whereas the presence of a herald patch preceding a more generalized eruption can suggest pityriasis rosea. The presence of burrows characterizes scabies. Burrows appear as a 3- to 10-mm (0.1- to 0.4-in) grayish-white line (only about 1 mm [0.04 in] wide). Vesicles, pustules, and nodules may also be present in scabies.

It is important to distinguish if any secondary lesions, such as linear excoriations, are present. Secondary infections are also important to diagnose and treat because they can complicate many of the papulosquamous eruptions.

Associated cutaneous features can also aid in diagnosis. Hyperlinear palms, keratosis pilaris (erythematous 1- to 2-mm [0.04- to 0.08-in] folliculocentric papules often on lateral upper arms, anterior thighs, and cheeks), and perioral or periocular lichenified papules are often seen in children with atopic dermatitis.

Overall health, including height and weight, should be assessed. Failure to thrive in conjunction with eczematous skin changes should raise suspicion for an immunodeficiency.

Box 138.2. What to Ask

Papulosquamous Eruptions

- How long has the child had the rash?
- What did the rash look like when it first appeared?
- Are other family members affected?
- Have any medications been used to treat the rash or any been given prior to the onset of the rash?
- Is pruritus present?
- Does the child have any other symptoms, such as wheezing or rhinorrhea?
- Does the child have a history of any contact between the affected skin and any irritating substance?
- Has the child been febrile?

Laboratory Tests

Certain diagnostic tests may help clarify the etiology of certain papulosquamous eruptions. In children with atopic dermatitis, approximately 30% may have coexisting food allergies and 70% may have coexisting respiratory allergies. Food allergies tend to develop during early infancy, whereas respiratory allergies may develop during childhood. While it is important to identify food (and later on, environmental) allergies via skin or radioallergosorbent/ImmunoCAP testing, which measures allergen-specific IgE (see Chapter 95), parents must understand that food allergies infrequently cause or exacerbate atopic dermatitis. Patients with atopic dermatitis often have elevated IgE antibodies on testing and may be incorrectly diagnosed with a food allergy. A positive skin or blood test result does not imply a true food allergy unless it is clinically confirmed with a food challenge test. Based on misperceptions on the role of food allergies in atopic dermatitis, parents may, on their own, institute dietary restrictions for their child, which often results in gross undertreatment of the skin itself and may even lead to dangerous levels of malnutrition. This unwarranted dietary restriction may also lead to an unintended loss of tolerance of foods, resulting in a higher risk of reactions. Therefore, proper referral and counseling are especially important in infants who have atopic dermatitis and food allergies. Atopy patch tests can be used to detect positive aeroallergens, with dust mites being the most commonly implicated and clinically relevant culprit. Patch testing may identify allergens causing contact dermatitis. Serologic IgE may or may not be elevated in children with atopic dermatitis.

The burrow of the mite that causes scabies may not be readily apparent. Scrapings with mineral oil help identify the mite, eggs, or feces (scybala)—any of these are diagnostic. Multiple burrows or web spaces are scraped. Scrapings of skin also assist in diagnosing candidal or tinea infections. These scrapings should be mixed with 10% to 20% potassium hydroxide, which facilitates the dissolution of epithelial debris and allows for identification of the spores or hyphae.

If a secondary bacterial infection is suspected, cultures of the skin are indicated. Most papulosquamous eruptions are diagnosed clinically and no other specific diagnostic tests, short of a skin biopsy, assist in the diagnosis.

Management

Management is determined by the diagnosis.

Management of atopic dermatitis hinges on skin barrier function and the reduction of dryness and irritation with vigilant skin care. There has been debate whether frequent short baths daily versus bathing infrequently is more beneficial. It is most crucial that these patients bathe for short times only, applying cleansers only to the face, groin, and other soiled areas. The cleanser should be soap free, or the soap should be nonirritating, nondrying, and perfume and dye free. The skin should be patted dry after bathing with immediate application of emollient or medication. Thick emollients, such as petroleum jelly or other greasy ointments, are preferable. For school-age children, using greasier emollients at night under pajamas and thinner emollients during the day may increase compliance. Avoiding scratchy clothing such as wool can be helpful, as can humidifiers in the winter to prevent excessive environmental dryness. Humidifiers should be cleaned regularly to prevent mold buildup, and a cool mist is considered safer to prevent burns. Effective strategies to reduce house dust mite burden, including bedding covers and vacuuming, may lead to a modest improvement of atopic dermatitis symptoms.

Topical steroids are used to treat various papulosquamous eruptions, especially during flares. These are the mainstay of therapy designed to minimize inflammation. The agents usually prescribed in cases of atopic as well as seborrheic dermatitis are triamcinolone 0.025% or 0.1% and hydrocortisone 1% creams or ointments. Although ointment vehicles allow for better penetration and, often, less irritation, they are often disliked for their greasy texture, minimizing their usefulness because they are not applied regularly. The weaker topical steroids (eg, hydrocortisone) should be used for the face and groin and the higher strengths (eg, triamcinolone) in areas of thicker skin. Chronic use should be discouraged to avoid skin atrophy. Parents can be educated on applying the medication to the appropriate areas for 1 to 2 weeks for flares, with maintenance use on weekends or a few days per week. Sometimes brief courses of systemic steroids may be needed during more severe exacerbations, but if a patient is requiring oral steroids regularly, a referral to a dermatologist may be needed to consider other treatments, such as systemic immunomodulators or UV therapy, both of which are used for atopic dermatitis and psoriasis. Oral steroids may be required for rhus contact dermatitis, which is among the more common forms of allergic contact dermatitis, and should be given for 2 to 3 weeks to prevent flaring.

For scaly scalp psoriasis, seborrheic dermatitis, and atopic dermatitis, several treatments can be used. For pruritus and inflammation, a topical steroid in gel, liquid, oil, or foam vehicle can be applied. Mineral or baby oil can help loosen scale, which can be washed out using a gentle shampoo or antiseborrheic shampoo. It should be massaged gently onto the scalp and allowed to sit for several minutes before rinsing.

Tacrolimus and pimecrolimus are topical calcineurin inhibitors, which can be used as steroid-sparing agents, most often in mild cases of atopic dermatitis, seborrheic dermatitis, and inverse (intertriginous) psoriasis. Dermatologists, allergists, and immunologists prescribe these medications in conjunction with topical steroids for their patients. As stand-alone agents, they are not as effective as steroids for more severe cases and are substantially more expensive. As of January 2006, a black box warning was placed on these 2 medications because of theoretical risks of skin cancer and lymphoma among patients using these drugs. The warning was based on the risk in transplant patients who are on systemic calcineurin inhibitors. One cohort study showed an association between the use of topical tacrolimus and the development of B-cell acute lymphoid leukemia in pediatric patients with atopic dermatitis. However, multiple epidemiological studies showed no evidence that topical calcineurin inhibitors are associated with increased risk for developing malignancies such as skin cancer and lymphoma.

In 2016, the US Food and Drug Administration approved the use of crisaborole (trade name Eucrisa) as a topical nonsteroidal treatment for mild to moderate atopic dermatitis in patients 2 years of age and older. There are also ongoing clinical trials on its potential role as a treatment for psoriasis. In 2017, the US Food and Drug Administration approved the use of the first biologic medication, dupilumab (trade name Dupixent), a monoclonal antibody, as an injectable treatment for moderate to severe atopic dermatitis in adults. The safety of this medication for use in the pediatric population is currently being investigated.

In psoriasis, topical steroids are often used in conjunction with calcipotriene ointment or cream. Tar and anthralin are still used as adjunctive topical treatments, although they are falling out of favor due to their messy quality and more favorable alternatives. Systemic agents, including biologic drugs, are also used in the treatment of moderate to severe psoriasis. In 2016, etanercept (trade name Enbrel) was the first biologic to be approved for pediatric plaque psoriasis.

Antihistamines may play a role in reducing pruritus, especially at bedtime, due to their sedating effect. Hydroxyzine and diphenhydramine work well in the evenings. For daytime, fexofenadine hydrochloride, cetirizine hydrochloride, and loratadine are less-sedating choices. Regular use of antihistamines during a flare can help to break the itch-scratch cycle often observed in children with atopic dermatitis. The other conditions can have variable degrees of pruritus for which antihistamines can be useful. Clipping fingernails decreases the risk of skin trauma after scratching.

Antibiotics are indicated if secondary infection is present. The most common pathogen involved is *Staphylococcus aureus*. Staphylococcal antigens also exacerbate the inflammation of atopic dermatitis. Treatment with antistaphylococcal systemic antibiotics such as cephalosporins may be needed for more widespread secondary infections. Topical antibiotics such as mupirocin may be used in localized secondary infections. Streptococcal-associated guttate psoriasis should also be treated with appropriate antibiotics.

Seborrheic dermatitis is generally treated with a combination of products, including topical keratolytics, corticosteroids, and antifungals (see Chapter 136). The seborrheic dermatitis of infancy can be treated with topical shampoos containing selenium sulfide and gentle sloughing of the scaly lesions using a soft brush or cloth. Topical calcineurin inhibitors have anti-inflammatory properties without skin atrophy side effects but are generally reserved for periorbital or recalcitrant cases because of the cost of the medications.

Atopic dermatitis can be complicated by infection with herpes simplex (eczema herpeticum), in which case treatment should be initiated with acyclovir. Involvement of the periorbital skin or nasal tip is concerning for eye involvement and warrants an ophthalmologic consultation. If involvement is severe, the patient may need to be hospitalized for intravenous antiviral therapy. Children with atopic dermatitis are also prone to viral infections resulting in warts and molluscum contagiosum; these should be managed accordingly.

Coinfection with *Candida,* which occurs with seborrheic dermatitis and psoriasis, requires the use of topical medications such as nystatin, clotrimazole, or miconazole. Antifungal shampoos may also help in reducing the scaling due to fungal agents such as *Malassezia.* Tinea corporis responds to topical antifungal agents. Tinea capitis requires administration of systemic antifungals (see Chapter 136).

The treatment for pityriasis rosea remains controversial, especially because it is a self-resolving condition. There are several studies demonstrating effectiveness of acyclovir, erythromycin, or UV therapy to speed recovery.

Several medications are used to treat scabies. Currently, the preferred product is 5% permethrin cream. It is approved for infants 2 months or older, although its safety and efficacy has been reported in a 23-day-old. It should be applied from head to toe in infants and from neck to toe in small children and adults, left on for 8 to 12 hours, then rinsed off. Lindane, which has been used for more than 50 years and was previously used worldwide, is a 1% cream. Because of concern about the percutaneous absorption of lindane and its potential neurotoxicity, it is no longer widely used and is not available in some areas. Oral ivermectin is also a successful scabicide. A single dose of 200 mcg/kg, repeated in 1 week, can be used in children weighing more than 15 kg (>2.2 lb) and women who are not pregnant or breastfeeding. All scabicides should be readministered 7 days after initial treatment. Patients with crusted scabies typically require a combination of permethrin with oral ivermectin; addition of salicylic or lactic acid can improve the hyperkeratosis. The effective elimination of scabies necessitates that all affected household members be treated simultaneously and that bed linens and clothing be washed in hot water. Patients should be warned that the pruritus of scabies often takes several weeks to subside and can be treated supportively with steroids and antihistamines.

Prognosis

In general, the prognosis for children with papulosquamous eruptions is excellent with appropriate management, for which accurate diagnosis is critical. Atopic and seborrheic dermatitis usually improve as children get older. However, chronic problems such as hand dermatitis, which can be exacerbated by occupational exposures, can become a significant problem in patients with atopic dermatitis. Children with significant atopic dermatitis should be counseled to avoid prolonged contact with water. People with occupations with frequent handwashing or contact with water, such as hairdressers, hospital workers, and food service workers, are at increased risk of hand dermatitis. It is also critical to manage the expectations of the patient and family, in that completely clear skin is not the primary goal of treatment. Rather, the primary goal is prevention of flares with a good skin care maintenance regimen. Families of children with severe atopic dermatitis can have difficulty in maintaining a good quality of life for these patients, and the entire family structure can be affected, as chronic care can be challenging. Children with atopic dermatitis frequently experience remissions and exacerbations, particularly associated with seasonal changes. Prevention and maintenance must be stressed. It is advisable that patients with recalcitrant eczema have further workup with an allergist to identify potential triggers.

Many of these eruptions, such as lichen striatus and pityriasis rosea, are self-limited and only need symptomatic treatment. Psoriasis has a more chronic course, and early diagnosis and treatment can help to reduce disease severity and progression. Chronic disease such as atopic dermatitis and psoriasis can be psychologically challenging for children because they can often be ridiculed at school and excluded from activities for unfounded fears of contagiousness. It may be necessary to educate teachers as well and provide emotional and psychological support for these children. Clinicians may also screen for depression and anxiety, with tools such as the Patient Health Questionnaire (www.phqscreeners.com).

Scabies and tinea will improve with appropriate management and education to prevent recurrence.

CASE RESOLUTION

The infant's presentation is characteristic of seborrheic dermatitis. The baby experienced the onset of symptoms as a young infant (most atopic patients develop symptoms after 2 months of age). Seborrheic dermatitis can often affect the head and face of young patients. Xeroderma is also apparent.

The most important topic to discuss with the mother is good skin care. The mother should be advised that although she may use the baby oil to loosen the scale on the scalp, she should shampoo afterward with a mild antiseborrheic shampoo to prevent buildup. A mild topical steroid, such as hydrocortisone 1% ointment, may also be recommended, although chronic use should be dissuaded. If skin scrapings reveal secondary infection with *Candida,* an antifungal cream should be added to the regimen; if a secondary bacterial infection is suspected, a culture should be taken and treatment with topical or systemic antibiotics initiated. Short baths with a mild cleanser and regular application of emollients are critical.

The mother should also be educated on potential flares with vaccinations and infections, as well as with climate changes. It is important that the infant catch up on her vaccinations, but cautioning the mother about a potential flare can prevent concern.

CHAPTER 139

Morbilliform Rashes

Houmin Li, MD, PhD; Delphine J. Lee, MD, PhD, FAAD; and Ki-Young Yoo, MD

CASE STUDY

A 10-month-old girl is brought to the clinic with a history of rhinorrhea, cough, and fever for 3 days prior to the onset of a confluent, erythematous rash. The rash started on her face. She has been irritable, and her eyes are red and teary. Her immunizations include 3 sets of diphtheria, tetanus, and acellular pertussis; polio; rotavirus; *Haemophilus influenzae* type b; conjugated pneumococcal; and hepatitis B vaccines. No one at home is ill. The girl was seen in the emergency department 2 weeks earlier because she caught her finger in a car door. On physical examination, the girl's temperature is 39°C (102.2°F). A confluent eruption of erythematous macules and papules is evident on the face, trunk, and extremities. Rhinorrhea and conjunctivitis are also present.

Questions

1. What are the common causes of febrile maculopapular or morbilliform rashes in children?
2. What features help the differential diagnosis of morbilliform rashes?
3. How does a child's nutritional status affect the child's reaction to certain exanthem-inducing viruses?
4. What are the public health considerations concerning viral exanthems in children?

Exanthems are skin findings resulting from an underlying disease, most often caused by a viral infection, although in a few cases, they may be due to bacteria or other rare pathogens. In children, these exanthems are most commonly macular, papular, or mixed. The rash of measles is described as *morbilliform,* and this adjective is used to describe similar-appearing eruptions of macules and papules. Frequently, these rashes present in conjunction with fever, and additional nonspecific symptoms include myalgia, rhinorrhea, conjunctivitis, headache, gastrointestinal (GI) symptoms, and lymphadenopathy. Rarely, other internal organs, such as the liver, spleen, lung, heart, and central nervous system (CNS), are also damaged in serious cases. The exanthems of various underlying pathogens can also be seasonal and have unique presentations. Although many of the common childhood illnesses of the past are now prevented by immunizations, not all segments of the population are adequately immunized. In addition, some children are not eligible for immunization because of their young age. Allergic reactions to medications, particularly antibiotics, may also result in similar eruptions and can be accompanied by symptoms of low-grade fever and pruritus. Differentiating viral exanthems from allergic reactions may be difficult in febrile children who have been empirically started on antimicrobial agents.

Epidemiology

In most children, viruses that cause exanthems produce mild disease without significant morbidity or long-term sequelae. Of greater concern to the public health is the risk of potential spread through the population. Morbilliform eruptions are a common presenting symptom, particularly in certain age groups and at certain times of the year.

Measles, also known as rubeola, is caused by an RNA virus and has markedly decreased in the United States since the live vaccine was introduced in 1963. It is transmitted by direct contact with infectious droplets or by airborne spread. In temperate climates, it is most frequently seen in the winter and spring. In the pre-vaccine era, measles was a significant cause of morbidity and mortality. Periodic resurgences have occurred, particularly among unimmunized preschoolers, older adolescents, and young adults. In addition, young infants are also at risk because of decreased levels of passively transferred maternal immunity related to lack of maternal natural infection or immunization. Vaccine-related immunity apparently wanes more rapidly in mothers than does naturally acquired immunity. Because of the increased number of cases in preschoolers and children with primary vaccine failure who received the vaccine appropriately, a 2-dose recommendation by the American Academy of Pediatrics was implemented in 1989, although there continue to be cases each year. Although no longer endemic in the United States, decreasing vaccination rates have resulted in an increased risk for outbreaks of previously eradicated infectious diseases, specifically measles. The incubation period of measles is about 10 days. Individuals are infectious from about 3 to 5 days before the onset of rash until 4 days following its appearance.

Rubella is also caused by an RNA virus and is no longer considered endemic in the United States, with rare cases reported annually. Sporadic outbreaks are reported, generally in foreign-born or under-immunized persons, and the last confirmed endemic case in the Americas was diagnosed in Argentina in 2009. However, about 5% to 10% of US individuals older than 5 years are considered to be susceptible. Peak incidence is in the late winter to spring, and it is likely transmitted via direct or droplet contact from nasopharyngeal

secretions. Although generally a mild disease, its most serious manifestation is congenital rubella syndrome, which may develop in the offspring of infected pregnant women, with the greatest risk of congenital defects during the first trimester. The incubation period is 14 to 23 days.

Erythema infectiosum, also called fifth disease, is most commonly seen in school-age children during late winter to early spring. Most adults have antibodies indicating previous infection. The disease is caused by an acute infection with parvovirus B19, a DNA virus, and spread through respiratory secretions, percutaneous exposure to blood or blood products, and vertical transmission from mother to fetus. The incubation period is generally 4 to 14 days but may be up to 21 days.

Exanthem subitum, also known as roseola infantum, generally affects children from 6 months to 2 years of age, as maternal antibodies are protective until the age of 6 months. The illness is due to infection with human herpesvirus (HHV) 6 or 7, although HHV-6B, a DNA virus, is most commonly the etiologic agent. The virus is shed in the saliva, even among healthy, previously infected individuals. Almost all children are seropositive for HHV-6B by the age of 4 years. Reactivation is possible, although not common, and there is no seasonal pattern. The incubation period for HHV-6 is likely 5 to 15 days and is unknown for HHV-7.

Enteroviruses are the most common cause of exanthems in the summer and fall. They are all RNA viruses of the picornavirus group and include coxsackieviruses (groups A and B), echoviruses, and enteroviruses. Infection is spread through fecal-oral and respiratory routes as well as via fomites. There is also vertical transmission. Infection is more common in young children and people with poor hygiene. The incubation period is usually 3 to 6 days.

Kawasaki disease, an acute self-limited vasculitis, is of uncertain etiology, although an infectious cause is suspected due to epidemics occurring usually in the winter and spring. Most patients are between 6 months and 5 years of age. Males outnumber females by a ratio of 1.5:1. The incidence of the disorder among Asians is higher than in other populations, suggesting genetic factors play a role. The incubation period is unknown.

Gianotti-Crosti syndrome, also known as papular acrodermatitis of childhood, has historically been associated with hepatitis B infection. In the United States, it is believed to be a host response to multiple viral infections including, but not limited to, hepatitis B, Epstein-Barr virus (EBV), parvovirus B19, HHV-6, and the enteroviruses. It is seen most frequently in children 1 to 6 years of age.

Scarlet fever is a cutaneous reaction to several pyrogenic exotoxins produced by group A streptococcus. It is transmitted through respiratory secretions. Scarlet fever is usually seen in young children between 1 and 10 years of age with pharyngitis. It occurs most commonly in cooler climates during the late fall, winter, and early spring. The incubation period is 2 to 5 days.

Rocky Mountain spotted fever (RMSF) is caused by *Rickettsia rickettsii,* an intracellular organism. Infection is transmitted by the bite of *Ixodes* ticks, which are reservoirs and vectors of the organism. It can be seen throughout the United States, with most cases seen in the southern states. Children of any age are at risk, with those 5 to 9 years of age and those not recalling a tick bite, an occurrence in about one-half of pediatric cases, having the greatest mortality. The highest incidence of infection is seen between April and September. The incubation period lasts from 2 to 14 days.

Clinical Presentation

Morbilliform eruptions may involve the face, trunk, or extremities. The eruption is usually erythematous, and the lesions are flat or slightly raised. Occasionally, lesions within the mouth, referred to as enanthema, are evident. Most children are febrile (Box 139.1) and may have other symptoms.

Pathophysiology

The mechanism for development of a rash is variable. In some cases, the rash is the reaction of the body to infection or to the presence of a toxin. In general, the sequence involves exposure to an infectious agent and then acquisition of the agent, most commonly through droplet infection or fecal-oral contamination. The agent, usually a virus, then replicates, perhaps in the reticuloendothelial system. Lymph nodes enlarge, reflecting the involvement of the reticuloendothelial system. Associated viremia may be present.

In Kawasaki disease, vasculitis affects multiple organ systems. Various cytokines and autoantibodies play a role in the inflammatory response. In a toxin-mediated rash (eg, scarlet fever), previous exposure to the toxin is believed to sensitize the individual.

Diagnosis and Differential Diagnosis

While many exanthems can be easily recognized clinically, the decreased frequency of many of these usual childhood diseases means that physicians encounter these conditions less frequently than in the past. Familiarity with the appearance of these conditions is critical to diagnosis. Using a database of pictorial representations can be valuable. Such databases may also have ways to search by features such as rash morphologies, symptoms, exposures, skin color, body location, age, immune status, and many other factors. Morbilliform exanthems are associated with several infectious diseases, such as measles, rubella, erythema infectiosum, roseola, enterovirus infections, Gianotti-Crosti syndrome, Kawasaki disease,

Box 139.1. Diagnosis of Morbilliform Rashes in Pediatric Patients

- Macular, papular, or combined rash
- Fever
- Enanthema (lesions in the buccal mucosa, uvula, and pharynx)
- Lymphadenopathy
- Respiratory symptoms
- Gastrointestinal symptoms

scarlet fever, and RMSF. Drugs can also cause eruptions similar to those caused by the aforementioned diseases.

The rash associated with measles is preceded by the 3 Cs of cough, coryza, and conjunctivitis in addition to fever, which last for several days before the eruption of the exanthem. Lesions on the buccal mucosa, called *Koplik spots*, are well-circumscribed white-gray papules (Figure 139.1) that appear during the prodrome and resolve after 3 to 4 days. This enanthema, although rare, is pathognomonic for measles. The measles rash itself usually begins on the head, particularly behind the ears and around the margin of the scalp, and then spreads cephalocaudally. After 2 to 3 days, the eruption becomes confluent and copper-colored, fades in the order it appeared, and then may desquamate. The greatest morbidity and mortality are seen in individuals who are immunocompromised and malnourished. Complications include secondary bacterial infection, pneumonia, and encephalitis.

Rubella produces a relatively minor illness in children, although adults, particularly women, may experience painful arthritis. Up to one-half of infections are asymptomatic. There can be a prodrome of fever, headache, conjunctivitis, and upper respiratory symptoms. The eruption consists of fine erythematous macules and papules that become near confluent, starting on the face and progressing caudally to the trunk, resolving after 3 days. Lymphadenopathy, particularly of the postauricular or suboccipital nodes, is characteristic of the disease. *Forchheimer spots* are pinpoint rose-colored macules that can develop on the soft palate in patients with this infection. Congenital rubella syndrome results in multisystem anomalies that can follow maternal infection and is part of the TORCH congenital infections (toxoplasmosis, other agents [syphilis, hepatitis B, varicella-zoster virus, human immunodeficiency virus (HIV), parvovirus B19, enteroviruses, lymphocytic choriomeningitic virus], rubella, cytomegalovirus, and herpes simplex virus).

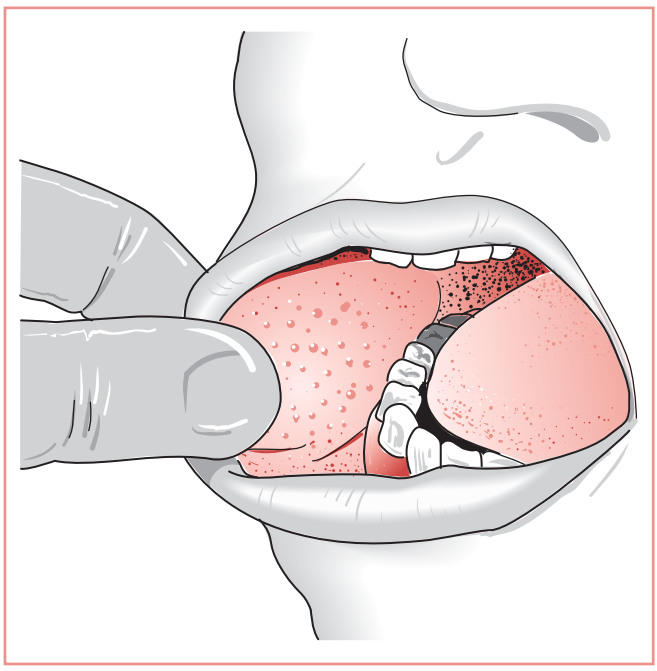

Figure 139.1. Koplik spots.

Erythema infectiosum is characterized by a distinctive eruption that may be preceded by mild prodromal symptoms, including low-grade fever, headache, myalgia, and malaise. Eruption generally occurs 7 to 10 days after the prodrome. The facial rash consists of erythematous patches on the cheeks with sparing of the nasal bridge and periorbital areas. This "slapped-cheek" appearance generally fades after several days and is considered the first stage of the illness. In the second stage, the extremities may develop a lacy reticulated rash of macules and papules 1 to 4 days later that can be pruritic. Palm and sole involvement are rare. This usually lasts about a week but may have recurrences over several weeks in the third stage, with triggers such as activity, sunlight, emotional stress, and hot baths. Most children are only mildly ill and may attend school, but children with underlying hematologic disorders may experience aplastic crises because of the affinity of parvovirus B19 for developing red blood cells. Children who are immunocompromised are also at risk for chronic anemia. Pregnant females may transmit this infection to their fetuses, which can result in fetal hydrops, growth retardation, anemia, isolated pleural and pericardial effusions, high-output congestive failure, and fetal loss. Adults with parvovirus infection frequently develop arthritis, although only 10% of children experience this symptom. Neurologic disturbances, including encephalitis and neuropathies, may follow parvovirus infection, although this is rare. *Papular-purpuric gloves-and-socks syndrome* is a self-limited acute eruption linked to parvovirus B19 infection. It usually occurs in the spring and summer, characterized by often-pruritic edema and erythema and progressing to purpuric macules and papules with a sharp line of demarcation at the wrists and ankles. A nonspecific enanthema of petechiae and erosions can occur. Symptoms of myalgia, lymphadenopathy, anorexia, and fatigue may follow the rash. The exanthem generally resolves after 1 to 2 weeks with no residual sequelae.

Exanthem subitum (roseola infantum) usually causes a fairly mild illness in children, although there can be associated complications. Defervescence usually accompanies the rash, which consists of fine, non-pruritic, blanchable, pink macules or papules with a surrounding halo that generally appear first on the trunk and then spread centrifugally. Some affected individuals may develop an enanthema consisting of erythematous papules on the soft palate and uvula called *Nagayama spots*. Periorbital edema can also be seen. On average, the rash evolves over 12 hours and usually resolves by 2 days. Infants may appear sickest during the prodromal phase, when fever is high (temperature often ≥39.5°C [≥103°F]), and infants are irritable as a result. Fever generally lasts 3 to 5 days and can be accompanied by upper respiratory symptoms and lymphadenopathy. Seizures during the febrile period can occur in up to 15% of primary infections. Workup to rule out sepsis is often warranted.

Skin eruptions associated with enterovirus infections are highly variable. They may be distinct and characteristic, such as hand-foot-and-mouth disease, most commonly associated with coxsackievirus A16 and enterovirus 71 (see Chapter 140). However, many of the enteroviral exanthems are less distinctive and have a generalized morbilliform appearance. Neurologic complications associated

with enteroviral infections include aseptic meningitis and encephalitis and have been reported in infections with coxsackievirus B and enterovirus 71. Other systems affected by enteroviral infections include respiratory, GI, ophthalmic, and cardiac. In a 2011–2012 North American outbreak caused by coxsackievirus A6, affected individuals had distinctive skin findings mimicking eczema herpeticum (see Chapter 140), as well as Gianotti-Crosti syndrome-like rash and petechial or purpuric eruptions.

The rash of Kawasaki disease is also highly variable; it may be morbilliform, urticarial, or scarlatiniform or resemble erythema multiforme. During the first week of illness, there may be desquamation of the perineum. The diagnosis of Kawasaki disease requires fever (generally temperature >39.0°C [>102.2°F] lasting at least 5 days) and 4 out of the following 5 findings: bilateral non-purulent conjunctivitis; changes in the oropharyngeal mucosa including fissured lips, oral erythema, and strawberry tongue; changes in the extremities such as erythema/edema or desquamation; cervical lymphadenopathy with 1 node measuring at least 1.5 cm (0.2 in) in diameter; and the exanthem described previously. Irritability, arthralgia, abdominal pain, and diarrhea are not uncommon. Incomplete Kawasaki disease can be diagnosed when only 2 of the additional criteria are met; thus, the health professional should consider this diagnosis when persistent high fever and only 2 or 3 of these symptoms are present. The major complication of Kawasaki disease is coronary artery abnormalities, and males and those younger than 12 months are at increased risk.

The exanthem of Gianotti-Crosti syndrome consists of monomorphic, pink- to skin-colored, usually non-pruritic papules on the face, buttocks, and extremities, with sparing of the trunk. There is often a prodrome of fever and upper respiratory symptoms with associated generalized lymphadenopathy and hepatosplenomegaly. The exanthem fades after 2 to 3 weeks but can last up to several months.

Scarlet fever is primarily a disease of childhood. Onset is marked by sudden high fever, headache, vomiting, malaise, and sore throat. Within 12 to 48 hours, erythema develops on the neck, chest, and axillae. The rash quickly becomes generalized to a sandpaper-like rash of fine red papules on an erythematous background. Linear accentuation in the axillary, antecubital, and inguinal folds is known as Pastia lines. The face is flushed, except around the mouth (circumoral pallor). There is pharyngeal injection with exudate developing after a few days. The tongue is initially white with prominent red papillae (Figure 139.2), known as strawberry tongue. As the scarlet fever rash resolves, desquamation begins in 7 to 10 days, lasting up to 6 weeks.

The rash of RMSF begins as blanchable pink macules or papules that evolve into petechial or purpuric non-blanching lesions. They begin on the wrists and spread centripetally. The palms and soles are almost always involved. Exanthem is preceded by symptoms of fever, headache, and malaise. Gastrointestinal symptoms such as nausea, vomiting, and diarrhea can be present. The rash generally develops 2 to 3 days after the prodrome.

Morbilliform rashes are the most common type of cutaneous drug eruption. The most common culprits include sulfonamides, penicillins, cephalosporins, and anticonvulsants. They generally begin as erythematous macules and papules on the trunk that spread to the extremities symmetrically. There is usually concurrent eosinophilia. Pruritus and low-grade fever can also be present, often confounding the diagnosis. Although most drug rashes begin 1 to 2 weeks after starting a drug, an eruption may develop after a drug has been discontinued. After stopping the offending medication, the rash usually resolves over 1 to 2 weeks, but some individuals show improvement even if the offending medication is continued. The underlying pathogenesis of many of these drug rashes continues to be unclear; however, recent studies found that levels of a soluble fatty acid synthetase ligand were increased in patients with drug-induced morbilliform eruptions, as well as in those with toxic epidermal necrolysis, but negative in those with viral exanthems.

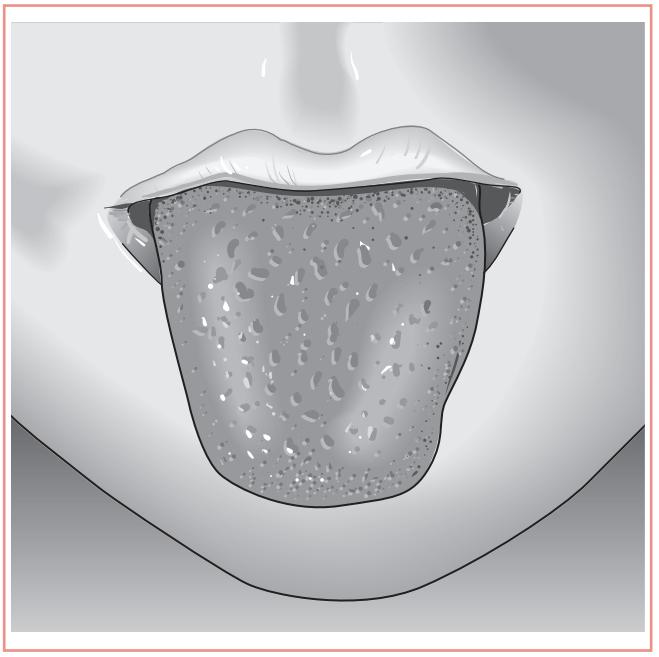

Figure 139.2. Strawberry tongue.

Infection with EBV is associated with rash in young children and in adolescents on antibiotics, usually ampicillin or amoxicillin. Eruption is morbilliform, and the lesions may be erythematous or copper-colored. Fever, upper respiratory symptoms, lymphadenopathy, hepatosplenomegaly, and facial and peripheral edema, including unilateral periorbital edema, may be noted. The rash is likely due to an immunologic interaction between the infectious agent and the drug.

Evaluation

History

A thorough and detailed history should be obtained, including characteristics of the skin rash, the progression of areas involved, overall distribution, and the relationship with rash and other symptoms such as fever. This will be very helpful to make the correct diagnosis (Box 139.2).

Box 139.2. What to Ask

Morbilliform Rashes

- What does the rash look like? Has a similar rash occurred before?
- What is the order of progression of the rash? Are lesions in the mucosa?
- What symptoms, if any, are associated with the rash or occurred before the onset of rash?
- How long has the child had these symptoms?
- Is the child taking any medications (antibiotics)?
- Does the child have any ill contacts?
- What is the child's immunization status?

Physical Examination

The focus of the physical examination is to help define the characteristics of the eruption, such as location, extent, and degree of coalescence. The presence of any associated physical findings, such as fever, lymphadenopathy, enanthema, desquamation, rhinorrhea, conjunctivitis, organomegaly, or CNS symptomatology, should be determined.

Laboratory Tests

Laboratory assessment may be helpful in certain conditions, although most of these diagnoses are made clinically. Serologic testing is most valuable for defining a community outbreak of a specific disease such as measles. In most viral exanthems, the results of serologic studies are not available until the condition has resolved and the patient has recovered. Tests may include acute and convalescent titers for specific viruses. Alternatively, immunoglobulin (Ig) M levels of antibodies against certain infections may be used to document that the infection was recent. Repeat testing may be needed for partially immunized individuals. Polymerase chain reaction may also be useful. Isolating the virus can confirm the diagnosis but is often difficult to obtain. Because neutropenia and lymphocytosis characterize many viral illnesses, such findings are not helpful in differentiating specific causal agents. Lymphocytosis, with characteristically atypical lymphocytes, distinguishes EBV infection. Although a heterophil antibody test result is usually positive in older children and adolescents, the test may be nonreactive in young children, in whom infection is documented by specific EBV serology.

Pregnant women with suspected parvovirus B19 infection should have IgM and IgG levels drawn. If infection is confirmed, serial ultrasonography should be performed to monitor for symptoms of fetal hydrops. Confirming diagnosis of rubella in a pregnant woman is also important because of the potential risk of congenital rubella syndrome.

Kawasaki disease is associated with elevation in markers of inflammation, including leukocytosis, thrombocytosis, elevated erythrocyte sedimentation rate, and C-reactive protein, although no test is diagnostic. Sterile pyuria is noted in 70% of the cases. Scarlet fever is characterized by leukocytosis. Eosinophilia can also be seen after a few weeks in up to 20% of patients. Laboratory confirmation, via rapid streptococcal test or throat culture, should be done to confirm that the pharyngitis is caused by group A streptococcus, not a virus. If pharyngitis has resolved, serologic studies such as antistreptolysin O provide evidence of the recent infection.

A 4-fold or greater change in titer between acute and convalescent serum as determined by indirect immunofluorescent antibody assay is diagnostic for RMSF. Many patients will have thrombocytopenia, leukopenia, anemia, and hyponatremia. In general, any child presenting with headache, fever, and possible exposure to tick bite should be evaluated for this disease.

Imaging Studies

Echocardiography to check for evidence of coronary artery aneurysm is a mandated part of the evaluation in Kawasaki disease during the acute phase and with serial repeat examinations, more frequently and earlier in those at high risk in the face of a normal initial echocardiogram.

Management

Management of most viral exanthems is supportive and symptomatic. Hydration is critical when GI symptoms such as vomiting and diarrhea are present. Antihistamines should be used for symptoms of pruritus in addition to regular use of emollients. Painful oral lesions can be treated with topical analgesics. In cases in which complications such as encephalitis or pneumonia develop, hospitalization is indicated. Spread of infection, such as measles, to susceptible contacts can be reduced through the use of vaccine within 72 hours of exposure or Ig within 6 days. Measles vaccine should be administered after the Ig in children who have been exposed, with the time interval dependent on dose received and age of the child. The measles, mumps, and rubella vaccine is administered for the 2-dose vaccine series to children at 12 to 15 months of age and again at 4 to 6 years of age. Measles, mumps, rubella, and varicella (MMRV) vaccine is available for children 12 months to 12 years of age in the United States, although there is greater risk for febrile seizures with MMRV vaccine. HIV infection is not a contraindication to measles vaccination, unless the patient is severely immunocompromised, but MMRV vaccine should not be administered to these individuals. Currently, administration of vitamin A is recommended to all children with measles regardless of their country of residence. Antibiotic therapy should be initiated if bacterial coinfection is suspected but should not be started empirically. The management of Kawasaki disease includes the administration of intravenous Ig and aspirin, which should be started within 10 days of onset of fever. The current recommendation is to administer a single dose at 2 g/kg given as an infusion over 10 to 12 hours. Periodic echocardiography is also required in these patients, with close monitoring by a cardiologist.

If there is a concern for hepatitis in patients with Gianotti-Crosti syndrome, workup should be initiated.

Control measures are important because most morbilliform exanthems are due to infectious agents. Children with postnatal rubella should be kept from school or child care facilities for 1 week after onset of rash. Those with congenital rubella syndrome are

considered contagious for 1 year, and caregivers must be educated. Females receiving rubella vaccine should not become pregnant for 28 days following vaccination. Hand hygiene is an important control measure that should be used to minimize spread of many of these viruses.

Public education about the importance of immunizations is vital to reducing the effect of diseases such as measles and rubella. Although the number of cases in the United States is low, importation of these viruses from other countries mandates continued widespread vaccination. In addition, parental concerns of potential adverse reactions due to vaccinations have led to vaccine refusal by some.

Pregnant women infected with parvovirus B19 with ultrasonography suggestive of fetal hydrops should be referred to a tertiary care facility because intrauterine blood transfusions have proven successful. Routine exclusion of pregnant women from the workplace where erythema infectiosum has been identified is not recommended because the virus is transmitted before the onset of rash and, thus, exclusion is unlikely to be effective. Patients with aplastic crisis and chronic parvovirus infection may be contagious for extended periods and require longer periods of precautions. In addition, patients with papular-purpuric gloves-and-socks syndrome are considered infectious when clinical symptoms of their eruption are present. Patients with aplastic crises may need transfusions, and intravenous Ig has been used successfully in immunocompromised patients with chronic infection. However, most cases of erythema infectiosum do not require absence from school or treatment beyond supportive care.

Intravenous Ig and high-dose aspirin continue to be first-line treatment to decrease the risk of coronary artery aneurysms in patients with Kawasaki disease. Aspirin should be continued indefinitely in patients in whom coronary abnormalities do develop.

The goal of therapy in scarlet fever is to prevent acute rheumatic fever by initiating antibiotics within 9 days from the onset of symptoms. Penicillin is the drug of choice. Erythromycin can be used in patients allergic to penicillin. It is unclear if treatment can prevent the onset of post-streptococcal glomerulonephritis.

Treatment with doxycycline is the drug of choice in patients of any age for infection with *R rickettsia* and should be started as soon as RMSF is suspected.

Prognosis

The prognosis for most morbilliform rashes of childhood is generally good, with full resolution of symptoms unless children are very young, have congenital disease, have an underlying condition, or develop long-term complications. In some young infants, viruses that cause exanthems may produce severe complications such as pneumonia and encephalitis. Subacute sclerosing panencephalitis is a late-onset, rare, and serious degenerative CNS disease that occurs as a complication of wild-type measles infection. Some patients with roseola may develop chronic neurologic sequelae, but most cases are benign. The prognosis for Kawasaki disease is usually favorable with appropriate management. Up to 25% of untreated children and a fraction of those who have been treated may develop coronary artery aneurysms, sometimes with symptoms remaining silent for years, thus requiring vigilance during the acute phase. Kawasaki disease is the leading cause of acquired heart disease in children in the United States. In patients with severe infection with RMSF, long-term neurologic complications can be seen.

CASE RESOLUTION

The infant has the classic symptoms of measles. Normally, such a young infant would not yet have received immunization against measles because the first dose is administered at 12 to 15 months of age with the second dose at 4 to 6 years of age. Immunoglobulin will likely not modify the disease in this patient because her rash is nearly confluent, suggesting exposure more than 6 days ago. She should be evaluated for evidence of complications, including pneumonia. Unimmunized household contacts, as well as pregnant women and other contacts younger than 1 year, should receive Ig. Treatment is supportive.

CHAPTER 140

Vesicular Exanthems

Caleb Jeon, MD; Meiling L. Fang Yuen, MD; and Ki-Young Yoo, MD

CASE STUDY

A 2-year-old boy is evaluated for a 2-day history of fever (temperature: 39.5°C [103.1°F]), runny nose, decreased appetite, and a rash over the abdomen. He has had no previous known exposures to chickenpox (varicella) and no history of varicella vaccination. He attends child care daily. No one at home is ill. The boy is currently taking no medications except for acetaminophen for fever, and he has no history of dermatologic problems. On physical examination, his heart rate is 120 beats per minute, respiratory rate is 20 breaths per minute, and temperature is 38.0°C (100.4°F). The boy's overall appearance is nontoxic. The skin examination is significant for a few scattered erythematous vesicular lesions over the abdomen and 1 erythematous papule on the back. The rest of the examination is normal.

Questions

1. What are the most likely causes of vesicular exanthems in febrile children?
2. How can types of vesicular rashes be differentiated on the basis of patient history?
3. What are the key historical questions to ask?
4. What is the natural course of varicella?
5. What treatment options are available for children with varicella? How is the management different for immunocompromised children?
6. What options are available for vesicular exanthems other than chickenpox?

Exanthems are generalized, erythematous rashes with an underlying cause. They are most frequently caused by viral or bacterial infections. However, they can also be caused by noninfectious etiologies such as autoimmune disorders, drug reactions, genetic disorders, and physical injury. Infectious eruptions are most commonly morbilliform in the pediatric population, but they can present as vesicular, bullous, petechial, or purpuric eruptions. *Vesicles* are elevated, fluid-filled lesions that measure 1 cm or less (≤0.4 in) in diameter. Those that are larger than 1 cm (>0.4 in) are called *bullae*. *Vesicles* often lose their initial morphology quickly because they can break spontaneously or coalesce into bullae. They can arise de novo or from macules or papules. Vesicles may be discrete, grouped, generalized, or linear, depending on their etiology, and their specific distribution is often helpful in formulating a differential diagnosis.

History and Physical Examination

A thorough history should be obtained (Box 140.1). Health professionals must inquire about the patient's general health as well as the specific details of the eruption.

Although the physical examination focuses on the skin, other aspects of the examination are helpful diagnostically. Vital signs should be assessed to verify the presence or absence of fever. The oropharynx should be examined closely for any lesions on the tongue, gingiva, buccal mucosa, palate, anterior tonsillar pillars, and posterior pharynx. The lips should also be examined for any evidence of vesicular lesions that may occur with a primary or recurrent herpes simplex infection.

Patients should be completely unclothed to permit a thorough examination of the skin. The distribution of the lesions should be noted. Physicians should determine whether the vesicles are grouped in a particular dermatomal distribution, as with zoster (shingles), or more generally distributed and in various stages of development, as with varicella. A linear distribution may suggest contact with poison ivy or oak. Physicians should also note the following: Do the lesions include or exclude the palms and soles? Are the buttocks involved?

Box 140.1. What to Ask

Vesicular Exanthems

- How long has the child had the rash? Where is it located?
- Does the child have associated symptoms such as fever, runny nose, cough, or sore throat?
- Does the child have nonspecific symptoms, such as decreased appetite?
- If the child has any symptoms accompanying the rash, did these develop at the same time as the rash?
- What is the immunization status of the child?
- Is there any reason to suspect that the patient is relatively immunocompromised from chronic steroid use, chemotherapy, or an acquired immunodeficiency?
- Does the child have a history of similar lesions?
- Does anyone else in the family have a similar rash?
- Has the child been camping or hiking in the woods?
- Are there pregnant contacts?

Are the lesions concentrated on 1 specific part of the body, such as the feet and toes or the hands? Are the sizes of the lesions uniform? If not, are other larger bullous-like lesions present in addition to vesicles? It is also helpful, if at all possible, to examine the skin of family members for similar lesions.

Vesicular exanthems are eruptions of distinctive lesions that are raised and fluid filled (Box 140.2). They may be located anywhere on the child's body and, depending on the etiology, may or may not be pruritic. Other symptoms that may accompany such rashes include fever, upper respiratory symptoms, and gastrointestinal and central nervous system (CNS) involvement.

Epidemiology

Epidemiological factors can help differentiate infectious from noninfectious etiologies. Patient age, season of the year, presence or absence of similar cases in the community, and regular attendance at child care or school, which may contribute to exposure, should all be considered. Biological sex and ethnicity are usually less informative but can help distinguish certain diseases causing exanthems.

Primary varicella-zoster virus (human herpesvirus [HHV] 3), or chickenpox, is among the most common vesicular exanthems seen in childhood. Males and females are equally affected. Most reported cases in the pre-vaccine era were in children younger than 10 years. Since universal vaccination has been implemented, children aged 10 to 14 years are becoming the group with the greatest incidence of infection, although it is still less than during the pre-vaccine period. It is primarily transmitted person-to-person by airborne spread of aerosolized viral particles from vesicles of infected persons. It may also be transmitted through respiratory secretions and vertically from mother to fetus. It is extremely infectious, and transmission to susceptible household contacts is greater than 90%. The incubation period ranges from 10 to 21 days after exposure but can be longer (21–28 days) if varicella-zoster immune globulin is administered. Neonates born to mothers with active infection around the time of delivery can develop varicella 2 to 16 days after birth. Patients are considered contagious from 1 to 2 days before onset of cutaneous lesions until all are crusted over.

Human herpesvirus 1 and 2, also called herpes simplex virus (HSV), affect most adults worldwide. Historically, HHV-1 infections generally occurred outside the genital area and HHV-2 within the anogenital area. Now, either virus can be found in both areas. Neonatal infection is generally acquired at delivery from an infected mother who is often unaware of her infection. Human herpesvirus 1 is typically transmitted by direct contact with oral secretions or lesions and HHV-2 from direct contact with infected genital secretions. Shedding of viral particles can occur in the absence of active infection. The incubation for HHV infection beyond the neonatal period is 2 days to 2 weeks. Most affected neonates will have signs of clinical infection in the first postnatal month.

Hand-foot-and-mouth disease and herpangina are caused by enteroviral infections and occur worldwide. Outbreaks involving child care centers, schools, summer camps, hospital wards, military installations, communities, large geographic areas, and entire countries have been reported. They are transmitted person-to-person by the fecal-oral route. They also can be transmitted by contact with oral and respiratory secretions and, in the case of hand-foot-and-mouth disease, vesicle fluid. Most cases of these 2 conditions occur in infants and children. Hand-foot-and-mouth disease is most commonly caused by infection with coxsackievirus A16 or enterovirus 71 and is among the most recognizable viral exanthems in children and adults. The principal enterovirus serotypes associated with herpangina are coxsackieviruses A1 to A6, A8, A10, and A22. These enteroviral infections occur most commonly in summer and early fall. The usual incubation period for most enteroviruses is between 3 and 6 days.

Box 140.2. Diagnosis of Vesicular Exanthems in Pediatric Patients

- Raised, fluid-filled vesicles on the skin.
- Lesions may be pruritic.
- Possible associated fever, upper respiratory infection symptoms, myalgia.
- History of affected contacts.
- Lesions on mucous membranes.

Diagnosis and Differential Diagnoses

Primary Varicella-Zoster Virus (Chickenpox)

Primary varicella-zoster virus (chickenpox) infection usually consists of hundreds of vesicles, existing in various stages of resolution. Lesions progress from erythematous macules and papules to vesicles and, eventually, to pustules that then crust and heal normally without scarring unless secondarily infected and deeply inflamed. Characteristically, the vesicle has been described as a "dewdrop on a rose petal." Associated prodrome includes malaise and mild fever. Symptoms tend to be more severe in infants and older patients. Since universal vaccine implementation, breakthrough cases have become more common and have a milder clinical presentation. Fetal infection during the first or early second trimester can result in fetal demise or in congenital varicella syndrome, consisting of limb hypoplasia, cutaneous scarring, ophthalmic abnormalities, and CNS defects. Infection acquired from 5 days antepartum to 2 days postpartum can also be fatal because of the absence of protective maternal antibodies. Bullous varicella can result when *Staphylococcus aureus* infects the vesicles of chickenpox, with greater chance of scarring.

Modified varicella, also known as "breakthrough varicella," can occur in vaccinated people. Breakthrough varicella is usually milder than natural varicella, with less than 50 lesions, low or no fever, and shorter duration of rash. Most studies have noted breakthrough varicella occurring in fewer than 1% to 3% of vaccinated children

each year after vaccination. The rash may be atypical in appearance with fewer vesicles and predominance of maculopapular lesions. Breakthrough varicella is contagious, although less frequently transmitted than natural varicella.

Herpes zoster, a reactivation of a latent infection with varicella-zoster virus, can also cause a vesicular rash. The virus, which rests dormant in neuronal cells, travels along the nerves when reactivated and becomes released into the skin. It is generally a disease of older people, although children can be affected. In zoster, the lesions are grouped unilaterally in the distribution of 1 to 3 sensory dermatomes. It can be quite painful, and postherpetic neuralgia can last for months. In immunocompromised patients, the rash of zoster can become disseminated.

Human Herpesvirus 1 and 2 (Herpes Simplex Virus)

The onset of clinical illness of HSV-1 is usually sudden, with the appearance of multiple characteristic vesicular lesions superimposed on an inflammatory, erythematous base. Primary infection may also be associated with systemic symptoms, such as fever and malaise. The lesions can be painful and last for 10 to 14 days. Vesicles are usually grouped in a single anatomical site; however, autoinoculation of distant locations can occur. Although the symptoms can be severe, most primary HSV-1 infections are asymptomatic. Once HSV infection has occurred, the virus lives in a latent state in nerve cell bodies in ganglion neurons and can reactivate. The frequency and severity of reactivation is determined by many factors, including immunodeficiency or stress.

The clinical manifestations of primary genital HSV infection are highly variable. The initial presentation can be severe with painful genital ulcers, dysuria, fever, and tender local inguinal lymphadenopathy. In other patients, however, the infection is mild, subclinical, or entirely asymptomatic. There are no clear differences in clinical presentation based on infecting virus (ie, HSV-1 vs HSV-2).

Disseminated, CNS, or skin, eyes, and/or mouth HHV infection in an infant is usually caused by HHV-2, very severe, and often accompanied by skin findings. In children and adolescents, HHV-1 gingivostomatitis and perioral vesicles are the most common clinical findings and can also be asymptomatic. A prodrome of paresthesia with recurrent infection is not uncommon. There can also be an ulcerative enanthema. Human herpesvirus 1 and 2 persist for life in the sensory ganglia and, when reactivated, result in single or grouped vesicles, often on the vermilion border with an erythematous base. Triggers include stress, UV exposure, and fever.

Hand-foot-and-mouth Disease and Herpangina

Hand-foot-and-mouth disease is associated with a brief, mild prodrome of fever, malaise, and mouth pain. The exanthem consists of erythematous macules and papules with a central gray vesicle. Generally, the volar surfaces of the hands and feet, as well as the buttocks, tend to be involved. In a recent North American 2011–2012 epidemic, infection with coxsackievirus A6 resulted in hand-foot-and-mouth disease with more extensive areas of cutaneous involvement and more protean morphologies, as well as localization to areas of active dermatitis, termed "eczema coxsackium." The concomitant enanthema is seen on the tongue, buccal mucosa, palate, uvula, and anterior tonsillar pillars. In herpangina, patients acutely develop fever, malaise, headache, and neck pain. There is a painful enanthema of small grayish-white vesicles on the soft palate, uvula, buccal mucosa, pharynx, and tonsils. These ulcerate with a surrounding red halo.

Bullous Impetigo

Impetigo is the most common bacterial skin infection in children. Bullous impetigo is a less common form of impetigo than the non-bullous forms. Bullous impetigo is most frequently seen in the summer in warm, humid conditions and is easily spread among individuals in close contact. The infection may be classified as primary impetigo (direct bacterial invasion of previously normal skin) or secondary impetigo (superinfection at sites of minor skin trauma such as abrasions, minor trauma, and insect bites, or underlying conditions such as eczema) and is also sometimes referred to as impetiginization. There can be associated fever, weakness, and diarrhea, although there are often no systemic symptoms. Small vesicles enlarge rapidly into flaccid bullae that easily rupture. These lesions can be generalized and can arise from normal-appearing skin. The infection is usually caused by *S aureus,* phage group 2, and is a localized reaction to exfoliative toxin that causes loss of cell adhesion in the superficial epidermis by targeting the protein desmoglein 1. This condition affects mostly neonates, infants, and younger children.

Scabies

Scabies is transmitted during prolonged close contact with an infested individual. Scabies has an incubation period of 4 to 6 weeks in patients without previous exposure. Reexposed patients develop symptoms a few days after repeat exposure. Caused by the tiny mite *Sarcoptes scabiei,* it can cause an intensely pruritic, generally papular eruption, although vesicular lesions can occur. Commonly, secondary excoriations are seen (see Chapter 138). In older children and adults, interdigital folds, flexor wrists, waistline, trunk, and genital area are more commonly affected. A linear burrow is pathognomonic but often difficult to identify clinically. Patients younger than 2 years have involvement predominantly of the head, neck, palms, and soles. In this age group, the eruption is more likely to be vesicular. Arthropod bites can also result in isolated and scattered vesicles.

Fungal Pathogens

Fungal pathogens that cause tinea pedis include *Trichophyton rubrum, Trichophyton mentagrophytes, Trichophyton tonsurans,* and *Epidermophyton floccosum.* Infection can directly cause a scaly or vesicular rash or can result in a hypersensitivity reaction to the fungi, presenting as vesicles on the palms, soles, sides of the fingers, and, occasionally, on the extremities and trunk. *Trichophyton mentagrophytes* can cause vesicles and bullae on the medial foot. It can be associated with an id reaction, in which deep-seated pruritic

vesicles develop secondary to tinea infection elsewhere. An id reaction, most commonly on the hands, face, and trunk, can also result from tinea capitis, usually caused by *T tonsurans* and *Microsporum canis,* although it does not cause a vesicular exanthem on its own (see Chapter 136). The incubation periods of fungal infections are variable, and exact limits are unknown.

Pompholyx (Dyshidrotic Eczema)

Pompholyx (dyshidrotic eczema) is a disease that can occur in children with chronic eczematous dermatitis or atopic dermatitis but can occur in children who are nonatopic as well. The clinical appearance of pompholyx can be identical to that of an id reaction or fungal infection and consists of tapioca, pearl-like, deep-seated vesicles frequently seen on the palms and soles as well as the lateral sides of the fingers that are extremely pruritic. Secondary impetiginization (bacterial superinfection) is common. Cases can be acute and recurrent, as well as chronic.

Allergic Contact Dermatitis

A delayed type IV hypersensitivity reaction secondary to contact with plants of the genus *Toxicodendron* is a common cause of allergic contact dermatitis. The main allergen in these plants is a catechol. Rhus dermatitis is the prototypical allergic contact dermatitis, which develops about 1 to 3 days after exposure to plants such as poison ivy, oak, and sumac. Linear papules and vesicles are seen at points of contact between the plant antigen and the skin (see Chapter 138). Contact with other allergenic substances may also produce a vesicular rash, including nickel, rubber compounds, fragrances, and preservatives in cosmetics.

The differential diagnosis of acute vesicular exanthems can be organized according to the distribution of the lesions. Distinctive locations, as well as specific patterns, are important to consider in each individual case. The presence or absence of fever can assist in developing the appropriate differential diagnosis (Figure 140.1 and Box 140.3). Epidemiological as well as historical information may suggest the diagnosis. For example, known exposure to varicella-zoster virus (chickenpox) 10 to 21 days prior to a vesicular eruption facilitates diagnosis of this disease. A history of hiking, camping, or other outdoor activities suggests possible contact with poison ivy or oak. In addition, the presence of a specific prodrome can often be elicited with primary or recurrent herpes simplex. Pain on swallowing often occurs with enteroviral infection. A history of similar lesions lessens the likelihood of acute primary infection and suggests a chronic condition such as the recurrent disorder pompholyx.

Laboratory Tests

Typically few, if any, laboratory studies are necessary in healthy children with vesicular eruptions because the diagnosis is often made clinically. Clinical diagnosis is becoming more challenging because of fewer cases of varicella and milder, atypical cases in the vaccinated population. A Tzanck test of the base of a vesicle showing multinucleated giant cells may be useful in making a preliminary diagnosis of herpes simplex or varicella. Direct fluorescent antibody and polymerase chain reaction are rapid methods to diagnose varicella. Polymerase chain reaction can detect viral DNA from swabs of vesicles or scabs. This test is highly sensitive and widely available. Culture and polymerase chain reaction should be obtained for diagnosis of neonatal herpes simplex infection.

Definitive confirmation of scabies can be made by microscopic examination of skin scrapings from suspicious lesions. The presence of the adult mite or ova, larvae, nymphs, or feces (scybala) is diagnostic. For children with suspected tinea pedis, scale collected

Box 140.3. Common Causes of Acute Vesicular Exanthems

Infectious

Viral

- Varicella-zoster
- Human herpesvirus 1 and 2
- Enterovirus

Bacterial

- *Staphylococcus aureus*

Fungal

- *Trichophyton rubrum*
- *Trichophyton mentagrophytes*
- *Trichophyton tonsurans*
- *Microsporum canis*
- *Epidermophyton floccosum*

Infestations

- Scabies (*Sarcoptes scabiei*)
- Arthropod bites

Noninfectious

- Allergic contact dermatitis
- Pompholyx (dyshidrotic eczema)
- Id reaction

from a skin scraping can be prepared with potassium hydroxide and examined under the microscope. Fungal cultures can also be obtained.

Pathophysiology

Vesicles and bullae arise from a cleavage at various levels of the skin within the epidermis (intraepidermal) or at the epidermal-dermal junction (subepidermal). Sometimes the 2 types of lesions can be differentiated based on the amount of pressure required to collapse the lesion, especially if the lesion is a large bulla. In addition, the thickness of the wall of a bulla can be estimated by its translucency or flaccidity. A biopsy of the lesion, however, is the only way to reliably differentiate between the 2 areas of separation, although this will not necessarily provide the diagnosis. Specific changes occur in the epidermis depending on the etiology of the vesicular exanthem. For example, with certain viral infections such as HHV, varicella, and herpes zoster, a hydropic (ballooning) degeneration of epidermal cells occurs.

In bullous impetigo, the vesicles and bullae are caused by staphylococcal exfoliative toxin that causes loss of cell adhesion in the superficial epidermis by targeting the protein desmoglein 1, which causes the keratinocytes in the granular layer of the epidermis to split apart. There are no bacteria seen within the blister cavity, and a few inflammatory cells can be present.

The rash caused by scabies infestation is the result of a hypersensitivity reaction to the proteins of the parasite. In vesicular lesions, there is spongiosis, or intercellular edema, in the epidermis caused by the mite, which can result in a vesicle. Spongiosis also leads to vesicle formation in pompholyx, although the pathogenesis of this disease is not known. Although pompholyx is also known as dyshidrotic eczema, "dyshidrotic" is a misnomer because this disease is not related to sweat gland dysfunction or occlusion. Spongiosis is also present in id reactions and allergic contact dermatitis.

Management

The mainstay of treatment for most vesicular eruptions is parent/guardian and child education as well as reassurance. For example, most varicella, herpes simplex, gingivostomatitis, hand-foot-and-mouth disease, and herpangina infections are self-limited and no treatment, except parental/guardian reassurance and education on adequate hydration, is necessary. These diseases can, however, be quite serious, as shown by the recent epidemic of enterovirus 71 in Asia, which resulted in death in severe cases. Any neonate with lesions suggestive of herpes simplex should also be worked up and treated aggressively because sequelae can be devastating. Depending on the etiology of the vesicular rash, children who are immunocompromised, such as those with HIV or AIDS, and patients who are undergoing treatment with chemotherapeutic agents or systemic corticosteroids may require specific intervention with the use of antiviral agents.

Topical agents such as calamine lotion and oatmeal baths should be used in children with intense pruritus or multiple lesions. Topical products, which are potentially sensitizing (eg, diphenhydramine-containing agents), should be used cautiously and discontinued if the condition is not improving. Cool, wet compresses with plain water or aluminum acetate (Burow solution) can be quite soothing in cases of rhus dermatitis, scabies, or tinea pedis.

Antipyretics (eg, acetaminophen) may be used to treat otherwise healthy children with varicella. Aspirin-containing medications should be avoided in children with varicella because of the association with Reye syndrome. Oral analgesics may also be indicated for symptomatic relief of pain associated with herpetic gingivostomatitis or enterovirus mouth lesions.

Oral antihistamines (ie, diphenhydramine or hydroxyzine) may be used in children with varicella or scabies for treatment of pruritus. These drugs are also helpful in treating pompholyx and rhus dermatitis. Although the sedating antihistamines are generally more effective, nonsedating antihistamines can also be used in the daytime, particularly for the more chronic pompholyx.

Steroids may be effective in the control of some vesicular rashes; however, the health professional must first be certain the lesions are not secondary to varicella or herpes simplex. In certain cases, steroids may be used in infectious diseases, such as eczema herpeticum, but in conjunction with antiviral therapy and under close monitoring. Topical steroids can be used for outbreaks of vesicles of pompholyx, as noted previously, reserving oral steroids for severe outbreaks. In severe cases of rhus dermatitis, a course of systemic steroids, such as prednisone, 1 to 2 mg/kg per day, may be warranted and generally requires at least 2 to 3 weeks of therapy. Topical steroids can also be used to treat an id reaction, as well as treating the underlying cause of the reaction. Use of an oral histamine-2 blocker, such as ranitidine or famotidine, can help prevent gastritis as a complication of oral prednisone.

Oral acyclovir or valacyclovir is not recommended routinely for the treatment of uncomplicated varicella in otherwise healthy children but should be considered when the risk of developing moderate to severe disease is increased. Acyclovir or valacyclovir is recommended in unvaccinated patients older than 12 years; those with chronic cutaneous or pulmonary disorders; those receiving chronic or short, intermittent courses of corticosteroids (systemic or aerosolized); or those receiving salicylates long-term. It can also be considered for secondary household infections and for those who may experience more severe disease. Intravenous (IV) acyclovir or oral valacyclovir, initiated within 24 hours of rash development, is recommended for patients who are immunocompromised. Oral acyclovir or valacyclovir may be warranted in pregnant women with varicella in their second or third trimester, with IV acyclovir for pregnant women with more serious complications. Acyclovir is most effective if initiated within the first 24 hours of the exanthem, although the effects on symptoms may be minimal. Varicella-zoster immune globulin may help modify the course of the disease.

An additional recommendation for children with varicella is to keep fingernails short to prevent superinfection of lesions from scratching. Children should drink plenty of fluids to avoid dehydration. Patients are considered contagious from 1 to 2 days prior to the onset of the rash until the lesions are all dried and crusted (usually 5–7 days after the rash develops), at which time they may return to school. In children with persistent or recurrent fever, secondary complications should be considered, such as bacterial superinfection with *S aureus* or group A beta-hemolytic *Streptococcus.* A rare association between primary varicella injection and invasive group A beta-hemolytic streptococcal infection resulting in streptococcal toxic shock syndrome and necrotizing fasciitis has been recognized.

Since 2006, the recommendation has been for 2 doses of varicella vaccine because immunity appears to wane with only 1 dose and sporadic outbreaks occur. Incidence of varicella infection has decreased significantly since this implementation, with 98% effectiveness with 2 doses versus 86% for 1 dose in a post-licensure study. Recipients of 2 doses are less likely to have breakthrough disease or zoster.

Intravenous acyclovir is the treatment of choice for neonates with herpes simplex infection. Primary genital infections should be treated with oral acyclovir or valacyclovir. Children with recurrent, frequent (>6 times a year) outbreaks of herpes simplex may benefit from suppressive therapy with 1 of these agents. *Herpetic whitlow* is a herpes simplex infection on the fingertip, usually as a result of direct autoinoculation from oral or genital lesions. Treatment is not required, although it may help with pain and faster healing. Herpes gladiatorum and "herpes rugbiaforum" are cutaneous herpes simplex infections on the skin of wrestlers and rugby players, respectively. While they do not require treatment with antiviral agents such as acyclovir, athletes should refrain from engaging in person-to-person contact when herpes lesions are present. *Eczema herpeticum* is a herpes simplex infection in children with underlying atopic dermatitis or other chronic skin disease that results in rapidly progressive widespread vesicles in areas of active underlying disease that then erode and crust. There can be significant fever and irritability, and severe infection may warrant hospitalization for treatment with IV acyclovir. Treatment with topical calcineurin inhibitors (eg, tacrolimus) is contraindicated.

Localized bullous impetigo in otherwise healthy patients can be treated with topical mupirocin 2% or retapamulin 1% ointments. Benefits of topical therapy include fewer side effects and lower risk for contributing to bacterial resistance compared with oral therapy. While over-the-counter triple antibiotic ointments (consisting of bacitracin-neomycin-polymyxin B) do have some activity against the organisms causing impetigo, they may not be as effective for treatment. Therefore, treatment of impetigo with these agents is not recommended. Bacitracin and neomycin can also cause contact dermatitis. More widespread or complicated infections require oral antistaphylococcal therapy with agents such as amoxicillin and clavulanate (Augmentin) or cephalexin (Keflex). Of note, children 8 years and younger should not be treated with doxycycline because of the potential for drug-induced tooth discoloration. Recurrent disease should warrant workup for carriage and treatment if needed. Local knowledge of methicillin-resistant *S aureus* rates and bacterial cultures should be considered.

In scabies, permethrin is recommended given its high efficacy and safety. However, topical sulfur is typically used for the treatment of infants younger than 2 months because of lack of regulatory approval for permethrin use in infants in this age group. Lindane should not be given to children younger than 10 years because of risk for systemic toxicity (see Chapter 138).

For the treatment of tinea pedis, topical antifungal agents in powder, cream, or ointment formulations can be effective when applied twice daily until clear. Discomfort can be alleviated with cool water or Burow solution soaks. Tinea pedis can be difficult to control. Its treatment is centered on meticulous foot hygiene. Because careful foot care is often not a priority for most patients, complete eradication is not realistic. Patients should be instructed to wash their feet and change their socks when they return from school, dry their feet completely, avoid occlusive shoes, and wear open-air shoes or sandals whenever possible. Topical antiperspirants may be needed (aluminum chloride). Cotton socks are recommended. In severe or refractory cases, an oral antifungal preparation such as griseofulvin, terbinafine hydrochloride, or itraconazole may be prescribed. Tinea capitis also requires oral antifungal therapy (see Chapter 136).

Prognosis

Overall, the prognosis for vesicular exanthems caused by infection is good, with most children recovering in 1 to 2 weeks, depending on the etiology. Secondary infections can occur with varicella, however, and should be suspected in children with persistent or recurrent fever. Additional complications in patients who are not immunosuppressed include bacterial superinfection of the skin, pneumonia, CNS involvement, Reye syndrome, glomerulonephritis, and arthritis. Complications from herpes simplex infections include conjunctivitis, keratitis, and encephalitis.

Secondary infections with skin flora can be a complication of any of these skin conditions because denuded lesions allow for superinfection. In addition, many of these rashes can be pruritic, resulting in open, excoriated skin.

CASE RESOLUTION

The toddler has a classic presentation of primary varicella (chickenpox). Management should include symptomatic treatment with acetaminophen and antihistamines, along with topical preparations such as calamine lotion and oatmeal baths. The parents should be instructed on the natural course of this infection and be informed that the infection is highly contagious. In addition, symptoms indicating possible complications, such as persistent or recurrent fever, tenderness, warmth, redness or swelling of the skin, leaking pus, and shortness of breath, should be reviewed with the parents.

PART 14

Social Determinants of Health

CHAPTER 141

Social Determinants of Health: Principles

Victor Cueto, MD, MS; Baraka D. Floyd, MD, MSc, FAAP; and Fernando S. Mendoza, MD, MPH, FAAP

CASE STUDY

John is a 12-year-old boy who is at your clinic for a sports physical. He is with his older sister because his mother is working and could not bring him in for the visit. He has 3 younger siblings at home. John says he is getting "mostly Cs" in school. When asked why he might be struggling in school, he responds by saying, "I'm trying my best." He plans on playing football this fall and is excited about the possibility of a "scholarship someday." His older sister remarks, "You can't be getting to school late if you want to get good grades."

Questions

1. What is the value of information about a patient's school and school performance? What is the best approach to learning about a patient's school performance?
2. How would you solicit information about a family's nonmedical needs and concerns?
3. What is the relevance of information about a family's structure and resources?
4. What role can a pediatrician play in assisting a family's access to necessary resources?

Children are born, live, grow, develop, and learn within an ecosystem that determines and influences their health, well-being, and overall life course; the factors comprising this ecosystem are known as the *social determinants of health* (SDoH). These factors are rooted in history, institutions, communities, and culture but are continually shaped by changes in the surrounding socioeconomic environment. The SDoH exist either in concert with health and well-being (ie, strengths or assets) or in opposition to health and well-being (ie, risks or needs). The combination of risks and strengths are not static; rather, they act in a dynamic fashion to uniquely shape and influence a child's life at any given time.

The SDoH have been conceptualized and categorized in myriad ways. The World Health Organization Commission on Social Determinants of Health formulated a comprehensive framework that conceptualizes the intersections of and relationships between the structural and intermediary determinants that affect health and well-being (Figure 141.1). This construct highlights the dynamic connections between the factors at play in patients' lives. On a national level in the United States, the public health initiative Healthy People 2020 has distilled the large constellation of the SDoH into overarching themes identified by 5 key domains that provide for actionable areas of focus: neighborhood and built environment, social and community context, health and health care, education, and economic stability (Figure 141.2).

The duality of individuals existing within the broader context of a population is an important point for the physician to consider. At a population level, it has been proposed that social factors and the social ecosystem account for more than one-half of the influence on health (Figure 141.3). The other significant contributors are health behaviors and medical care. In sharp contrast, the contribution of genes and biology are rather small. At the individual level, these findings underscore the immense importance and influence of social determinants on individual health.

The recognition that the health of individuals and populations hinges on much more than the underpinnings of physiology is of central importance to understanding the role of health professionals in the larger context of patients' lives. In fact, as SDoH themselves, health professionals play an integral role as mediators of other influential factors in their patients' lives. In the role of mediator, the individual physician has the ability to support favorable situations and mitigate adverse conditions and consequences in the lives of that physician's patients.

Pediatricians in particular have the unique potential to optimize the healthy development and life-course trajectory of the children and adolescents under their care. This presents both a challenge and an opportunity to recognize and address the SDoH that influence the lives of individual patients, the population served in the clinical setting, and the community in which the pediatrician practices.

Role of the Pediatrician

From its inception, the specialty of pediatrics has had a rich tradition of recognizing and working to ameliorate SDoH. As witnesses to the effect of social, political, and economic policies on children, pediatricians have expertise that necessarily extends beyond the diagnosis and management of disease. The combination

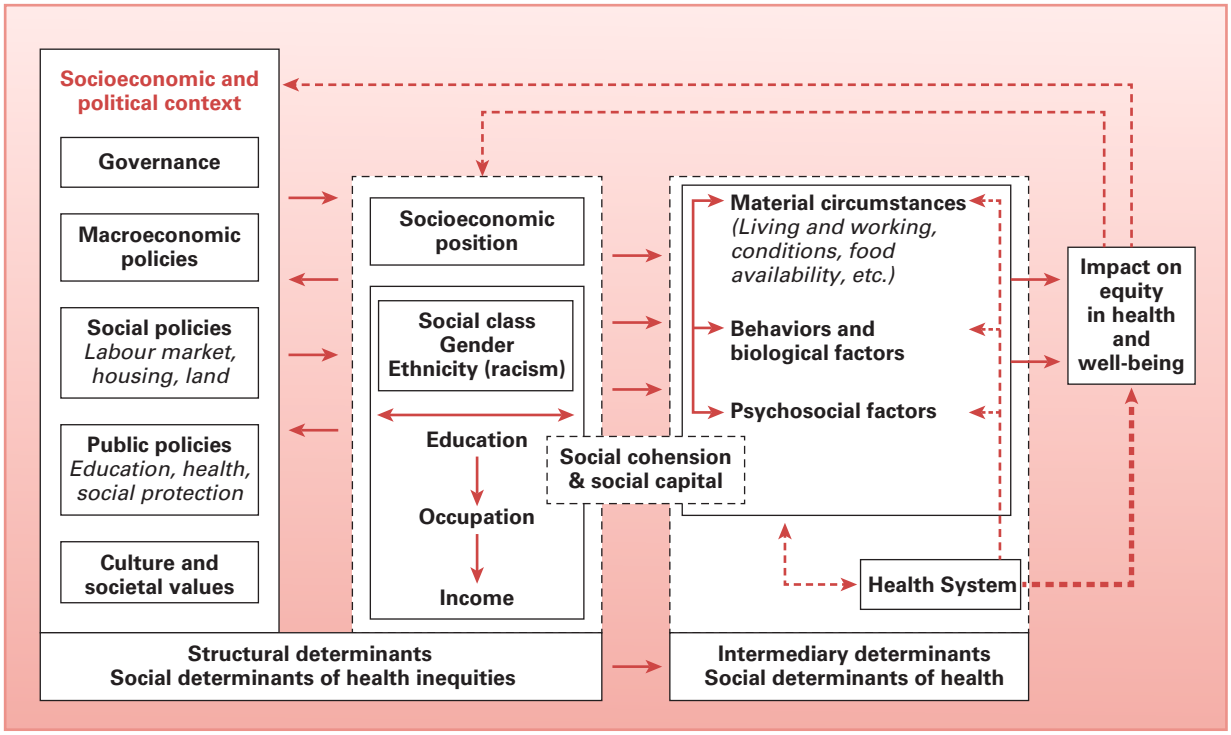

Figure 141.1. World Health Organization Commission on Social Determinants of Health conceptual framework for social determinants of health.

of pediatricians' expertise of the growth and development of children as well as their status as trusted voices and advisors in society on behalf of children allows pediatricians to serve as both advocates for children and active agents of change in children's lives. In practice, however, balancing the demands of providing medical care with the task of recognizing, assessing, and addressing the circumstances that can hinder or optimize the health and well-being of children is challenging. However, an organized process is available that can and should be applied to address SDoH. Moreover, the thoughtful approach and concerted effort required of pediatricians concerning these circumstances is not unlike that applied to identifying, assessing, diagnosing, and managing medical conditions. Similar to the traditional clinical approach to care, this process is characterized by actionable items, including screening, triage, identification, assessment, and intervention or referral. Most important, the skills and tools involved in this process also serve to augment and complement medical care, with the shared benefits of improving physical and mental health and promoting healthy growth and development.

Screening for Needs

Various screening procedures, tools, and questionnaires are commonly used in pediatrics. Most medical visits involve a patient intake process, which usually includes the use of questionnaires, triage, and assessment of vital signs. The primary reason for presentation is assessed, and measurements such as weight, height, temperature, and blood pressure are recorded. Similarly, well-child and health supervision visits usually include targeted age-based screening and assessment of developmental milestones. Additionally, new patients or patients who have not been seen recently often are asked to report on known health conditions and recent changes in health status. Patients and families are less commonly screened for the components and domains of the SDoH.

As a result of recommendations from the American Academy of Pediatrics and other trusted sources, however, screening for mental health symptoms, psychosocial stressors, and food insecurity have recently become more commonplace in some practice settings. Dedicated screening for the social determinants particular to any given patient should be included as part of usual protocol for all patients. Such screening is akin to obtaining vital signs in that it allows the physician to identify risks to health that may be as important to well-being as height or weight, if not more so. For example, knowing from height and weight measurements that a child has obesity is less beneficial than also knowing that the child has a parent who is unemployed and whose family is experiencing food insecurity. The information drawn from both screenings is of vital importance both during the clinical encounter and in the approach to management.

Screening requires a balanced approach involving integration of the clinical workflow, existing and emerging needs in the community, and knowledge of available resources. Furthermore, relying on clinical judgment alone for the existence of SDoH needs or risks in each family is problematic. Like the ability of pediatricians to recognize anemia, obesity, maternal depression, and developmental risk, pediatricians may recognize risk factors for negative SDoH in a patient's history, but identification of opportunities to support families requires a systematic approach and goes beyond recognition. Negative SDoH are often stigmatizing and linked to a family's past trauma, and as a result a family may be less likely to volunteer any needs to the pediatrician. This requires

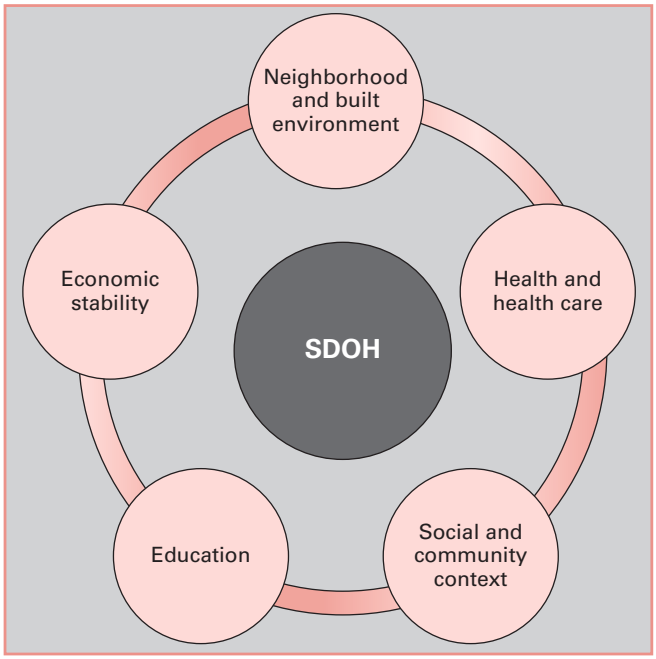

Figure 141.2. Healthy People 2020 focus areas for social determinants of health (SDOH) in the United States.

health professionals to rely on their own unconscious biases along with their clinical experience to judge which families may have additional needs in an already busy, short encounter and can lead to over-detection or under-detection of SDoH risks and strengths.

Screening for SDoH affords pediatricians the opportunity to affect long-lasting change in patients' lives, but effecting meaningful change requires purposeful preparation. Understanding the needs and assets of the population and community served in a given clinical setting is essential. To begin this process, a needs assessment is conducted to understand what needs are most prevalent in the community served. The information gathered through the needs assessment is paired with an asset map to help the physician and staff match identified needs to available resources. This pairing is important to ensure that a physician does not develop a screening protocol that will identify risks that cannot be addressed using existing local resources. This process provides an opportunity to leverage knowledge of community stakeholders (Box 141.1) to augment information gleaned in the needs assessment. In the clinic with limited time and resources for undertaking a formal needs assessment and creating an asset map, the knowledge and experience of key stakeholders with positive relationships with the community can be leveraged to increase feasibility.

Many validated tools exist to screen for SDoH needs, but no standard tool has yet been identified. Few tools exist to assess SDoH assets. Single-domain screening tools (eg, the 2-item Food Insecurity Screener) focus on 1 specific domain, whereas comprehensive screening tools (eg, the 12-item Well Child Care, Evaluation, Community Resources, Advocacy, Referral, Education [WE CARE]) focus on multiple domains of risk. In this ever-evolving landscape, many practices choose questions from validated screening tools to create their own tailored screening tools based on their own needs assessment and local asset map. Screening modality, whether verbal, paper, or electronic, is also tailored to the workflow of each clinical setting. Personnel performing the screening usually depend on the screening modality. For example, in clinical settings in which families complete previsit questionnaires electronically, SDoH screening may be performed as part of that questionnaire, but in settings in which other screenings are paper based and delivered by ancillary staff, SDoH screening may be included with those other paper-based workflows.

Most SDoH needs are not identifiable via growth parameters, laboratory studies, or physical examination; thus, specific screening for SDoH has been recommended as part of routine well-child care. Additional consideration should be given to SDoH related to the disease process or the presenting symptom, or as otherwise indicated. Food insecurity screening at follow-up visits for obesity and weight checks for failure to thrive are excellent examples of situations in which additional consideration should be given to SDoH. Likewise, standard questions about habitability and smoking at an asthma visit might be enhanced by asking additional questions about financial needs and resulting parental stress should the parent mention the recent loss of a job. In the clinical setting in which formal screening is not conducted or in which a validated screening tool or individual to perform such a screening are not available, the physician can use the IHELLP (income, habitability, education, legal status, literacy, personal safety) mnemonic to guide discussions with families to identify needs.

Although each clinical setting and family situation is unique, certain best practices can be followed when performing SDoH screening. *Universal screening*, or screening all families, decreases the likelihood that implicit bias will negatively affect screening and increases sensitivity of the instrument. *Screening for risks and strengths* identifies assets of which families may not have been aware, and these assets can be used to counterbalance challenges the family is experiencing and build parental confidence and self-efficacy. To elicit strengths, the physician can either engage the family in

Box 141.1. Social Determinants of Health: Risks and Strengths

Risks

- Educational attainment
- Poverty
- Bullying
- Immigration status
- Intimate partner violence
- Neighborhood violence
- Social/economic stress
- Parental mental health
- Social disruption
- Family structure
- Parental obligations/time constraints
- Lack of financial or social resources
- Lack of knowledge about services (eg, social support, educational)
- Immigration status

Strengths

- Family/community connectedness (ie, social capital)
  - — Growth mindset
  - — Education
  - — Family structure (ie, supportive, caring adults to nurture child)
  - — Resiliency
  - — Family role models
  - — Safe neighborhoods
  - — Safe, high-quality schools
  - — Stable and habitable housing
  - — Access to nutritious food
  - — Access to job opportunities
  - — Access to reliable transportation
  - — Access to medical care, including behavioral health and wellness care
  - — Social customs, practices, norms
- Strengthening Families Protective Factors[a]
  - — Parental resilience
  - — Concrete supports
  - — Social connections
  - — Knowledge of parenting and child development
  - — Social and emotional competence of children
- Centers for Disease Control and Prevention protective factors[b]
  - — Nurturing
  - — Stability
  - — Safety

Resources

- Government services
  - — Supplemental Nutrition Assistance Program (SNAP)
  - — Special Supplemental Nutrition Program for Women, Infants, and Children (WIC)
  - — Temporary Assistance for Needy Families (TANF)
  - — Earned-Income Tax Credit (EITC)
- Community agencies
  - — Anti-poverty agencies
  - — Specific advocacy agencies (eg, intimate partner violence)
  - — Food banks
- Early childhood systems
  - — Parenting supports
  - — Developmental supports (eg, Early Head Start, Head Start)
  - — Home visiting
- Social/civic groups
  - — United Way, YMCA
  - — Churches/Religious institutions
- Medical-legal partnerships

problem solving for a particular risk to help them identify their strengths or highlight strengths noted during the clinical encounter. Screening tools should be linguistically appropriate with attention to literacy level such that respondents with limited English proficiency or low literacy in any language can use them. If screening is delivered verbally, interpreters should be used to communicate with families with limited English proficiency. Because families may feel shame, guilt, or frustration about having SDoH needs or fear being reported as neglectful if they disclose needs, the physician should pose clear questions and remain nonjudgmental.

Principles of trauma-informed care should be used with screening because SDoH needs are often linked to past traumas, both individual and societal. For these families, disclosing needs is usually not risk free, whether the risk is the real risk of deportation or the theoretical risk of being reported as neglectful for having food insecurity and requiring support to meet the family's nutritional needs. Because many families are not accustomed to answering SDoH questions in clinical care, families should be presented with a clear rationale for screening and expected results. For written and electronic screening tools, a simple statement included on the tool itself is recommended. Screening should also be culturally and structurally competent, acknowledging that in the ever-changing lives of families, structural and intermediary social determinants work together to affect health equity (Figure 141.3). Recognition and acknowledgement of the current socioeconomic and political contexts as well as some understanding of the historical context for why inequities exist, is imperative. Purposeful acknowledgement of what cannot be addressed by the family alone because of the effects of certain systemic societal factors validates a family's experience.

Screening effectively without providing meaningful intervention does little to improve a family's outcomes. After screening to determine existing needs and assets, the physician must confirm what help the family desires to facilitate appropriate intervention. The role of appropriate universal and targeted screening cannot be overstated. It is the essential first

step in a complete and comprehensive assessment that will inform and guide management.

Comprehensive Assessment

In addition to screening, a comprehensive assessment and understanding of the unique factors present in each patient's life is incomplete without a robust family and social history. Medical students are often taught the maxim that a thorough history is indispensable and the key to most diagnoses. In practice, however, elements of a full and complete history may be overlooked or underappreciated. As indicated by presenting symptoms, screening, or known needs, the physician must aim to broaden the traditional cursory family and social history to fully account for the dynamic between medical, social, and family factors.

The family history must be inclusive of queries concerning family structure, paying particular attention to relationships and the roles of each caregiver in a patient's life, as well as where a child routinely spends time. Using this approach both elucidates a family's social context and helps the physician identify family preferences and practices.

While taking this history, it is important for the physician to be aware of and acknowledge the physician's own unconscious and conscious biases to avoid either imposing the norms of the examiner onto the family or inadvertently judging a family for not assimilating to the norms of the culture to which the examiner ascribes. For example, a biased view may incorrectly judge a family with 2 generations living in the same home as indicative of economic strain, rather than the preferred choice and practice for the family. Conversely, a child with a large number of caregivers with concomitant family dysfunction may be cause for chaos and may constitute a negative social determinant, whereas another child with stable family relationships will simply have more care and affection from a larger group of caregivers. The physician must appropriately and respectfully probe to fully understand the context of the history obtained.

A dedicated family and social history is also essential to explore relevant connections to medical conditions and findings. Special attention should be paid to common reports in children, because often presentations are not straightforward. For example, "belly pain" or "headache" may be a somatic manifestation of underlying psychosocial stress or strain. Such attention is particularly important in identifying mental health needs. Similarly, a seemingly stable family structure may belie underlying tensions and concerns, such as the well-adjusted family that may otherwise be coping with neighborhood safety concerns or immigration needs. Conversely, simple questions, such as, "What are your plans for the summer?" could uncover an unknown potential benefit from additional resources, such as educational enrichment summer programs offered by the local municipality.

Finally, a comprehensive assessment of the intersection of social and medical needs is of utmost importance when managing co-occurring social and medical complexity. Consider the case of a child with cerebral palsy who has previously exhibited failure to thrive and presents for follow-up after a recent admission for pneumonia. The physician should revisit elements from the family and social history that may be relevant to either the recent admission or future management at home, paying careful attention to possible changes in the child's environment, such as schooling, caregivers, housing conditions, and employment. A change may have occurred in medical attention at school or in insurance coverage for a necessary medication. Even seemingly trivial details, such as installation of new flooring in a home or a new family pet, may have relevance for their role in exacerbating underlying allergies. Any and all details are helpful in building a detailed history for use in making a complete assessment.

No substitute exists for a thorough and conscientious approach to history taking. The guiding force in this endeavor is a desire to become as intimately acquainted as possible with the conditions present in the lives of the patient and family. The physician must strike a balance between obtaining new information and confirming past information, with the aim of building a strong patient relationship or exploring a focused need. Most important, comprehensive history taking requires thoughtful weighing of the relevance of both positive and negative findings to each patient in light of individual screening, known or preventable conditions, possible complications, and potential benefits. The goal of the physician should be to make a comprehensive and unbiased assessment of the risks and strengths present for every child and family.

Differential Diagnosis of Risks and Strengths

Social determinants of health often have a negative connotation as consisting solely of risks, when in reality, every family has both risks and strengths that lie along a continuum rather than absolute positives or negatives. Approaching and narrowing a SDoH differential is unique in that the family—not the physician—is the expert in its own lived experience. Framing an approach to SDoH in terms of risks and strengths, in collaboration with a family, can help prioritize interventions as well as activate and empower the family.

Although identifying risks from screening tools and a history is relatively straightforward, elucidating a full differential that incorporates the interconnectedness of risks, strengths, and resources requires additional consideration (Box 141.1). Risks can be categorized based on Maslow's hierarchy of needs (Figure 141.4). Thoughtful specific attention to each level of this hierarchy (physiologic, safety, belonging, esteem and respect, achieving potential) helps to identify and address many of a family's vulnerabilities, and is especially important given children's particular susceptibility to the effects of their environment. Social and physical risks tend to be cumulative. Further clarifying the context of these risks directly with the family provides insight into stressors and life events that may have preceded or precipitated risks and helps the physician determine whether these risks are transient or fixed.

Unlike risks, SDoH strengths typically are gleaned from the history rather than specific screening tools. Narrowing the differential can be performed by general problem solving or problem solving around a particular risk with the family, such as specifically asking, "Who do you reach out to when you need help?" or "How can we go about helping with this today?" Such questions clearly signal

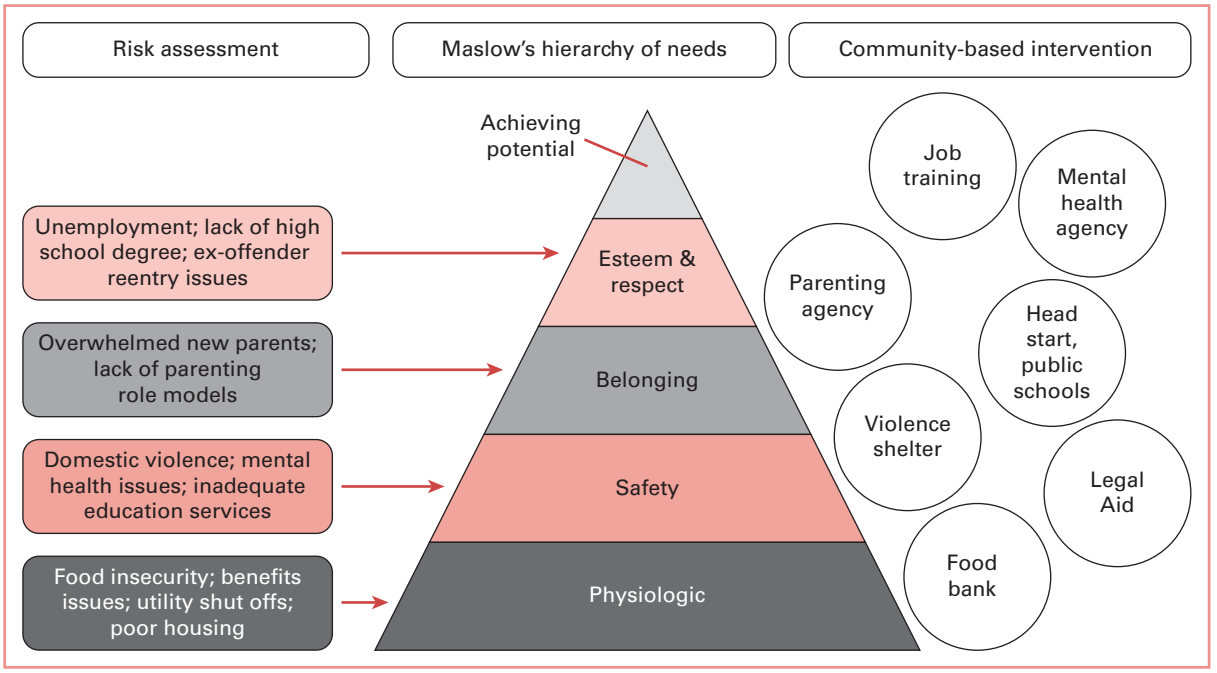

Figure 141.4. Conceptual road map that links risk assessment to community-based interventions using Maslow's Hierarchy of Needs.

that the pediatrician and family are members of a team working to solve this problem for the child, and such an approach often helps the family identify strengths they had not considered.

Two commonly used frameworks delineate the domains of strengths. The first is the Strengthening Families Protective Factors Framework, which has 5 protective factors: (1) parental resilience (ability to problem solve when presented with challenges and know when to ask for help); (2) social connection (network of support that includes family, friends, and community supports); (3) concrete supports in time of need (basic needs, such as food and shelter); (4) knowledge of parenting and child development (understanding what to expect for a child's behavior based on age); and (5) social and emotional competence of children (a child's ability to self-regulate and communicate needs and feelings in a developmentally appropriate manner).

The second framework is the Centers for Disease Control and Prevention (CDC) protective factors of nurturing, stability, and safety. These include access to nutritious food, job opportunities with transportation to get to them, and medical care encompassing behavioral health and wellness care. Safety specifically highlights neighborhood and school safety, and stability highlights stable and habitable housing. The Protective Factors Framework provides a relational approach, whereas the CDC protective factors provide an approach that can easily mirror specific domains of SDoH risk.

Documenting the risks and strengths of a particular family at a particular point in time runs the risk of conceptualizing these needs and assets as static, which rarely is the case. Using the 3 As of assess, agree, and address scaffolds an approach that takes this into account. Assess involves using the comprehensive evaluation (ie, screenings and a full social history) to guide the physician's next steps. Agree involves the physician using the teach-back method to summarize what was learned in the interview and probing further to clarify strengths and risks. Additionally, proactively engaging the family in problem solving identifies shared targets and a plan for what the family finds most pressing. It also provides space for negotiation and clarification when the physician's concerns may differ considerably from those of the family, thereby allowing the family to use its strengths to temporize the situation until the family is ready to address its next prioritized concern. Finally, the pediatrician and family can discuss treatment options to address the family's prioritized risks and strengths.

Management: Providing Targeted Resources and Support

The role of the pediatrician in managing the SDoH consists of providing targeted resources and support. The most essential needs of the patient exist beyond the walls of the clinic, and the physician can provide a necessary link between needs and resources. Children are seen in outpatient pediatric care at least 10 times in the first 2 years after birth; thus, pediatricians are uniquely positioned to affect children's lives. Even with this number of contacts, the SDoH risks and strengths children encounter outweigh the influence of these health care encounters and cannot be fully addressed through clinical care alone. Therefore, at each office visit it is necessary to highlight strengths while identifying and addressing potential risks to health. Similar to engaging collaborative management with medical subspecialists when specialty care is required, often the physician must refer to other professionals and partners in the community with the necessary expertise and resources. A useful approach is providing targeted resources for identified needs in accordance with Maslow's hierarchy of needs (Figure 141.4). It is equally important for the physician to recognize, highlight, and support strengths

as well as promote self-efficacy at each office visit. In managing SDoH, the pediatrician embarks on an iterative process with each patient and family in which each follow-up visit serves as an opportunity for further advocacy and problem solving with families as well as an opportunity to highlight even the smallest successes as concrete examples of self-efficacy on which to build the family's strengths, confidence, and agency. Ultimately, the physician must take a family-centered approach imbued with shared decision making to develop an adaptive and evolving individualized care plan to optimize the healthy trajectory of each child.

CASE RESOLUTION

A thorough social and family history reveals that John's mother is a single parent working 2 jobs and that although John has some free time after school, often he is tasked with helping his older sister take care of his younger siblings when his mother is working the night shift. Screening for social needs identifies that his older sister reports that their family is coping with an overcrowded living situation and recently increased cost of rent. A dedicated psychosocial history and screening reveals that John has been having increasing difficulty with math assignments. He also often feels generally anxious and worried, but more so before tests. He is able to confide in his older sister, whom he considers a confidant and advisor. Further probing reveals that John is happiest when he is with his whole family, including his older sister, his mother, and all siblings. Although she is not a parent, John's sister is most concerned with how she can help John be more successful in school. Although they both wish they had more room in the home, John and his sister are proud of their unique contributions to help their family and the way in which they help each other. In addressing the housing insecurity, you refer the family to a local community housing support agency. You arrange for John to be seen by a behavioral counselor for cognitive therapy for his anxiety. You also share a handout for an after-school educational and tutoring program run by the local parks and recreation department, which John and his siblings can attend and still have family time in the evening. Finally, your office staff forwards a letter to the school system to initiate an evaluation for an Individualized Education Program (IEP). You schedule a follow-up visit to reassess John's anxiety and the status of the IEP as well as to confirm connection to the housing agency and after-school program.

CHAPTER 142

Adverse Childhood Experiences: Trauma-Informed Care

Suzanne Roberts, MD, FAAP, and Geeta Grover, MD, FAAP

CASE STUDY

Chris is an 11-year-old boy presenting to your clinic for concerns about frequent bedwetting. He is accompanied to the visit by his stepfather. His parents are divorced, and his biological father is currently in jail for domestic violence. His biological father has a history of alcohol use and attention-deficit/hyperactivity disorder. His mother has a history of depression. Chris shares that he is embarrassed by his almost nightly bedwetting, and his stepfather adds that Chris has never been dry at night. His stepfather further mentions that Chris was recently suspended from school for 1 day for hitting another child. When the stepfather went to pick up Chris that day, the teacher stated Chris was having difficulty focusing in class and that his reading skills were below grade level. Chris commented, "Yeah, I hit him. He took some of my lunch and I really got mad."

Questions

1. What is an Adverse Childhood Experiences score, and how is it calculated?
2. What presenting symptoms might trigger adverse childhood experiences screening? What questions should you ask the family or patient to help determine the cause of unexplained symptoms?
3. How would you determine Chris's score? How does this score affect his risk for chronic disease?
4. What is meant by "Pair of ACEs"?
5. What is meant by protective/resilience factors? Can you identify any for Chris in the case study?

Children require safe, stable, nurturing relationships at home and in their community to promote optimal health and well-being throughout the life span. Children's responsive relationships with caregivers build healthy brain architecture and wiring over time. Adverse childhood experiences (ACEs) during the first 18 years after birth include exposure to abuse, neglect, and household dysfunction; disrupt healthy development; and can have a negative effect on adult mental and physical health and functioning. The ACE score is a determination of the number of ACEs to which a patient has been exposed. This score is based on the types of trauma included in the 3 categories of ACEs (ie, abuse, neglect, household dysfunction) (Box 142.1). Each individual ACE type counts for 1 point. The lowest score achievable is zero (no ACEs) and the highest is 10 (every ACE type). A child who has been exposed to emotional abuse and parental divorce, for example, is assigned an ACE score of 2.

The detrimental effects of these ACEs include adoption of unhealthy behavioral coping strategies, increased risk of chronic disease in adulthood, and difficulty with interpersonal relationships and work performance (Box 142.2). A dose-response relationship is observed, with exposure to more ACEs being associated with increased risk for more adverse outcomes later in life. Experience of 6 or more of these ACEs can result in up to a 20-year reduction in life span. Exposure to ACEs can affect the next generation as well, with the children of parents who experienced childhood adversity being at increased risk for developmental delays and health-harming behaviors.

Box 142.1. Categories of Adverse Childhood Experiences (ACEs) Used in Calculating the ACE Score

Abuse

- Emotional
- Physical
- Sexual

Neglect

- Emotional
- Physical

Household Dysfunction

- Domestic violence
- Incarcerated household member
- Mental illness
- Parental separation or divorce
- Substance and/or alcohol abuse

Box 142.2. Adverse Effects of Adverse Childhood Experiences Over the Life Span

Unhealthy Coping Strategies

- Alcohol and/or drug use, including intravenous drug use
- Multiple sexual partners
- Sedentary lifestyle or obesity
- Smoking

Health Effects

- Autoimmune disease
- Cancer
- Chronic pulmonary disease
- Diabetes
- Ischemic heart disease
- Liver disease
- Stroke

Mental Health Effects

- Depression
- Suicide attempt(s)

Lifestyle Effects

- Missed work
- Poor academic achievement
- Poor health quality of life
- Risk of intimate partner violence

More recently, other forms of adversity experienced in the environments in which children live, learn, and play (eg, poverty, racism, bullying, community violence) have been recognized as having similar negative effects on lifetime health. These environmental conditions in which children are born, grow, live, work, and age are referred to as the *social determinants of health* (see Chapter 141). According to the World Health Organization, the social determinants of health are responsible for most health inequities, that is, "the unfair and avoidable difference in health status seen within and between countries." In the United States, the wealthiest segment of the population has a 10- to 15-year longer life span than the poorest segment, an outcome that is related to differences in health-related behaviors, chronic disease, and injury. Together, ACEs and adverse community environments comprise the "Pair of ACEs" (Figure 142.1).

The Pair of ACEs tree illustrates how adversity within the family and adversity in the community together negatively affect children. Adverse childhood experiences exert their deleterious effect on health through excessive activation of the body's stress response on the developing brain and body. A child adapts to the negative home and world experiences the child encounters at the expense of longer term health. Positive supportive experiences at home and in the community can buffer and mitigate the effects, however. Because of the pervasive nature and long-lasting consequences of childhood adversity, addressing its roots and effects is an urgent public health concern.

Epidemiology

The original Adverse Childhood Experiences (ACE) Study published in 1998, based on information from more than 17,000 middle-class Americans, documented clearly that childhood adversity contributes significantly to negative adult physical and mental health outcomes. Sixty-four percent of adults recalled having at least 1 ACE, with 12% reporting 4 or more ACEs. Subsequent surveys have confirmed similar results in many states and many countries. Exposure to ACEs cuts across all strata of society. However, exposure to a higher number of ACEs disproportionately affects adults identifying as low income, low education, multiracial, or bisexual. The most common ACEs recalled by adults were emotional abuse, parental separation or divorce, and household substance abuse. Several ACEs tend to co-occur and can have intergenerational effects.

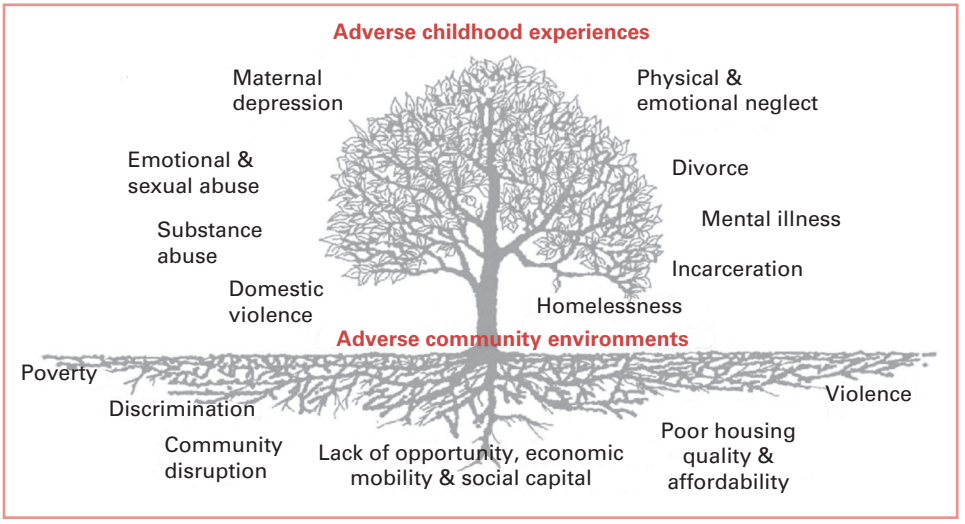

Figure 142.1. Pair of ACEs (adverse childhood experiences) tree.
Reprinted with permission from Ellis WR, Dietz WH. A new framework for addressing adverse childhood and community experiences: the building community resilience model. *Acad Pediatr*. 2017;17(7 suppl):S86–S93.

In the 2012 National Survey of Children's Health, parents in the United States reported that 46% of children had exposure to at least 1 ACE and, depending on the state of residence, 8% to 17% of children had 4 or more ACEs. The most common ACEs parents reported were economic hardship, parental separation or divorce, and parental alcoholism and/or substance abuse. In some states, parental mental illness and community violence were also prevalent. A recent study of more than 700 children, most of whom (67%) had experienced 1 or more ACEs and 12% of whom had experienced 4 or more ACEs, found that increased ACE score correlated with increased risk of learning and behavior problems and obesity. This correlation was especially marked for learning and/or behavior problems. Children with 4 or more ACEs were 32 times more likely to have learning and/or behavior problems in school than children with no ACEs.

Clinical Presentation

In a clinic setting in which a physician might see 20 patients per day, at least 2 patients may have experienced at least 4 ACEs. In the pediatrics clinical setting, a patient may be actively experiencing the pair of ACEs. The presentation is variable and related to the child's developmental stage, temperament, and family protective factors. A high number of ACEs in childhood may present as behavior concerns at any age (eg, aggression in a toddler, attention-deficit/hyperactivity disorder [ADHD] in the school-age child, and promiscuity or drug use in the teenager); developmental delays in the preschool-age child and learning concerns in the school-age student; physical symptoms, including functional symptoms (eg, stomachache, headache, poor sleep); and medical or psychiatric conditions (eg, poorly controlled asthma, encopresis, depression, suicidality). Nonadherence to medical treatment plans and missed appointments may also be signs of family adversity (Box 142.3).

Box 142.3. Presenting Signs of Adverse Childhood Events in Pediatric Practice

Learning/Behavior

- Attention-deficit/hyperactivity disorder
- Aggression
- Classroom disruption
- Speech delay
- Tantrums

Mental Health

- Anxiety
- Depression
- Substance use
- Suicidality

Other Health

- Missed appointments
- Morbid obesity
- Poorly controlled chronic illness
- Treatment nonadherence

Pathophysiology

Early childhood experiences influence the neural wiring for learning, memory, and behavior, and they shape the evolution of the neuroendocrine, autonomic, metabolic, and inflammatory systems. The architecture of the brain is built over time through experiences the child has in the child's family and community environments. In the first few years after birth, new neural connections (ie, synapses) are formed every second, and the brain reaches 80% of its adult size by age 3 years. Responsive interactions between child and caregiver are the building blocks that support healthy brain and body circuitry. Learning occurs when certain neural connections are strengthened resulting from use and others are pruned away because of lack of stimulation.

After the early childhood years, another major critical period of brain development occurs during adolescence, from puberty through the young adult years. Especially important during this time is the development and maturity of the prefrontal cortex of the brain. The prefrontal cortex has been dubbed "the CEO" of the brain, because it is the area responsible for executive function skills, including impulse control, attention, working memory, organization, planning, and mood modulation. Unbuffered stress and insults such as tobacco, alcohol, and other substance use during this second sensitive period of brain development can adversely affect the wiring of the prefrontal cortex.

During childhood and adolescence, the wiring of the brain's stress regulation system is under construction to respond in positive, tolerable, or toxic ways to perceived threats in the environment. When a person perceives a threat to his, her, or their safety, the brain and body adaptively release the hormones cortisol, norepinephrine, and epinephrine in preparation for a "fight, flight, or freeze" response. This evolutionarily conserved hormonal response results in the physiologic changes that allow the person to respond to the stressor. With a *positive stress response*, the elevations in heart rate, blood pressure, and hormone levels are short-lived and return to normal after the threat has passed. With a *tolerable stress response*, stronger threats may produce a more prolonged but not damaging response, because of the presence of buffers, such as the presence of supportive adults in a child's life. With a *toxic stress response*, however, the stress response system remains chronically activated, resulting in changes in brain and body physiology (Figure 142.2). In the absence of buffers assuring the child he or she is safe, exposure to ACEs can trigger the excessive activation of the stress response that is the biologic mechanism by which social and environmental circumstances result in detrimental effects on health (Figure 142.3).

Differential Diagnosis

Recognition that childhood adversity is common and pervasive should lead the health professional to consider ACEs-related trauma and consequences of excessive stress activation in the differential diagnosis of many common childhood reports. The child who presents with learning or behavior concerns (eg, aggression, excessive tantrums, speech delay, classroom disruption, ADHD); mental health problems (eg, depression, suicidality, substance abuse); and other health issues (eg, morbid obesity, poorly controlled chronic

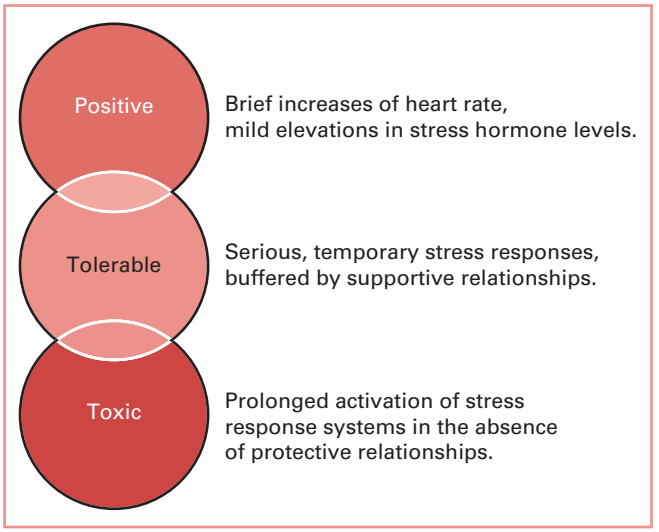

Figure 142.2. Levels of stress response.
Reprinted with permission from Center on the Developing Child at Harvard University. http://developingchild.harvard.edu

illness, treatment nonadherence, missed appointments) should undergo ACEs screening to help inform the child's treatment plan.

Evaluation

Because ACEs occur across all populations, routine screening would be ideal. Addressing exposure to traumatic events in a primary care practice can be considered challenging, however. Barriers to screening may include the health professional's lack of time during the office visit, lack of comfort in addressing sensitive family topics, and lack of training in managing positive screening results, as well as lack of community resources for family linkage. Starting such a screening practice can seem daunting. As a first step, the pediatrician may consider ACEs screening for the child with unexplained somatic symptoms, behavioral concerns, or changes in educational or socioemotional functioning. Sometimes the right question to ask is not, "Why are you behaving this way?" but, "Can you tell me what has happened to you?" For the younger child, the physician may ask the caregiver, "Since the last time I saw your child, has anything really scary or upsetting happened to your child or anyone in your family?" This same question may be addressed directly to the older child. The pediatrician must take the time to understand what has happened to the child before trying to "fix" the problem.

The practice with interest in implementing broader screening can use any of several standardized measures to identify factors that put children at risk for ACEs, including screenings for maternal depression, food insecurity, parental substance abuse, and domestic and/or community violence. Currently, no universally agreed on standard screening instrument exists for ACEs exposure in pediatrics. However, several tools have been developed for a pediatric population that can help the medical home in identifying these children, including Bright Futures Pediatric Intake Form, Center for Youth Wellness ACE-Q materials, Survey of Well-being of Young Children (SWYC), and Safe Environment for Every Kid (SEEK) questionnaire (Table 142.1). These and other clinical assessment

Safe Environment for Every Kid (SEEK)	Developed for pediatrics; validated	Longer; training required to administer

Abbreviation: ACEs, adverse childhood experiences.

tools are available on the American Academy of Pediatrics website, The Resilience Project (www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/resilience/Pages/Resilience-Project.aspx). Practices that implement ACEs-related screening should identify supportive resources in the local community with which to link families with at-risk screening results. Additionally, the physician should evaluate the family for protective factors that contribute to resilience in the presence of adversity (Box 142.4).

Management

Recognition of the role of ACEs as contributors to the presenting symptom facilitates the development of a more comprehensive treatment plan. *Trauma-informed care* in the medical setting involves delivering services in an environment of physical and emotional safety for families and health professionals, helping caregivers and children gain a sense of agency and control in their lives by sharing information with them, and involving the caregivers and children as active participants making decisions about the treatment plan. Children need to regain expectations that they are safe and lovable and that life has meaning. Attention to nutrition, exercise, sleep hygiene, and daily routines are important, as is addressing the psychosocial needs of children and their parent(s)/guardian(s).

Educating the family on the role of ACEs in the child's condition and providing referrals to social supports in the community, parenting programs, and psychotherapy can be added to the standard medical treatment of the presenting condition. Examples of evidence-based mental health programs for children who have experienced ACEs include Parent-Child Interaction Therapy and trauma-focused cognitive behavioral therapy. Complementary treatments, such as therapeutic yoga, can be considered if available in the area. An intergenerational approach will benefit parents who themselves have experienced ACEs and who may exhibit reduced parenting capacity or maladaptive responses to their children. Programs that encourage responsive relationships, reduce external stressors, and build executive function skills for adults and children can be transformative. Follow-up in the pediatrician's office is important, because the medical home can be a source of stability and support for families affected by trauma.

Sometimes the stressors that families experience can be overwhelming for the health professional as well. Acknowledging the effect on physicians and staff is part of a trauma-informed approach.

Box 142.4. Family Protective Factors That Contribute to Resilience in the Presence of Adversity

- Close relationships
- Parental resilience (bounce back)
- Awareness and application of positive parenting and child development practices
- Social connections (eg, friends, relatives, community members)
- Concrete support in times of need
- Sense of purpose (eg, faith, culture, identity)
- Individual competencies (eg, problem-solving skills, self-regulation, sense of agency)

Prevention

Primary prevention efforts to reduce the effect of ACEs on health involve reducing exposures to stressors and building buffers at multiple levels: society, neighborhood, school, family, caregiver, and child. Laws protecting civil rights, family leave policies, earned-income tax credits for working parents, home visiting programs, early childhood education, neighborhood safety, trauma-informed schools, afterschool programming, and positive parenting programs are examples of multilayer efforts to increase buffers in the community. Examples of evidence-based parenting programs include The Incredible Years, Circle of Security, and Guiding Good Choices. In the pediatric office, care for the parent or guardian during the well-child visit can include promoting bonding and secure attachment, providing guidance on normal child development and challenges, sharing coaching strategies on managing crying and misbehavior, and promoting literacy. The pediatrician can participate in the Reach Out and Read literacy initiative (see Chapter 34) and may wish to encourage the parent or guardian to use the Vroom child development mobile application, if possible. For the child, building resilience requires opportunities to build a sense of self-efficacy and self-regulatory capacities. For the family, faith, hope, and cultural traditions can be sources of strength (Box 142.5).

Secondary prevention efforts, such as screening for maternal depression, hostile parenting, food or housing insecurity, and developmental delays, and providing linkages to community resources are within the pediatrician's scope of practice in supporting a child's optimal development.

Prognosis

Adverse childhood experiences do not dictate the future of the child. Although it is easier to build neural connections right the first time rather than trying to fix them later, the potential for neuroplasticity

Box 142.5. Opportunities for Primary Prevention of Adverse Childhood Experiences

Society
- Civil rights laws
- Family leave policies
- Earned-income tax credits

Neighborhood
- Safety
- Early childhood education
- After-school programs

Pediatrician
- Promotion of bonding/secure attachment
- Guidance on normal child development (eg, Vroom app)
- Strategies for managing crying and misbehavior (eg, Zero to Three videos)
- Promotion of Literacy (eg, Reach Out and Read)

Family
- Home visiting programs
- Parenting programs
- Cultural or faith traditions

Child
- Developing self-regulation (eg, making choices; play games such as Simon Says, Red Light Green Light)
- Promoting self-efficacy (eg, goal setting, ability to learn from mistakes, praise effort, build on strengths)

exists throughout the life span. Children survive and even thrive despite the trauma in their lives. For these children, ACEs are counterbalanced by protective factors. Adverse events and protective factors experienced together have the potential to foster resilience. Knowledge of what constitutes resilience in children is evolving, but it is known that several factors are related to such protection, including cognitive capacity, healthy attachment relationships, motivation to learn, self-regulation skills, and supportive environments. The 7 Cs of resilience coined by Kenneth Ginsburg, MD, are competence, confidence, connection, character, contribution, coping, and control. Resilience is built over time, and the presence of a stable, caring adult in a child's life is critical in this process. These relationships provide the buffer and give children a sense of value: "I matter."

Additionally, differential individual susceptibility plays a role, with some children more affected than others by their environmental circumstances. It is important to help parents and guardians recognize that children in the same household can respond differently to the same event. Future directions for research include identifying children who would benefit most from tailored interventions. Studies of individuals living in the world's "Blue Zones" of longevity have found that lifestyle factors can also help mitigate effects of childhood adversity, including being physically active; having healthy eating habits, social ties, and family support; and faith.

CASE RESOLUTION

A thorough family and social history reveals that Chris currently lives with his mother, stepfather, and 2 younger sisters in supportive housing. The stepfather has known Chris since he was an infant and has been married to his mother for the past 8 years. The family became homeless 4 years previously when the stepfather lost his job. Since that time, they have lived in various shelters, in their car, and with relatives until being placed in housing 6 months previously. The family continues to struggle with financial hardships and food insecurity. Chris's biologic father has been incarcerated since Chris was 2 years old; his father has a history of domestic violence, substance abuse, and ADHD. Chris's mother has a history of learning issues and depression. Chris has attended at least 6 different schools in the past 4 years and has been at his current school for 4 months. His stepfather recalls that Chris had an Individualized Education Program (IEP) a few years previously, but because of the family's frequent moves, his IEP records have been lost and the school been unable to locate them either. Chris had been having behavioral outbursts for approximately 2 years but had been doing relatively well this year, until the recent hitting incident. He looks forward to going to school. His teacher likes him and has been working with him outside of class to help remediate his reading skills.

You review the history and conclude that Chris has an ACE score of 5; he has experienced all 5 household dysfunction criteria. Additionally, he has a history of homelessness, a factor that is not included in the original ACEs profile. Further exploration of protective factors is warranted, but based on initial intake such factors include Chris's positive relationships with his stepfather and his teacher as well as the family's access to supportive housing. The physical examination is normal, as is the urinalysis. You discuss behavioral management strategies for the nocturnal enuresis. To further understand Chris's attention and behavior concerns, you provide the family with the National Initiative for Children's Healthcare Quality Vanderbilt Assessment Scale to be completed by his teacher and parents. To address his learning concerns, you write a letter to request an evaluation for an IEP. You provide a book to Chris and remind him to read 20 minutes every night. The family is already connected to a local community housing support agency, and through this agency, Chris is receiving in-home therapy and his parents are receiving parenting support services. You schedule a follow-up visit to further assess and treat his bedwetting, attention, behavior, and learning concerns.

CHAPTER 143

Commercially Exploited Children and Human Trafficking

Jordan Greenbaum, MD

CASE STUDY

At age 17 years, Joe ran away from home to escape family violence and maternal substance use. He had no money or resources while living on the street, so he exchanged sex acts for money, food, shelter, clothes, and drugs. Many of the other homeless youth were doing the same, and they provided support to each other. None of the youth was operating under the control of a "pimp." Joe continued to engage in "survival sex" until age 19 years, at which time he met a man who promised to get him more clients and money. Joe agreed to the arrangement and stayed with this man for 1 year, giving him 30% of what he earned. Eventually Joe made the decision to stop this work, but when he announced this to his "friend," the man beat him and told Joe he could not quit and must continue selling sex to "earn his keep." Further, the man threatened to tell Joe's family that he was selling sex unless Joe agreed to deliver drugs to a dealer in another city. Joe's involvement in commercial sex and the drug trade continued for 6 months. Today, Joe arrives at your clinic and requests testing for HIV and sexually transmitted infections.

Questions

1. What are some of the risk factors associated with a trafficked individual?
2. What is the typical sequence of events that precede becoming trafficked?
3. In a patient, what are possible indicators of human trafficking?
4. What is the best means of approaching a patient who may be experiencing sex or labor trafficking?
5. Is Joe, the patient in the scenario, being trafficked? Why or why not?

Epidemiology of Child Trafficking

According to United States federal law, *child sex trafficking* occurs when an individual engages a minor (younger than 18 years of age) in a commercial sex act (ie, any sexual act that involves an exchange of something of value); no force, fraud, or coercion is necessary. Thus, children or adolescents exchanging sex for food or money to purchase luxury items are trafficked persons, as are those who are engaged in the production of child sexual exploitation images (formerly referred to as "child pornography") and those working in strip clubs. Neither involvement of a third party in the sexual transaction nor transportation of the individual from 1 place to another is necessary to constitute child sex trafficking. However, once the youth turns 18 years of age, the adult definition of sex trafficking applies, which requires the demonstration of force, fraud, or coercion as a means of exploitation. Thus, Joe, the patient presented in the case study, was being sex trafficked while he was a minor (ie, exchanging sex to fill critical survival needs), but once he turned 18, the survival sex was no longer considered "trafficking" because no obvious force, fraud, or coercion was involved. When Joe is working for the "friend" and that person assaults him when Joe wants to leave commercial sex work, Joe becomes a victim of adult sex trafficking because force has been used; Joe's previous "consent" in the commercial sexual activity becomes irrelevant.

Throughout this chapter, the term "victim" is used in its objective, legal sense as indicating a person who has been harmed as a result of some event or action or who has suffered as the result of someone else's actions. The term does not refer to how the individual may feel or perceive himself or herself as a result of the event or events and is not intended to be used to label that individual.

Both *child labor trafficking* and *adult labor trafficking* involve recruiting, harboring, transporting, providing, or obtaining an individual for labor using force, fraud, or coercion. This may involve either use of physical or psychologic tactics or abuse of the legal system in an effort to force an individual to work (ie, involuntary

servitude). It may also involve charging an individual an exorbitant amount and forcing the individual to work off the debt (ie, debt bondage). Children and adults may be trafficked in a wide variety of industries, both legal and illegal. Some of the more common industries include domestic servitude (eg, nanny, live-in maid), construction, agriculture, nail salons, sales crews, the hospitality industry, restaurants, and peddling or begging. Individuals may be trafficked in criminal activities, such as drug dealing or theft. In some cases, especially among females, both labor and sex trafficking occur. Joe is experiencing both labor and sex trafficking: he is coerced (via threats) to engage in illegal drug activity and is being forced to engage in commercial sex work.

Reliable prevalence rates for labor and sex trafficking are elusive, given the criminal nature of the activity, the reluctance of trafficked persons to report the crime, the lack of a centralized database and consistently used definitions, and the fact that many individuals do not realize they are being exploited. Statistics of identified trafficked persons suggest that girls are more vulnerable to sex trafficking than boys, although reporting bias, underrecognition, and reluctance to report likely contribute to the lack of identified males. Both males and females are vulnerable to labor trafficking, especially in the adolescent age group. Risk factors for child trafficking are described in Table 143.1. Research consistently demonstrates very high rates of prior abuse and neglect, as well as runaway/homeless status and involvement with child protective services and/or juvenile justice systems among sex-trafficked youth; these factors are very likely relevant to labor trafficking as well, although less research is available on this type of exploitation. Poverty, natural disasters, forced migration, and dysfunctional family situations may drive a child into a labor or sex trafficking situation. Exploitation may occur at any age, although adolescents age 13 to 17 years tend to be overrepresented. Limited research suggests that intrafamilial trafficking may involve younger children, on average, than trafficking involving non-family members, and may involve children in a wider age range. Trafficking occurs among children of all races, ethnicities, religions, cultures, and socioeconomic statuses.

Table 143.1. Risk/Vulnerability Factors for Child Trafficking: Socioecological Model

Level	*Description*
Individual	History of sexual violence; physical abuse and/or neglect Homeless, runaway, or throwaway status[a] Involvement with juvenile justice system and/or child protection services Substance misuse Untreated mental health and/or behavioral problems LGBTQ+[b] status Migration (especially unaccompanied minors) Lack of official documents (eg, immigration document, card, or visa, birth certificate)
Relationship	Intimate partner violence Family poverty and/or unemployment Family dysfunction Limited education Parent/guardian and/or peers involved in commercial sex work or purchasing sex Intolerance of LGBTQ+ status Forced migration
Community	Tolerance of sexual exploitation Lack of community resources High crime rate (especially organized crime) Tourism and/or transient populations in area Lack of awareness about child trafficking Adult sex work in area Gang activity
Societal	Gender-based violence and discrimination Cultural attitudes and/or beliefs Natural disasters Political and/or social upheaval, military conflict Law enforcement and/or political corruption Lack of acknowledgment of child rights

[a] Throwaway status: child told to leave home or told not to return home.

[b] Lesbian, gay, bisexual, transgender, queer/questioning, or other sexual minority (see Chapter 57).

Clinical Presentation

Research suggests that a large proportion of identified trafficked persons, especially those who are involved in sex trafficking, seek health care during or shortly before their period of exploitation. In 1 study of adolescent/young adult trafficked persons, 82.5% were seen at the local children's hospital within the year prior to identification. In another study of sex-trafficked adolescent females, 42.9% had received health care within the 2 months prior to identification. Numerous studies from around the globe have documented a wide array of adverse physical and mental health effects associated with trafficking, including physical injury (from work-related accidents, to physical or sexual assault); HIV and other sexually transmitted infections (STIs); nonsexually transmitted infections, such as tuberculosis; malnutrition and dehydration; unplanned pregnancy and complications thereof; substance misuse; chronic pain; posttraumatic stress disorder; depression and suicidality; somatic symptoms; and behavioral problems.

Given the plethora of adverse health consequences, trafficked children and youth may present with any of a wide variety of chief concerns. Such individuals may present for evaluation of sexual or physical assault (often with a false history provided), requests for STI or pregnancy testing, other genitourinary symptoms, behavioral issues, attempted suicide, drug intoxication, or sexual abuse. They may present with chronic medical conditions that are unrelated or only indirectly related to their exploitation (eg, asthma exacerbation from lack of access to the patient's medications). Evidence of adverse health effects may be noted incidentally, such as a finding of scarring from cigarette burns on physical examination.

Care may be sought in a variety of health care settings. Although studies show a large proportion of trafficked persons seeking care

in emergency departments and reproductive care clinics (especially Planned Parenthood), trafficked persons may also attend clinics for teenagers, community health centers, school clinics, private pediatrician practices, specialty clinics, mental health clinics, psychiatric hospitals, dental practices, or surgical practices. Trafficked children and adolescents may present to a health care facility alone or with peers (who may be traffickers, other survivors, or friends unaware of the exploitation). They may be accompanied by a parent or other relative (who may or may not be a true relative and who may or may not be involved with the trafficking), an employer, or some other adult.

Trafficked persons may be very reluctant to disclose their exploitative situation to health professionals. This may be secondary to distrust of authority, language barriers, shame, guilt, fear of retaliation by a trafficker, fear of arrest or deportation, fear of being sent back to foster care, or a desire to protect the trafficker, whom the trafficked person feels is looking out for his, her, or their best interest. In the latter case, a patient may have developed strong "trauma bonds" with the trafficker related to the highly stressful, manipulative character of the relationship. These bonds may prevent the trafficked person from realizing the exploited status and result in the trafficked person actively defending the trafficker. In other cases, a patient may not perceive the situation to be exploitative because it has been normalized or because the individual is unaware of his or her human and legal rights.

If spontaneous disclosure by a patient is unlikely, presenting symptoms may be varied, and a patient may or may not be accompanied by a trafficker, how does a health professional recognize a trafficked child or youth, or one who is at high risk for exploitation? The health professional should be aware of risk factors for trafficking and some of the potential indicators that may be present at the time of the health visit (Table 143.2). It is important to note that the indicators are nonspecific and may be absent in a given case.

Evaluation

A traumatized patient, such as a patient who has experienced sex or labor trafficking, needs a trauma-informed approach to health care. According to the Substance Abuse and Mental Health Services Administration, the trauma-informed approach incorporates a realization that traumatic experiences may profoundly affect the individual, family, group, organization, and community. Trafficked children and youth often have experienced repeated severe trauma, both before and during their period of exploitation. Their feelings, attitudes, and behaviors are shaped by these experiences; they interpret the world around them, including the words and behaviors of others, through a trauma lens. Stress reactions and behaviors developed to survive in a dangerous situation may lead traumatized patients to behave in ways that, to a health professional, appear maladaptive. A trauma-informed physician can recognize signs of trauma and trauma-related stress and respond in a supportive, nonjudgmental, and empathic manner. Such physicians demonstrate openness, respect, and cultural sensitivity. They take steps to increase the patient's sense of safety (physical and psychological), trust, and resilience. Additionally, these health professionals

Table 143.2. Potential Indicators of Child Trafficking

Evaluation	*Indicator*
Initial presentation	Patient presents either alone or with multiple peers requesting treatment Patient or companion gives inconsistent or implausible history Patient appears depressed, fearful, or quite anxious Patient is unfamiliar with the city or town, cannot give address where staying Patient's companion is: Domineering and apparently intimidating to the patient Speaking for the patient or trying to insist on translating for the patient Reluctant to answer health professional's questions, impatient for discharge Reluctant to leave patient alone with the health professional Is not the patient's guardian
History	Sexual, emotional, or physical abuse or neglect Runaway, homeless, or throwaway status[a] Involvement with child protective services or juvenile justice system LGBTQ+ Behavior problems and/or mental health history >5 sex partners Multiple prior sexually transmitted infections Pregnancy (or fathering a child) Forced migration Patient is an immigrant and not in control of official documents Relatives and/or peers participate in commercial sex work, whether selling or buying
Physical examination	Flat affect; withdrawn or hostile/aggressive Signs of posttraumatic stress disorder (eg, dissociation, hypervigilance, triggered anxiety responses) Patterned injuries or injuries in protected areas (neck, ears, torso, upper arms, thighs) Evidence of anogenital trauma or infection Signs of substance use/misuse Signs of malnutrition, dehydration Certain types of tattoo (eg, sexual inuendo, street name, gang insignia) Patient inappropriately dressed for weather Patient with large amount of cash, a few expensive items, multiple cell phones

[a] Throwaway status: Child or youth is told to leave home or told not to return home.

Abbreviation: LGBTQ+, lesbian, gay, bisexual, transgender, queer/questioning, or other sexual minority.

make every effort to minimize re-traumatization associated with the health visit. They use a *victim-centered approach*, in which the best interest of the patient drives all questions, discussions, plans, and activities. Key concepts of a trauma-informed approach to care are presented in Table 143.3.

Effectively working with trafficked individuals involves respect for fundamental human rights, including respect for the patient's race/ethnicity, sex, gender, sexuality, religion, social status, and cultural beliefs, without demonstrating bias or discrimination. It involves respecting a patient's right to information that is provided in an understandable manner and the patient's right, as developmentally appropriate, to actively participate in the patient's own care. Additionally, it involves respecting the patient's rights to privacy and confidentiality.

Table 143.3. Concepts of a Trauma-Informed Approach to Care

Concept	*Attitudes and Behaviors*
Screen for trauma (ie, human trafficking)	The physician is aware of risk factors and potential indicators of human trafficking and asks questions to assess the level of risk for exploitation. *The goal is not necessarily to obtain a disclosure but to assess risk so as to be able to respond appropriately and offer resources.* If the health professional is a mandated reporter, the professional's response to a patient deemed to be at high risk for exploitation is the same as for a patient who is known to be trafficked; that is, report to authorities and offer resources/referrals and anticipatory guidance. Having certainty about exploitation is not required, and pushing a patient to disclose is not appropriate.
Safety	The health professional takes steps to increase the patient's physical comfort (eg, uses private, youth-friendly room; inquires about the patient's basic physical needs) and decrease stress and anxiety. The health professional ensures the physical safety of the patient and staff and interviews the patient with the companion(s) out of the room.
Trust	The health professional takes time to build rapport; maintains nonjudgmental, empathic attitude; actively listens to the patient; demonstrates interest in learning about the patient's situation; and avoids making assumptions.
Respect	The health professional demonstrates respect by explaining what the professional wants to do and why (eg, reasons for asking questions, conducting examination, ordering tests), seeks permission (truly informed consent) for every step of the health visit, and accepts the patient's perspective and decisions without argument or applying pressure to change the patient's mind.[a] The health professional listens more than talks.
Transparency	The health professional explains limits of confidentiality early in the medical interview, uses simple language when explaining the process of the visit and suggestions for treatment, and thoroughly explains the process of reporting to authorities (as applicable).
Strengths-based approach	The health professional seeks to identify patient strengths (ie, resilience), facilitates patient awareness and appreciation of the patient's own strengths, and acknowledges that the patient is the expert on himself or herself.
Patient engagement and empowerment	The health professional actively encourages patient questions, discussion and suggestions for care; asks the patient questions about the patient's own view of the situation and what might help improve it; solicits feedback on the health professional's ideas for treatment and referral; and offers the patient choices and control whenever possible throughout the health care visit.
Cultural sensitivity	To the extent possible, the health professional is aware of and sensitive to cultural differences between the professional and the patient; and the health professional takes steps to understand the patient's cultural perspective and to respect cultural preferences when possible. The health professional asks questions about how the patient perceives relevant problems and solutions as well as the patient's views on health care and on the patient's current life situation.
Emphasis on minimizing re-traumatization	The health professional asks only the questions necessary to guide the examination, evaluation, anticipatory guidance, treatment, and referrals and to assess safety; monitors the patient for verbal and nonverbal signs of distress during the medical interview and examination; takes steps to reassure and support the patient; and has a plan in place to manage major psychological distress.
Available resources/referrals	The health professional or a designee creates a list of community, regional, and national resources to provide to the patient; establishes relationships with community victim service agencies and knows their services and eligibility requirements; and arranges a "warm hand-off"[b] to the referral agency when possible.

[a] Respecting a patient's decision about evaluation and treatment assumes the absence of life-threatening health issues that require emergent care, such as uncontrolled bleeding.

[b] In the "warm hand-off," the health professional directly contacts the victim service agency to discuss and arrange the referral or assists the patient with making contact while in the health facility (eg, allowing patient to use the telephone in a private room, providing the agency number, offering assistance as needed).

If a patient presents with risk factors for, potential indicators of, or other concerns for possible trafficking, the health professional will need to ask additional questions to assess risk (with the patient's assent). Questions to consider are shown in Box 143.1.

If the patient is willing, it is helpful to include in the medical history a detailed reproductive history, including information such as gender identity and sexual orientation, number of sexual partners, age at first sexual intercourse, and use of condoms. Addressing these issues opens the door for anticipatory guidance, helps indicate what resources or referrals may be necessary, and assists the health professional in gauging risk for sexual exploitation. Because of the very high rates of posttraumatic stress disorder and depression among victims of sex and labor trafficking, a brief mental health screening is appropriate to determine whether emergency psychiatric intervention is necessary. Screening for substance misuse is also indicated.

With patient consent, a thorough head-to-toe physical examination will allow assessment of nutrition, hydration, and any evidence of chronic disease. The trauma-informed approach extends to the physical examination, and it is important that the health professional explain each aspect of the examination and proceed slowly, being mindful of any sign of distress from the patient. Thorough documentation of extragenital and genital injury is important; this is best done with photographic documentation and a thorough written description of injuries. A chaperone (not the individual[s] accompanying the patient) must be present for the examination to monitor the patient for signs of distress. It is common for sex-trafficked youth to experience anxiety and distress with the anogenital examination, and if episodes of the patient's victimization have been recorded in the past, the use of cameras or videorecorders during the examination may trigger additional stress. For suspected sex trafficking and cases of labor trafficking that might also involve sexual exploitation and/or assault, an anogenital examination should be offered to the patient. If the health professional is not confident in conducting a detailed anogenital examination, it is appropriate to contact a specialist, such as a sexual assault nurse examiner or a child abuse pediatrician.

Box 143.1. Sample Questions for Assessing Risk for Trafficking

- I see many kids who live on the streets or run away from home, and most of them have a very hard time obtaining the money they need to survive. Many have to resort to exchanging sex to get food, shelter, money, drugs, or other things. Do you know anyone who has had to do that? Have you ever felt like you were in that position? Can you tell me about that?
- Has anyone ever offered to pay you to have sex? If so, do you feel comfortable telling me about that?
- Can you tell me a bit about your job? Maybe take me through a typical day for you?
- Are the working arrangements you have now at your job what you expected they would be? If not, can you tell me a bit about that? How are they different from what you expected?
- Has there ever been a time when someone asked you to do or forced you to do something that made you feel uncomfortable? Do you feel comfortable telling me about it?

Thorough documentation of anogenital findings is necessary, with special attention to the hymen and perihymenal structures in females, because this is a common area of injury in sexual assault. In many cases, however, the anogenital examination is completely unremarkable, with no evidence of injury, even if the patient reports genital trauma and bleeding in the past. The adolescent hymen and the anus are capable of considerable distention to accommodate objects larger than their resting diameter without sustaining injury. When injury does occur, it typically heals rapidly (within days to a few weeks) and completely, without scarring. Thus, a negative anogenital examination neither supports nor refutes the possibility of sexual exploitation.

A sexual assault evidence kit may be indicated, depending on the time of the last sexual encounter and the time frame used by the local police jurisdiction for obtaining trace evidence. As with all other aspects of the evaluation, the kit should not be obtained without the patient's assent. Sexual assault evidence kits typically contain detailed instructions. Swabs should only be collected from areas involved in sexual contact. A strict chain of evidence should be maintained when collecting, storing, and submitting the kit to law enforcement.

Once the examination is complete, it is important to discuss the results with the patient and ask if the child or youth has any questions or concerns about his or her body. Trafficked individuals may harbor anxiety about a variety of issues, including possible infertility, future health, or possible permanent damage from work-related injuries and toxic conditions.

Testing for pregnancy and STIs should be offered, following Centers for Disease Control and Prevention guidelines for STIs. This includes testing for *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, syphilis, HIV, and hepatitis B virus. Consideration should also be given to testing for other infections as appropriate, such as herpes simplex virus, hepatitis C virus, tuberculosis, and infections endemic to the patient's home country. Laboratory tests for malnutrition or vitamin and mineral deficiency may be indicated. Depending on the medical setting, vision and hearing tests should be considered, as well as administration of vaccines and discussion of contraception (especially long-acting, reversible contraception). The health professional providing care for a foreign national trafficked individual may obtain guidance on medical screening and care for immigrant children from the Centers for Disease Control and Prevention as well as the American Academy of Pediatrics resources *Red Book* and Immigrant Child Health Toolkit.

Because of the high risk of ascending infection and the likelihood that the patient will not be able to attend a follow-up appointment, it is advisable to offer prophylaxis for *N gonorrhoeae*, *C trachomatis*, and *T vaginalis*. Emergency contraception should be offered to females. HIV post-exposure prophylaxis should be considered in this very high-risk population; however, it is not suitable for all patients, especially those who are unable to comply with a rigorous regimen of daily medications. The risks and benefits should be discussed with the patient, and the health professional may seek advice from infectious disease specialists.

Documentation is an important aspect of the patient visit, and all efforts should be made to adopt strategies to protect privacy and confidentiality to the fullest extent. These strategies may differ according to facility resources and protocol. The need to document patient history, including risk factors and high-risk behaviors, physical findings, test results, and diagnoses as accurately and thoroughly as possible to ensure optimal continuity of care must be weighed against the possibility of a trafficker gaining access to the patient's records (eg, forcing the patient to access the electronic medical record, reading discharge summaries) and possible stigmatization associated with exploitation, especially sexual exploitation.

Management

All reports and referrals should be made with the patient's best interest in mind. Engaging the patient in care planning is critical, because the patient is the expert on the patient's own living situation. Although the health professional must abide by mandatory reporting laws, that individual must also make every effort to advocate for the patient to be treated as a person in need of services, not a criminal in need of incarceration. Not all law enforcement and child service workers have received training on labor and sex trafficking, so some may mistakenly assume the patient is a "child prostitute" who should be punished for engaging in a crime or that the immigrant patient who is in the country illegally should be deported. The health professional may need to explain to these other professionals the victimization and manipulation involved in child trafficking and explain that sex trafficking force, fraud, or coercion are not required for a situation to be labeled sex trafficking.

Most trafficked individuals have a great many needs, ranging from medical and behavioral health (Box 143.2), to housing, food, crisis intervention, immigration assistance, legal assistance, translation assistance, and education and job skills training, as well as family support and services. Multidisciplinary collaboration is necessary to meet these needs, and the health professional plays a critical role in this as well. The health professional may provide direct services and offer referrals to the patient, always seeking consent before taking action. As indicated in Table 143.3, all efforts should be made to make referrals using a warm hand-off. That is, the health professional or other designated staff should directly contact the referral agency or organization to discuss and arrange the referral, or facilitate the patient making contact during the health visit. Possessing a current list of community, regional, and national resources is critical to linking trafficked patients with services. A valuable national resource in the United States is the National Human Trafficking Hotline (1-888-373-7888; https://humantraffickinghotline.org/). The National Hotline has trained staff to assist trafficked individuals and professionals alike, including interpreters for more than 100 languages. Additional assistance may be obtained by contacting state or local law enforcement and anti-trafficking task forces or local child advocacy centers.

A patient may not be ready to accept offers of assistance or may feel it is not safe to do so. Creative means of providing hotline numbers have been proposed, including inserting a small sheet of paper in a tampon container or lipstick holder or entering the National Hotline number into the patient's mobile phone under a fake friend's name. Regardless, it is critical to respect the patient's decision about accepting or rejecting services, making it clear that the child or adolescent is welcome to come to your facility in the future if he, she, or they needs help. If feasible, scheduling follow-up appointments in the medical setting to monitor the patient and continue to build trust and rapport is recommended. Acceptance, support, and an open-door policy increase the likelihood that a trafficked individual will return and accept help if and when the individual feels it is appropriate.

Box 143.2. Common Health and Behavioral Health Needs of Trafficked Persons

Health

- Medical home (accessible, affordable, acceptable) that provides services, such as primary care, immunizations, anticipatory guidance, testing for sexually transmitted infections and HIV, and family planning services
- Obstetrics/gynecologic referral when appropriate
- Examination at a child advocacy center or by a sexual assault nurse examiner
- Care by a health professional specializing in issues related to being lesbian, gay, bisexual, transgender, queer, questioning, or other sexual minority
- Specialist care when appropriate

Behavioral Health

- Assessment for trauma-related symptoms, with trauma-focused therapy as appropriate administered by a trauma-trained provider
- Substance abuse assessment and possibly rehabilitation
- Management of chronic mental health disorders

Prognosis

Re-trafficking of children and youth is common, and it is especially likely in situations in which patients do not view their situation as exploitative. Such individuals may honestly believe their trafficker is their romantic partner and loves them, that their employer is looking out for their best interests, or that "everyone gets treated this way" and their exploitative working conditions are "normal." Alternatively, they may realize they are being exploited but see no way out of the situation and feel they must continue to work until they have paid off their debt. They may be coerced or forced to return to the trafficking situation by those controlling them. It may take several cycles of seeking health care, refusing services, and returning to the exploitative situation before the individual is able to extricate himself, herself, or theirself. When such individuals make the decision to exit their situation, it is critical that they know where they can receive help and support, and the health professional must be ready to provide that help and support.

Prevention

The health professional has a role to play in the prevention of child trafficking. Educating and counseling parents/guardians and patients about risk factors, common recruitment strategies (eg, false

romance, offers of jobs that are "too good to be true"), and possible indicators of child trafficking may help vulnerable youth avoid victimization and enable parents and guardians to recognize early signs of exploitation. Screening patients for risk factors and offering resources to address those factors may prevent victimization (eg, homeless shelters; resources for individuals who identify as lesbian, gay, bisexual, transgender, queer, questioning, or other sexual minority; crisis hotline numbers for teenagers; food pantries; community mental health services; immigrant/refugee organizations; legal aid). At the organizational level, the health professional can advocate for the development of facility protocols to address suspected human trafficking and educate other health professionals about the issues. In the community, the health professional can join multidisciplinary task forces on human trafficking, work with the media to increase public awareness of the issue, and support community organizations that serve trafficked individuals. Finally, the health professional can advocate for policies and laws that increase services for trafficked individuals and improve access to resources that address the social determinants of health, which so often render youth vulnerable to trafficking.

CASE RESOLUTION

You build rapport with Joe by asking him what he likes about himself, what he likes to do, and what famous people he likes. You explain the limits of confidentiality and the voluntary nature of all aspects of the visit. Additionally, you explain that you ask all of your patients questions about their health and background, including some questions that are sensitive, to determine if there is some way you can help them feel better and stay safe. He agrees to answer questions. When you inquire about past medical history, he reports prior gonorrhea and chlamydia infections; he has had "lots" of sexual partners. He has a history of "bipolar" disorder. Joe indicates that he is living with an older man and has a history of running away from home multiple times because of maternal drug use. He appears reluctant to provide details of his living situation or other social history. He does not disclose his sex and labor exploitation to you. You are concerned that he has multiple risk factors for exploitation and inquire more about his time when he was living on the street as a teenager. You ask if he was ever in a position in which he had to consider trading sex for something he needed, such as food or shelter. He hesitates, looks away, and then says, "Yes, but I never did it." He changes the subject and starts talking about his recent genitourinary symptoms. On physical examination you note linear scars on his back, which he vaguely acknowledges as, "from being hit a long time ago." He provides no details. He has a purulent penile discharge that tests positive for gonorrhea.

You talk to Joe about STIs and condom use. You counsel him about the concept of exploitation by those who seek to take advantage of people, either by forcing or coercing them into having sex for money or exploiting them in other types of work. You ask if he would be interested in any information about this and offer to give him the number of the National Human Trafficking Hotline to call if he or a friend ever feels he, she, or they is being exploited. You offer resources for homeless shelters in case he wants to leave his present living situation and ask if there are other community resources he thinks he might need. You arrange for a follow-up appointment in 2 weeks.

CHAPTER 144

Physical Abuse

Melissa K. Egge, MD, FAAP, and Melissa D. Siccama, MD

CASE STUDY

A 6-month-old boy arrives at the emergency department after becoming limp and nonresponsive at home. The mother states that her son was fine when she left him in the care of her boyfriend before going to the store for cigarettes. When she returned 1 hour later her son was asleep, but then he seized and stopped breathing. The infant is being ventilated by bag-valve-mask ventilation. On examination, the infant is pale and limp. His heart rate is 50 beats per minute, and his blood pressure is 130/80 mm Hg. He has no external signs of injury.

Questions

1. What are the types of injury that may be seen in physically abused children?
2. What are the major lethal injuries associated with physical abuse of children?
3. What are the presenting signs in the child with head injury?
4. What diagnostic studies are indicated in the child with suspected physical abuse?
5. What are the legal obligations of the physician in the area of child abuse?

Physical child abuse was first described in the pediatric literature in 1962 in a classic paper on the battered child syndrome. Child abuse or maltreatment takes many forms, including physical abuse, failure to thrive (Chapter 146), sexual abuse (Chapter 145), emotional abuse, prenatal exposure to substances (eg, drugs, alcohol) (Chapter 148), and *medical child abuse*, the latter of which is a complex disorder previously known as "Munchausen syndrome by proxy" in which parents confabulate or create a medical condition in their child.

The nature and extent of inflicted injuries are variable and may include bruises, burns, fractures, lacerations, internal hemorrhage, and ruptures. The physician must be aware of the legal obligations related to the suspicion of child abuse. It is the responsibility of the physician to assess the nature of the injuries, initiate appropriate medical therapy, and determine if the history offered is consistent with the medical findings.

Epidemiology

It is estimated that the rate of childhood victimization in the United States is 1 in 7 and that approximately 15% to 20% of these children suffer some form of physical abuse. Certain factors are associated with physical abuse. Most victims are young children; two-thirds are younger than 3 years and one-third are younger than 6 months. Caring for young children is frequently demanding, so crying infants and toddlers undergoing toilet training are particularly at risk for abuse. Factors such as lower socioeconomic status, substance abuse, poor parenting skills, and domestic violence place children at increased risk for abuse.

Clinical Presentation

Children who have been physically abused present with injuries that range from nonsevere to lethal (Box 144.1). Visible bruises, bites, and burns may be noted. An infant may initially present with a sentinel injury, a minor injury that is initially underappreciated by the nonoffending caretaker and often the physician. Examples of sentinel injuries include a bruise in a pre-mobile infant, subconjunctival hemorrhage, and frenulum injury. Sentinel injuries should be considered warning signs of future, more severe abusive injury. A child may also have symptoms related to fracture, such as crying or refusal to walk or move an extremity. The more severely injured child may present with seizure, apnea, shock, or cardiopulmonary arrest.

Box 144.1. Diagnosis of Physical Abuse

- Bruises
- Bites
- Burns
- Fractures
- Intracranial hemorrhage
- Intra-abdominal hemorrhage
- Brief resolved unexplained event
- Retinal hemorrhage
- History that changes
- Injuries not explained by history

Pathophysiology

Injuries in children who experience physical abuse are the result of direct trauma inflicted on the children. Abusive parents often have unrealistic expectations of their children, resulting in frustration and abuse when the child does not meet the expectations. Parents who have often been victims of abuse themselves know only corporal punishment as a disciplinary modality. These parents often exhibit poor impulse control; they do not intend to harm their children but rather desire to alter their child's behavior. As a result, sometimes the outcome is unexpected.

Head injuries, the most deadly form of abuse, may result from a direct blow to the head or from rotational head movement (eg, shaking). Classically, a crying infant is vigorously shaken and experiences diffuse axonal injury or intracranial hemorrhage. In particular, subdural hemorrhage may occur from shearing of the bridging veins. The infant may also become apneic during or after the trauma. Seizures, cerebral edema, hypoxic brain injury, and retinal hemorrhages may also occur. Such injuries are frequently associated with a fatal outcome or long-term damage to the central nervous system.

Abdominal trauma is the second most common cause of fatal child abuse and typically is caused by a direct blow to the abdomen. Skeletal fractures result from multiple different types of traumatic forces to the bones. Rib fractures are most classically associated with the head trauma of shaking and are caused by compression of the ribs by the hands holding the infant or child.

Differential Diagnosis

When evaluating the child with physical injury, the major differentiation is the distinguishing of injuries that are abusive or inflicted from those that are accidental. The physician should be suspicious of changing histories, histories that are inconsistent with the injuries sustained, and histories that do not match the developmental capabilities of the child. Unwitnessed injuries in young children, particularly preambulatory infants, should also be suspect.

Bruises, burns, and fractures may be abusive or accidental. Normal ambulatory children commonly sustain bruises over bony prominences, such as the forehead, elbows, and shins, with unintentional, accidental trauma. Bruises over soft areas (eg, cheeks, pinnae of the ear) and on protected areas (eg, inner thighs, neck) are more suggestive of inflicted trauma. Injuries to the oral mucosa may result from efforts at forced feeding or occlusion of the mouth in an effort to silence crying. Retinal hemorrhages in infants most often result from abusive head trauma, such as shaking. They may also be the result of other medical conditions that usually can be discerned from the history and physical examination and by consultation with an ophthalmologist. Ideally, a pediatric ophthalmologist performs indirect retinal examination of dilated eyes within 24 hours of the patient's admission (Box 144.2).

Box 144.2. Causes of Mild Retinal Hemorrhage

- Abusive head trauma
- Unintentional head trauma
- Birth trauma
- Retinopathy of prematurity
- Blood dyscrasia
- Leukemia/lymphoma
- Meningitis/sepsis
- Extracorporeal membrane oxygenation
- Hyponatremia or hypernatremia
- Vasculitis
- Papilledema
- Hypertension
- Cytomegalovirus retinitis
- High-altitude illness
- Carbon monoxide toxicity
- Osteogenesis imperfecta
- Glutaricaciduria

Children may be intentionally burned by being immersed in hot water or having hot objects, such as irons or cigarettes, held against them. The child who is immersed in hot water develops circumferential burns that may envelop an entire extremity. Such a burn is usually in a glove or stocking pattern or in a doughnut pattern on the buttocks. These burns are distinct from splash or spill burns, which take on an irregular drip pattern. In distinguishing inflicted from accidental burns, a scene investigation is often helpful to measure the water temperature in the home water heater and determine the length of time required to reach that temperature in the location of the alleged incident. Families should be advised to set their water heaters to 120°F to prevent accidental scald injuries.

Long bone fracture, especially of the humerus and femur, are suspect, particularly in the preverbal or preambulatory child. Certain fractures, such as classic metaphyseal lesions as well as fractures of the rib, sternum, and scapula, are strongly suggestive of inflicted trauma.

Numerous medical conditions may mimic abuse. Bullous impetigo may resemble burns. A coagulopathy may result in multiple bruises. Leukemia, thrombocytopenia, and aplastic anemia are also associated with bruising. Osteogenesis imperfecta or rickets may result in multiple fractures. Bone cysts and osteoporosis caused by inactivity from multiple causes (eg, cerebral palsy, paralysis, meningomyelocele) may predispose to the development of pathologic fracture.

Evaluation

The child who presents with injuries requires evaluation with a careful history and complete physical examination. The infant with altered mental status, apnea, or seizures should be evaluated in a similar manner because these symptoms may be secondary to intracranial injury.

History

The history should focus on an explanation for the medical findings (Box 144.3) and, in infants and toddlers, a thorough developmental history should be included. The child should be interviewed alone if

Box 144.3. What to Ask

Physical Abuse

- What caused the injury?
- Was the child healthy until the injury occurred?
- Has the child sustained similar injuries in the past?
- Is the family history positive for any conditions that would account for easy bruising or fragility of the bones (eg, von Willebrand disease, osteogenesis imperfecta)?
- Is the child developmentally normal? What are the child's motor skills?
- Who was with the child when the injury occurred?
- What was done immediately after the injury? Was medical care sought?

of an appropriate age. The physician should determine if other risk factors, such as domestic violence or substance abuse, are present.

Physical Examination

A child's state of hygiene and growth parameters should be noted, and the physical examination should be comprehensive. The location, color, and size of bruises, abrasions, lacerations, or other skin trauma should be recorded. Dating of bruises cannot be done because the degradation rate of hemoglobin, and therefore the rate of color change, varies according to the depth and extent of the bruise and by the child's health and nutritional status. Large blue-gray spots, which occur commonly on the back and buttocks in darker-skinned children, are termed *mongolian spots* or *congenital dermal melanocytosis.* These should not be mistaken for bruises.

The physician should also note any skin findings that resemble characteristic patterns of inflicted skin trauma, such as slap marks to the face or gag marks around the mouth. Pinch marks can also be seen on the genitalia of a toddler undergoing toilet training. Belts, cords, and blunt objects may leave patterned marks on the skin after a child is hit with the object. Bite marks are composed of indentations, bruises, or breaks in the skin that reflect the configuration of teeth that is unique to the perpetrator (Figure 144.1). Inflicted burns may also assume a characteristic pattern depending on the mechanism of injury (Figure 144.2).

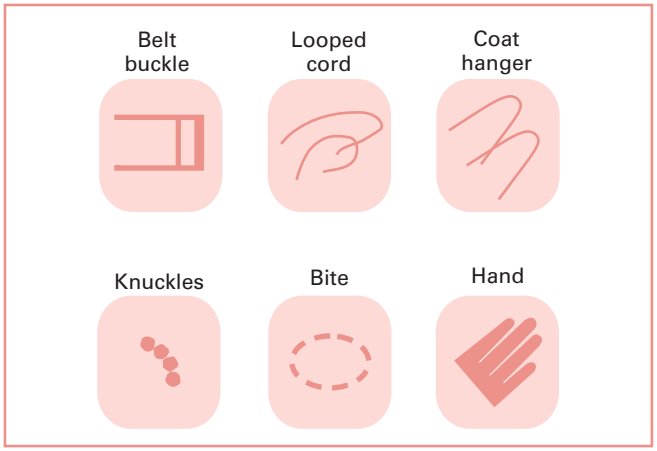

Figure 144.1. Patterned bruises associated with inflicted trauma.

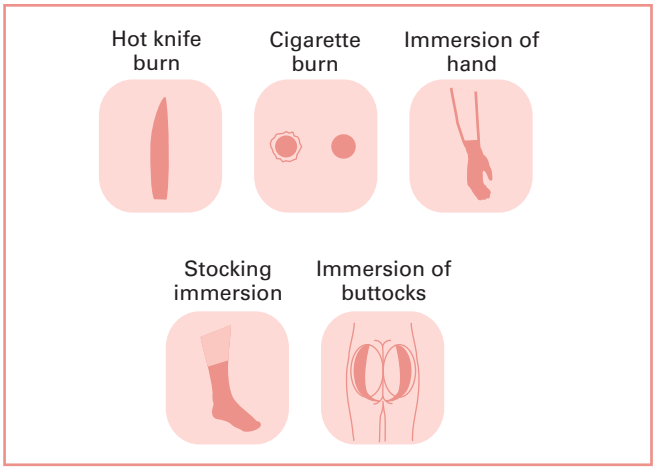

Figure 144.2. Patterned burns associated with inflicted trauma.

The extremities, skull, and rib cage should be carefully examined to detect the presence of skeletal trauma. Findings such as decreased range of motion, tenderness, swelling, redness, or bruising may be associated with an underlying bone fracture. These findings are not always present, however, particularly if the fracture is in its healing stages.

An infant with head or abdominal injury may exhibit no external signs of trauma. Infants and young children with head injury may have seizures, apnea, vomiting, increased crying, or altered mental status, often with no explanation concerning the etiology. The retina should be evaluated for hemorrhages in these children. The child with abdominal injury may present in shock or with symptoms such as vomiting, abdominal pain, or distention. Additionally, the child may have a rigid abdomen with guarding and decreased bowel sounds. Inflicted abdominal injuries may include hematomas of the bowel wall, bowel perforations, or trauma to the liver, spleen, pancreas, or kidneys.

Laboratory Tests

The child who presents with bruises should undergo a hematologic assessment with a complete blood cell count and differential (including a platelet count), a prothrombin time, and a partial thromboplastin time. Cultures from lesions may help differentiate impetigo or ecthyma from burn injury.

The child who presents with fracture should undergo assessment with a chemistry panel (including blood urea nitrogen and creatinine) and calcium, phosphorus, and alkaline phosphatase levels.

The child with suspected abdominal trauma should undergo evaluation with a complete blood count, urinalysis, liver function studies, amylase, and lipase. These studies may demonstrate anemia secondary to hemorrhage, hematuria from renal injury, or elevated liver or pancreatic enzymes resulting from trauma to a solid or hollow viscus organ (see Chapter 76).

A urine toxicology study should be considered as part of the evaluation in the child who presents with altered level of consciousness.

Imaging Studies

The child younger than 2 years who is a suspected victim of physical abuse is at the highest risk for an inflicted skeletal fracture. For this reason, such patients should undergo a radiographic skeletal survey

to identify any acute or healing fractures. Bone scintigraphy is also useful in detecting occult fractures and may be useful in conjunction with the skeletal survey. Follow-up skeletal survey (excluding the skull radiograph) in 2 weeks can also be useful to assess for fractures that were not noted at the time the initial radiographs were obtained.

The child with suspected nonaccidental head trauma should undergo computed tomography (CT) and magnetic resonance imaging of the brain and spine.

Abdominal radiographs may demonstrate air-fluid levels from dysmotility, distended loops of bowel, or free air under the diaphragm. Abdominal and pelvic CT with intravenous contrast is indicated for the patient in whom liver enzymes are greater than 80 U/L in the setting of suspected abdominal trauma. Bowel or solid organ disruption or hemorrhage may be evident on CT.

Management

Treatment of the child who is a suspected victim of abuse focuses on medical stabilization, careful and thorough documentation of medical findings, and psychosocial investigation. Injuries should be managed as appropriate. The child with extensive internal injuries frequently requires admission to an intensive care unit. Consultation with appropriate surgical specialists in neurosurgery, orthopedics, or general surgery should be obtained.

The psychosocial assessment of the family often requires the expertise of a social worker. Further assessment may require an in-home evaluation, such as that conducted by law enforcement or child protective services. All US states and territories require that physicians who suspect child abuse report these suspicions to the appropriate agencies. The physician does not have to be certain that abuse occurred.

These agencies pursue the investigation and provide supportive family services as necessary. A child may be removed from the home and placed in foster care to ensure the child's safety. Cases of suspected abuse are usually assessed in dependency court to determine the safety of the child's environment, ability of the parent(s) or guardian(s) to care for the child, and in criminal court to assess the culpability of suspected perpetrators. The physician may be expected to offer testimony in such hearings.

Prognosis

The prognosis is variable. Some children succumb to inflicted injuries before coming to medical attention, and others sustain permanent neurologic damage. Even in cases in which the physical well-being of the child is ensured, often the child's mental and emotional well-being is significantly affected, requiring intensive and ongoing mental health care.

Recent longitudinal studies in adults have shown a link between adverse childhood experiences and health problems in adulthood (see Chapter 142).

Prevention

The physician should preemptively discuss with families those developmental stages with increased risk for parental frustration and subsequent child abuse, including infant colic, toddler potty training, and tantrums. Infant crying is the most common trigger for abusive head injury. The pediatrician may offer guidance in managing these difficult situations and should assess the coping skills of the parent(s)/guardian(s) with such behaviors when they arise. The pediatrician should also inquire about stressors particular to each family, such as unemployment, mental health issues, social isolation, and intimate partner violence. Support systems for the family should be identified and positive attributes praised.

CASE RESOLUTION

The case study is a classic case of abusive head trauma. The infant was left alone with an individual no prior experience caring for a young infant. The infant has evidence of increased intracranial pressure and may have traumatic axonal injury or intracranial hemorrhage. The infant is intubated, administered anticonvulsant agents, and admitted to a pediatric intensive care unit. Consultation with neurosurgery, ophthalmology, and social services is obtained. Appropriate imaging studies and skeletal surveys are performed when the infant is sufficiently stabilized, and the child is ultimately diagnosed with subdural hemorrhage, retinal hemorrhages, and rib fractures.

CHAPTER 145

Sexual Abuse

Sara T. Stewart, MD, MPH, FAAP

CASE STUDY

A 4-year-old girl is brought to the emergency department with the report of vaginal itching and discharge. Her past health has been good, and she has no medical problems. She lives with her biological parents and her 2-year-old brother.

On physical examination, the vital signs are normal and the child is well, except that the genital area is swollen and erythematous and a green vaginal discharge is present. The girl is interviewed briefly but denies that anyone has touched her. The mother states that she has never left her daughter unattended and is angered by the questions about possible sexual abuse.

Questions

1. What are the anogenital findings in prepubescent and postpubescent children who may have experienced sexual abuse?
2. What behavioral problems are common among children who have been sexually abused?
3. What are the pitfalls in disclosure interviews of children who have been sexually abused?
4. What is the significance of sexually transmitted infections in children who have been sexually abused?

Child sexual abuse is the involvement of children and adolescents in sexual activity that they cannot consent to because of their age and developmental level. An age disparity exists between the targets, who are younger, and the perpetrators, who are older. The intent of the abuse is the sexual gratification of the older individuals, and the abusive incident(s) may or may not include physical contact. Sexual abuse may include acts of oral, genital, or anal contact by or to a child and may involve acts such as exhibitionism or involvement in pornography. It is differentiated from "sexual play" by the difference in the developmental levels of the participants and the coerciveness of the behavior.

Sexual abuse has been recognized with increasing frequency since the 1980s, in part because medical knowledge about the anogenital anatomy in molested and nonmolested prepubescent children has expanded. Technical advances have altered the manner in which these children are evaluated. In particular, the colposcope, with its potential for magnification and photographic or video recorded documentation, has been valuable. Parental awareness and school-based programs have resulted in increased disclosures about abuse as well as a greater willingness on the part of adults to believe these disclosures.

Patient interviews are another key component of the assessment process that has been shaped by continued research in the field. Non-leading, open-ended questions are asked by interviewers as few times as possible, and when available, specialized forensic interviewers ask these questions.

Epidemiology

In 2015, an estimated 676,000 children were targets of child maltreatment in the United States, and just under 10% of these were targets of sexual abuse. Exact figures on the prevalence of child sexual abuse are not readily available because they depend on reports of a condition that may not come to medical attention for many years. Anonymous surveys indicate that approximately 20% to 25% of women and 10% to 15% of men have been sexually abused before reaching adulthood.

Targets of sexual abuse come from all socioeconomic and ethnic groups. Girls experience sexual abuse at a rate 5 times that of boys. Some investigators believe that the statistics for boys are falsely low because boys are generally reluctant to disclose their abuse. Men are more commonly the perpetrators than women, and at least 20% of perpetrators are adolescents. Frequently, the sexual abuse has been occurring for several years. Perpetrators are usually known by the targets, and recent national data showed that 37% of perpetrators were biological parents, 23% were nonbiological parents, and 40% were other individuals. The mean time from onset of abuse to disclosure is 3 years. Sometimes children are not ready to disclose but the abuse is discovered incidentally because the targets develop symptoms, such as vaginal discharge or functional symptoms.

Clinical Presentation

Most cases of child sexual abuse come to the attention of authorities after the child discloses the abuse. Associated physical or behavioral symptoms may or may not be present. Physical symptoms in the anogenital area may include bleeding, pain, swelling, dysuria, vaginal discharge, or difficulty passing stool. More often, however, children have no specific anogenital symptoms. Instead, they have nonspecific symptoms, such as headache or abdominal pain, or vague systemic symptoms, such as fatigue (Box 145.1).

Behavioral changes may also be noted as these children respond to the stress of being targeted and of their environments. These

Box 145.1. Diagnosis of Child Sexual Abuse

- Anogenital erythema
- Anogenital bleeding
- Genital discharge
- Anogenital scarring
- Behavioral symptoms (eg, encopresis, enuresis)
- Disclosure of abuse
- Somatic symptoms (eg, abdominal pain, headache)
- Sexually transmitted infections
- Sexualized behavior
- Pregnancy (adolescents)
- Delinquency, promiscuity (adolescents)

changes may include sleep disturbances, hyperactivity, enuresis, encopresis, decreased appetite, and depression. The sexually abused adolescent may manifest school failure, delinquency, and suicide attempts. A child may also respond with sexual behavior or sexual knowledge that is considered inappropriate or excessive for age.

Psychophysiology

Children are subjected to sexual abuse after becoming entrapped. They may be enticed with promises of rewards or presents or may be made to feel special or grown up by being allowed to engage in adult behavior. Some children do not regard the sexual experiences as threatening but rather as a means by which they can obtain the love they crave. Only when they grow older do they realize that these sexual relationships were not normal or appropriate.

Other children are coerced into sexual activity with threats of physical harm. Once they have acquiesced, they are maintained in the relationship with threats of reprisal if they disclose the abuse. Children feel guilty and responsible for what has happened. This sense of responsibility for family disruption is often perpetuated by the legal system, which may remove the children from their families or place the offending family member in custody.

Finally, some children enter into sexual relationships out of curiosity. They too become entrapped, particularly because they were initially willing to participate.

As a child reacts to an abusive experience, it is common to feel a need for secrecy. As a result, disclosures of abuse are often delayed, and when they do occur, the child often provides the information incrementally over time. A child may also recant disclosures about abuse; such recantations are not considered to reliably indicate that the abuse did not occur.

Differential Diagnosis

Several medical conditions involving the anogenital area may be mistaken for acute or chronic changes resulting from sexual abuse (Box 145.2).

A child may sustain accidental blunt or penetrating injury to the genital area. The most common of these are straddle injuries that occur from falls with impact to the genital area. Pain and bleeding

Box 145.2. Conditions Mistaken for Sexual Abuse

Genital

- Accidental trauma
- Lichen sclerosus et atrophicus
- Urethral prolapse
- Labial adhesions
- Congenital malformations
- Hemangioma

Anal

- Inflammatory bowel disease
- Hemorrhoids
- Anal abscess associated with neutropenia
- Perirectal abscess
- Perianal streptococcal infection

are the most common symptoms with these injuries, and external genital structures, such as the labia majora, labia minora, and periurethral areas, are typically affected. The hymen is unaffected.

Genital bleeding is also a frequent symptom in girls with urethral prolapse, a condition that is reported most often in prepubescent black girls between 4 and 8 years of age. These girls have a protuberant mass extruding from the urethra. The condition is of uncertain etiology, but it is not related to abuse.

Lichen sclerosus et atrophicus, which is a less common dermatologic condition that can also be confused with the sequelae of sexual abuse, typically is characterized by atrophic, hypopigmented skin in a figure-of-8 configuration in the anogenital area with associated macules, papules, and hemorrhagic blisters. The skin changes may be misinterpreted as scarring from prior abuse and because the atrophic skin is easily traumatized, findings may also be confused with recent abuse. One factor that may differentiate this condition from injuries related to sexual abuse is that the hymen is unaffected in lichen sclerosus et atrophicus.

Labial adhesions occur most commonly in toddlers and may be confused with scarring from prior sexual abuse. The adhesions occur as the result of inflammation in the genital area of a prepubertal (ie, hypoestrogenic) female. Such inflammation has multiple causes, including poor hygiene, recurrent vulvovaginitis, and trauma. The presence of labial adhesions is not a specific indicator of past sexual abuse.

Congenital malformations may also affect the anogenital area. Failure of midline fusion along the median raphe can have the appearance of denuded skin and may be confused with an abrasion or superficial laceration of the area. This failure of fusion is a congenital finding, however, and no bleeding is evident, as would occur with a traumatic injury. Other congenital malformations include hemangiomas that may bleed and be mistaken for traumatized tissue. These hemangiomas are most often noted in infants and children younger than 2 to 3 years, and they usually regress with time.

Medical conditions may also affect the perianal area and may be mistaken for abuse. Crohn disease may result in fissures, fistulas, perirectal abscesses, or tags. Generally, Crohn disease affects older children and produces other symptoms, such as fever, weight loss, and problems passing stool, or extraintestinal symptomatology. Perirectal abscesses may occur in patients with neutropenia, sometimes as the presenting symptom of leukemia. Hemorrhoids occur rarely in children, and their presence should raise concern for intra-abdominal venous congestion.

Conditions causing vaginal discharge may be related to sexual abuse, particularly if they are secondary to sexually transmitted infections (STIs), such as gonorrhea or chlamydia infection (Box 145.3). Other agents, including *Candida*, shigella, and group A β-hemolytic streptococci, may produce similar symptoms, yet not be sexually acquired. The streptococci may produce a painful erythematous rash in the perianal area, which is frequently misdiagnosed as secondary to trauma or sexual abuse.

Evaluation

The extent and urgency of the evaluation is in part dependent on whether the allegations involve an acute abusive episode or an episode that occurred in the past. An acute abusive episode (occurring within the previous 72 hours) warrants an immediate assessment for evidence that may otherwise be lost within hours.

History

When a child presents with a physical finding, statement, or behavior that raises the concern of possible sexual abuse, it is important for the examiner to ask carefully thought out, non-leading questions to determine whether the level of suspicion has been reached such that the examiner is mandated to report the concern to a child protective services agency. Beyond that, an attempt should be made to minimize the number of times the child is questioned about the abuse-related incidents. It is also important to establish sufficient medical history to address any pressing clinical issues. Such a history should include a review of systems, menstrual history, sexual activity history, past incidents of abuse, and any prior genital trauma or medical procedures of the anogenital area. A psychosocial history should also be obtained, because behavioral problems, depression, anxiety, suicidality, homicidality, and other issues requiring mental health expertise are common in children who have been sexually abused (Box 145.4).

Because most targets of sexual abuse have a normal physical examination, the history is often of primary importance. As a result, the child must also be interviewed by someone with professional expertise in the areas of interviewing and child sexual abuse. This individual may be a physician or a social worker, psychologist, rape counselor, or detective or district attorney assigned to the abused child unit. The interview should be structured to include open-ended questions, such as, "Can you tell me what happened?" (Box 145.5). Interview tools, such as drawings, may be used but are best left to experts with experience in these controversial modalities. Statements that children make should be recorded in the medical record as close to verbatim as possible.

Physical Examination

It is helpful for the examiner to be familiar with the normal anogenital anatomy of prepubescent children. The anatomy of boys remains constant throughout childhood, except for the increase in size of the penis and testes and the appearance of pubic hair during adolescence. Figure 145.1 shows the normal anogenital anatomy of prepubescent girls, which changes from infancy through adolescence. All girls are born with a hymen, which is thick and full and covers the hymenal orifice in newborns. As maternal hormones regress, the hymen becomes thinner and more

Box 145.4. Problems Reported in Children Who Have Been Sexually Abused

- Enuresis
- Encopresis
- Sexualized behavior
- Pseudomaturity
- Vaginal discharge
- Sleep disturbances
- Suicide
- School failure
- Delinquency (adolescents)
- Promiscuity (adolescents)

Box 145.3. Conditions Associated With Vaginal Discharge

- Gonorrhea
- Chlamydia
- *Trichomonas*
- Bacterial vaginosis
- Candidiasis
- Shigellosis
- Group A β-hemolytic streptococcus infection
- Vaginal foreign body

Box 145.5. What to Ask

Child Sexual Abuse

- Can you tell me what happened?
- Has anything like this happened before? If so, what happened the first time?
- Who did this to you?
- Has anyone else done this to you?
- How often has this happened?
- Where were other people (eg, your mother) when this happened?
- Did you tell anyone? Who? What did they do?

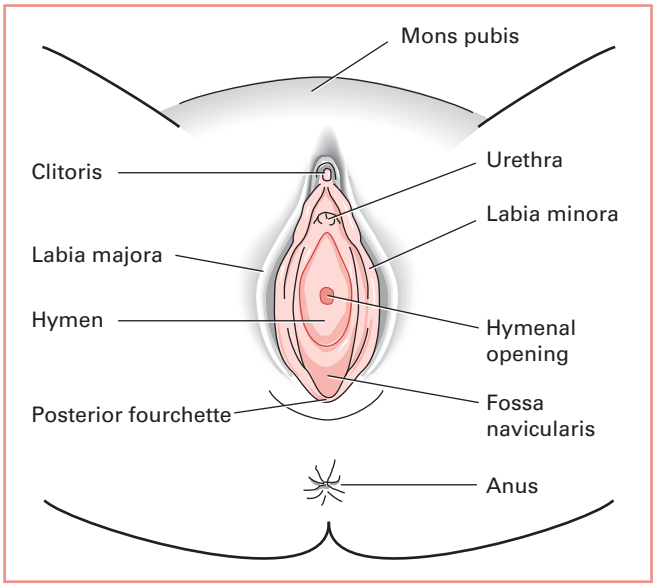

Figure 145.1. Normal anogenital anatomy of the prepubescent girl.

translucent, frequently taking on an annular or crescentic configuration. When puberty begins, the hymen once again becomes thickened, scalloped, and full. Careful examination of the hymen may involve positioning a child in not only the supine frog-leg position but also the prone knee-chest position (Figure 145.2). For a variety of reasons, often no genital abnormalities are noted on examination of targets of sexual abuse. Penetration of the hymen in the postpubertal adolescent may result in stretching without tearing of the tissue, and in the prepubescent child, hymenal transection may heal with little residual evidence of the trauma. Many types of abuse (eg, orogenital contact, fondling) commonly leave no visible findings. The medical examiner must therefore realize that a normal anogenital examination does not preclude sexual abuse.

In cases of acute molestation, evidence of injury may be readily apparent, particularly if the examination is performed with the assistance of magnification, such as colposcopy. Injuries that may be noted include ecchymoses, petechiae, active bleeding, abrasions, and lacerations. Those caused by penile penetration commonly involve the hymen in the 6-o'clock position and the area of the posterior fourchette (Figure 145.1).

The evaluation of the child who has been molested in the past or on a chronic basis is more problematic. Many injuries heal with little residual scarring. Scarring that does occur may appear as a notch or concavity in the contour of the hymenal edge. The pattern of blood vessels may also be interrupted, and areas of increased or decreased vascularity may be apparent. Sometimes a marked reduction in the amount of hymenal tissue is present in an area of prior trauma.

Male genitalia are less often injured by sexual abuse. More often the injuries seen in prepubescent boys, as well as in some girls, involve changes in the perianal area. The incidence of these changes in all children who have been sodomized is unknown but is believed to be low. When changes do occur, they may appear as scars, tags, or irregularities in perianal rugae and anal tone.

Laboratory Tests

When the molestation has occurred within 72 hours of the examination and the mechanism of injury could have resulted in deposition of body fluids on the child, forensic evidence should be collected as required by law enforcement. For adolescents, DNA evidence may be retrieved up to 120 hours after the assault. This evidence usually involves samples of vaginal washings and dried secretions, which are evaluated for the presence of DNA in an effort to identify the perpetrator. Clothing that was worn at the time of the assault should also be submitted, because it is frequently positive for DNA evidence. Forensic packages, which are referred to as "rape kits" and are distributed by law enforcement agencies, have specific instructions concerning the appropriate collection of samples. Completion of the rape kit is best performed by a nurse or physician who has undergone specialized training in the process.

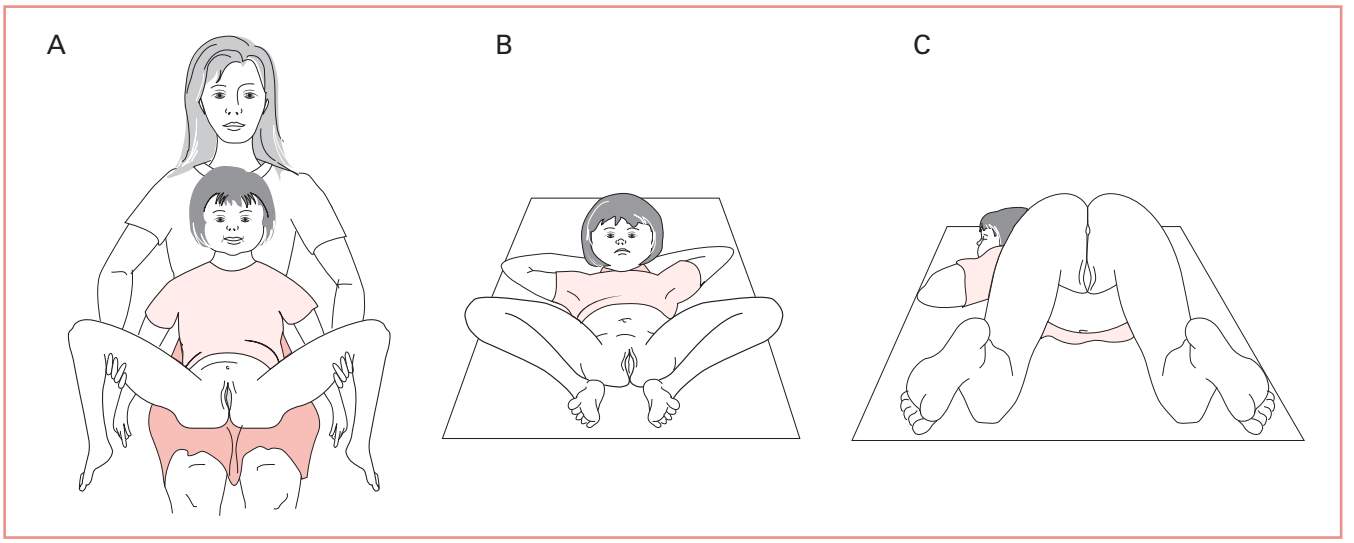

Figure 145.2. Various positions for an anogenital examination in a prepubescent girl. A, Seated on the mother's lap. B, Supine, frog-leg position. C, Prone, knee-chest position.

Studies indicate that 1% to 5% of children who were sexually abused acquire an STI as a result of the abuse. Because of this, testing for STIs is typically targeted toward any child with a history of genital, oral, or anal penetration; a sibling with an STI; an assailant with a history of an infection; or a child, sibling, or assailant with signs or symptoms of an STI. If testing is indicated, cultures should be obtained from the involved body areas (eg, vagina or urethra, rectum, throat). At a minimum, a child with genital discharge should be evaluated for *Neisseria gonorrhoeae, Chlamydia trachomatis*, and *Trichomonas vaginalis*. The presence of these infections in a prepubertal child, in the absence of perinatal transmission, is indicative of prior close genital contact. Most frequently this is the result of sexual abuse. It is impossible to determine the etiology of vaginal discharge based only on its clinical characteristics.

All tests for STIs in prepubertal children should be evaluated in a reliable laboratory because of the legal implications of venereal infections in young children. Culture is considered the standard for diagnosing gonorrhea and chlamydia in this setting because of its high specificity. Newer nucleic acid amplification tests (NAATs) may have higher sensitivity in some settings, and although they may be used in the evaluation for gonorrhea and chlamydia in the pubertal or prepubertal child, they should not be used as the sole method of evaluation. A positive NAAT should be confirmed by culture or by a second nucleic acid test targeting a different DNA sequence. Many experienced laboratories have protocols for automatic confirmatory testing of a positive NAAT in a prepubertal child, with testing for a second DNA sequence. Culture rather than NAAT should be used to test for gonorrhea and chlamydia in extragenital sites.

Testing for HIV, syphilis, hepatitis B, and hepatitis C should be performed if signs or symptoms of the diagnosis are present, another STI is detected, the perpetrator is known to be infected, or the patient or family specifically request the testing. Genital warts can be diagnosed clinically, and any lesions suspicious for human herpesvirus 1 or 2 should be cultured and typed. Although culture remains the standard for diagnosing human herpesvirus infection, because of the low sensitivity of culture, polymerase chain reaction may also be performed on the lesion. Serologies for human herpesvirus type-specific glycoprotein G antigens may be helpful if culture and polymerase chain reaction are not available. Pregnancy testing should be considered in any postpubertal girl.

Table 145.1. Management of Sexually Transmitted Infections in Children

Infection	*Medication*	*Dose*
Neisseria gonorrhoeae	Ceftriaxone sodium	250 mg IM × 1 dose (weight ≥45 kg)
	OR	
	Cefixime	400 mg PO × 1 dose (weight ≥45 kg)
	Ceftriaxone sodium	25–50 mg/kg IM × 1 dose (maximum: 125 mg) (weight <45 kg)
Chlamydia	Erythromycin	50 mg/kg/day divided qid × 14 days (maximum: 2 g/day) (weight <45 kg)
	OR	
	Azithromycin	60 mg/kg PO × 1 dose (maximum: 1 g) (weight <45 kg)
	Doxycycline	100 mg PO bid × 7 days (age >8 years, weight ≥45 kg)
	OR	
	Azithromycin	1 g PO × 1 dose (age >8 years, weight ≥45 kg)
Genital herpes	Acyclovir	400 mg PO tid × 7–10 days (weight ≥45 kg)
		80 mg/kg/day divided qid × 7–10 days (maximum: 3.2 g/day) (weight <45 kg)
Trichomonas	Metronidazole	45 mg/kg/day divided tid × 7 days (maximum: 2 g/day) (weight <45 kg)
		2 g PO × 1 dose (weight ≥45 kg)
Bacterial vaginosis	Metronidazole	15–25 mg/kg/day divided tid × 7 days (maximum: 2 g/day) (weight <45 kg)
		500 mg PO bid × 7 days (weight ≥45 kg)
Syphilis	Penicillin G benzathine	50,000 U/kg, single IM dose (maximum: 2.4 million U)

Abbreviations: bid, twice a day; IM, intramuscularly; PO, orally; qid, 4 times a day; tid, 3 times a day.

Management

The management of children who have been sexually abused has 3 major components. First, any medical problem sustained as a result of the abuse, such as traumatic injuries, must be addressed. Additionally, STIs should be managed (Table 145.1). See Chapter 60 for a more extensive discussion of STIs in adolescents. The adolescent who has been the target of an acute assault should be offered pregnancy counseling, STI prophylaxis, and emergency contraception as medically indicated. Second, the emotional well-being of the patient must be ensured. In cases of acute assault, crisis intervention is mandatory. If a child has been the target of chronic or prior sexual abuse, referral to appropriate counseling services should be done. Third, the physician must report the incident of sexual assault or abuse to the appropriate agencies, as mandated by the laws of the locality in which the physician practices. The physician may be required to testify in court about particular findings and whether abuse occurred. Testifying may be intimidating. It is helpful for the physician to review the medical records in advance of the appearance in court and discuss this information with the attorney who issues the subpoena to the physician.

Prognosis

Several factors influence the prognosis in cases of child sexual abuse, including the relationship of the perpetrator to the child, chronicity of the abuse, support after the disclosure, and preexisting psychosocial conditions. Typically, physical injuries are nonexistent or minor, and healing occurs with minimal residual evidence. In most cases, psychological counseling is indicated. Such counseling is beneficial,

and emotional recovery is not only possible but likely to occur in a supportive environment.

Studies of adverse childhood experiences have shown that child sexual abuse is associated with an increased risk of medical, psychological, and social problems in adulthood (see Chapter 142).

CASE RESOLUTION

The mother claims that no one has access to her child; however, the girl's symptoms strongly suggest an infection with *Neisseria gonorrhoeae.* Secrecy about abuse is quite common. The child and mother should be interviewed by a skilled person. Cultures for gonorrhea should be carefully collected and sent to the most reliable laboratory. Antibiotic therapy may be initiated if the child is symptomatic. The case may be referred immediately to social services and law enforcement agencies if a disclosure is made. Alternatively, if the child denies the abuse, the referral may be deferred pending laboratory confirmation of the diagnosis.

CHAPTER 146

Failure to Thrive

Carol D. Berkowitz, MD, FAAP

CASE STUDY

A 2-year-old girl is brought to the office because of her small size. She was born at term but weighed only 2,200 g (4.9 lb [<5th percentile]) and measured 43 cm (16.9 in [<5th percentile]). The mother is a 30-year-old gravida 5, para 4, aborta 1 who smoked during pregnancy but denies using alcohol or drugs. She received prenatal care for only 2 weeks just prior to delivery, and she claims to have felt well.

The child's physical health has been good. She is reported to be normal developmentally but speaks only 4 to 5 single words. She has not yet started toilet training.

The family history is negative for medical problems, including allergies, diabetes, and cardiac and renal disease. The mother is 5 feet (152 cm) tall, and the father is 5 feet, 4 inches (163 cm) tall. The girl has 3 siblings, aged 5 years, 4 years, and 3 years, all of whom are normal. The father is no longer in the household. The mother is not employed outside the home, and she receives public assistance. She states that frequently there is not enough food in the home, although she receives food stamps (ie, Supplemental Nutrition Assistance Program).

On physical examination, the girl is below the fifth percentile in height and weight. Although she is quite active, she does not use any understandable words. The remainder of the examination is normal.

Questions

1. What are the key prenatal factors that affect the growth of children?
2. How can caloric adequacy of a diet be assessed?
3. How do parental measurements affect their children's stature?
4. What are the behavioral characteristics of the infant with environmental failure to thrive?
5. What are some strategies to increase caloric intake of infants and children?
6. What, if any, laboratory studies should be routinely obtained when evaluating a child for failure to thrive?

Failure to thrive (FTT) is a condition in which a child is not growing and developing at an appropriate rate for their age. The term is most often applied to infants and toddlers younger than 3 years. Failure to thrive is not a disease or even a diagnosis but represents a sign that a child's size or rate of growth is below the expected. The term FTT first appeared in the pediatric literature in 1933 and was used for children whose growth impairment related to a suboptimal environment. Before 1933, the condition was referred to as "cease to thrive." The terms "growth deficiency," "growth impairment," "undernutrition," and "inadequate growth" are sometimes used interchangeably.

Historically, FTT has been divided into 2 distinct categories—organic and nonorganic. In *organic FTT*, an underlying medical problem, such as cystic fibrosis or congenital heart disease (CHD), is believed to contribute to the failure to grow at an appropriate rate. In *nonorganic FTT*, also referred to as *environmental deprivation*, inadequate growth is attributed to lack of nourishment and a non-nurturing home environment. Some physicians use the term FTT exclusively to mean environmentally related growth impairment. It is important to recognize that many children with growth problems have organic as well as environmental components, a condition sometimes referred to as *multifactorial FTT* or *mixed FTT*.

The diagnosis of FTT is entertained when the growth parameters of children as plotted on a standardized curve are below the fifth percentile in height and/or weight. Children who are above the fifth percentile may also be diagnosed with FTT if the rate of growth has decelerated and 2 major percentiles (eg, decreased from the 75th percentile down to the 10th percentile) have been crossed within 6 months (Box 146.1). Studies have shown, however, that between birth and 6 months of age, approximately 40% of healthy infants cross 2 major percentiles on the weight-for-age curve (up or down), as do up to 15% of children between 6 and 24 months of age. Similar trends are noted for length. The physician should, however, carefully track these infants to be certain that such changes are related to the child's genetic disposition and not an environmental or medical problem.

The challenge for the physician caring for the child with FTT is to determine the etiology of the problem, which may not be readily apparent. Nonspecific, nondirected laboratory tests are not helpful because their yield is low and their cost is high. The evaluation of the small, underweight child requires a careful history and physical examination as well as an assessment of caregiver-infant interactions. A home visit helps because it permits evaluation of the caregiver-infant relationship in a more natural setting and an assessment of the family's economic and food resources.

Box 146.1. Diagnosis of Failure to Thrive

- Weight <5th percentile
- Height <5th percentile
- Weight for height <5th percentile
- Rate of growth lower than expected
- Deceleration of the growth rate
- Parental concern about the child's eating
- Delayed developmental milestones
- Disturbed interactional skills

Epidemiology

The prevalence of FTT varies in different segments of the population. Poverty puts children at risk for undernutrition, and 12% of Medicaid recipients are below the third percentile in weight. Child neglect can result in FTT but is not a necessary component; 60% to 70% of cases of child abuse are reported for child neglect. Several other factors may contribute to variations in growth. All of these are not the result of a pathologic process but may reflect variations in individual genetic potential.

Environmentally related FTT may occur in different family settings. In some families, an acute depressive episode in the mother is the key component (see Chapter 24). Family living conditions are good, and the educational background of the mother is adequate. The depressive episode may be related to a loss that occurred during the pregnancy or shortly after delivery or to perinatal mood and anxiety disorders, a group of mental health conditions associated with pregnancy and delivery and manifested after birth. In these cases, the mother is too depressed, withdrawn, or preoccupied to interact effectively with her children. The condition may affect 25% to 30% of mothers, and the prevalence is influenced by many factors, including poverty, race, and access to health care. In other families, financial resources are marginal. The mother may be chronically depressed, and the father may be involved in alcohol or substance abuse. Domestic violence is a frequent occurrence (see Chapter 142). Spacing between children is fewer than 18 months, and the number of children is often the same as the age of the oldest child. The mother is too overwhelmed to meet the needs of all the children. A third type of family also involves a mother with depression and who has experienced losses, usually of a chronic nature. Her financial and educational backgrounds are adequate, but she views 1 of her children (the child who now presents with FTT) as bad or evil and the source of all her problems. As a result, an individual child is singled out, and the neglect is intentional.

Clinical Presentation

The child with FTT presents with low weight, short stature, poor appetite, or failure to gain weight or grow taller. Sometimes a parent or guardian may express concern; at other times, a teacher may detect a child's growth problems. Some children with FTT are diagnosed during a health maintenance visit or during evaluation for another medical problem, such as a febrile illness. Following a child longitudinally will give the physician a better sense of the child's growth pattern and a clue to the etiology of observed growth impairments. When nutrition is suboptimal, weight tends to decrease first, followed by length and, ultimately, head circumference.

Pathophysiology

The common pathway for the development of FTT, regardless of etiology, is insufficient calories to meet the nutritional needs of the child (Box 146.2). Caloric intake may be inadequate for several reasons. Some factors are societal, specifically poverty and inadequate access to food. Other factors may involve increased caloric needs. Certain chronic conditions are characterized by increased caloric expenditure (eg, some forms of chronic lung disease) or increased loss of ingested food (eg, diarrhea, malabsorption syndromes).

In environmentally related FTT, a disturbed caregiver-infant relationship contributes to reduced caloric intake and associated gastrointestinal symptoms (ie, vomiting). Although various disturbances in mother-FTT infant dyads have been described, maternal depression is the most common maternal feature noted in environmentally related FTT. Infants withdraw after unsuccessful attempts to interact with nonresponsive mothers, and infants become apathetic and disinterested in food. Alternatively, overactive mothers, some of whom have an untreated bipolar (eg, manic-depressive) disorder, are out of synchrony with their infants. The infants become agitated, especially during feedings, and cannot feed and frequently vomit. These infants, who may interact with persons other than their mothers, usually do well in other environments or when their mothers receive appropriate therapy.

Older children with long-standing environmental deprivation have disturbed hypothalamic-pituitary functioning. The etiology of this dysfunction is uncertain but has been attributed to sleep disturbances with an effect on levels of growth hormone.

Some children develop FTT as a result of a feeding disorder. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition

Box 146.2. Factors Affecting Calories Available for Growth

Insufficient Intake

- Poverty
- Inadequate access to food
- Improper formula preparation
- Eating difficulties
- Vomiting

Increased Loss

- Malabsorption

Increased Needs

- Congenital heart disease
- Chronic lung disease

(*DSM-5*) includes a new diagnostic category, avoidant/restrictive food intake disorder (ARFID), which includes individuals of all ages with reduced food intake without necessarily having body image concerns. The *DSM-5* describes 3 examples of ARFID: sensory sensitivity (includes children with texture aversions); low appetite or lack of interest in food (ie, picky eater); and avoidance of specific foods because of a prior traumatic experience (eg, choked while eating meat.)

Differential Diagnosis

The growth of the child with FTT may be impaired in weight, height, head circumference, or any combination of growth parameters. If weight is the only abnormal parameter, inadequate caloric intake, excess caloric loss, or increased caloric expenditure is likely the major problem. If height is reduced and weight is appropriate or high for height, the diagnosis may be short stature rather than FTT. Small head circumference in the setting of low growth parameters is suggestive of a central nervous system basis for the growth delay. It is important to determine if the child's skills are developmentally appropriate when determining the etiology of FTT. Affect and interactional skills should be noted as well. Environmentally deprived infants are apathetic and noninteractive. They appear hypertonic and may be diagnosed with cerebral palsy or have features suggestive of infantile autism spectrum disorder; however, their symptoms resolve with a change in surroundings.

The most common causes of short stature include familial short stature and constitutional delay. The child with familial short stature is small because the parents are short. The bone age of the child with familial short stature is the same as the child's chronologic age. Except for a deceleration in growth, which usually occurs between ages 6 and 18 months, the child with constitutional delay appears healthy. Unlike the child with familial short stature, the child with constitutional delay has a delayed bone age that is comparable to the child's height age (ie, the age when height is at the 50th percentile), however. In the child with familial short stature or constitutional delay, growth parameters at birth are usually normal.

The child with low growth parameters at birth may have been born preterm or have experienced intrauterine growth restriction (IUGR). Most studies support the notion that well preterm infants exhibit catch-up growth (head circumference by 18 months, weight by 24 months, and height by 40 months). The ill preterm infant may not demonstrate such catch-up growth because of increased caloric needs related to residual medical problems (eg, chronic lung disease) or impaired nutritional intake resulting from certain conditions (eg, cerebral palsy with discoordinated swallowing). Overall, 15% of infants who are classified as IUGR or small for gestational age do not exhibit catch-up growth. Significant evidence now exists that IUGR may be associated with insulin resistance and subsequent propensity to obesity and metabolic syndrome. Disturbances in leptin, ghrelin, and adiponectin have also been described. This has significant implications for the management of these infants vis-à-vis their nutritional intake. It is postulated that some individuals are "programmed" to be slighter and smaller, and nutritional interventions to achieve a more average weight have deleterious effects later in life.

The child who is small for gestational age may have experienced any of several in utero insults that affect postnatal growth, including exposure to cigarettes, alcohol, and illicit drugs. Additionally, maternal infection with such diseases as rubella may result in a congenital infection in the infant with subsequent growth impairment.

Several other conditions may result in disturbed growth, including endocrine disorders, skeletal dysplasia, food allergies, and malabsorption. These conditions occur less frequently and are usually more readily apparent as children undergo evaluation for the growth problem.

Evaluation

History

Careful questioning about certain specific topics provides clues to diagnosis in approximately 95% of cases. The physician should learn about the pregnancy and delivery, the family history (including parental heights), the child's medical and dietary history, and the child's feeding pattern.

It is important to obtain an in-depth history of the pregnancy and delivery (Box 146.3). The infant's birth weight and gestational age are key pieces of information. Low birth weight is said to account

Box 146.3. What to Ask

Pregnancy and Delivery

- Was the pregnancy planned?
- How did the mother feel when she learned that she was pregnant?
- Was prenatal care obtained?
- How many times has the mother been pregnant?
- Is there a history of abortions (spontaneous or therapeutic)?
- How much alcohol did the mother drink during the pregnancy, if at all?
- How much did the mother smoke during the pregnancy, if at all?
- How much did the mother use drugs (prescribed or illicit) during the pregnancy, if at all? If drugs were used, which ones?
- Did the mother take any medications during the pregnancy?
- Did the mother have any rashes or illnesses during the pregnancy?
- How did the birth of the baby affect the family structure?
- Has the mother felt depressed or anxious?
- Has the mother felt little interest or pleasure in doing things?
- Was the baby term or preterm?
- How much did the infant weigh at birth?

Medical, Feeding, and Family History

- Is the child's growth rate normal or slow?
- Has the child had any previous illnesses (eg, gastroenteritis, recurrent pneumonia)?
- Does the child tire easily?
- Is the child taking any medications, and if so, for how long?
- Is the child a picky eater?
- Is the child hesitant to try new foods?
- What does the child eat over the course of a given day?
- How tall are the parents?
- Do any medical problems run in the family?

for 20% to 40% of short stature in children from low-income families. It is helpful to confirm that neonatal screening for genetic and metabolic diseases was normal. Recurrent spontaneous abortions suggest that a mother may have an underlying problem, such as a balanced chromosomal translocation that results in fetal wastage. The mother who has experienced repeated losses may have difficulty bonding with subsequent babies. The physician should determine whether the mother used cigarettes, alcohol, or drugs during the pregnancy by asking the mother questions beginning with the phrase, "How much?" Any medications taken by the mother may affect the subsequent growth of the infant.

A review of the child's medical history may also provide a clue to the etiology of FTT (Box 146.3). It is essential that the physician obtain as many of the previous growth parameters as possible to determine whether the child is small but growing at a normal rate or if the rate of growth is slow or has fallen off. Previous illnesses should be assessed, because these events may interrupt growth temporarily. Certain symptoms may be indicative of underlying organic disorders, and recurrent infections raise the possibility of a congenital or acquired immune disorder, including infection with HIV. A history of easy fatigability may be a clue to CHD. Although most children with CHD grow normally, growth problems may occur with congestive heart failure, some forms of cyanotic heart disease, and complex atrial septal defects, especially if associated with pulmonary hypertension. A history of diarrhea may be suggestive of an underlying gastrointestinal disorder with subsequent malabsorption. The child with urinary incontinence may have renal disease that interferes with growth. The presence of seizures may be a sign of a central nervous system problem that makes it difficult to obtain adequate nutrition. Some children with seizures are heavily medicated and are too sleepy to eat.

It is important to query whether the child is on any medications. The chronic use of some medications, such as corticosteroids and certain stimulants used to manage attention-deficit/hyperactivity disorder, have been associated with decelerated linear growth in some children.

It is important to obtain a family history and a social history. Determination of parental heights, which is best accomplished by measuring the parents, is critical. This is particularly important in the child with short stature. Specific mid-parental height curves allow the physician to determine if a child's height is appropriate given parental stature.

A nutritional assessment is an essential part of the history. It is important to assess whether the child restricts his, her, or their food intake or avoids certain foods. The physician or another member of the health care team, such as a dietitian, can perform this assessment. A history of feeding problems may suggest the need for an evaluation by an occupational therapist. The dietary history can be determined by using a 24-hour recall of the child's intake during the previous day or a prospective 3-day diary in which a parent records the kinds and quantities of foods the child eats. This nutritional information can be used to find ways to alter the child's diet to ensure adequate and balanced meals.

Physical Examination

The essential component of the physical examination is determination of growth parameters. Calculation of the body mass index (BMI = weight [kg]/height [m]^2) is useful in children older than 2 years, and weight-for-length is useful in those younger than 2 years. The child with a low BMI is experiencing an element of undernutrition, but the short child with a normal BMI is not. Infants and children younger than 2 years should be plotted on a weight-for-length curve to determine their degree of undernutrition or overnutrition. The World Health Organization has developed and distributed growth curves for children up to 24 months of age. These curves reflect optimal rather than average growth and were developed from a longitudinal study of healthy breastfed infants. These curves, as well as those for individuals older than 2 years, can be accessed at www.cdc.gov/growthcharts/who_charts.htm. Measuring arm circumference and triceps skinfold thickness is also useful and provides information about body composition that is not obtained by height and weight. Children should be evaluated for dysmorphic features (eg, limb length discrepancy in Silver-Russell syndrome). It is important to remember that children with Down syndrome grow at different rates than other children, and separate standardized curves for assessing these children are available (see Chapter 42). Separate curves are also available for children with Turner syndrome and Williams syndrome as well as other disorders. The presence of 1 major congenital anomaly or 2 minor anomalies is suggestive of the existence of other anomalies and the chance of a genetic syndrome. The incidence of growth hormone deficiency is reportedly higher in children with cleft lip and palate. Children with heart murmur may have FTT related to CHD or to a syndrome such as Williams syndrome, in which the heart disease is but 1 feature.

Infants with environmentally related FTT exhibit certain behavioral characteristics that are easily recognized. These infants avoid making eye contact and exhibit gaze avoidance. They are not cuddly and do not like being held. When held, they may arch their backs in an effort to avoid the holder. Their muscles seem tense, and they are often considered to be hypertonic. These children may also exhibit specific disabilities, including oromotor dyspraxia and sensorymotor disorder, and they may demonstrate food texture aversion or difficulty with chewing and swallowing (ie, sensory food aversion). Children with neurologic disabilities often exhibit difficulties with oral skills.

Psychosocial Assessment

The evaluation of children with FTT and their families entails a detailed psychosocial assessment to determine what environmental factors may be affecting children's growth. Such an assessment is helpful even if the FTT has a medical basis because chronic disease affects family functioning. An extensive psychosocial evaluation focusing on the social determinants of health (eg, living conditions, adequacy of food supply, economic resources) and adverse childhood experiences (the latter particularly of the caregivers) can be carried out by the primary care physician (see Chapters 141 and 142, respectively).

Laboratory Tests

Routine laboratory tests appropriate for any pediatric health maintenance visit should be obtained in the child with FTT if these studies have not been performed recently. Such tests include hemoglobin, lead level (screening as determined by risk factors and geographic area), and urinalysis. Other laboratory tests are indicated by the findings in the history and physical examination. For instance, stool for ova and parasites should be obtained in a child with diarrhea who has immigrated from or spent time visiting a developing country. No recommended uniform diagnostic evaluation for FTT exists. Evaluation for endocrinopathies, such as hypothyroidism or growth hormone deficiency, should be carried out in the child whose bone age is less than the height age or who exhibits symptoms of these disorders. Genetic consultation or chromosomal assessment should be performed in the child with dysmorphic features or in families with a history of fetal wastage.

Imaging Studies

Radiography to determine bone age is useful in the child with short stature that is not related to parental heights. As stated previously, the child with familial short stature has a bone age the same as the child's height age and chronologic age. The child with constitutional delay has a bone age that is consistent with the child's height age but below the chronologic age.

Management

Any recognized underlying medical problem (eg, nephrogenic diabetes insipidus) should be managed appropriately. The child with IUGR who is not demonstrating catch-up growth may be a candidate for growth hormone therapy. Consultation with pediatric endocrinology is warranted.

Adequate Caloric Intake

Ensuring that a child receives appropriate caloric intake is essential. The caloric intake, which averages 120 to 150 cal/kg per day for most infants, should be based on the ideal weight rather than actual weight (see Chapter 28). For the infant on formula, the physician should review the exact preparation of formula with the mother. Overly diluted formula results in an unusually large intake volume with a lack of weight gain. For the infant who is breastfed, the physician should observe a feeding session to be certain the mother has an adequate milk supply and the infant is able to suck and swallow appropriately (see Chapter 29). The breastfed infant can be weighed before and after feeding to estimate the volume intake if concern exists about the adequacy of the mother's milk supply. Some infants with FTT have neurologic problems that prevent them from sucking and swallowing consistently without becoming fatigued.

The infant who is a slow feeder may require formula concentration (Table 146.1). These infants may also receive added calories in the form of glucose polymer (eg, Polycose) or oil, such as medium-chain triglycerides, mixed in the milk. The older child may be placed on supplemental feedings, such as PediaSure, Boost, or instant breakfast drinks, prepared with whole milk. Instant breakfast drinks are a less expensive form of nutritional supplementation than proprietary nutritional formulas, are well tolerated, and are available in different flavors (ie, vanilla, chocolate, strawberry). Up to 24 ounces per day of the breakfast drinks can be consumed and are given in addition to, not in place of, a balanced diet.

Table 146.1. Concentration of Infant Formula to Increase Caloric Intake

Concentrated Infant Formula (13-oz can)		
Formula (oz)	*Water (oz)*	*Calories (cal/oz)*
13	13	20
13	10	23
13	8	25
Powdered Formula		
Formula (scoops)	*Water (oz)*	*Calories (cal/oz)*
1	2	20
5	8	25

One food supplement that has been used globally to treat severe acute malnutrition is ready-to-use therapeutic food (eg, Plumpy'Nut, a peanut-based paste with sugar, vegetable fat, and skim milk and enriched with vitamins and minerals). It is not used in the United States and has variable acceptance in developing nations, in which up to 60% of caregivers report problems with acceptability of taste.

The mother should be advised that many children preferentially tolerate 6 small meals a day rather than 3 large ones. Additionally, the parent or guardian should be advised that access to non-nutritional foods, such as cookies, adversely affects children's appetites. Excess consumption of fruit juices should also be limited because it decreases the intake of other foods and may induce diarrhea. The physician should inform the parent or guardian about foods that can be added to the child's diet to increase caloric intake, including powdered milk, cheese, sour cream, avocado, and peanut butter. Often, children have a few favorite foods. Although food variety is appealing to adults, many children prefer a small number of nutritious foods. They should be allowed to consume these foods freely.

Children with neurologic disorders and associated problems with chewing and swallowing may require chronic *gavage*, that is, feeding through a gastric feeding tube.

Parenting Issues

Some parents need more help with appropriate child-rearing practices than the physician can provide. These parents can be referred to parenting programs that address multiple aspects of the parenting process. The mother with a substance use problem may need to participate in drug treatment programs (see Chapter 148). Other caregivers may need individual counseling for depression or emotional problems (see Chapter 24).

In some middle-class families, mealtime has evolved into a battle of wills. For some children eating at school is more enjoyable than than eating at home and they benefit from the social atmosphere of dining with their friends. The parent or guardian should be counseled about avoiding conflicts about meals with children, because the children win simply by closing their mouths. The caregiver should be encouraged to allow toddlers independence around mealtime. Eating in front of the television, however, should be discouraged.

Families may also require supplementary services to ensure that food supplies are adequate and financial resources sufficient. Such services include the Supplemental Nutrition Assistance Program (SNAP; formerly food stamps); the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC); and Temporary Assistance for Needy Families (TANF).

Regardless of the individual needs of the family, it is critical that the physician craft a therapeutic alliance with the child's caregivers.

Home Visitation

Home visitation services provide useful diagnostic information and help the parent or guardian implement advice. Such information may include lack of access to running water, overcrowding, and inadequate food resources. Home visitation may be available in the community through the use of public health nurses or private visiting nurse agencies. These nurses should interact with the primary care physician to enable determination of families' compliance with treatment recommendations.

Child Protective Services

Involvement by child protective services may be necessary if the parent or guardian is unable to comply with medical recommendations, the child does not grow, or intentional neglect on the part of families is occurring. In some families with children with FTT, the home environment is not safe for children, and children require placement elsewhere. Families in which 1 child is singled out as "bad" and is intentionally neglected need immediate referral to child protective services, and some families overwhelmed by multiple problems, including parental substance use, also need such a referral to additional community resources.

Hospitalization

Hospitalization is occasionally necessary if the infant with FTT is severely malnourished, and food must be given in a controlled environment to assess the infant's ability to gain weight. Additionally, the infant with intercurrent illness may require inpatient care. Alternatively, a health professional may determine that the home environment is unsafe and that no other placement (eg, foster care) is available and that hospitalization is therefore indicated.

If concern exists for refeeding syndrome, the patient should be admitted to the inpatient setting. This syndrome was first described during World War II in Japan, and data on the condition in children are limited. The disorder encompasses a severe electrolyte imbalance in which the serum level of intracellular ions (eg, phosphate, magnesium, potassium) is low, and *refeeding syndrome* occurs when a patient moves from a catabolic to an anabolic state. Refeeding syndrome is best managed by a multidisciplinary team focusing on early correction of phosphates, magnesium, and potassium, correcting any acid-base imbalance, vitamin (thiamine) supplementation, and slow low-energy refeeding.

Regardless of etiology, the child with FTT usually gains weight in the hospital. Thus, hospitalization of the child with FTT simply to demonstrate appropriate weight gain in a different environment is considered neither appropriate nor cost-effective. Some insurance companies do not pay hospitals for inpatient management of children with FTT. Additionally, some children with environmentally related FTT do not gain weight in the hospital because they are subjected to many diagnostic tests that interfere with nutritional intake (eg, receiving nothing orally while awaiting the procedure), and they acquire nosocomial infections.

Prognosis

Many children with FTT respond dramatically to change in diet or environment. Improvement in affect and cognitive functioning frequently follows nutritional improvement. These children grow and both achieve and maintain normal stature. With early intervention, cognitive abilities also can be fully realized. Even when intervention has been delayed, catch-up growth and development are expected, although 25% to 30% of affected children may have weight and occasionally height below the fifth percentile. Continued monitoring for residual psychosocial or neurodevelopmental disabilities is appropriate even after growth has normalized. School performance and cognitive outcome in children who have experienced FTT are poorer than in children who have not experienced FTT. It is unclear if this association is related to early iron deficiency anemia, lack of calories or other micronutrient deficiencies, or psychosocial-environmental deficits.

CASE RESOLUTION

The term child had a low birth weight, which suggests IUGR. Although the mother reports using no alcohol or drugs, such denial is not uncommon. The child's growth pattern should be determined to learn if the rate of growth has changed recently, and BMI should be calculated to check for undernutrition and short stature. A mid-parental height curve should be used to determine if the child's short stature is related to the parents' short stature. Intervention should involve mobilizing resources for the child and family to ensure adequate food as well as financial and emotional support.

CHAPTER 147

Fetal Alcohol Syndrome

Melissa K. Egge, MD, FAAP

CASE STUDY

A 6-year-old boy is brought into the clinic by his maternal aunt, who expresses concerns about her nephew's behavior that are echoed by his kindergarten teacher. The teacher has reported that the child has a limited attention span and is often disruptive in class. The child's growth parameters have remained at the third percentile since birth. He has a smooth philtrum, thin upper lip, and short palpebral fissures.

Questions

1. What conditions and birth defects are included under fetal alcohol spectrum disorder?
2. What are the diagnostic criteria for fetal alcohol syndrome?
3. What is the differential diagnosis of the facial characteristics of fetal alcohol syndrome?
4. What typical behavioral and learning problems are experienced by the child with fetal alcohol syndrome?
5. What therapeutic interventions are appropriate to recommend for the child with fetal alcohol syndrome?

Fetal alcohol spectrum disorder (FASD) encompasses the spectrum of clinical findings caused by prenatal alcohol exposure. The 4 subcategories of FASD are fetal alcohol syndrome (FAS), partial FAS, alcohol-related neurodevelopmental disorder, and alcohol-related birth defects. A diagnosis of *partial FAS* requires facial dysmorphism in addition to growth disturbances or central nervous system (CNS) abnormalities. *Alcohol-related neurodevelopmental disorder* involves the functional impairments associated with prenatal alcohol exposure; however, clear diagnostic criteria are still being developed. *Alcohol-related birth defects* include structural birth defects that are associated with, but are not specific for, prenatal alcohol exposure (Box 147.1). This chapter will focus on FAS.

Fetal alcohol syndrome is a clinical diagnosis necessitating careful evaluation by an experienced physician to recognize the physical, behavioral, and cognitive abnormalities in an affected child. Diagnosis may be made at birth, but often the condition is not diagnosed until school age. Fetal alcohol syndrome has been recognized in the medical literature for decades and in historical literature for centuries; however, refining the criteria for diagnosis has been an ongoing process. Several entities have created guidelines to help analyze children with FAS, but in 2004, the Centers for Disease Control and Prevention (CDC) published broad-based criteria that are helpful for several reasons (Box 147.2). First, they educate physicians and caregivers about the wide spectrum of phenotypes that manifest after prenatal alcohol exposure. Second, they use the most recent CDC criteria for FAS, which helps capture the greatest number of potentially affected children with the goal of providing earlier intervention with a wider scope of services. Criteria must be met in all 3 categories of facial features, growth problems, and CNS abnormalities. For the patient with suspected FAS but for whom diagnostic criteria are incompletely met, the term FASD may be used to couch the findings, especially in the setting of confirmed maternal alcohol exposure. In the future, diagnostic criteria may be developed for other subcategories of FASD. Currently, however, the term FASD is not intended for diagnostic purposes but rather a descriptor of recognized phenotypes along a spectrum leading up to FAS.

Part of the difficulty in delineating a phenotype for alcohol exposure is that the degree of exposure is variable during embryogenesis (and organogenesis); factors include quantity ingested, concomitant drug exposures, malnutrition, and individual genetic responses to exposure. This wide variability in degree of exposure and individual response results in a multitude of clinical presentations.

Epidemiology

Prenatal alcohol exposure is much more common than the number of diagnosed cases of FAS would suggest. It has been estimated in surveys of women of childbearing age in the United States during 2011-2013 that approximately one-half of nonpregnant women of childbearing age reported some alcohol consumption and approximately 18% reported binge drinking (>4 drinks on 1 occasion) in the past 30 days. Among pregnant women, approximately 1 in 10 reported any alcohol use and 3% reported binge drinking in the past 30 days. Although estimates of children affected by FAS vary by region and population, an estimated 1 in 1,000 live births would meet criteria for diagnosis.

The estimate jumps 10-fold when certain high-risk groups are the focus. Approximately 1 in 100 children in foster care and nearly that many Native American children (3–9 per 1,000) meet criteria for diagnosis of FAS. Inclusion of children who meet some but not

- Atrial or ventricular septal defects, aberrant great vessels, and tetralogy of Fallot

Skeletal/Extremity
- Shortened fifth digits, clinodactyly (ie, curved fifth digit), radioulnar synostosis, Klippel-Feil syndrome, flexion contractures, hemivertebrae, camptodactyly (ie, flexion contracture of digit), scoliosis, short metacarpals, short/webbed neck, hockey stick palmar crease

Renal
- Aplastic, dysplastic, hypoplastic kidneys
- Ureteral duplications, hydronephrosis, horseshoe kidney

Ocular
- Strabismus, refractive problems secondary to small globes, ptosis
- Retinal vascular anomalies

Auditory
- Conductive hearing loss, neurosensory hearing loss

Skin
- Hemangiomas, hypoplastic nails

Genitourinary
- Hypoplastic labia majora

Facial Features That Are Common but Not Required for Diagnosis
- Railroad track ears
- Epicanthal folds
- Flat nasal bridge
- Cleft lip

Box 147.2. Diagnostic Criteria for Fetal Alcohol Syndrome: Centers for Disease Control and Prevention[a]

- Facial features (all 3 required, with findings based on racial norms)
  - — Palpebral fissure length ≤10th percentile for age
  - — Smooth philtrum (University of Washington Lip-Philtrum Guide rank 4 or 5)
  - — Thin upper lip (University of Washington Lip-Philtrum Guide rank 4 or 5)
- Growth parameters (≥1 required at any age [not height for weight])
  - — Height ≤10th percentile
  - — Weight ≤10th percentile
- Central nervous system abnormalities (≥1 of the following):
  - — Structural (1 required)
    - Head circumference ≤10th percentile for age and sex
    - Brain abnormality at imaging
  - — Neurologic
    - Seizures
    - Measured delay in motor skills
    - Abnormal neurologic examination not attributed to another condition
  - — Functional (1 required)
    - Cognitive delay or global developmental delay (<3rd percentile)
    - Deficits in ≥3 functional domains (<16th percentile)
      1. Cognitive
      2. Executive function
      3. Motor function (fine or gross)
      4. Attention-deficit/hyperactivity disorder symptoms
      5. Deficits in social skills
      6. Other (eg, sensory, memory, language)

[a] Criteria must be met in all 3 overall categories (facial features, growth problems, central nervous system abnormalities) for a diagnosis of fetal alcohol syndrome.
Adapted from *Fetal Alcohol Syndrome: Guidelines for Referral and Diagnosis.* Atlanta, GA: Centers for Disease Control and Prevention; 2004. https://www.cdc.gov/ncbddd/fasd/documents/FAS_guidelines_accessible.pdf.

all criteria for FAS results in a prevalence of 1% to 5% or higher in high-risk populations.

Pathophysiology

Alcohol is a teratogen, and like other teratogens its effect on the developing fetus depends on several factors, many of which are difficult to record. Although it is important to ask about the timing, quantity, and pattern of prenatal alcohol exposure, it is often difficult to obtain an accurate history. Additionally, because of genetic differences in women's ability to metabolize ethanol by alcohol dehydrogenase, each fetus receives a unique "dose" during gestation. Also individualized is each woman's nutritional intake and use of other drugs or medications. Alcohol acts as a toxin to cause damage and apoptosis to neurons in the fetal brain. Alcohol also inhibits proper migration, development, and functioning of cells during embryogenesis, contributing to structural anomalies in multiple organ systems, such as the kidney, heart, and brain.

Clinical Presentation

Signs and symptoms of FAS may be recognized at birth or not until later in childhood. At birth, a neonate may present with asymmetric intrauterine growth restriction, small for gestational age, head circumference disproportionately smaller than the body, or appropriate for gestational age. A variety of birth defects have been associated with fetal alcohol exposure, and many of these have been demonstrated in animal models. A newborn may exhibit signs of withdrawal from alcohol or concomitant drug exposure. With time, the infant may demonstrate failure to thrive or poor weight gain resulting from poor nursing. Infants exposed to alcohol in utero also present with nonspecific symptoms of irritability and dysregulated sleep patterns. In toddlerhood, developmental delays may be recognized by a caregiver or during developmental screening questions by a primary care physician. As a child approaches school age, a teacher may report behavioral concerns and poor school performance. Concerns such as distractibility, hyperactivity, and difficulty processing multistep directions may be raised in school. Additionally, a child may exhibit signs of fine motor delay, such as difficulty tying shoes or fastening buttons. Deficits in visual-spatial and math concepts are common for children with fetal alcohol exposure. Age-appropriate social skills are lacking in affected children, who often do not develop

street smarts. They take the blame, succumb to peer pressure, and are oblivious to social norms. Approaching the teenage years, the classic facies may become less distinctive. As teenagers mature, their cognitive and behavioral weaknesses predispose them to mental health issues, such as depression, anxiety, and problems with substance abuse.

Diagnosis

Facial Dysmorphia

Three classic facial features are required for the diagnosis of FAS. The characteristics are typical of midface hypoplasia and include short palpebral fissures, smooth philtrum, and thin upper lip. Other facial characteristics, such as epicanthal folds and flat nasal bridge, may be present but are not required for diagnosis. To accurately measure the palpebral fissures, the child should look directly up while the distance between the endocanthion (inner corner of the eyelids) and the exocanthion (outer corner of the eyelids) is measured. Palpebral fissure length (PFL) must be less than 2 standard deviations below the mean for a diagnosis of FAS.

The University of Washington Lip-Philtrum Guides for white patients (and others with similar lips) and black patients (and others with similar lips), which account for ethnic differences in contour of lips, are used (Figure 147.1). The images are ranked 1 through 5, with 5 representing the most affected phenotype, with the thinnest lip and smoothest philtrum. For children of other ethnicities, a best approximate is used. To properly use the Lip-Philtrum Guides, the child's face should be relaxed to avoid the lip and philtrum appearing thinner and smoother. The physician should evaluate the child's face within a specific horizontal planar view to avoid the illusion of a thinner lip. Guidelines on how to use the images are available on the University of Washington FAS website (http://depts.washington.edu/fasdpn).

Growth Problems

The criteria for growth deficiencies may involve the child's weight or length or both at any time. With the CDC criteria, a patient may qualify to meet criteria for growth problems based on birth or postnatal measurements. The child's weight or length must be less than or equal to the 10th percentile for age and sex. It is important, however, to evaluate other organic and environmental etiologies of short stature or poor weight gain, such as poor nutrition. Considerations for small head circumference are accounted for in the CNS abnormalities.

Central Nervous System Abnormalities

The criteria for neurologic problems may be met several ways because children develop an array of cognitive, behavioral, and developmental deficits. Criteria for structural abnormalities are met by a head circumference at the 10th percentile or below at any age or 3% or less when the child's weight and height are less than 10%. An experienced neuroradiologist may detect an abnormally small cranial structure, such as the cerebellum or corpus callosum, on magnetic resonance imaging. Manifestations of structural abnormalities include seizure activity not attributed to another cause or other focal deficits. Other functional CNS abnormalities may not be recognized until the child enters school and is compared with peers.

Differential Diagnosis

The hazards of using a "gestalt approach" to diagnosing FAS can result in inappropriate stigmatizing labels and missed opportunity to diagnose another genetic disorder that may carry a different prognosis. Several syndromes share facial features of FAS (Table 147.1). Fetal alcohol syndrome should be considered a diagnosis of exclusion in cases in which in utero alcohol exposure cannot be confirmed.

Evaluation

It is important that an appropriately trained professional assesses the child for each component of diagnosis; however, initial data should be gathered prior to referral.

History

A confirmed history of maternal alcohol consumption is not required for diagnosis, according to the CDC guidelines, but it should be documented if available. The physician should ask the parent or parents in a nonjudgmental way about all risks to a child's development, including maternal alcohol use before and during pregnancy. Some less stigmatizing ways to ask about alcohol consumption include: When did you learn that you were pregnant? How much did you drink before you were pregnant and before you knew you were pregnant? How much does your partner drink? Regular screening of parental alcohol use should be incorporated into routine child health supervision and developmental surveillance.

A detailed developmental history is important to document, including feedback from teachers and child care providers.

Physical Examination

As detailed previously, the physician should document the child's PFL measurement and score on the Lip-Philtrum Guide. Current and previous height, weight, and head circumferences should be plotted on an appropriate growth chart. Any additional physical features may be recorded as well to support diagnosis.

Diagnostic Studies

No laboratory test can confirm the diagnosis of FAS or another diagnosis on the FASD spectrum. The lack of a forthcoming history of alcohol consumption by the mother is an additional obstacle to diagnosis. Some alcohol biomarkers may be obtained from the mother or the newborn when suspicion of prenatal alcohol exposure arises. Ethyl glucuronide, fatty acid ethyl esters, and phosphatidylethanol are some alcohol markers under investigation that may be obtained from hair, nails, blood, urine, umbilical cord blood, or meconium with varied sensitivities, specificities, and windows of detection. Consent for testing may be required.

Imaging studies to screen for cranial malformations are not currently recommended unless the child is experiencing focal neurologic deficits or seizure activity. Similarly, targeted imaging of other organ systems is warranted in the patient with signs of an abnormality (eg, echocardiography in the patient with heart murmur).

Consultation with a geneticist may be appropriate to rule out other disorders with similar phenotype (Box 147.1).

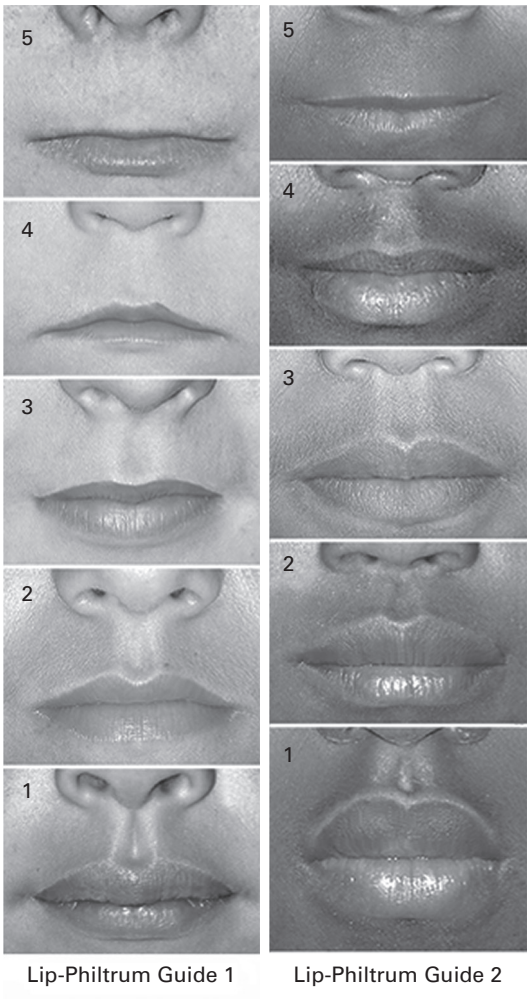

Figure 147.1. Lip philtrum guidelines for white patients and others with similar lips (left) and for black patients and others with similar lips (right). © and adapted with permission from Susan (Astley) Hemingway, PhD, University of Washington.

Management

Once a diagnosis related to alcohol exposure is suspected by a physician, the referral process should begin. A specialist in dysmorphology or an experienced physician may take the detailed measurements of the PFL and rank the facial features. Depending on local resources, evaluation of the patient by a multidisciplinary team is ideal. A child psychologist or developmental specialist can assess age-appropriate skills and need for therapeutic intervention. Only validated instruments should be used to test developmental capabilities. When delays are detected, referral to appropriate therapies should be initiated through early intervention services. An Individualized Education Program may be requested of the school by a caregiver who retains the child's educational rights. Public schools may provide occupational, physical, and speech therapies and social skills training. A psychiatrist may select therapies and medications particular to a child's unique mental health needs (see Chapters 133 and 134). Social workers are integral to providing support and additional resources to the family. As teenagers approach adulthood, referrals to vocational training and programs to transition young adults to independent living are important.

Table 147.1. Syndromes With Facies Resembling Fetal Alcohol Syndrome[a]

Syndrome	*Long or Smooth Philtrum*	*Thin Upper Lip*	*Small Palpebral Fissures*
Cornelia de Lange	+	+	–
Aarskog	+	–	–
Williams	+	–	+
Dubowitz	–	–	+
Toluene embryopathy	+	+	+
Brachmann-de Lange	+	–	–
Fetal valproate	+	+	–
Maternal phenylketonuria	+	+	+
Floating-Harbor	+	–	–
22q11.2 deletion (eg, DiGeorge, velocardiofacial, Opitz)	+	–	+

[a] Two additional syndromes with facies resembling fetal alcohol syndrome are fetal hydantoin syndrome (midface hypoplasia, wide-spaced eyes) and Noonan syndrome (low nasal bridge, wide-spaced eyes, epicanthal folds).
Abbreviations: +, present; –, absent.

Prognosis

Many of the neurotoxic effects of alcohol on the developing fetus have lasting sequelae. Early interventions may improve but not correct cognitive deficits and associated mental health issues of aging children and adults with FAS. The mental health disorders are thought to be the result of adverse childhood experiences (eg, ridicule, harassment, failures) related to a child's behavioral and cognitive deficits. Some of the mental health disorders include oppositional defiant disorder, conduct disorder, depression, adjustment disorder, anxiety disorders, substance abuse, and sleep disorders. Many adults with FAS do not finish high school and become unemployed or incarcerated. A fraction of adults with FAS require assisted living arrangements.

CASE RESOLUTION

The child meets diagnostic criteria for FAS. It is recommended to the caregiver that she initiate obtaining "educational rights" over her nephew so she can request an Individualized Education Program from his school administrator. An assessment for attention-deficit/hyperactivity disorder, such as the *Conners 3* or the *National Initiative for Children's Health Quality (NICHQ) Vanderbilt Assessment Scale,* or another standardized measure for this disorder, should be given to the caregiver and teacher to each evaluate the child. Prescription for stimulant medications may be warranted in conjunction with behavioral therapy. Depending on local resources, the caregiver and child may be referred for psychotherapy, including parent-child interactive therapy, in which the patient's aunt may be coached on how to cope with his behaviors in the most positive, effective manner.

CHAPTER 148

Infants of Substance-Using Mothers

Sara T. Stewart, MD, MPH, FAAP

CASE STUDY

A neonate is born by emergency cesarean section because of abruptio placentae. The mother is a 29-year-old gravida 6, para 4, aborta 2 with a history of crack cocaine and heroin use during pregnancy. The newborn is 36 weeks' gestational age with a birth weight of 2,400 g (5.3 lb) and length of 43 cm (16.9 in). Physical examination is normal. The newborn does well for the first 10 hours but then develops jitteriness with irritability, diarrhea, sweating, and poor feeding. A urine toxicology test on the newborn and mother are positive for cocaine.

Questions

1. What complications affect the neonate secondary to in utero drug exposure?
2. What withdrawal symptoms does the newborn experience as a result of in utero drug exposure?
3. What typical behavioral and learning problems are found in the child with in utero drug exposure?
4. What are the appropriate treatment strategies for the neonate who has experienced in utero drug exposure?
5. How does the legalization of marijuana affect the counseling of the mother about breastfeeding?

Maternal substance use during pregnancy places neonates at risk for several medical, psychosocial, and developmental problems. The particular problems experienced by newborns depend on the drug (or drugs) to which they have been exposed; many have been exposed to multiple drugs in addition to cigarettes and alcohol. The long-lasting effects of alcohol exposure are well established (see Chapter 147), but the effects of newer drugs are less well defined. Illicit drugs change in their popularity, form of use, and availability at different points in time.

The environment into which a child is born also affects the child's health and development. Environments in which substance use is common are frequently suboptimal for normal growth and development because of the effect of substance use on parenting; fragmentation of families; intimate partner violence; incarceration of significant family members; illnesses, including HIV infection; limited financial resources; homelessness or substandard housing; unemployment; child abuse and neglect; and limited access to health care. Because of these environmental issues, many drug-exposed neonates are cared for by foster parents or nonparental family members. These factors also make it difficult to determine, in a given newborn, which problems are caused by the drug exposure versus accompanying environmental conditions. This differentiation is of less significance to the physician than the researcher or epidemiologist because the physician will care for the problems exhibited by the drug-exposed newborn regardless of etiology.

Epidemiology

In 2016, 13% of women between the ages of 15 and 44 years in the United States reported having used illicit substances in the past month, which is an increase from prior years. Although data collected via maternal self-report are typically an underestimate of prevalence, a national survey reported that 6.3% of women used illicit substances in the past month while pregnant. The same survey also found that 8% of women reported drinking alcohol and 10% reported smoking cigarettes in the past month while pregnant. Meconium analysis has demonstrated not only extensive differences in the prevalence of in utero drug exposure between hospitals (eg, public versus private) but has also shown differences in the substances of choice in different geographic areas. Polysubstance use is the most common clinical scenario in all communities, and national data on women of childbearing age have shown marijuana to be the most commonly used substance, followed by opiates, hallucinogens, cocaine, and methamphetamine.

Clinical Presentation

Many of the different substances that women use while pregnant can result in similar sequelae in the newborn, infant, or child. In utero growth restriction, irritability, disordered eating or sleeping, and hypertonicity may be seen in affected newborns and infants. Older children may have developmental delays, symptoms of attention-deficit/hyperactivity disorder, learning disabilities, or behavioral

difficulties (eg, oppositional or impulsive behavior). Prenatal exposure to opiates, such as heroin or methadone, may cause symptoms in the newborn of neonatal abstinence syndrome (NAS) (ie, drug withdrawal), including respiratory, gastrointestinal (GI), or nervous system effects, such as apnea, tachypnea, emesis, diarrhea, irritability, hypertonicity, tremors, seizures, temperature instability, and sneezing. Symptoms often occur within 72 hours of birth, but because of the long half-life of methadone, symptoms of methadone withdrawal may take up to 5 days to manifest.

Alcohol and cocaine have been associated with birth defects as well. Abnormalities such as absent limbs, cardiac defects, genitourinary anomalies, ocular anomalies, and microcephaly have been reported with cocaine exposure. Alcohol has been associated with a spectrum of effects, termed fetal alcohol spectrum disorder (see Chapter 147). Within this spectrum, a subset of patients fit the well-defined criteria for a diagnosis of fetal alcohol syndrome, including facial dysmorphology, growth deficiency, and neurodevelopmental disabilities. The presence of the following 3 sentinel features in the facial dysmorphology is the most sensitive and specific diagnostic finding for fetal alcohol syndrome: a flat philtrum, thin upper lip, and short palpebral fissures. The spectrum of neurodevelopmental problems includes diagnoses such as microcephaly and seizures, as well as many types of developmental, cognitive, and behavioral difficulties. Also included within fetal alcohol spectrum disorder is a category for alcohol-related birth defects, which includes anomalies such as congenital heart defects, skeletal deformities, renal anomalies, hearing loss, ophthalmologic abnormalities, and cleft lip and palate.

With the legalization of marijuana in some states, prenatal marijuana exposure is under increased discussion. Studies on marijuana exposure have shown inconsistent results on the neonatal outcomes of intrauterine growth restriction, increased arousal, and sleep disturbance. More consistent results exist concerning neurobehavioral effects on the older child. When tested in the elementary years, children exposed to marijuana in utero had an increased likelihood of difficulty with visual perception as well as memory and language tasks. Risk for attention difficulties is increased in childhood, and adolescents are at risk for problems with executive functioning.

Pathophysiology

Drugs used by pregnant women may affect newborns in 3 different ways: the drugs may be addictive and result in symptoms of withdrawal during the neonatal period; they may be toxic and lead to impaired functioning and neurodevelopmental disabilities; and they may be teratogenic and cause congenital anomalies and a dysmorphic appearance. The ultimate effects of the drugs are a complex interaction of environmental and genetic influences that are variable depending on the timing of the prenatal exposure. Differences in maternal metabolism of drugs result in differences in fetal exposure to toxins, and genetically determined differences in fetal susceptibility to the toxins lead to a spectrum of effects in exposed neonates. During gestation, the effects of drug exposure also vary depending on the timing of exposure. Each organ has a unique period of susceptibility as it forms during the first trimester. Prenatal substance exposure during this period is more likely to result in organ malformation. The second and third trimesters primarily involve organ growth, cell differentiation, and functional maturation of organs; thus, exposure during this period is more likely to result in growth abnormalities or functional difficulties. The specific effects of the different substances on the developing fetus can be understood in terms of their biochemical properties.

In utero exposure to opiates, such as heroin and methadone, results in physiological addiction. These drugs bind to opiate receptor sites in the brain and GI tract. When the drugs are no longer present after birth, the newborn experiences withdrawal. Animal models have also found that prenatal exposure to opiates can result in decreased density of cortical neurons and decreased development of neurons.

Cocaine and its metabolites cross the placenta and concentrate in amniotic fluid. Cocaine is toxic and teratogenic, and it interferes with 3 neurotransmitter pathways in the brain. Cocaine blocks the reuptake of norepinephrine. This is associated with tachycardia, hypertension, diaphoresis, and an increased incidence of preterm labor. Diffuse vasoconstriction may affect the placenta and result in anomalies such as placental infarcts or abruptio placentae. The fetus may also be affected by the vasoconstriction and its resultant hypoperfusion and ischemia and may develop anomalies, such as atresia of the GI tract, stroke, or absent limbs. Cocaine decreases the reuptake of dopamine. This effect is apparent in cocaine-using mothers who have decreased appetite and subsequent poor nutrition during pregnancy. Stereotypical behavior, hyperactivity, euphoria, confidence, and heightened sexuality may be associated with sexual promiscuity and increased risk of acquiring HIV and sexually transmitted infections (STIs). Cocaine decreases serotonin reuptake, resulting in decreased sleep. The sleep cycle of neonates who were exposed to cocaine in utero is often disrupted.

Methamphetamine is commonly manufactured from ephedrine or pseudoephedrine and has greater central nervous system (CNS) penetration than its metabolite, amphetamine. It has direct toxic effects on the CNS and causes increased release and decreased reuptake of dopamine, norepinephrine, and serotonin. These neurotransmitter alterations result in symptoms that are similar to those described for cocaine. A large prospective study of infants prenatally exposed to methamphetamine did not find increased risk of cardiac, skeletal, craniofacial, or respiratory issues, as had been previously reported; however, these newborns are at risk of being born small for gestational age.

Direct effects of methamphetamine use are dose- and frequency-dependent in the adult user. It has been shown to have cardiovascular, pulmonary, renal, and hepatic toxicity. Higher dose and increased frequency have also been associated with psychosis and toxicity to subcortical structures. More recent data have noted subcortical white matter and gray matter changes in children with prenatal exposure to methamphetamine.

Prenatal marijuana exposure results in toxic effects to the developing brain, with resultant risk of neurodevelopmental effects.

Existing studies show no association between cannabis use during pregnancy and fetal anomalies, but exposed neonates may show some mild symptoms of increased arousal and sleep difficulties; no physiologic withdrawal from marijuana occurs as does with opiates. Endogenous cannabinoid receptors are present in the fetal brain, and it is believed that exposure to exogenous cannabinoids results in supraphysiologic stimulation of the receptors. This, in turn, affects synaptogenesis and developing neurotransmitter systems.

Reports have documented the occurrence of withdrawal symptoms within days after birth in neonates with prenatal alcohol exposure, but more common effects of prenatal alcohol exposure are direct cellular toxicity and teratogenesis. The specific mechanism by which alcohol and its metabolites damage fetal tissues is unknown, but it has been shown to affect CNS neuronal migration and synaptogenesis. For a given level of alcohol intake, the precise level of fetal exposure to metabolites is likely to vary among women, depending on maternal genetic makeup and the resulting variability in alcohol metabolism. Timing of the exposure during different periods of development can also result in different teratogenic effects on the fetus. Exposure during the first trimester may affect organogenesis or craniofacial development; exposure in the second and third trimesters can cause poor growth and neurotoxicity. Maternal alcohol use may also be associated with poor nutrition, resulting in poor delivery of nutrients to the fetus.

Phencyclidine (PCP) has sympathomimetic effects, including increases in blood pressure, heart rate, respiratory rate, deep tendon reflexes, and tone. Additionally, PCP has cholinergic effects, causing sweating, flushing, drooling, and pupillary constriction. Neonates exposed to PCP in utero do not exhibit these symptoms but display neurologic and developmental disorganization.

Differential Diagnosis

Major differential diagnoses relate to the symptomatology produced by the used substance or substances (Box 148.1). Neonates exposed to addictive substances, most commonly opiates such as methadone and heroin, may present with symptoms of withdrawal (Box 148.2). Irritability and jitteriness may be symptoms of drug withdrawal or direct drug neurotoxicity but may also be caused by hypoglycemia, hypocalcemia, hypomagnesemia, and sepsis. Seizures occur in 1% to 3% of neonates exposed to heroin in utero, and the differential diagnosis for neonatal seizures includes intracranial hemorrhage, hypoxic-ischemic encephalopathy, CNS infection, CNS malformation, and metabolic disorders. Gastrointestinal symptoms, such as vomiting or diarrhea, may be confused with reflux, formula intolerance, obstruction, or infectious gastroenteritis.

Dysmorphic appearance may also be the result of alcohol or drug exposure. Fetal alcohol syndrome is the most clearly defined dysmorphic syndrome related to maternal substance use during pregnancy. In making such a diagnosis, other genetic disorders that may have overlapping findings should be considered as well.

Failure to thrive (FTT) may be a presenting symptom in the newborn, infant, or child with a history of in utero drug or alcohol exposure. (See Chapter 146 for a discussion of the differential diagnosis of FTT.) It is important to consider maternal substance use in all patients who have been diagnosed with FTT, particularly if they were born small for gestational age.

Older children may present with a wide range of neurodevelopmental and behavioral problems. Common behavioral symptoms include impulsivity, inattention, hyperactivity, and antisocial behavior. Although many of these symptoms have been correlated with prenatal drug exposure, postnatal environmental factors, such as continued parental substance use, violence, inconsistent or poor parenting, and foster care placement, are also significant contributors. As a result, it may be difficult to clearly determine the precise etiology of developmental and behavioral problems in a child exposed to drugs or alcohol.

Maternal substance use should be considered in all neonates who present with STIs such as syphilis, hepatitis B, hepatitis C, and HIV.

Box 148.1. Diagnosis of Newborns of Substance-Using Mothers

- Symptoms of withdrawal (see Box 148.2)
- Congenital anomalies
- Developmental delay and behavioral disorders
- Growth retardation
- Sexually transmitted infections

Box 148.2. Symptoms of Neonatal Abstinence Syndrome

- Irritability
- Jitteriness
- Tremors
- Hypertonicity
- Seizures
- Mottling
- Temperature instability
- Vomiting
- Diarrhea
- Apnea
- Tachypnea
- Sweating
- Poor feeding
- Sleeping difficulties

Evaluation

History

The possibility of maternal substance use should be considered in the setting of certain maternal risk factors, including the absence of prenatal care, evidence of poor maternal nutrition, poor maternal weight gain, presence of STIs, symptoms of acute intoxication, abruptio placentae, precipitous delivery, and a history of domestic violence.

The newborn with symptoms of withdrawal should be evaluated for the possibility of maternal substance use. This assessment involves an appropriate history as well as a toxicologic evaluation.

Mothers disclose their drug history to varying extents, depending on the circumstances of the interview. Mothers who are concerned about the health and well-being of their newborns and do not fear legal repercussions are more likely to discuss their drug use. An appropriate drug history should be obtained in a nonjudgmental manner (Box 148.3). Studies have shown that the use of a structured questionnaire rather than a cursory interview increases the incidence of reported substance use by 3- to 5-fold.

Physical Examination

The newborn should be assessed for common complications related to maternal substance use. A full physical examination should be performed to check for the presence of any malformations. Growth measurements should be noted, and the physician should evaluate for evidence of growth impairment or microcephaly. The preterm neonate should be monitored for problems related to prematurity, such as intraventricular hemorrhage and necrotizing enterocolitis. Assessment for signs of NAS should be done in the days after birth (Box 148.2). Neurologic and developmental status should be assessed and monitored at each visit. Abnormalities such as hypertonicity, coarse tremors, and extensor leg posture are frequently noted in the neonatal period, and disturbances in fine and gross motor coordination may persist through the toddler years.

Laboratory Tests

In addition to obtaining a toxicologic history, screening for drugs should also be performed. The legal guidelines for screening mothers for drugs vary in different localities. Generally, if clinical symptoms indicate a need, a neonate can be screened on medical grounds without specific parental consent because the information obtained is important in the care of the newborn. Screening of the mother's urine without her consent is more problematic, however, because of the potential legal implications of a positive test result.

Drug testing of the infant can be performed on urine, meconium, hair, or the umbilical cord; urine and meconium testing are the most commonly used techniques, however, because they are noninvasive, inexpensive, and widely available. Urine testing can detect drug exposure within the 3 days before specimen collection, and meconium testing can detect exposure after 20 weeks of gestation. Meconium is more sensitive and specific than urine testing but is more sensitive to specimen collection and storage technique. The best results are often obtained from a combination of maternal urine and newborn meconium testing. It is important to realize that a negative screening test result does not rule out the possibility of exposure, because a drug metabolite may be present but not to the level of the detection threshold of the particular test. Newer techniques include neonatal hair and umbilical cord analysis. Hair analysis can detect drug exposure in the third trimester, and it remains unclear what time frame is reflected in umbilical cord testing.

Most screening tests of urine, meconium, and hair samples use immunoassay techniques, which are inexpensive and sensitive but not very specific. False-positive results may be obtained for multiple illicit substances. Common scenarios include a positive amphetamine screening result in a patient who has taken over-the-counter medication containing ephedrine or pseudoephedrine, or a positive opiate screening result in a patient who is using cough medicine with dextromethorphan. For this reason, and because of the potential legal implications of a positive result in this setting, it is strongly recommended that positive immunoassay results be confirmed with further testing of the sample via gas chromatography or mass spectrometry.

Further evaluation in the neonatal period should include an evaluation for the presence of STIs, particularly HIV, hepatitis B, hepatitis C, and syphilis.

Box 148.3. What to Ask

Newborns of Substance-Using Mothers

- During the pregnancy, did the mother use any substances, such as alcohol, cigarettes, marijuana, or prescription or illicit drugs?
- Has she ever used these substances? Is she currently using these substances?
- If so, how much? How frequently? By what route? To what extent is she trying to abstain?
- Is the mother at risk for sexually transmitted infections? Has she ever been tested?
- Did the mother have prenatal care? When did the care start?
- What is the status of other children in the family?
- Does the partner use any substances such as alcohol, cigarettes, marijuana, or illicit drugs?

Imaging Studies

No routine imaging has been recommended based solely on a history of substance exposure in utero. Instead, imaging should be directed by symptomatology. For example, the newborn with a heart murmur and history of prenatal alcohol exposure warrants a cardiac evaluation and possible echocardiography. Additionally, the newborn with prenatal drug exposure and abnormal neurologic examination should undergo a thorough neurologic evaluation, which may include neuroimaging.

Management

In the neonatal period, treatment of the newborn exposed to drugs in utero requires attention to associated conditions such as preterm birth, in utero growth restriction, and in utero infection with STIs.

The first approach to managing NAS involves nonpharmacologic methods. The goal of this approach is to create a calm, soothing environment that minimizes stimulation to the baby. Common symptoms of irritability, crying, and poor sleeping are managed with swaddling, cuddling, and gentle manual rocking. The swaddling helps minimize stimulation and promotes longer durations of sleep, and the gentle tactile sensation of cuddling and rocking is also beneficial. Other techniques for minimizing stimulation in infants include using dim lighting and low-noise environments. Feeding is often frequent and is done on demand to minimize irritability. When

possible, rooming-in of infant with mother is recommended to promote bonding and breastfeeding, both of which have been shown to reduce the incidence and severity of symptoms with NAS. Some exposed newborns may have slow or disordered feeding and may require evaluation by an occupational therapist, lactation consultant, or nutritionist as well. Breastfeeding is not restricted for mothers unless the mother is continuing to use illicit drugs, has polysubstance use, or has HIV infection.

The assessment of withdrawal symptoms in the neonate typically is done using a standardized scoring tool to assist in the documentation of symptom severity. After scores reach a threshold level, pharmacologic treatment may be required. Although no known ideal drug and dosing regimen exists for the management of NAS, the best method for reducing the duration of newborn hospital stay and the duration of NAS treatment is the establishment and use of standardized treatment protocols that are based on best practices. For the neonate exposed to an opiate in utero, treatment has traditionally been with an opiate, such as methadone or morphine. Morphine is often preferred over methadone because of its shorter half-life, which results in the ability to titrate doses more rapidly. More recently, sublingual buprenorphine has been studied and is being used in the management of NAS. Compared with the opiates, buprenorphine has been found to result in shorter durations of treatment and shorter hospital stays. Phenobarbital is used in cases of nonopiate exposure or as an adjunct to morphine or methadone. Diazepam, paregoric, and tincture of opium are no longer used because of toxic ingredients or associated complications. Medications should be tapered over time, allowing infants to outgrow the dosage.

Involvement of social services is also a key component of management. In many jurisdictions, child protective services must be notified of positive toxicologic test results on newborns or their mothers. Likewise, it may also be necessary to report to these agencies if a newborn displays symptoms of neonatal drug withdrawal. These agencies are generally responsible for performing a home assessment and determining the adequacy of the home environment. In some cases, the newborn may be assigned to a foster home and the parent or parents may be ordered to participate in a drug treatment program and parenting classes.

After the newborn period, the focus of management is on the provision of well-child care and developmental monitoring. Attention should be paid to physical growth and administration of immunizations. If a sensory impairment or neurodevelopmental delay is apparent, the child should be referred to appropriate community agencies for services. Federal programs that operate under the Individuals with Disabilities Education Act provide interventional services for disabled and at-risk children 6 years and younger.

Symptoms of attention-deficit/hyperactivity disorder or other behavioral problems in older children may require intervention, with recommendation for specific school programs as well as pharmacologic treatment. Regular assessments of school performance should be obtained from children's teachers. Standardized neurodevelopmental tests should be administered at periodic intervals to ensure appropriate progress.

Prognosis

Many neonates, particularly those exposed to alcohol in utero, experience long-term sequelae and disability. Most commonly, these effects are subtle but can have far-reaching effects for the child. Remedial educational programs help manage but do not cure problems. Recent studies have shown that for children who were exposed to drugs, the environment in which they are raised is a significant factor affecting their ultimate outcome. A stable, nurturing environment minimizes the many adverse effects of prenatal drug exposure and promotes normal neurodevelopment by enforcing the acquisition of skills and knowledge.

CASE RESOLUTION

The case study highlights typical features of the neonate who was exposed to drugs in utero. Management includes testing for hepatitis B, hepatitis C, syphilis, and HIV and administering medication, such as morphine, methadone, or phenobarbital, if irritability does not respond to swaddling or other measures. The situation should be reported to child protective services to ensure an assessment of the neonate's home environment.

CHAPTER 149

Divorce

Carol D. Berkowitz, MD, FAAP

CASE STUDY

A 7-year-old girl who has been your patient for 5 years is brought in by her mother for abdominal pain that occurs on a daily basis and is not associated with any other symptoms. The pain is periumbilical. In obtaining the history, you learn that the father has moved out of the home and the parents plan to divorce. The mother believes that her daughter's symptoms may relate to the impending divorce, and she wants to know what else to expect.

Questions

1. What are the problems faced by children whose parents are undergoing divorce?
2. What are the age-related reactions of children in families undergoing divorce?
3. What are the custodial issues and arrangements after divorce?
4. What is the role of the pediatrician in counseling families undergoing divorce?
5. What anticipatory guidance can be offered about custody and remarriage?
6. How can the pediatrician help stepfamilies adjust?

Divorce is a legal term meaning the legal conclusion or dissolution of a marriage. Divorce has been equated to the "death" of a marriage and in some ways may be more devastating for children than the death of a parent. When a parent dies, that parent becomes idealized in the mind of the child, but when parents divorce, the noncustodial parent is often devalued. Even with a joint custody arrangement, each parent is frequently criticized by the other. For the child, the parents are no longer the ideal figures they once were. The challenge for the pediatrician is to maintain a neutral position, be supportive, and serve as a source of advice and guidance. Remaining neutral may be challenging because much of the contact may have been with 1 parent—usually the mother.

The pediatrician plays a specific and potentially unique role in caring for children experiencing parental divorce because other resources may be few and other agencies or individuals may lack an antecedent relationship with the family. Extended families are often geographically distant and less available to provide help. Religious institutions have often failed to assume a counseling role in this area; some religions view divorce unfavorably. Most families do not routinely seek out mental health services unless problems are more apparent. Therefore, it is critical for the pediatrician to become involved in anticipatory guidance of families considering and undergoing divorce. It is important to recognize that divorce is not a single event; rather, it is a process that occurs over time, and parental separation may antedate the actual divorce by months or even years. Anticipatory guidance focuses on preparing children and families for times ahead. Additionally, the pediatrician serves as a child advocate. The parents themselves are often so consumed by their own emotional turmoil that they may not be available or are not even aware of the stress and trauma their children are experiencing. The pediatrician should be knowledgeable about the effect of divorce on children and their subsequent psychological development. Additionally, the pediatrician can help as new families form, assisting the transition of caregivers into the role of stepparents and children into becoming stepsiblings.

Epidemiology

Divorce affects nearly 50% of marriages, although the rate recently has decreased to closer to 40%, attributed in part to the decrease in the marriage rate. In fact, separation of unmarried heterosexual partners is far more common than divorce between married individuals. Approximately 40% of all births are to unmarried women. Socioeconomic differences exist, with 11% of higher income parents divorcing as opposed to 17% of lower income couples. Divorce is more common among those who have served in the military. Couples are less likely to divorce while they remain with the military, instead divorcing after they leave the service. Veterans are 3 times as likely to be divorced as those who have never served.

The median length for a marriage in the United States is 11 years. On average, there are 800,000 divorces a year, and 90% of divorces occur outside of court. A divorce may be collaborative (ie, uncontested), in which the parents negotiate an agreement with the advice of a separate attorney for each parent. *Mediated divorce* involves a mediator but no attorneys, to reach an agreement. Children do not routinely have legal representation in the process. Mediators may assist in establishing visitation schedules and in general, children do not participate in these meetings either.

The legal profession has been endorsing greater focus on and participation of children in divorce disputes. Approximately 1.5 million children per year are affected by divorce. Nearly one-third of all

children live in households in which parents are divorced or remarried. Children between age 3 and 8 years are the major age group affected. Children involved with parental divorce require at least 2½ to 3 years to regain their equilibrium and master a sense of control, although developmental challenges may continue to emerge at different times after the divorce.

Divorce usually results in reduced economic resources to mothers and children. In the first year after divorce, the mother's income is reduced to 58% of the predivorce level. Even after 5 years, income for mothers and children is only 94% of the predivorce amount; for intact couples, income has risen to 130% during that period. Decreased income is often associated with multiple moves to more affordable housing, along with change in schools and loss of friends. More affordable neighborhoods may not provide the same resources and environment to which the children were previously accustomed.

Types of custody include sole, joint, legal, and physical. The types of custody define the legal responsibilities of each parent as well as the time spent between parent and children. *Bird's nest custody* is a unique form of joint custody in which children remain in the home and the parents take turns moving in and out. This is less common than other arrangements. Many states now promote joint custody, which is associated with higher levels of involvement by the biological father, increased child support payments, and greater paternal satisfaction. Issues of remarriage and stepsiblings are also important. Eighty percent of divorced men and 75% of divorced women remarry, and 40% of these remarriages end in divorce. As a result of the high rate of remarriage, 1 in 3 children in the United States has a stepparent. Eighty-six percent of stepfamilies include the biological mother and a stepfather. Children in stepfamilies often must readjust to differing roles in differing households and differing relationships between their biological parents, stepparents, biological siblings, and stepsiblings.

Psychophysiology

The experience that children have following parental divorce is influenced by many factors. When a divorce is contentious and children are exposed to hostility between their parents, high levels of stress can result in physiologic changes, including elevated levels of cortisol, which can be associated with sleep disturbances, anxiety, irritability, and weight change.

The individual child's temperament and personality also affect the child's adjustment to parental divorce. An easygoing child with strong self-esteem and a positive outlook fares better than a less easily adaptive child with a less optimistic personality. The reaction to divorce also depends, to a large extent, on the age of the child (Table 149.1). Generally, children do not have the cognitive ability to understand the meaning of divorce until they reach 9 or 10 years of age. The experience is also different for children without siblings, that is, "onlies." Not only do they lack brothers or sisters with whom to commiserate, they may also experience parental overconcern, manifested by being asked repeatedly how they are feeling and how they are doing. Studies have demonstrated that the negative effect of parental divorce on adolescent academic performance is mitigated by increased sibship size.

Table 149.1. Children's Reaction to Divorce by Age

Age	*Symptoms*
2½–4 years	Regressive behavior
5–6 years	Whiny, immature behavior
6 years–preadolescent	Disequilibrium Depression Somatic symptoms Poor school performance
Adolescence	Anxiety Depression Risk-taking behavior Substance/alcohol use Delinquency

Infants and toddlers (up to age 2 years) react to changes in routine and may experience sleeping and feeding disturbances, as well as increased spitting up and clinginess. Between 2½ and 4 years of age, a child may exhibit increased separation anxiety and regressive behavior. The child becomes needy and dependent, with behavior characterized by irritability, whining, crying, fearfulness, and sleep problems. Aggression and regression, particularly in the area of toilet training, may manifest. One-third of children in this age group continue to exhibit regressive behavior 1 year after divorce.

Children between 3½ and 5 years of age often show more aggressive patterns of behavior with hitting, biting, and temper tantrums. Regressive behavior may also be seen. Young children feel particularly responsible for their parents' divorce (ie, the parents are divorcing the child). At this point in development, children experience what Piaget has referred to as an egocentric way of thinking. Self-blame, decreased self-esteem, and a high level of fantasy, particularly about parental reunion, are apparent. Approximately 1 year after divorce, 65% of these children still show decreased levels of functioning. Preschool-age children may repeatedly ask the same questions as a means of processing and assimilating the information. Such questioning should be met with patience and reassurance.

Children 5 to 6 years of age are often depressed and may exhibit behavior that is less mature or age appropriate. Girls in this age group seem to react more poorly than boys to divorce. Two-thirds of girls are less well-adjusted 1 year after the divorce, as opposed to only approximately one-fourth of boys. Children of this age may seem moody and daydream, whine, or have temper tantrums.

Children between 6 years of age and adolescence seem to experience profound disequilibrium, with feelings of shame, anger, and loneliness. This anger may manifest as antisocial behavior. Older children also talk about an overwhelming feeling of sadness and grief. Their somatic reports include headache, abdominal pain, and an increase in symptoms of preexisting medical conditions (eg, asthma). Sometimes the somatic symptoms of children, particularly those in the school-age group, are attributed by 1 parent to the poor living conditions at the other parent's household. It

is important for the physician to anticipate that 50% of children involved in parental divorce show a deterioration in their school performance. Therefore, the school should be notified about the pending divorce and changes in family structure. Decreased school performance is attributed to decreased ability to concentrate, sadness, and depression or decreased conduciveness to do homework in 1 household over the other.

Parental divorce is particularly difficult for adolescents, who describe it as "extraordinarily painful." Problems may emerge during adolescence, and adolescents may exhibit externalizing behavior (eg, delinquency, risk taking, alcohol use) and internalizing behavior (eg, anxiety, depression). The experience is worse for younger adolescents. During the first stages of divorce, they feel a personal sense of abandonment and a loss of parental love. Older adolescents are concerned about their future potential as marital partners. They also feel anxious about financial security, especially money for college. De-idealization of both parents is precipitous. Adolescent girls do better than boys early on, but this reverses with time. This pattern is referred to as a "sleeper effect" or "delayed effect," with girls subsequently feeling rejected and unattractive as they reinterpret their parents' divorce with their additional maturation. Divorce during adolescence sometimes results in precocious sexual activity or risk- or thrill-seeking behavior. Studies suggest that paternal involvement after the divorce reduces the risk of alcohol abuse. Adolescents from divorced families are more likely to experience teenage parenthood. Adolescent girls from divorced families are less likely to succeed academically than girls from families in which divorce has not occurred. Additionally, adolescents may turn to alcohol or drug use to help cope with the stress of parental divorce. Boys may engage in illegal activities, such as burglary. Suicidal ideation is noted in teenage boys and suicide attempts more often in teenage girls, although this is influenced by whether the teenager is residing with the mother or the father.

Differential Diagnosis

Children who present with reports such as headache, abdominal pain, enuresis, and poor school performance should always be assessed for environmental factors that may be contributing to their symptomatology. When evaluating a child with suspected somatic concerns, it is always appropriate to consider organic etiologies.

Many parents who are undergoing a divorce do not appreciate the effect the divorce is having on their children. They are often caught up in their own personal feelings and are not aware of their children's symptomatology. Additionally, divorcing parents experience a deterioration in their physical and mental well-being, and divorced mothers have an increased rate of illness.

Parents engaged in custody disputes may express concerns that their child is maltreated by the other parent. These concerns may include allegations of sexual abuse, which may require a referral to a physician who specializes in child abuse pediatrics or a child advocacy center (see Chapter 145).

Questions about the family and family resources should be part of any health maintenance visit. A parent may not mention marital discord unless asked specifically. It is important to remember that parental divorce has a significant effect on family resources (see Chapter 141).

Evaluation

Regardless of a child's presenting concern, the focus of the evaluation should be on the interview. Determination of the full extent of the effect of home factors on children's symptomatology may take several visits. It is not appropriate to pursue extensive laboratory tests in search of an organic etiology without first adequately determining what changes are occurring within the household.

History

The medical evaluation of the child experiencing a parental divorce should include a review of the medical history and a discussion with the child of factors of change (Box 149.1). This may help open up a discussion that reveals that the parents are in the process of divorce or that 1 parent has moved out of the household. Specific parental concerns about child maltreatment should be noted in detail and consideration given to consultation with a physician certified in child abuse pediatrics.

Physical Examination

Any symptom or specific report, such as abdominal pain or headache, should also be addressed (see Chapters 125 and 129, respectively). Depression and the risk for suicide should also be evaluated (see Chapter 66). A complete physical examination is usually warranted because the child who is experiencing stress may also develop stress-related medical problems. If concerns exist about sexual abuse, a careful anogenital examination by an experienced examiner is indicated.

Laboratory Tests

Some simple baseline laboratory studies may be warranted, particularly in the child with reports such as abdominal pain or enuresis. These tests may include a complete blood cell count or urinalysis.

Box 149.1. What to Ask

Divorce

- Is anything different about the child's house now?
- What are the current living arrangements?
- Who lives in the house?
- Is this the house in which the child has resided previously?
- Does the child have to move between the residences of each parent?
- How does the family assure that the child has adequate resources (eg, clothes, books, toys) in each household?
- How are things going between the parents?
- Has the child shown any regressive or aggressive behaviors?
- Has the child been eating and sleeping normally?
- How is the child doing in school?

Management

Management of the child whose family is contemplating or undergoing divorce is complex. In addition to managing any somatic symptoms that may be related to the divorce, the physician plays a key role in anticipatory guidance. Children need to understand that they did not cause the divorce and that they will not be able to "cure" it. Physician involvement before parental separation helps. Initially, the physician should advise parents how to talk to children and what to expect in terms of their reaction. It is important for parents to tell children that they are separating from one another and not from the children. As stated previously, parents undergoing a divorce are in so much turmoil that they themselves may not see their children's distress. Additionally, parenting skills may be affected, and routine procedures, such as meals and bedtime, may become disrupted, sporadic, and irregular, and may vary depending on with whom the children are residing.

Box 149.2 summarizes advice given to parents when talking with their children. Parents should discuss who, when, how, where, and what. Ideally, children should be told of impending divorce by both parents with support from the extended family. Although such advice is recommended, studies report that 80% of preschoolers were told by 1 parent. Having both parents tell children is less likely to occur if 1 parent initiated the divorce and the other parent was blindsided by the action.

When to tell depends on children's ages. Younger children should be told a few days before the actual separation, although this too may be unrealistic because plans to separate may spread over a significant period of time (weeks to months). Older children should be told at least several weeks before. The physician should advise parents how to tell. Displays of emotion are permissible. Parents should be encouraged to show their emotions but not to the extent that they appear overwhelmed or uncontrollable.

Box 149.2. Talking to Children About Divorce

Who

- Who tells? Both parents.
- Who is told? Children, extended family, physicians, teachers, neighbors.

When

- Before either parent leaves.
- Age dependent.
  Older children: weeks ahead.
  Younger children: days ahead.

How

- Calmly, with emotional control.

Where

- Privately, in the home.

What

- Stress that children are not to blame; that the divorce is between parents, not between parents and children; it is the parents who cannot get along.
- Explain expected living arrangements.

Who to tell includes not only the children but also the extended family, neighbors, and school, so that the feeling of shame or secrecy are lessened. What to tell involves freeing the children of any blame for the divorce and answering their questions. Parents should be encouraged not to be critical of the other parent, but such advice may be difficult to follow even if the parties involved are not overtly hostile to each other.

It is important for physicians to minimize their involvement in custody disputes; however, if the physician has applicable knowledge, it is acceptable to render an opinion about the parenting skills of both parents. Historically, custody was granted to the mother in 90% of cases, but joint custody (both legal and physical) is now increasing. Questions that physicians should ask themselves when advising about custody include the following: What are the emotional ties between parents and children? Do children indicate a preference for 1 parent? Children may be overwhelmed by feelings of loyalty and be torn if asked to choose 1 parent over the other, which makes this a difficult problem. What is the capacity of each parent to provide emotional and physical support for children? It is important to consider a need for continuity, and it is vital to keep conditions as close as possible to the predivorce situation. Children should not have to move. It is necessary to periodically reassess living arrangements. The pediatrician may also refer parents to community programs that may involve didactic sessions as well as parent groups. One such program, the New Beginnings Program for Divorcing and Separating Families, has been shown to improve mother-child relationships and decrease internalizing behavior in children and externalizing behavior in adolescents.

The physician should be aware of demonstrated benefits of joint custody. Joint custody tends to maintain a parent-child attachment, and children experience a lesser sense of loss. They have more cognitive and social stimulation. Joint custody relieves the burden of single parenthood, and parents who have joint custody are less likely to use children as bargaining tools. Parents themselves are freer to enter into different relationships and are less emotionally dependent on their children. Although the physician should not become involved in monetary issues, concerns related to payment, insurance coverage, and cost of medical care are appropriate to discuss. The physician should consider involving the noncustodial parent in the child's health care. The noncustodial parent should be notified if medical problems occur.

The pediatrician may also be helpful in counseling the noncustodial parent about interacting with children. Unfortunately, contact with noncustodial parents may decrease rapidly after a divorce. Although 25% of children have weekly visits with their noncustodial father, 20% of children see their father only several times a year or not at all. Generally, visitation should reflect previous relationships as closely as possible. The noncustodial parent should be advised not to become a camp counselor who focuses on fun and games but to be an influential figure who helps the child or children meet the challenges of normal living, such as completing homework and doing chores and tasks. It is also important for the noncustodial parent to be consistent. If a meeting is planned, both parents must

show up. Although the parents are no longer married, they can still be co-parents rather than rivals. Rivalry may manifest in ways that include buying more clothes or toys for children, or taking them to costly special events or places. The noncustodial parent should be encouraged to participate in school and sports activities. Multiple modalities, such as e-mail, texting, and video calls can facilitate more frequent communication.

Divorced parents may attribute children's somatic concerns to poor care while under the care of the other parent. Allegations related to abuse, most often sexual abuse, may also arise. These allegations should be taken seriously. An appropriate medical and psychological evaluation is necessary (see Chapter 145). The most difficult situations involve allegations of sexual abuse of preverbal children, in which conclusions may be contingent on the physical findings, which are usually normal or inconclusive.

Issues related to parental dating and remarriage should be addressed at an early stage. Parents should be advised that pediatricians may be a resource in helping families readjust. Remarriage is often a difficult time for children because they experience feelings of rejection secondary to displacement by stepparents. Grandparents may also be a strong source of support and stability, especially if they live close by.

Remarriage may result in a family involving same-sex parents. Many children with gay or lesbian parents have undergone the divorce of their heterosexual parents. In the United States, same-sex marriage has been legal nationwide since 2015. Prior to that ruling by the US Supreme Court, individual states had legalized same-sex marriage, and the 2010 US Census report identified 131,729 married same-sex households. Children may, however, move to families with same-sex parents who are not married. The same report noted 514,735 same-sex unmarried partner households. Studies show that children raised by same-sex parents function similarly to those in heterosexual families.

The pediatrician can also serve as a resource for stepparents. Although stepparents do not have legal rights to consent for medical care of their stepchildren, they should become familiar with the children's medical history. Stepparents grow into their parenting role, and it takes 2 to 7 years for families to become blended. The pediatrician can help families adjust by recommending books or giving referrals to organizations, such as the National Stepfamily Resource Center (www.stepfamilies.info).

Prognosis

The prognosis for children undergoing a parental divorce depends, in large part, on the degree of dysfunction that existed in the family before separation and the ability of the children to communicate their concerns. It takes most children 2 to 3 years to adjust to parental divorce and 3 to 5 years to adjust to a remarriage. Supportive intervention by family, friends, and physicians is key to facilitating the necessary adjustment. For adolescents, a positive belief about parental divorce is a major predictor of their adjustment. Family resilience and hardiness as well as family communication are associated with a good adjustment. Being a child of divorced and remarried parents has been likened to having dual citizenship. The experience is rewarding if the countries are not at war with one another.

CASE RESOLUTION

The case study reflects that functional somatic symptoms are not uncommon, especially in school-age children of divorced parents. The mother and her daughter should be advised how stressful divorce is for children. A careful medical examination may reassure the mother and daughter about the child's physical well-being. Issues related to custody, financial responsibility, and the need for consistency should all be addressed. The pediatrician also should refer the family to outside agencies, if necessary.

CHAPTER 150

School-Related Violence and Bullying

Tracey Samko, MD, FAAP, and Catherine A. DeRidder, MD, FAAP

CASE STUDY

A mother brings in her 9-year-old son, Alex, who reports recurrent abdominal pain. His pain has become so severe that Alex misses school frequently. He denies any vomiting or diarrhea. His weight has been stable over the past 6 months. Alex's mother reports that lately he seems more withdrawn and passive. He used to be engaged in his schoolwork but now, with his frequent absences, has lost interest in school. His mother says he is often anxious or nervous about new situations.

Questions

1. How does school-related violence, including bullying, affect a child's health and well-being?
2. What is the relationship between bullying and adult criminal behavior?
3. What is cyberbullying?
4. Which children are at risk for being bullied or for becoming a bully?
5. What can the pediatrician do to help address violence in the school, home, and communities?

Violence is defined as an act of aggression that can be physical, sexual, or psychological. Its form, level of severity, and frequency are affected by biological, individual, clinical, intrapersonal, situational, and sociocultural factors. Categorization of violence is also dependent on the relationship of the perpetrator and the perpetrator's target, as well as the age of each party. Intimate partner violence occurs among individuals in an established relationship; child abuse predominantly occurs between an adult and a minor; and bullying usually occurs between peers. School violence occurs at school, at school-related events, in transport to and from school, or on school property. From a developmental perspective, bullying may be the earliest form of violence instigated by children and can progress to intimate partner violence, criminal delinquency, suicide, or homicide in adolescence and adulthood. Although violence may be considered a social issue, it affects the physical and mental health of all involved. The primary care physician has unique opportunities to prevent violence and identify those potentially at risk.

Prevalence and Risk Factors

Suicide and homicide represent the most lethal forms of violence. Suicide and homicide are responsible for more than one-third of deaths among persons age 10 to 24 years in the United States. Approximately 3 million youths are at risk for suicide, with 37% of at-risk individuals attempting suicide (see Chapter 66), and these rates have been steadily increasing since 2005. In 2016, suicide was the second leading cause of death among both 10- to 14-year-olds and 15- to 24-year-olds. It is estimated that approximately 16 youths die each day in the United States from suicide. Homicide is also increasing among children and adolescents. According to the Centers for Disease Control and Prevention, homicide is the fourth leading cause of death for youths 10 to 14 years of age and the third leading cause of death for individuals 15 to 19 years of age in the United States.

In 2014, more than 500,000 individuals younger than 24 years were treated in emergency departments for injuries sustained because of violence. In 2017, nationwide surveys of high school students noted that 23.6% reported being in a physical fight 1 or more times in the 12 preceding months. Sixteen percent reported carrying a weapon, such as a gun, knife, or club, on 1 or more of the 30 days preceding the survey. Furthermore, 6.7% of students reported not going to school on 1 or more days in the 30 days preceding the survey because they felt unsafe at school or on their way to and from school. Bullying was found to be much more prevalent than concern about physical violence, with 19% reporting being bullied on school property and 14.9% reporting being bullied electronically. Although nearly 25% of youth have experienced bullying, only 20% to 30% of those youth ever report it to an adult.

A 2014 meta-analysis of 80 studies found a mean prevalence rate of 35% for traditional bullying and 15% for cyberbullying. Those who reported being a bully or being a target were more likely to carry weapons to school and to be involved in frequent fights. Bullying itself is most common in the middle school years. Boys and girls experience similar rates of bullying. Boys tend to participate in physical and verbal bullying, whereas girls use more verbal and relational bullying, such as rumors and social exclusion.

Risk factors associated with bullying are complex and involve the individual, family, peers, and community (Table 150.1). Children are at risk for being bullied or becoming a bully in situations of power imbalance. This includes physical differences, such as age, size, and strength; as well as popularity; demographic characteristics (eg, member of a majority racial or ethnic group or socioeconomic status); social skills; physical abilities; and access to money, information, or technology. Demonstrated individual risk factors associated with violent behavior include exposure to violence as a witness or target, childhood aggression, antisocial behavior, substance use, depressed mood, and hyperactivity. Community risk factors include high concentrations of poverty and low levels of community participation. Protective factors include academic achievement, parent-family connectedness, and engagement of families and teachers. Targets of bullying are more likely to be children who are considered different from their peers, such as those with obesity; with a developmental delay or learning disability; or who are lesbian, gay, bisexual, transgender, or questioning (LGBTQ).

Bullying and its Consequences

Bullying is defined as repeated acts of verbal or physical intimidation, coercion, and aggression. An imbalance of power exists, with the more powerful attacking the less powerful, whether because of physical size, social power, or access to money/information. Bullying occurs in an environment that supports the behavior. Participants include the bully, the target, and the bystander. The bully is often an aggressive individual who uses violence to dominate others. In contrast with common perception, bullies do not have poor self-esteem but rather have a strong desire to control others. The target may be more passive and anxious. This individual is often less secure than his, her, or their peers and may be lonely, playing alone at school. When the target is attacked by a bully, the target usually withdraws rather than retaliates. A minority of youth may be classified as a bully-target or a provocative target. These individuals are anxious and aggressive; although they are primarily targets of bullying, they may provoke the bully.

Different forms of bullying exist. *Direct bullying* includes physical or verbal bullying. *Physical bullying* can involve hitting or kicking, whereas *verbal bullying* can involve spreading rumors and social exclusion. *Cyberbullying* can include bullying via email, social networks, or texting. The bully who uses cyberbullying can remain anonymous and send aggressive messages to many people. Cyberbullying frequently occurs in a public forum in which it can be seen and/or shared both by acquaintances and strangers as well as become part of the public record, where it can be accessed in the future. Because the bullying occurs online, it may go unnoticed by authority figures, is frequently anonymous, and can be difficult to track.

Bullying predominantly occurs in unstructured school environments, such as during recess, at lunch, on the way to or from school, in hallways, or on the bus. Children often do not report bullying to adults for fear of retaliation by the bully and the concern of disbelief by the adult. Despite exposure to high-profile school mass tragedies associated with bullying, many parents, teachers, and health professionals still believe bullying to be a normal behavior of children. Studies demonstrate that adults underestimate the prevalence of bullying events compared with student reports.

Bullying affects the physical and mental health of all involved. Fear and anxiety about the school environment is most common. Other clinical signs of bullying include bed-wetting, headaches, sleeping problems, abdominal pain, poor appetite, and feelings of tension or tiredness. This can progress to avoidance of school; academic problems, including lower academic achievement; and higher dropout rates. Of further concern, bullying can result in low self-esteem, depression, and suicide. Although a direct connection between childhood violence and adult outcomes has not been clearly established, temperament, social skills, biologic factors, timing (transient vs chronic), presence or absence of support by authority figures, and comorbid psychiatric conditions all likely play a role.

Six percent of adults in the United States report a lifetime history of bullying. In adulthood, higher rates of depression and poor self-esteem exist among individuals with a history of being bullied.

Table 150.1. Risk Factors Associated With Bullying

Risk Factor Type	*Target*	*Bully*
Individual	Physical traits different from peers, especially obesity Chronic illnesses Behavioral or emotional problems Sexual orientation (LGBTQ) Physical or learning disabilities	Poor academic achievement Behavioral or emotional problems Involvement with drugs, alcohol, or tobacco Criminal involvement
Family	Abuse (physical, sexual, or psychological) Witness to violence Poor family functioning	Abuse (physical, sexual, or psychological) Witness to violence Poor family functioning
Social environmental	Social rejection by peers Socioeconomic disadvantage Low commitment to school and school failure Inner-city upbringing	Association with delinquent peers/peer pressure Socioeconomic disadvantage Low commitment to school and school failure Inner-city upbringing

Abbreviation: LGBTQ, lesbian, gay, bisexual, transgender, questioning.

Adapted with permission from Waseem M, Ryan M, Foster CB, Peterson J. Assessment and management of bullied children in the emergency department. *Pediatr Emerg Care.* 2013;29(3):389–398.

Strong associations in adolescence and early adulthood have been made between bullying, suicide, and murder. The child who was targeted may react later in life with self-destructive acts or lethal retaliation.

Many of the recent killing sprees in the United States were committed by individuals who as children felt they were targeted. A review of 37 mass school shootings found more than two-thirds of perpetrators felt they had been persecuted, bullied, threatened, or attacked; often, they were acting out of revenge. Regardless of the scale, the rate of gun violence in the United States is higher than that of similar high-income countries.

A cohort study of 1,420 individuals age 9 to 26 years in western North Carolina found that targets of bullying had significantly higher likelihood of poor health, wealth, and social-relationship outcomes compared with children who were not bullied. Bullies who were not bullied themselves were not at increased risk for adverse outcomes as an adult when other environmental factors and childhood psychiatric disorders were controlled.

However, studies have found that boys who were bullies in middle school had at least 1 criminal conviction by age 24 years, and 35% to 40% had 3 or more convictions by age 24 years compared with 10% among a control group of boys who were not involved in bullying. Longitudinal studies report that bullies and bully-targets go on to more criminal activity than their counterparts. Those who are chronically bullied have worse outcomes than those who are bullied transiently. One study of Finnish boys reported 9% being bullies in childhood. These same individuals accounted for 33% of criminal activity in the study. Bullies were more likely to commit occasional infractions, whereas bully-targets were more likely to commit repeat offenses.

Bystanders are also affected, because bullying distracts from the learning environment. Furthermore, bystanders develop strategies to avoid being bullied themselves, including avoiding the restroom and staying home from school. One study reported that 1 in 5 secondary schoolchildren avoid restrooms out of fear at school. Another study stated that 7% of eighth graders stay home at least 1 day a month out of fear of other students.

Role of the Primary Care Physician

Assessment

Childhood bullying is a complex abusive behavior with demonstrated serious consequences. The physician is uniquely qualified to identify at-risk individuals, screen for psychiatric comorbidities associated with bullying, counsel families, and advocate for school-based interventions. Because bullies and targets commonly will not identify themselves as such, the physician needs a systematic approach to screen for this early form of violence. Integrating screening during anticipatory guidance may be optimal for toddlers and school-age children, whereas assessing risk factors at well- and acute-care visits may be necessary for adolescents.

Multiple instruments have been used in a research setting for identifying bullying or associated internalizing or externalizing symptoms, but they have not been widely implemented in the primary care setting. Screening younger patients requires conversations with the child and family members. The American Academy of Pediatrics developed Connected Kids: Safe, Strong, Secure, which can be integrated into Bright Futures for well-child care visits. This violence prevention program focuses on screening for risk, preventive education, and links to counseling and treatment resources. When talking directly with adolescents, the use of the psychosocial interview HEADSS (home, education and employment, activities, drugs, sexuality, and suicide/depression) may be useful in screening for high-risk behaviors and risk factors for violence (see Chapter 4).

When questioning a family about bullying, the physician must keep in mind that children often do not tell a parent that bullying occurred. When a parent is told about bullying, the parent may consider the situation to be normal behavior for young people and dismiss the event.

After bullying involvement is suspected, the physician can ask follow-up questions to further characterize the involvement and obtain more details (Box 150.1).

Prevention

Prevention efforts must be focused on the individual, family, and community. In early childhood, the parent can model for the child appropriate social interaction, how to resolve conflict, and how to manage frustration and anger. School-wide bullying prevention programs are effective and should be advocated. One example is the Olweus Bullying Prevention Program (www.violencepreventionworks.org), which focuses on caregivers and schools showing positive interest in students, setting firm limits for unacceptable behavior, using consistent nonphysical consequences when rules are broken, and acting as positive role models to ultimately change social and behavioral norms. For older children and adolescents, identifying psychiatric symptoms and providing the appropriate intervention may

Box 150.1. What to Ask

Bully

- How often do you bully others?
- How long have you bullied others?
- Where do you bully others (eg, school, sports, home, neighborhood)?
- How do you bully others (eg, hitting, insults, gossiping, text messaging, social networks)?
- How do you think the kids you bully feel?
- How does bullying make you feel?

Target

- Have you been bullied? If so, how often have you experienced bullying?
- How long have you experienced being bullied?
- Where are you bullied (eg, school, sports, home, neighborhood)?
- How are you bullied (eg, hitting, insults, gossiping, text messaging, social networks)?
- How do you feel when you are the target of bullying?

Adapted with permission from Lamb J, Pepler DJ, Craig W. Approach to bullying and victimization. *Can Fam Physician.* 2009;55(4):356–360.

prevent more serious violent behavior. At the individual level, physicians and parents can counsel children who are bullies or targets about appropriate behaviors (Box 150.2).

The authors of a randomized controlled study published in 2004 demonstrated the effectiveness of identifying at-risk youth age 7 to 15 years in a primary care setting and providing a family-level intervention to reduce violent behavior and injuries among youth. Families who received the telephone-based intervention focusing on positive parenting reported decreased parent-reported bullying, physical fighting, fight-related injuries requiring medical care, and child-reported bullying.

Some strategies should be avoided, including zero tolerance policies, which can disincentivize reporting; conflict resolution/mediation, which can give the impression that both the target and the bully are partly at fault; and group therapy, which may reinforce power dynamics and bully behaviors among the participants.

The US Department of Health and Human Services developed a resource kit on bullying, which is available at https://www.hhs.gov/ash/oah/adolescent-development/healthy-relationships/bullying/index.html. Printed resources are available for parents and teachers. PACER's National Bullying Prevention Center (www.pacer.org/bullying/) also has digital-based resources for parents, educators, teenagers, and youth. For LGBTQ youth, the physician can recommend GLSEN (formerly known as the Gay, Lesbian & Straight Education Network; www.glsen.org/) and the It Gets Better Project (https://itgetsbetter.org/).

The National Suicide Prevention Lifeline is available at www.suicidepreventionlifeline.org and 1-800-273-TALK (8255). This lifeline provides 24/7 crisis counseling and mental health resources. For LGBTQ youth, The Trevor Project offers a 24/7 crisis hotline at 1-866-488-7386 and www.thetrevorproject.org/.

The physician serves a vital role in youth violence prevention (Box 150.3). Prevention begins early in a child's development by providing positive reinforcement of appropriate pro-social behavior. Bullying is an early form of aggression. Bullying may seem harmless, but longitudinal studies as well as analysis of mass school shootings demonstrate the large effect aggression early in life can have on the future well-being of children, adolescents, and adults. Successful interventions require cooperation by parents, teachers, students, and health professionals. At a community level, pediatricians can advocate for incorporation of school-wide bullying awareness campaigns, educate themselves and others about violence prevention, contribute to ongoing research, and promote awareness of violence prevention/intervention strategies at local and state levels.

Box 150.2. The Role of the Physician in Counseling Bullies and Targets

- Be vigilant for signs and symptoms of bullying and other psychosocial trauma and distress in children and adolescents.
- Increase awareness of the social and mental health consequences of bullying and other aggressive behaviors.
- Screen for psychiatric comorbidities in at-risk youth and provide appropriate referrals for treatment for affected youth.
- Counsel affected youth and their families on effective intervention programs and coping strategies.
- Advocate for family, school, and community programs and services for targets and perpetrators of bullying and other forms of violence and aggression.

Box 150.3. Individual-Level Prevention Strategies

Advice for Targets of Bullying

- Resist reacting to the bully; hold your frustration and anger.
- Walk away from the situation; ignore the bullying.
- Avoid retaliation or bullying back.
- Tell an adult.
- Talk about the bullying event with your family.
- Assess each bullying situation individually.
- When possible, use a buddy system at school and while traveling to and from school.
- Develop friendships by joining social organizations.

Management of Bullies

- Reinforce that bullying is a serious problem.
- Set limits and provide consequences for acts of aggression.
- Emphasize tolerance for people's differences; everyone deserves respect.
- Determine whether friends are also involved in bullying; encourage others to report bullying behavior.
- Provide positive reinforcement for appropriate behavior.
- Work closely with teachers and school staff on behavior modification.
- Emphasize it is the behavior that is not acceptable, not the individual as a whole.

CASE RESOLUTION

Targets of bullying often present with psychosomatic symptoms, such as headache or abdominal pain. After organic etiologies have been ruled out, further questioning should focus on psychosocial stresses. Alex's abdominal pain is worse in the morning before going to school. When asked specifically about bullying, Alex states that a few of his classmates tease him and rough him up each day on his way to school. In the past few weeks, they have been sending him text messages about how they are going to haze him the next day. Alex has not told anyone about the experience because he thought he would be viewed as a coward. Alex shares that he would rather avoid going to school than face potential bullying.

The physician needs to assure Alex that it is not his fault that he is a target of bullying. Prevention should include interventions at the individual, family, and school level. Alex should walk away from the conflict when possible and feel comfortable about reporting the event to school staff. He may want to find a friend with whom he can walk to school. His family needs to understand that bullying is not a normal behavior of childhood. He should be encouraged to talk about bullying events and work with his family to identify solutions. The school should be notified of the event and encouraged to promote a non-bullying school environment.

CHAPTER 151

Intimate Partner Violence

Sara T. Stewart, MD, MPH, FAAP

CASE STUDY

A 6-year-old boy is brought in by his mother for an annual well-child visit. He sits quietly as his mother reports no significant medical history. His medical records reflect that at his last visit he was talkative, doing well in school, and enjoyed playing baseball. As you speak with his mother, she seems reticent and does not spontaneously offer information. You determine that the boy's school performance has declined significantly over the past year and that he no longer wants to play baseball.

On physical examination, the boy has linear ecchymoses over his buttocks, and you notice bilateral areas of bruising on his mother's upper arms. When you ask about the marks, she becomes tearful. You ask her if she would like to speak privately with you.

Questions

1. How often does child abuse and intimate partner violence co-occur?
2. What are potential strategies to screen for intimate partner violence?
3. What are common clinical presentations of victims of intimate partner violence and children exposed to intimate partner violence?
4. What are the long-term consequences of intimate partner violence on children?
5. What are key factors in determining the risk to a target of intimate partner violence?

Although several definitions of *intimate partner violence* (IPV) exist, the Centers for Disease Control and Prevention has defined it as a pattern of behavior that includes physical violence, sexual violence, stalking, and psychological aggression. It is perpetrated by an individual who is or was involved in an intimate relationship with an adult or adolescent, and the pattern of assaultive and coercive behaviors is meant to establish control over the other partner. This may include approaches such as social isolation, deprivation, and intimidation. Intimate partner violence is not only associated with negative physical and mental health outcomes for the victim but is also associated with negative mental health outcomes for children in the home. Childhood exposure to IPV is considered to have occurred when a child sees, hears, or observes the effects of verbal or physical assaults between partners. Intimate partner violence is also associated with an increased incidence of child abuse in the home.

Epidemiology

Intimate partner violence affects both sexes and occurs in all ethnic, socioeconomic, sexual orientation, and religious groups. Approximately 8.5 million women and 4 million men in the United States report experiencing physical violence, rape, or stalking from an intimate partner during their lifetime. Of adolescents who date, 12% of girls and 7% of boys have experienced physical violence in their dating relationship in the prior 12 months. In 2007, 14% of homicides nationwide were the result of IPV, and most of these victims were female. Although both men and women fall victim to IPV, women are more likely to sustain life-threatening injuries, resulting in an increasing disparity between victimization rates with increased severity of physical assault. The annual financial cost of IPV to society has been estimated at $8.3 billion, including medical and mental health costs as well as the indirect cost of lost productivity. In total, victims lose millions of days of paid work time annually.

Although no uniform profile exists of a victim or perpetrator of IPV, risk factors for victimization include a personal history of maltreatment as a child, adolescent or young adult age, disparity of status (eg, educational, professional) between partners, and high level of dependence of 1 partner on another. Batterers have also been found to frequently have a history of emotional or physical maltreatment as a child, a history of substance abuse, very low levels of self-esteem, and difficulty identifying and expressing emotion.

It is estimated that up to 15 million children in the United States are exposed to IPV in their homes annually, and these children are at risk of victimization themselves. They are almost 5 times more likely than unexposed children to sustain physical abuse and 2.5 times more likely to be victims of sexual abuse.

Clinical Presentation

Adult victims of IPV may present for medical care for themselves or may present for care of their children for issues related to the violence. Approximately one-third of victims injured in an assault by a partner seek medical care for their injuries. Although these

injuries vary in severity, skin injuries are most common. Injury can occur on any part of the body; however, injury to the head, neck, and face has been particularly associated with IPV.

Many victims present to primary care physicians and emergency departments, and only a fraction are correctly identified as suffering from IPV. A recent report noted that only 28% of abused women who sought care frequently (≥7 times) were ever identified as victims of IPV. Barriers to diagnosis are patient and physician based. A patient may not disclose the abuse because of fears of social, financial, or legal repercussions; concerns for safety based on prior threats from the abuser; feeling ashamed at being a victim; and inability to trust that others can help. The patient does not appreciate that violence frequently escalates. Often the patient fears an investigation by child protective services and loss of custody of any children in the process. The patient may fabricate a story (eg, a fall) to explain the injuries, thereby discouraging the physician from further inquiry. Even in the absence of a story, the physician may avoid inquiring about the injuries, citing time constraints and lack of knowledge to effectively respond if a disclosure is made.

A parent or guardian may also seek care for any children who manifest effects of the trauma, altered stress physiology, and disrupted caregiver attachment (Box 151.1). Children exposed to IPV are more likely than their peers to be anxious, fearful, and hypervigilant and have difficulty with aggression and peer relationships. Adolescents are more likely to have school failure, substance abuse difficulties, high-risk sexual behaviors, and violent dating relationships. As they progress to adulthood, these children are at increased risk for mental health disorders and substance abuse. The Adverse Childhood Experiences Study enumerates multiple negative overall physical and mental health consequences in adults exposed to IPV as children (see Chapter 142).

Pathophysiology

The prevalent dynamic in relationships with IPV is the need by 1 partner to dominate or have power over the other. Often, this characteristic is interpreted as devotion early in a relationship, but an abuser eventually isolates the victim socially and financially. Ultimately, the violence includes a physical or sexual component as well as a psychological one. The psychological component, which typically precedes any physical violence, includes threats, humiliation, and intimidation and can be the most difficult to treat.

The cycle of violence between intimate partners is chronic and cyclic in nature, with 3 phases. The first phase is the tension-building phase, in which the abuser uses verbal, emotional, and physical threats. The next phase is the violent episode, which includes some combination of physical, sexual, emotional, and psychological assault. The final phase is the honeymoon phase, in which the abuser apologizes and assures the victim that it will not happen again, and re-bonding occurs. These phases escalate over time as the violence becomes more frequent and more severe and the honeymoon phase shortens. At least 50% of women who suffer sexual IPV report multiple rapes, and two-thirds of men and women with physical violence report multiple episodes of assault as well. The violence can also continue after the relationship has ended, and this most commonly manifests as stalking of the victim by the abuser. The violence also becomes intergenerational, because children exposed to IPV are at increased risk for victimization and perpetration of violence in their future intimate relationships.

Particular circumstances exist in which IPV victims are at even higher risk of harm. Threats from the perpetrator to harm or kill the victim or another person, the use of drugs or alcohol at the time of the violent episode, and the use of a weapon are all associated with an increased risk of injury. Approximately 4% to 8% of women report having experienced IPV during a pregnancy. It has been hypothesized that this is a time of increased stress as well as a time when a woman's attention may be diverted from her partner, thus placing her at increased risk for harm. Victims are also at increased risk of injury or death at the time they report the abuse or attempt to leave the relationship. In comparison with the systems in place for children, no protective service agencies with mandates to protect these adult victims exist, and as a result, disclosure of IPV may not occur unless the victim feels that she, he, or they has a plan for escape.

Box 151.1. Signs and Symptoms of Childhood Exposure to Intimate Partner Violence

- Depression
- Anxiety
- Somatization
- Attention-deficit/hyperactivity disorder
- Aggression
- Developmental delay
- Low self-esteem
- Hypervigilance
- Poor academic performance or truancy
- Antisocial or delinquent behaviors

Differential Diagnosis

Adult or adolescent victims of IPV often present with vague symptoms, and women who have been abused are 3 times more likely than women who have not been abused to present with gynecologic complaints, such as recurrent sexually transmitted infections, vaginal bleeding, or chronic pelvic pain. These victims may also present with nonspecific symptoms of sleeping difficulties, appetite changes, weight loss, chronic pain, or syncope. They are 3 times more likely to experience depression and 4 times more likely to experience posttraumatic stress disorder (PTSD) than non-abused women and may present to their physician with symptoms of anxiety or after a suicide attempt. Other symptoms reflect conditions associated with stress, such as irritable bowel syndrome, headaches, or temporomandibular joint disorder. The pregnant victim may present with vaginal bleeding, preterm labor, placental abruption, or fetal distress. The most common adverse birth outcome attributed to IPV during pregnancy is low birth weight of the neonate.

Mental health manifestations of childhood exposure to IPV may vary depending on the developmental stage of the child; however, these children may present with developmental delay, low self-esteem, symptoms of PTSD and hypervigilance, poor academic performance or truancy, or antisocial behavior. Exposed children also have significantly more internalizing disorders (eg, depression, anxiety, somatization) and externalizing disorders (eg, attention-deficit/hyperactivity disorder, aggression) than nonexposed children.

Children in the home may also sustain direct physical trauma as the result of being held in a parent's arms during an episode of violence or in an effort to intervene and protect a parent during a violent episode. The children may also be direct targets of the violence and present with head, skin, skeletal, or abdominal findings caused by physical abuse (see Chapter 144).

Box 151.2. Risk Factors for Intimate Partner Violence

- History of childhood abuse
- Adolescent or young adult age
- Disparity in professional or educational status of partners
- Geographic or cultural isolation
- Dependency on partner because of chronic illness or disability
- Pregnancy
- Depression
- Anxiety
- Frequent physical injury
- Substance abuse
- Poor compliance with medical care

Evaluation

History

Many victims of IPV do not freely offer information about the violence occurring in their relationships, even if they present with overt injuries. Screening for IPV in medical settings is cited as the optimal approach and is an area of continued research. Several different screening tools have been used clinically, but no standard screening tool has yet been established. Proposed approaches in the primary care or emergency department environment have included universal screening of all women and targeted screening of women with high-risk signs and risk factors. Although each approach has its proponents, a 2013 US Preventive Services Task Force statement recommended that physicians screen all women of childbearing age. Universal screening may detect increased numbers of cases of IPV and "open the door" to effective intervention, but it remains unknown whether improved social, physical, or mental health outcomes have been achieved with this approach. Critics of universal screening argue that forcing the issue before a woman is psychologically and logistically ready to leave the situation may put her at increased risk of harm and decreased likelihood of success. However, a 2015 Cochrane Review found no evidence of harm resulting from IPV screening. The universal screening approach has not typically addressed the population of male victims of IPV.

Alternatively, targeted screening is performed in some medical settings on patients who present with risk factors for IPV (Box 151.2). Studies have shown that self-administered, written screening tools are more sensitive and are preferred by victims over verbal questioning.

Because IPV has been shown to have a direct effect on the health and well-being of children in the home, the pediatric medical setting is a potential site for IPV screening to occur. Targeted screening practices may focus on families of children with anxiety, depression, or somatization or in situations in which child abuse is suspected. Surveys of mothers generally support IPV screening in the pediatric office setting, and women who have been abused are more likely to seek medical care for their children than for themselves. Sensitivity to whether children should witness discussions of positive screening questions is necessary, because older children may react to or repeat portions of an overheard conversation, ultimately placing the victim, their mother, at increased risk of harm.

Physical Examination

Caregiver Injuries

Although blunt trauma from a hand or fist is the most common scenario for the abused partner, IPV can result in injuries from penetrating trauma. Injury can occur on any part of a victim's body; however, studies have shown that trauma to the head, neck, and face is most specific for IPV as the etiology compared with other traumatic events. Findings may also include bruising of the bilateral upper arms from being grabbed and patterned injury from being hit with an object. Strangulation may result in bruising or abrasions on the neck, facial petechiae, or subconjunctival hemorrhage.

Child Injuries

Children in the home in which IPV is occurring are at increased risk of physical abuse, and a complete unclothed physical examination should be performed to look for evidence of skin, head, skeletal, or abdominal trauma. Accidental injuries typically result in cutaneous bruises over bony prominences, such as knees and elbows, anterior shins, and the forehead. Unusual areas for accidental injury include the neck, ears, cheeks, medial thighs, and genital area. If physical abuse is suspected, additional radiographic imaging and an ophthalmologic examination may be indicated (see Chapter 144).

Management

The response to any disclosure of IPV should be supportive and focus on a safety assessment to determine the severity and immediacy of danger (Box 151.3). This should include an assessment of the pattern of escalating violence, availability of weapons to the abuser, and comfort level of the victim to return home. More imminent danger necessitates the creation of an emergent safety plan, and social work colleagues or professionals from an IPV shelter, hotline, or advocacy organization can assist with this. It is important for the physician to remain sensitive to the fact that leaving an abusive home is disruptive to the daily lives of the adult and child victims and may be a difficult step to take.

Box 151.3. Components of Safety Assessment

- Is the violence escalating?
- How severe has the violence been in the past?
- Is the victim comfortable returning home?
- Is child abuse occurring?
- Are weapons available to the perpetrator?
- Does the perpetrator have substance abuse issues or a mental health disorder?
- Does the victim have a social support network?

If immediate safety is of less concern, a victim may opt to take more time in creating a safety plan for leaving. This may include things such as collecting money, car keys, house keys, and important documents; asking neighbors to contact police if violence is overheard in the home; establishing a code that the victim can use to communicate to others that violence is occurring and that prompts the contact to take certain action on use of the code; and disarming or removing weapons from the home.

Although all states require that medical professionals report cases of suspected child abuse and neglect to child protective agencies, mandated reporting statutes for IPV and child exposure to IPV vary. State statutes fall into the following general categories with respect to IPV: requirement to report injuries caused by weapons, requirement to report injuries resulting from a crime, requirement to report IPV, and no mandatory reporting law. For those states with no mandatory reporting requirement, factors that may influence a physician's decision to report may include the potential for danger, the caregiver's ability to plan for safety, a victim's level of connection to family or community support, and the degree of suspicion that a child's exposure to IPV constitutes emotional abuse. Online resources, such as the *Compendium of State Statutes and Policies on Domestic Violence and Health Care,* published by the Family Violence Prevention Fund in 2010, can assist with the determination of local state laws on mandatory reporting of IPV. Any suspicion of child abuse should be reported to child protective services, regardless whether IPV is being reported as well. If child abuse and IPV are co-occurring, it is important to note this in the child abuse report so that appropriate measures can be taken in the child protection response. Any child with a history of exposure to IPV should also be referred for trauma-focused mental health services.

Prognosis

Direct victimization from IPV and childhood exposure to IPV are associated with increased risk of adult morbidities. Women who have experienced interpersonal violence are at risk for depression, anxiety, PTSD, and becoming victims of human trafficking, and they are 15 times more likely to abuse alcohol and 9 times more likely to abuse drugs than their peers who do not experience IPV. Childhood exposure to IPV is associated with an increased risk of adult morbidities, including substance abuse disorders, obesity, physical inactivity, depression, and suicide attempts. This is of particular concern because of the limited availability and often limited recognition of the importance of mental health resources in addressing the psychological effect of IPV in both adults and children.

For those women who do disclose the abuse and are referred to advocacy programs, preliminary data indicate that intensive programs may have a beneficial effect on reducing physical violence for several years. For other intervention strategies, the research is often limited and does not yet provide sound evidence of positive effects on physical, emotional, and quality-of-life outcomes. Further research is necessary to determine what components of the programs and what intensity and time frame of involvement are most beneficial in different clinical scenarios.

Although many IPV shelters and advocacy organizations have legal assistance available to victims, most victims do not obtain temporary restraining orders. Of those who do, in approximately two-thirds of cases the orders are violated by the abuser. Most cases are not prosecuted, and for those cases that do progress in the legal system, courts often struggle with how to address the IPV issues in the child custody and family treatment plans. Although multiple models of treatment programs exist for perpetrators of IPV, the evidence for sustained change in behavior is unclear. Barriers to behavior change include substance abuse, mental health issues, and relationship dynamics. Further research is necessary to modify treatment approaches to reduce recidivism.

Prevention

Prevention efforts may be primary, secondary, or tertiary. In this setting, primary prevention includes attempts to change social norms of violence and acts at the level of the individual, relationship, or community. Current efforts in primary prevention include attempts to break the generational cycle by studying and supporting resilience factors in those who do not perpetuate violence after childhood exposure, the development of safe dating programs to reduce adolescent dating violence, the creation of peer empowerment programs for adolescents and young adults to enhance their ability to identify and intervene in IPV that they witness, and the development of family-based interventions to enhance nonviolent communication skills.

Secondary prevention includes early detection of IPV, and a significant amount of research is underway on screening practices in the medical setting. Tertiary prevention is the attempt to prevent death and disability in families in which IPV occurs.

Sound research on IPV prevention remains a work in progress. Much of the current research has had methodological challenges, and many prevention strategies are not yet validated by sound evidence of benefit. Additionally, traditional thinking has been that most abusers are male and most victims are female, and prevention programs were built on this premise. Recent data, however, suggest that females also instigate IPV, so the subtleties of the patterns of violence of men versus women and how best to prevent them is a new area for growth and understanding.

CASE RESOLUTION

When alone with you, the mother reports that the boy's bruising occurred after her boyfriend hit him with a belt and that her marks occurred when the boyfriend was drunk and angry about the dinner she had prepared. She has contemplated leaving the relationship but is financially dependent on her boyfriend and pregnant with his child. He has threatened to harm her son if she leaves. She is afraid to return home but is not sure what to do.

You contact a social worker who assists in referring the mother and child to an IPV shelter and an IPV advocacy group. The social worker and the agencies work on an immediate safety plan while the mother and child wait in the office. As a mandated reporter of child abuse, you contact the child abuse hotline. The social worker assists you with the requirements in your state to report IPV or childhood exposure to IPV. The mother should be advised that a child abuse report was initiated, and child protective authorities should also be made aware that IPV and child abuse are co-occurring in this family.

PART 15

Chronic Diseases of Childhood and Adolescence

CHAPTER 152

Cancer in Children

Eduard H. Panosyan, MD; Moran Gotesman, MD; and Joseph L. Lasky III, MD, FAAP

CASE STUDY

A 10-year-old boy has a history of intermittent fevers of 39.0°C (102.2°F) for 1 month. For 2 days, he has experienced increasing shortness of breath with rapid respirations. His face is dusky and plethoric, and the veins in his neck are prominent. He has bilaterally enlarged cervical lymph nodes. The remainder of the examination is normal.

His blood cell count is normal, but the erythrocyte sedimentation rate is 110 mm/h. A chest radiograph reveals a large mediastinal mass.

Questions

1. What signs and symptoms are associated with malignant conditions in children?
2. What oncologic emergencies require immediate attention?
3. What factors correlate with the manifestation of cancer in children?
4. What is the role of the primary care physician in the care of the child diagnosed with cancer?

Epidemiology

Childhood cancer is rare. Approximately 12,400 children and adolescents younger than 20 years are diagnosed with cancer each year in the United States. The likelihood of a child developing cancer before the age of 20 years is 1 in 300 for males and 1 in 333 for females. The overall incidence of childhood cancer has been slowly increasing since the mid-1970s, but death rates have declined dramatically for most childhood cancers and survival rates have improved markedly since the 1970s. Cancer remains the leading disease-related cause of death in children younger than 15 years, however. The prevalence of cancer is higher in children younger than 5 years and in children between the ages of 15 and 19 years. Acute hematologic malignancies, sarcomas, and embryonic neoplasms with fewer mutations are more typical in the pediatric age group compared with adults, who develop genetically more complex cancers and carcinomas of epithelial origin. Acute leukemia is the most common childhood cancer, followed by brain tumors, lymphomas, neuroblastoma, Wilms tumor (ie, nephroblastoma), and other less common pediatric solid tumors (Figure 152.1).

Environmental factors, genetic predisposition, and developmental processes may all play a role in influencing the cancer risk of a child. Case-control epidemiology studies looking for the causes of pediatric cancer have evaluated foods, prenatal exposures of parents and affected offspring, electromagnetic fields, radon, and various other environmental factors with no conclusive evidence of causality to date. Although many environmental factors are known to induce carcinogenesis, current evidence does not support a major causative role for exogenous factors in childhood cancer. Most childhood cancers result from aberrations in early developmental processes. Some known risk factors for selected childhood cancers include infectious agents, such as Epstein-Barr virus (eg, B-cell lymphomas, Hodgkin lymphoma, nasopharyngeal carcinoma), HIV (eg, B-cell lymphomas, Kaposi sarcoma, leiomyosarcoma), and hepatitis B and C (eg, hepatocellular carcinoma); ionizing radiation (eg, leukemia, osteosarcoma, brain tumors); chemotherapeutic agents (eg, leukemia, osteosarcoma); immunodeficiency (eg, non-Hodgkin lymphoma); and genetic conditions. Approximately 4% to 10% of childhood cancer results from known inherited genetic mutations that result in a cancer predisposition. Children with trisomy 21 syndrome (ie, Down syndrome) have an increased risk of leukemia (eg, lymphoid and myeloid). Beckwith-Wiedemann syndrome is associated with an increased risk for hepatoblastoma, Wilms tumor, rhabdomyosarcoma, and neuroblastoma and warrants appropriate surveillance screening. Inheritance of mutations in tumor suppressor genes, such as the retinoblastoma gene or the p53 gene, predispose affected children in families with these mutations (eg, Li-Fraumeni syndrome) to particular malignancies at a greater frequency and an earlier age than in unaffected individuals. Some children with tuberous sclerosis or neurofibromatosis 1 will develop multiple types of brain tumors.

Clinical Presentation

Signs and symptoms of childhood cancer are varied, are often nonspecific initially, and can mimic many common pediatric conditions (Table 152.1). Acute lymphoblastic leukemia (ALL) is the most common childhood cancer, accounting for 80% of pediatric leukemia cases. Acute myeloid leukemia accounts for the remaining 15% to 20% of cases. The child with acute leukemia presents with signs and symptoms that reflect leukemic infiltration of the bone marrow and extramedullary locations. Presentation with generalized bone pain and signs and symptoms related to pancytopenia (ie, fever, fatigue, pallor, bleeding, bruising, infections) is common. Disseminated intravascular coagulation is more characteristic of acute myeloid leukemia, especially acute promyelocytic leukemia.

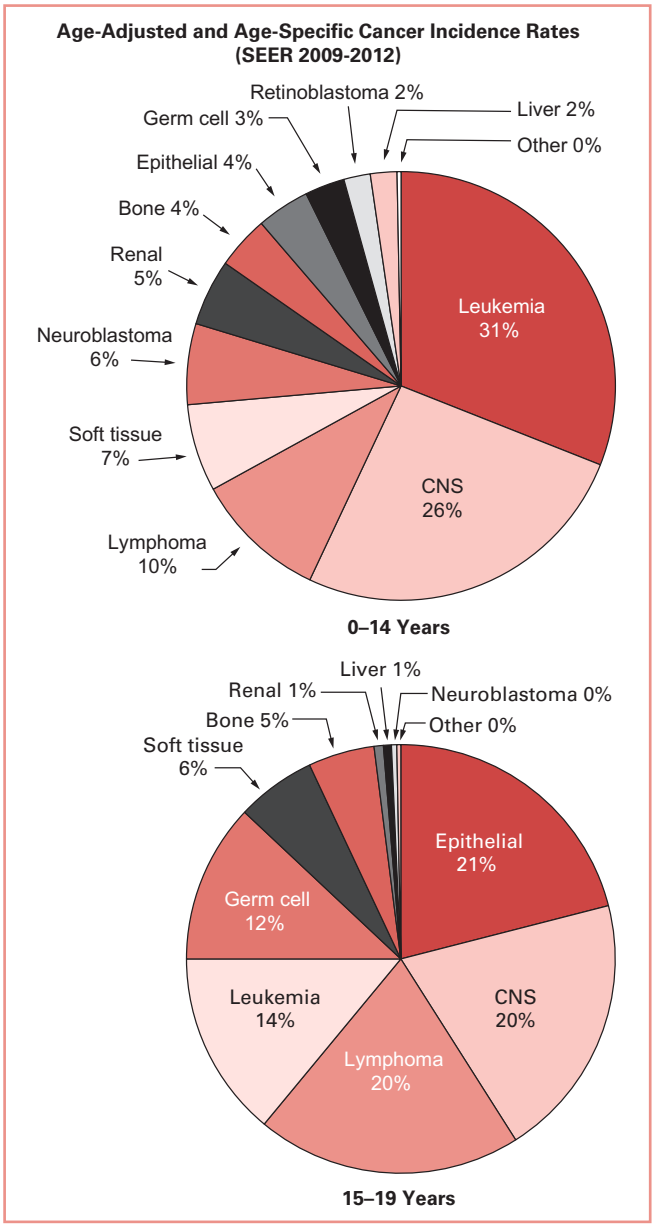

Figure 152.1. Cancer incidence rates for patients aged 0 through 14 years and 15 through 19 years in the Surveillance, Epidemiology, and End Results (SEER) Program from 2009 through 2012 by International Classification of Childhood Cancer group and subgroup and age at diagnosis, including myelodysplastic syndrome and group III benign brain/central nervous system tumors for all races for males and females. Incidence rates are age-adjusted and age-specific and are shown for leukemia, lymphoma, central nervous system (CNS) tumors, neuroblastoma, retinoblastoma, renal tumors, hepatic tumors, bone tumors, soft tissue tumors, germ cell tumors, carcinomas and melanomas, and other cancers. Retinoblastoma occurs infrequently in adolescents aged 15 through 19 years. Reprinted from Unusual Cancers of Childhood Treatment (PDQ®)–Health Professional Version. National Cancer Institute website. https://www.cancer.gov/types/childhood-cancers/hp/unusual-cancers-childhood-pdq#_105. Accessed November 26, 2019.

Leukemic infiltration of extramedullary sites can result in hepatosplenomegaly, lymphadenopathy, *chloroma* (ie, a green-colored tumor of myeloid cells), central nervous system (CNS), and sometimes testicular involvement. The child with high white blood cell counts at presentation, as in leukocytosis, can present with signs and symptoms of leukostasis typically involving the lung or brain. Tumor lysis syndrome can occur spontaneously or with the initiation of intravenous (IV) hydration or chemotherapy. Tumor lysis syndrome occurs as a result of breakdown of leukemic blasts that results in the release of metabolic by-products. It is characterized by a metabolic triad of hyperuricemia, hyperkalemia, and hyperphosphatemia, which places a child at risk for renal dysfunction or failure secondary to precipitation of urate or calcium phosphate crystals within the renal tubules. Involvement of the CNS by leukemia can result in signs of increased intracranial pressure (ICP), such as headache, vomiting, hypertension, seizures, and cranial neuropathies.

T-cell ALL or T-cell lymphoblastic lymphoma can present with a large anterior mediastinal mass and symptoms related to compression by the mediastinal mass on the trachea and blockage of venous return and lymphatic drainage, that is, *superior vena cava syndrome* (SVC syndrome). The child with SVC syndrome can present with wheezing, dyspnea, dysphagia, plethora, and cyanosis. Pleural or pericardial effusions may also be present. Superior vena cava syndrome can rapidly progress and constitutes a true oncologic emergency that requires prompt intervention.

Lymphomas in children can be divided pathologically into Hodgkin or non-Hodgkin lymphoma. The child with Hodgkin lymphoma typically has a prolonged history (often ≥2–3 months' duration) of painless enlarging cervical or supraclavicular lymphadenopathy. Affected lymph nodes can be firm, immobile, rubbery, and nontender. In two-thirds of cases, mediastinal adenopathy may be present, resulting in cough or wheeze. Constitutional symptoms, such as fatigue, pruritus, and anorexia can occur, as well as the classic "B" symptoms (ie, fever, night sweats, and weight loss ≥10% of body weight). Non-Hodgkin lymphoma can be distinguished as lymphoblastic or nonlymphoblastic. The child with lymphoblastic lymphoma often presents with supradiaphragmatic disease and may have cervical or supraclavicular lymphadenopathy, sometimes in association with a mediastinal mass or SVC syndrome (as previously described for T-cell lymphoblastic lymphoma). Central nervous system disease in such children is associated with signs of increased ICP. The patient with nonlymphoblastic lymphoma of the Burkitt or non-Burkitt type often presents with intra-abdominal disease that can manifest as intussusception, abdominal obstruction, hepatosplenomegaly, or obstructive jaundice. The child with sporadic Burkitt lymphoma can present with a rapidly enlarging abdominal mass associated with tumor lysis syndrome. Endemic Burkitt lymphoma (ie, African lymphoma) presents with facial or isolated jaw tumors. Additionally, the patient with lymphoma is at risk for developing 1 or more paraneoplastic syndromes. These include idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia, nephrotic syndrome, and peripheral neuropathies, which may be mediated by abnormal and lymphoma-driven humoral or cell-mediated processes. The child with lymphoma is also at risk for tumor lysis syndrome as described for leukemia. Generally, a patient may have entirely normal blood cell counts or a mild anemia, but occasionally the bone marrow may be infiltrated, giving a clinical picture similar to leukemia with anemia, thrombocytopenia, or neutropenia.

Table 152.1. Signs and Symptoms of Childhood Cancer

Disease	*Symptoms*	*Signs*
Leukemia	Fatigue, pallor Bone pain Fever, infection Bruising, bleeding Disseminated intravascular coagulation Superior vena cava syndrome Headache Seizures Oliguria/anuria Abdominal pain, diarrhea	Anemia Neutropenia Thrombocytopenia Lymphadenopathy Hepatosplenomegaly Mediastinal mass Petechiae, purpura Papilledema Cranial neuropathies Renal failure
Brain tumors	Supratentorial tumors Seizures Visual dysfunction Unilateral motor dysfunction Infratentorial tumors Deficits of balance Difficulty breathing Increased intracranial pressure Headache Vomiting Diplopia Motor weakness Loss of developmental milestones	Upper motor neuron signs Marcus Gunn pupils Parinaud syndrome Diabetes insipidus Appendicular dysmetria Sixth nerve palsy Cranial neuropathies Horner syndrome Papilledema Systemic hypertension Setting sun sign Large head size
	Lymphoma	
Non-Hodgkin	Supradiaphragmatic (ie, lymphoblastic) Respiratory difficulty, cough Superior vena cava syndrome Enlarged/enlarging lymph nodes Infradiaphragmatic (small, non-cleaved) Abdominal obstruction Intussusception Abdominal distension	Mediastinal mass ± effusions Lymphadenopathy Abdominal mass Hepatosplenomegaly Obstructive jaundice
Hodgkin	Constitutional symptoms (ie, fever, weight loss, pruritus)	Lymphadenopathy ± matted nodes
Neuroblastoma	Skin nodules Proptosis, raccoon eyes Nystagmus Diarrhea Spinal cord compression symptoms	Hypertension Abdominal mass Hepatosplenomegaly Horner syndrome
Rhabdomyosarcoma	Related to primary site (eg, urinary retention with genitourinary tumors)	Head and neck mass Extremity swelling/mass
Wilms tumor	Rapid development of abdominal swelling Painless hematuria	Abdominal or flank mass Hypertension Associated congenital anomalies Aniridia Hemihypertrophy Urogenital anomalies
Ewing sarcoma	Painful swelling of bone or surrounding soft tissues Constitutional symptoms (ie, fever, fatigue)	Pathologic fracture
Osteosarcoma	Painful swelling of bone	Pathologic fracture

The child with brain tumor can present with diverse signs and symptoms, depending on the anatomic location of the tumor (ie, subtentorial, supratentorial, or brain stem), age of the child (eg, infants with open sutures), and presence and degree of increased ICP. Subtentorial tumors, which are more common in children than adults, typically present with gaze palsies, cerebellar signs (especially truncal ataxia), dysmetria, or vomiting. Supratentorial tumors can cause seizures, upper motor neuron signs (ie, hemiparesis, asymmetrical hyperreflexia, and clonus), sensory changes, behavioral changes, decreased school performance, and disorders of the midbrain (eg, *Parinaud syndrome* [ie, paralysis of upward gaze]). Signs and symptoms of ICP are often in the forefront of complaints. Recurrent morning headaches, headaches that awaken the child at night, intense headaches, vomiting (often followed by temporal relief of morning headaches), lethargy, setting sun sign (ie, eyes deviating downward like a sun setting on the horizon), increasing head circumference and loss of developmental milestones in infants, and change in school performance in older children all warrant close evaluation. Certain conditions, such as tuberous sclerosis and neurofibromatosis 1, should increase the index of suspicion for brain tumor. Primary tumors intrinsic to the brain, that is, those of glial, neural, or choroid plexus origin, and extrinsic to the brain (ie, craniopharyngioma, germ cell tumor) are encountered most often in the pediatric population. Neural/embryonic tumors, such as medulloblastomas and primitive neuroectodermal tumors, are more typical for childhood age group. Metastatic brain lesions are less common in children than adults but may be encountered with neuroblastomas, lymphomas, or some renal tumors.

The child with spinal cord involvement from a primary spinal tumor or a paraspinal tumor (eg, neuroblastoma, Ewing sarcoma, leukemic chloroma) may present with persistent back pain, intense radicular pain, local bony tenderness of the affected vertebrae, abnormal reflexes, abnormal dermatomal sensory examination, weakness/evolving paralysis, and subtle symptoms of bowel or bladder dysfunction (ie, constipation, difficulty urinating). Suspicion of a spinal cord compression is an oncologic emergency for which timely, appropriate consultation must be sought.

Neuroblastoma is a malignancy of sympathetic ganglionic cell origin and can arise anywhere along the sympathetic nervous system. Most tumors arise in the adrenal or paraspinal region of the abdomen; additional sites include the neck, chest, pelvis, and, rarely, CNS. At presentation, tumors may be localized, with or without regional lymph node extension, or disseminated involving bone, bone marrow, liver, and CNS. The child with localized disease often is asymptomatic and the tumor is detected when radiographic imaging is performed for other medical purposes. The child with disseminated disease is ill-appearing and may present with fever, bone pain, and irritability. Paraneoplastic syndromes may also be present at diagnosis, with a variety of features, such as opsomyoclonus/myoclonus/ataxia (ie, random dysconjugate eye movements, myoclonic jerking), cerebellar ataxia, and diarrhea. Proptosis and hemorrhage caused by metastases involving the periorbital region can result in periorbital swelling and ecchymoses (ie, raccoon eyes). A cervical tumor may be associated with unilateral Horner syndrome (ie, unilateral ptosis, miosis, and anhidrosis). Central nervous system metastasis may present with signs and symptoms of increased ICP.

Nephroblastoma or Wilms tumor, an embryonic tumor of the kidney, usually presents as a painless abdominal mass, often detected by a parent while bathing the child. Associated symptoms may include fever, abdominal pain, or hematuria. Abdominal trauma can result in rupture and hemorrhage of these bulky masses, and a child may present with acute abdominal pain and swelling. On examination, the child may have hypertension, stigmata of associated genetic syndromes (eg, Beckwith-Wiedemann, Denys-Drash), or another isolated congenital anomaly, such as aniridia, hemihypertrophy, or hypospadias.

Bone sarcomas that occur in children include Ewing sarcoma, osteosarcoma, and other rarer sarcomas. These tumors are most common in adolescents and rarely occur in young children. Bone tumors can present with pain at the site of tumor, with or without an associated soft tissue mass. Osteosarcomas classically involve the metaphyseal portions of the long bones, with the distal femur and proximal tibia being the most frequently involved sites. Metastatic disease, which is present in 15% to 20% of cases, primarily involves the lung, although other sites of bone can be involved. Ewing sarcomas that occur in bone most commonly involve the flat bones of the axial skeleton. When affecting the long bones, they tend to arise in the diaphyseal region (unlike osteosarcoma). Twenty-five percent of cases will have metastatic disease at presentation involving lung, bone, or bone marrow. The child with Ewing sarcoma may also have associated constitutional symptoms, such as low-grade fever, fatigue, and weight loss. Extraosseous soft tissue components are also more common with Ewing sarcomas than osteosarcomas.

Rhabdomyosarcomas, which account for approximately one-half of the soft tissue sarcomas in children, present with signs and symptoms dependent on the location of the primary tumor. Sites include the head, neck, chest, abdomen, genitourinary tract, or extremities. Less than 25% of children will present with metastatic disease, but when present it can involve lymph nodes, lungs, bone marrow, and bone. Head and neck sarcomas commonly arise in parameningeal and orbital sites and can present with recurrent headache, vomiting, visual problems, and proptosis. Abdominal and pelvic primary tumors can present with a palpable abdominal mass, pain, constipation, urinary obstruction, or dysuria. Genitourinary tract tumors most often involve the bladder or prostate and can present with pain, constipation, and urinary obstruction. One classic presentation occurs in girls who present with a grape-like mass at the introitus and vaginal bleeding; this is caused by tumor involving the vagina or uterus and is known as *sarcoma botryoides*. Primary tumors involving an extremity present with swelling at the site of tumor that can be painful and tender on palpation.

Pathophysiology

Although the macroscopic causes of pediatric cancer are not well elucidated, significant progress has been made in determining some of the cellular and molecular events that actively trigger or fail to prevent malignancy. Growth factors are responsible for stimulation

of cellular proliferation, and growth factor receptors transduce this signal into the cell via cytoplasmic secondary messengers, which in turn transmit the signal to nuclear regulatory factors. These factors ultimately regulate transcription of new RNA and protein, resulting in the desired cellular response of stimulation or inhibition of growth. Malignant cells have a genetic makeup that differs from the constitutional karyotype of the host. A series of mutations occurs in genes that regulate cell growth and differentiation, resulting in dysregulation of cell growth, differentiation, and death. Oncogenes promote cell growth and tumor suppressor genes inhibit cell division. With inappropriate overexpression of an oncogene or underexpression of a tumor-suppressor gene, inappropriate cell growth and division may occur, resulting in a malignant transformation.

Usually, multiple genetic aberrations are present that result in malignant transformation of a cell. One of the most important tumor suppressor genes is *p53*. The *p53* gene encodes for a nuclear protein that is expressed in all cells of the body and serves to induce cell cycle arrest or apoptosis in response to DNA damage. Inactivation of *p53* has been identified in numerous cancers. An initial event can alter or knock out 1 allele of a *p53* gene pair, and a second event results in loss of heterozygosity for that genetic locus. An inherited abnormality of *p53* (ie, Li-Fraumeni syndrome) or a serendipitous accident to *p53* can cause heterozygosity for that gene. If a second event knocks out complete function of *p53*, a DNA-damaged cell can escape the signal to arrest its growth or undergo apoptosis. The result can be a malignant transformation that allows the abnormal cell to grow unchecked. The retinoblastoma gene is another classic and well-studied tumor suppressor, the loss of which results in malignant transformation of the cell.

The threat of cancer to a living organism lies in its uncontrolled growth. By growing unchecked and invading, compressing, and metastasizing to vital organs, malignant cells threaten normal life functions and cause symptoms specific to the affected area of the body.

Differential Diagnosis

Cancer is rare and often challenging to diagnose in children. Many of the presenting symptoms can be nonspecific and easily attributed to more common childhood conditions. To add to the difficulty, a pediatric practice will, on average, see a case every 5 to 7 years. Differential diagnoses for some common childhood symptoms that may suggest an underlying malignancy are discussed herein.

Lymphadenopathy is a common pediatric physical finding and is most frequently the result of infection (see Chapter 100). Acute bacterial adenitis, usually involving the head and neck region, is typically associated with local signs of inflammation, such as erythema, warmth, and tenderness. Cervical adenopathy resulting from viral illness is typically bilateral, and the lymph nodes are usually mobile, soft, and nontender. Generalized lymphadenopathy or regional lymphadenopathy characterized by firm, matted, rubbery lymph nodes should raise the suspicion for an underlying malignancy. Lymphadenopathy that is persistent or progressive, despite empiric antibiotic therapy or resolution of infectious symptoms, also merits further evaluation for malignancy. Leukemia often presents with generalized lymphadenopathy, usually in association with hepatosplenomegaly and abnormal laboratory findings. Lymphoma typically presents with regional lymphadenopathy, often in the cervical or mediastinal region, in conjunction with other signs of systemic illness. Metastatic disease (eg, neuroblastoma, rhabdomyosarcoma) may also present with regional lymphadenopathy. Nonmalignant causes of neck masses that can be mistaken for cervical lymphadenopathy include structural anomalies, such as branchial cleft cysts or cystic hygromas (see Chapter 94).

Bone and joint pain are common symptoms in children with acute leukemia because of bone marrow involvement and may be generalized. This presentation can be confused with various rheumatologic conditions. Localized bone pain is a common presentation for the child with primary bone cancer (eg, osteosarcoma, Ewing sarcoma) and often is attributed by the child or parent/guardian to some trauma. It is not unusual for the diagnosis to be delayed several months. Differential diagnosis includes infection (eg, osteomyelitis), trauma, musculoskeletal conditions, and benign bone lesions.

Headache is a common symptom encountered by the general pediatrician, and few of these headaches are caused by intracranial brain tumors (see Chapter 129). When evaluating a child with headaches, signs to raise the index of suspicion for a brain tumor include persistent vomiting, recurrent morning headaches or headaches that awaken the child, worsening headaches, associated neurologic abnormalities, and visual changes (eg, papilledema on examination). In infants, increasing head size, setting sun sign, and loss of acquired developmental milestones are red flags. The differential diagnosis for headaches in children is broad and includes infections (eg, meningitis, sinusitis), migraines, hydrocephalus, hemorrhage, and seizures.

An abdominal mass in an infant or child is always concerning and merits an evaluation. The most common malignant causes for an abdominal mass in this age range include neuroblastoma, nephroblastoma (ie, Wilms tumor), hepatoblastoma, non-Hodgkin lymphoma (ie, Burkitt lymphoma), sarcomas, and germ cell tumors. Massive hepatosplenomegaly resulting from leukemic or lymphomatous infiltration can also be palpated as an abdominal mass. Nonmalignant etiologies of an abdominal mass may include hepatomegaly or splenomegaly, renal cysts, hemangiomas, or constipation.

Pancytopenia or single cytopenias are always worrisome for a malignancy involving bone marrow. Acute leukemia is the most common malignancy involving bone marrow and can present with leukopenia, anemia, thrombocytopenia, or any combination of these. Any malignancy that can metastasize to the bone marrow (eg, neuroblastoma, lymphoma, Ewing sarcoma, rhabdomyosarcoma) can also produce pancytopenia or depression of 1 of the cell lines resulting from replacement of the bone marrow. Pancytopenia can also occur as a primary bone marrow failure syndrome, such as Fanconi anemia, or as an acquired aplastic anemia resulting from infections (eg, post-hepatitis), drugs (eg, chloramphenicol, anticonvulsant agents), radiation, or idiopathic causes. Transient mild depression

of the cell lines (most often leukopenia or anemia) from infectious causes is quite common during childhood. Depression of more than 1 hematopoietic cell line merits a closer evaluation and consultation with a pediatric hematologist.

Evaluation

History

The history should focus on the duration and evolution of symptoms as well as the presence or absence of constitutional symptoms (eg, anorexia, fever, night sweats, weight loss). The effect of the symptoms on daily activities (eg, school attendance, sports) should be determined and will clue the physician to the scope of the illness. The presence of recent or persistent infections, medications (especially steroids), or unusual environmental exposures should also be ascertained (Box 152.1). Relevant medical history should be considered. A previous cancer diagnosis would raise the index of suspicion for relapse or a secondary malignancy. Certain immunodeficiencies and genetic syndromes are associated with an increased risk for malignancy (eg, trisomy 21 syndrome and leukemia) and should also be considered. A family history of childhood cancers or genetic syndromes is also important.

Physical Examination

A thorough physical examination is essential, with particular attention paid to symptomatic areas (Table 152.1). Generally, the lymph nodes should be carefully assessed for enlargement or malignant characteristics (ie, firm, fixed, rubbery nodes or nodular conglomerates) and the abdomen for organomegaly or masses. The skin should be evaluated for the presence of pallor, petechiae, or purpura that would suggest anemia or thrombocytopenia. A thorough search for signs of persistent infection should be performed and, if present, may reflect bone marrow disease with neutropenia. Neurologic symptoms, including headache, vomiting, or focal concerns, warrant a full neurologic examination. Increased ICP may manifest as papilledema or sixth nerve palsy. In the infant, increased ICP can manifest with a large head size, full fontanels, or setting sun sign. A report of back pain also merits a full neurologic examination with close attention to any sign of spinal cord compression that may be suggestive of a possible spinal or paraspinal mass.

Box 152.1. What to Ask

Cancer

- How long has the child had the symptoms?
- Does the child have a family history of cancer?
- Does the child have a history of constitutional symptoms (eg, fever, weight loss, night sweats)?
- Does the child have a history of recent onset of pallor, fever, bleeding and/or bruising, pain, swelling, hematuria, or malaise?
- Has the child been attending school or participating in routine activities?
- Has the child been exposed to any environmental toxins?
- Has the child been taking antipyretic agents and/or nonsteroidal anti-inflammatory drugs on a regular basis or any prescribed antibiotics or steroids?

Laboratory Tests

In a child with nonspecific or constitutional symptoms concerning for malignancy, it is reasonable to begin with a complete blood cell count, peripheral blood smear, and comprehensive chemistry panel (eg, electrolytes, renal and liver function). If a malignancy is suspected, lactate dehydrogenase is useful as a nonspecific marker for increased cell turnover. If leukemia or lymphoma is suspected, evaluation for tumor lysis syndrome (by checking uric acid, potassium, phosphate, and calcium) should be performed. Additionally, certain tumors secrete or synthesize characteristic markers and metabolites that are pathognomonic for their diagnosis. For example, elevated levels of the sympathetic neurotransmitter metabolites vanillylmandelic acid and homovanillic acid are found in the urine of individuals with neuroblastoma or pheochromocytoma. Tumor markers, such as α-fetoprotein and β-human chorionic gonadotropin, are characteristic of germ cell tumors. Additionally, α-fetoprotein is a useful tumor marker for hepatoblastoma and, rarely, pancreatoblastoma as well. Monitoring of these levels is useful as an indicator of response to therapy or relapse. Other laboratory values, such as ferritin or erythrocyte sedimentation rate, can be elevated and reflect an underlying systemic illness (Table 152.2).

Imaging Studies

Radiologic studies are a necessity in the initial evaluation and staging of most childhood cancers. After the diagnosis of malignancy has been confirmed, appropriate imaging studies to assess the local and metastatic spread of the disease should be performed before the initiation of therapy. The type of studies performed depends on the specific malignancy and its associated pattern of metastatic spread. Common studies performed include plain radiography, computed tomography, magnetic resonance imaging, and gallium or positron emission tomography scans. For leukemias and lymphomas, an initial chest radiograph is necessary to evaluate for a mediastinal mass (most commonly seen in T-cell leukemia/lymphoma). Additional imaging is typically not necessary for leukemia; however, lymphomas warrant further diagnostic imaging for staging, whether computed tomography or gallium or positron emission tomography scans. Required imaging for evaluation of specific childhood cancers is provided in Table 152.2.

Pathology

The child with suspected malignancy should be referred to a children's cancer center where there are specialized pediatric oncologists, radiologists, surgeons, and pathologists who can work together to establish the best approach for diagnosis, whether biopsy or removal of tumor, and handling of tissue. Collection of fresh tissue at biopsy for specialized genetic testing and tumor banking is important and can contribute significantly to a complete pathologic diagnosis.

For certain clinical scenarios, obtaining tissue for pathologic diagnosis is difficult. The child who presents with a large mediastinal mass may be in respiratory distress, for example, secondary to SVC syndrome, and at high risk during anesthesia. In this situation, coordinated

Table 152.2. Diagnostic Tests and Imaging Studies Used in the Evaluation of Common Childhood Cancers

Disease	*Diagnostic Tests*[a]	*Imaging Studies*
Leukemia	Bone marrow aspirate and biopsy Cytogenetic analysis of bone marrow CBC with platelet count, differential, reticulocytes Flow cytometry of peripheral blood PT, PTT, fibrinogen Serum electrolytes, Ca, PO_4 BUN, creatinine, uric acid, LDH CSF cell count, differential, cytology	Chest radiography (look for mediastinal mass) Abdominal ultrasonography for hepatosplenomegaly
Brain tumors	In case of suspected germ cell tumors: serum and CSF α-fetoprotein, β-human chorionic gonadotropin, carcinoembryonic antigen CSF cytology for medulloblastomas, primitive neuroectodermal tumors and ependymomas	MR imaging of brain with gadolinium MR imaging of spine for selected tumors
Lymphoma	CBC with platelet count, differential, reticulocytes Bilateral bone marrow aspirate and biopsy CSF cell count and cytology (EBV PCR for immunocompromised patients with suspected CNS lymphoma) Serum LDH, electrolytes, Ca, PO_4 ESR, ferritin	Gallium scan, PET scan CT of chest, abdomen, pelvis Brain MR imaging for CNS lymphomas
Neuroblastoma	CBC with platelet count, differential Serum electrolytes, liver and renal panel Serum ferritin Serum LDH, uric acid Urine HVA and VMA Bone marrow aspirate and biopsy	CT or MR imaging of primary tumor site CT of chest, abdomen, pelvis (± head) with contrast Bone scan Iobenguane scan
Rhabdomyosarcoma	CBC with platelet count, differential Electrolytes, liver and renal panel Bone marrow aspirate and biopsy CSF cell count and cytology (head and neck primary parameningeal tumors only)	CT or MR imaging of primary tumor site CT of chest, abdomen, pelvis Bone scan, PET scan
Nephroblastoma (ie, Wilms tumor)	CBC with platelet count, differential Electrolytes, liver and renal panel Urinalysis PT, PTT, fibrinogen	Chest radiograph CT of primary tumor site Ultrasonography of inferior vena cava CT of chest Bone scan
Ewing sarcoma	ESR CBC with platelet count Bone marrow aspirate and biopsy Serum LDH	Plain radiographs of primary site CT or MR imaging of primary tumor site CT of chest Bone scan
Osteosarcoma	Bone biopsy	Plain radiographs of primary site CT or MR imaging of primary tumor site CT of chest Bone scan
GCTs (extracranial)	Serum α-fetoprotein β-human chorionic gonadotropin Carcinoembryonic antigen	Chest radiograph (for thoracic lesions) Abdominal (or testicular) ultrasonography CT or MR imaging of primary tumor site CT of chest

Abbreviations: BUN, blood urea nitrogen; Ca, calcium; CBC, complete blood cell count; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EBV, Epstein-Barr virus; ESR, erythrocyte sedimentation rate; GCT, germ cell tumor; HVA, homovanillic acid; LDH, lactate dehydrogenase; MR, magnetic resonance; PCR, polymerase chain reaction; PET, positron emission tomography; PO_4, phosphate; PT, prothrombin time; PTT, partial thromboplastin time; VMA, vanillylmandelic acid.

[a] Tumor biopsy (with few exceptions, eg, intracranial GCT secreting α-fetoprotein/β-human chorionic gonadotropin, inoperable brain stem gliomas) is required for diagnoses of most malignancies. Rarely, thoracic or abdominal hematologic lymphomas in an unstable patient may be diagnosed from cytology of pleural effusion or ascitic fluids.

efforts should be made to obtain pathology specimens in the least invasive manner, before the initiation of therapy. Diagnosis often can be made by less invasive procedures (eg, complete blood cell count, peripheral blood flow cytometry, bone marrow aspirate/biopsy, thoracentesis) that may require very minimal sedation. If it is necessary to start therapy, biopsy should be performed as soon as clinically tolerated.

Management

If a diagnosis of cancer is suspected or confirmed in a child, referral to a pediatric cancer center where appropriate diagnostic procedures, tissue handling, and treatment can be provided is important.

Diagnosing and managing childhood cancer requires a multidisciplinary team consisting of pediatric oncologists, surgeons, radiation oncologists, pathologists, and other pediatric subspecialists. Additionally, supportive ancillary services, such as social work, child life, child psychology, pain service, palliative care programs, and religious support, are important. When making a referral for a child with a suspected cancer, the referring physician should prepare the family with the physician's suspicions and the likely workup that will ensue at the accepting center. It is also necessary to initiate robust psychosocial support.

Because the management of specific childhood cancers is beyond the scope of this chapter, the discussion herein focuses on the general principles of pediatric oncologic management. The primary therapeutic modalities for the management of childhood cancer include chemotherapy as a systemic treatment, surgery or radiation for local control, and myeloablative therapies followed by hematopoietic stem cell transplantation. Neoadjuvant (preoperative) chemotherapy sometimes is implemented for solid tumors to make surgery feasible with less morbidity and to treat undetectable micrometastases (too small to detect by scanning) upfront. Increasingly, as the molecular aberrations of cancer are becoming understood, cancer-targeted therapies are becoming more prevalent. Conventional, cytotoxic anticancer therapy is likened to a "shotgun" approach in which cancer cells and normal cells are subject to toxicity. The effects of therapy on normal tissues and organs can manifest acutely (limiting the acute dose) or in the long term (affecting quality of life). As more and more children are surviving childhood cancer, the late effects of therapy are increasingly evident, further emphasizing the need for risk-adapted therapy, cancer-targeted therapy, and a reduction of treatment-related toxicities.

The National Cancer Institute Children's Oncology Group initiated a Pediatric MATCH clinical trial using precision medicine to manage advanced solid tumors in children. This trial first screens for genetic changes in tumor samples in search of druggable targets. If such a target is identified, the patient can be enrolled in a corresponding treatment arm to evaluate efficacy of the drug.

Other advances in this field include immunotherapeutic approaches to manage childhood cancer. Promising examples include chimeric antigen receptor T cells and bispecific antibodies that engage immune cells against refractory leukemias, and monoclonal antibodies against neuroblastoma. Other therapies manipulating natural killer cells are in development.

Optimal outcome depends on several factors, including correct pathologic diagnosis; careful medical management, including administration of chemotherapy and monitoring of side effects; precise customization of radiation fields if radiation therapy is necessary; optimal surgical resection for local control, if indicated; and therapeutic ability and experience with administration of treatment to children. Centers that specialize in the management of pediatric cancer are experienced in the diagnosis and treatment of rare malignancies and are thus best equipped to treat affected children. Additionally, the standard of care for children with cancer is treatment according to research study protocols from national collaborative research groups (eg, Children's Oncology Group), available at most specialized pediatric cancer centers. Posttreatment analysis of children treated on protocols at specialized pediatric cancer centers shows disease-free survival rates that are significantly better than those of children treated outside this setting. Similarly, treatment of adolescents and young adults on protocols at specialized pediatric cancer centers yields better outcomes than in those treated by oncologists who typically treat adults. These differences are perhaps the result of greater biological responsiveness of pediatric cancers, better tolerability of multi-agent chemotherapy regimens by younger patients, and, in part, compliance endorsed by parents.

The placement of indwelling central venous catheters is standard in cancer therapy in pediatric patients, making frequent venous access for diagnostic and therapeutic purposes more easily tolerated by children. External catheters (eg, Broviac, Hickman) or internal subcutaneous catheters are selected depending on the underlying diagnosis and intensity of therapy. All indwelling catheters are at risk for infection from contamination of blood (ie, line infections) or infections around the catheter site itself (ie, tunnel infection). Most central line infections can be managed with IV antibiotic therapy; however, certain pathogens (eg, fungi) are difficult to clear and require line removal. Central venous catheters may also be complicated, with thromboses requiring local thrombolytic therapy or long-term (3–6 months' duration) anticoagulation therapy.

In the interest of cost containment and convenience as well as children's well-being, it is often more feasible for children to be closer to home between chemotherapy cycles. The primary care physician should be familiar with the management of various infectious complications to which children undergoing cancer therapy are subject. Fever in the child with neutropenia (especially with absolute neutrophil count ≤500 cells/μL) requires a different therapeutic approach than fever in the otherwise normal child. Until proven otherwise, the child with fever and neutropenia (usually induced by chemotherapy, sometimes in combination with radiation therapy) must be assumed to have a serious bacterial infection. The patient should be treated accordingly, with hospitalization, prompt initiation of IV antibiotics, thorough examination for site of infection, and careful hemodynamic monitoring. Initial treatment consists of wide spectrum antibiotic coverage for *Staphylococcus aureus,* gram-negative enteric organisms, and *Pseudomonas aeruginosa* (eg, cefepime with or without an aminoglycoside, vancomycin). Additional coverage for anaerobic infection (eg, mucositis), viral infection (eg, herpes stomatitis, varicella), and

other pathogens (eg, fungi) depends on the child's treatment history and clinical findings. Additional proactive supportive care, including aggressive antiemetic, anti-constipation, and analgesic regimens; IV hydration; administration of granulocyte colony-stimulating factors; and blood product transfusions, minimizes complications secondary to intensive chemotherapy. Standard of care for a child undergoing chemotherapy also includes *Pneumocystis jiroveci* prophylaxis. Live vaccines are omitted for these children, usually until near complete immune reconstitution takes place after chemotherapy.

Prognosis

The prognosis for children with all forms of cancer has dramatically improved over the past 4 decades. Nearly 80% of children diagnosed with cancer can expect to be long-term survivors. Figure 152.2 shows the improvement in cure rates for the most common childhood cancers. This success is largely the result of the efforts of national collaborative group science and treatment protocols and best can be exemplified by historical improvements of childhood ALL survival resulting from improved therapies (Figure 152.3). With increased survivorship, however, new concerns have arisen with respect to long-term effects of treatment, risks of secondary malignancies, and complex social and psychological issues. In a large study of childhood cancer survivors, adults treated for a childhood cancer in the 1970s and 1980s were 3 times more likely than their siblings to have developed a chronic health condition. Risk-adapted therapies and continued multidisciplinary surveillance of childhood cancer survivors through adulthood will help to optimize more favorable outcomes.

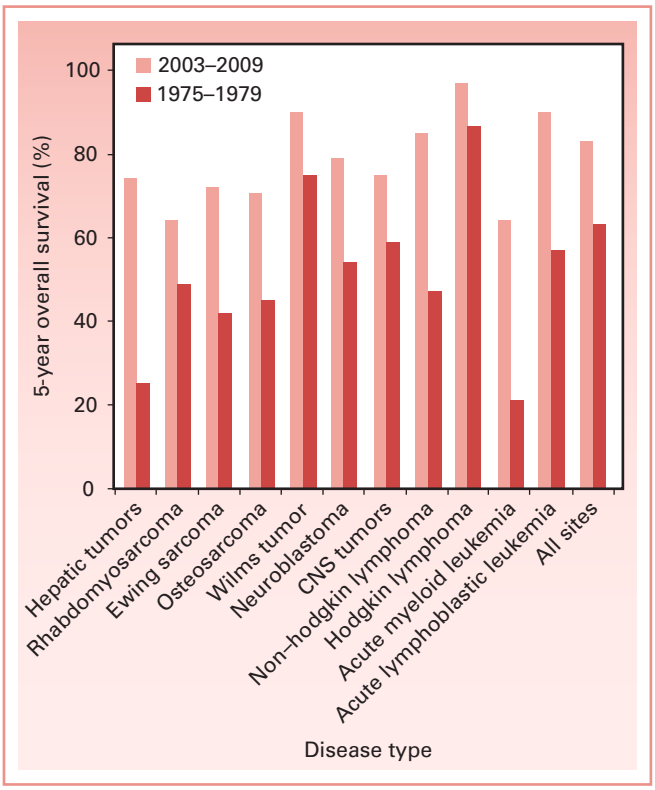

Figure 152.2. Five-year survival rate for 2 time periods for pediatric cancer diagnosed from birth to age 19 years. Five-year survival is presented for all sites (per the International Classification of Childhood Cancer) and specific histologic subtypes contrasting outcomes for children diagnosed between 1975 and 1979 with those diagnosed between 2003 and 2009. Data obtained from the National Cancer Institute SEER program from 9 SEER registries based on patient cases observed through 2010.

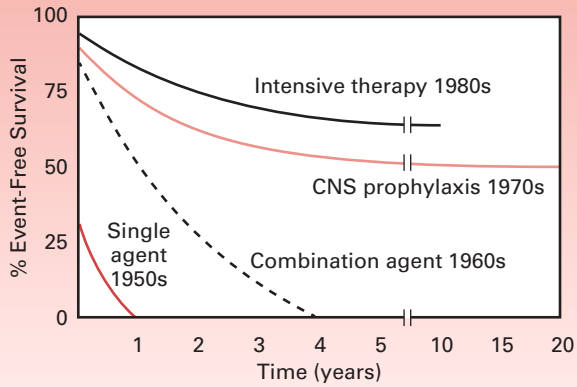

Figure 152.3. Historical perspective of the treatment of childhood acute lymphoblastic leukemia. The single-agent era resulted in few complete remissions and no cures. The combination-agent era without adequate central nervous system (CNS) treatment resulted in high complete remission rates but almost uniform mortality. Between the mid-1960s and the 1970s, combination chemotherapy and CNS treatment resulted in prolonged, disease-free survival for approximately 50% of children. Intensive therapy in the 1980s and 1990s resulted in an event-free survival of 75% to 80% of children.

Reprinted with permission from Silverman LB. Acute lymphoblast leukemia. In Orkin SH, Fisher DE, Look AT, Lux SE, Ginsburg D, Nathan DG, eds. *Oncology of Infancy and Childhood.* Philadelphia, PA: Saunders Elsevier; 2009:297–330.

CASE RESOLUTION

The boy undergoes a mediastinoscopic biopsy of the mediastinal mass, which reveals lymphoblastic lymphoma. No evidence of disease in the bone marrow or spinal fluid is present, which would indicate a worse prognosis. Treatment involves chemotherapy, and the prognosis is quite good. Symptoms of SVC syndrome caused by obstruction from the tumor resolve with shrinkage of the tumor secondary to therapy.

CHAPTER 153

Chronic Kidney Disease

Mark Hanudel, MD, MS; Marciana Laster, MD, MS; and Isidro B. Salusky, MD

CASE STUDY

During a consultation for diarrhea and dehydration in a 7-year-old boy, the pediatrician notes growth retardation. The boy's parents report decreased appetite, decreased level of physical activity, and bed-wetting, despite the patient having been previously potty trained. The medical history is significant for multiple episodes of fever caused by presumed ear infections during his first years after birth and 1 episode of urinary tract infection, without further studies. After hydration, the physical examination reveals a pale and short patient (height 101 cm [39.8 in]; <5th percentile) with a blood pressure of 125/85 mm Hg, the latter of which is indicative of stage 2 hypertension for age, sex, and height. Routine laboratory studies reveal anemia, a serum creatinine level of 1.4 mg/dL, and 3^+ proteinuria.

Questions

1. How is renal function estimated in the pediatric patient?
2. What are the relevant questions to ask about medical and family history in the child who presents with chronic kidney disease?
3. What additional diagnostic tests should be performed to determine the etiology of the kidney disease?
4. What are the approaches to the treatment of the child with chronic kidney disease?

The kidney is mainly responsible for excretion or clearance of waste products; however, it also plays an important role in the regulation of acid-base status, electrolytes, and water and the synthesis of erythropoietin (EPO), renin, and 1,25-dihydroxycholecalciferol. Thus, when the kidney is affected, the regulation of multiple functions is disturbed. To differentiate chronic kidney disease (CKD) from acute kidney injury, CKD is defined as at least 3 months of abnormal renal function. Currently, glomerular filtration rate (GFR) is the best method for the estimation of renal function and for the detection, evaluation, and management of CKD. The GFR varies according to sex, age, and body size and reflects the amount of plasma cleared by the kidney (Box 153.1). It can be challenging to evaluate GFR in children; however, the formula first published in 2009 has been shown to be accurate for a range of GFRs, from 15 to 75 mL/min/1.73 m^2. Early recognition of CKD is important to prevent complications associated with progressive decline in renal function. Signs and symptoms of CKD in children are nonspecific; thus, it is vital that the primary medical professional, usually a pediatrician or family practitioner, recognizes the earliest signs and symptoms of CKD and institutes proper medical care. Prompt referral to a pediatric nephrologist must be made, and follow-up consultations by both physicians should be performed regularly to optimize treatment of these children.

The Kidney Disease: Improving Global Outcomes (KDIGO) "2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease" states that pediatric CKD may be diagnosed by GFR less than 60 mL/min/1.73 m^2 for at least 3 months or GFR greater than 60 mL/min/1.73 m^2 accompanied by evidence of structural abnormalities or other markers of functional kidney abnormalities, including proteinuria, tubular disorders, or pathologic abnormalities detected by histology or inferred from imaging. For children age 2 years or older, kidney function can be staged based on GFR (Table 153.1). Stages 1 and 2 are defined by a GFR of greater than or equal to 90 mL/min/1.73 m^2 and 60 to 89 mL/min/1.73 m^2, respectively. Chronic kidney disease staging is important because management guidelines are based on CKD stage, and CKD progression is associated

Box 153.1. Method of Evaluating the Glomerular Filtration Rate in Children

1. Measuring the true GFR

Reference standard: inulin clearance, iothalamate, iohexol

Expensive, time-consuming

Not for everyday practice

2. Evaluating the GFR

A. Measured from a 24-hour urine collection

$$\text{GFR} = \frac{\text{Urine creatinine (mg/dL)} \times \text{Volume of urine (mL)}}{\text{Time of urine sampling (min)} \times \text{Plasma creatinine (mg/dL)}}$$

GFR (normalized for 1.73 m^2) = creatinine clearance × 1.73/body surface area

B. Estimated from a spot blood sample

GFR (mL/min/1.73 m^2) = 0.413 × Height (cm)/Plasma creatinine (mg/dL)

Abbreviation: GFR, glomerular filtration rate.

with certain comorbidities. Ameliorating CKD-associated comorbidity may reduce long-term cardiovascular disease risk factors and improve clinical outcomes. Particular importance should be placed on managing growth, proteinuria, acidosis, anemia, hypertension, and metabolic bone disease. After the GFR declines to 15 to 29 mL/min/1.73 m^2 (stage 4 CKD), the patient and family should be prepared for renal replacement therapy and possible renal transplantation. End-stage renal disease (ESRD), or stage 5 CKD, is defined as a GFR of less than 15 mL/min/1.73 m^2 or the need for dialysis or transplant. All children with CKD should be referred early to a pediatric nephrologist to facilitate treatment of the patient and education of the family. In adult patients with CKD, late referral is associated with increased rates of morbidity and mortality.

In newborns, normal GFR is less than 60 mL/min/1.73 m^2, and body surface area-adjusted GFR values do not reach adult levels until 2 years of age. Thus, GFR threshold values used to stage CKD are not applicable to children younger than 2 years. Many references exist for normal GFR in preterm and term neonates; among the most comprehensive tables is included in a 2007 review article (see Selected References). Glomerular filtration rate values between 1 and 2 standard deviations below the mean should be considered moderately reduced, and GFR values at least 2 standard deviations below the mean should be considered severely reduced.

Studies of adult patients with CKD have found that morbidity and mortality associates not only with GFR level but also with degree of albuminuria; thus, the 2012 KDIGO guidelines recommend classifying adult CKD by GFR and albuminuria category. Although similar large-scale trials assessing albuminuria severity and clinical outcomes in pediatric patients with CKD are currently lacking, prospective studies are ongoing. As such, albuminuria is not currently used to classify pediatric CKD, although it may be used in future, pending further clinical data accumulation.

Epidemiology

The incidence of CKD in children is unknown. Current estimates are based on the number of children accepted for dialysis and renal transplantation; however, some children do not require dialysis or transplantation until adulthood. In 2008, the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) reported 7,037 patients with an estimated GFR of less than or equal to 75 mL/min/1.73 m^2. The causes of CKD can be broadly categorized into 2 main groups: congenital and acquired. Congenital conditions, such as obstructive uropathy, aplasia/hypoplasia/dysplasia, reflux nephropathy, and prune-belly syndrome accounted for most of the diagnoses (53%) reported in 2008 and are referred to by the acronym CAKUT (congenital abnormalities of the kidney and urinary tract). Among the acquired conditions, focal segmental glomerulosclerosis is the most prevalent diagnosis at 9%. Overall, males are more often affected by CKD (64%). Age at registry entry varies, with 20% of children entered into the registry before 2 years of age, 16% between 2 and 5 years of age, 32% between 6 and 12 years of age, 28% between 13 and 17 years of age, and 4% after the age of 17 years; however, time at registry entry does not strictly correspond to age at time of CKD diagnosis.

Clinical and Biologic Presentation

The child with CKD often is asymptomatic or presents with nonspecific symptoms, and abnormal renal function is detected during a routine health examination or screening. For a small percentage of these patients, CKD is incidentally discovered when the patient presents with other illness, such as diarrhea and dehydration. Before receiving a diagnosis of CKD, a patient may also be referred to a specialty physician for the evaluation of growth retardation, hypertension, or anemia (Box 153.2). Occasionally, a history of recurrent episodes of fever without a source or partially treated urinary tract infection (UTI) secondary to undiagnosed vesicoureteral reflux is uncovered. A child may also report vague generalized symptoms, including malaise, anorexia, and vomiting, which may be associated with advanced renal failure.

Metabolic and Water/Electrolyte Abnormalities

The child with a congenital abnormality, such as obstructive uropathy or renal dysplasia, may develop polyuria resulting from an inability to concentrate urine, and salt wasting and polydipsia may become prominent features of the patient's disease. In such cases, blood pressure is usually normal. A history of bed-wetting may therefore be a clue to CKD. In contrast, the child with advanced CKD may have impaired sodium excretion, resulting in water retention and, consequently, fluid overload and secondary hypertension. Hyperkalemia is not an

uncommon component of CKD, and it becomes evident when the GFR falls below 10 mL/min/1.73 m^2. Hypokalemia is a less common problem and may be secondary to excessive diuretic use or strict dietary restriction; it may also be the hallmark of tubulointerstitial disease (eg, proximal tubulopathy) during the early stages of CKD.

Metabolic acidosis is mainly caused by the overall decrease in ammonium excretion from a reduced number of nephrons. Decreased excretion of titratable acid, as well as bicarbonate wasting in cases of proximal renal tubular acidosis, may also play a role.

Glucose intolerance may occur in some children with CKD despite elevated insulin levels. This may occur independently or in association with genetic diseases, such as hepatocyte nuclear factor-1β mutations, which induce renal cysts and atypical diabetes mellitus. The linear correlation between a decline in renal function and insulin resistance even at the early stages of CKD has been shown in adults. More than 50% of children develop hyperlipidemia by the time they reach ESRD. The characteristic plasma lipid abnormality is a moderate hypertriglyceridemia. A high prevalence of hypercholesterolemia and low levels of high-density lipids and albumin are characteristic as well. These derangements have a role in the manifestation of cardiovascular disease.

Growth Failure

Failure to thrive is the hallmark of CKD in children, and the degree of growth retardation varies according to the age of presentation. Because maximal growth occurs during the first few years after birth, children with congenital renal problems are the most affected. In the NAPRTCS, height deficits were greatest for children younger than 5 years, with nearly 50% below the third percentile for age and sex. Growth failure occurs early in the course of CKD and affects up to 35% of this population; by the time of renal transplantation, many children have severe short stature. Moreover, children with more severely impaired renal function tend to have more severe height deficits as well. Sexual development and bone age often are delayed in affected patients. Uremia, anorexia, and frequent vomiting contribute to the protein and calorie malnutrition frequently observed in younger children with CKD. Early, intensive management often is required to maximize nutritional status and optimize growth.

Mineral and Bone Disorders Associated With Chronic Kidney Disease

The effect of CKD on mineral and bone disorders (MBD) may be immediate (eg, biologic disequilibrium of calcium, phosphate, vitamin D, and parathyroid hormone [PTH]) or delayed (eg, growth retardation, bone pain, fractures, bone deformities, extraskeletal and vascular calcifications, increased morbidity and mortality). The development of CKD-MBD begins early in the course of CKD; clinical manifestations include growth retardation and skeletal deformities, such as genu valgum, ulnar deviation of the hands, pes varus, and slipped capital femoral epiphysis. Whereas the term *renal osteodystrophy* refers specifically to different bone lesions as defined by bone histomorphometry, the term *CKD-MBD* is used to define clinical and biochemical abnormalities as well as the long-term consequences of alterations in bone and mineral metabolism associated with CKD. Thus, CKD-MBD is manifested by 1 or a combination of the following abnormalities: abnormalities of calcium, phosphorus, PTH, or vitamin D metabolism; abnormalities in bone histology, linear growth, or strength; and vascular or other soft tissue calcification.

Anemia

The anemia of CKD is normochromic and normocytic. Insufficient EPO production occurs in the setting of GFR less than 30 mL/min/1.73 m^2. Anemia is frequently accompanied by decreased serum iron levels, increased total iron-binding capacity, and low reticulocyte counts. The patient undergoing dialysis is predisposed to develop bleeding tendencies secondary to platelet dysfunction and mechanical hemolysis.

Hypertension

The rate of hypertension in children with CKD varies from 38% to 78%. Prolonged hypertension may accelerate deterioration of renal function. An acute rise in blood pressure may cause seizure in a child with CKD. Other manifestations include headache, epistaxis, congestive heart failure, nerve palsies, and cerebral hemorrhage. Hypertension is a frequent finding in children with CKD secondary to polycystic kidney disease or chronic glomerulonephritis.

Cardiac Dysfunction

The patient with CKD is at increased risk for left ventricular hypertrophy (LVH), vascular calcification, and congestive heart failure. Left ventricular hypertrophy, as diagnosed on echocardiography, is present in 75% of adults with CKD; hypertension and anemia are important contributing factors. Left ventricular hypertrophy also occurs in pediatric patients with CKD, with a prevalence of 10% to 20% in CKD stages 3 and 4. Fluid overload, refractory hypertension, severe anemia, and uremic cardiomyopathy may contribute to congestive heart failure.

Neurologic Dysfunction

The child with CKD may have impaired neurodevelopment related to the age of presentation. Memory deficits, lack of concentration, depression, and weakness may occur. Children younger than 5 years are more affected because significant brain growth and maturation occur during the early years. The child with severe uremia may experience global developmental delay and seizures. Unless neurodevelopmental delays are recognized promptly and early intervention is instituted, neurologic dysfunction is often progressive. Some genetic diseases involving cerebral and renal development may play a role in developmental delay.

Pathophysiology

The Final Common Pathways in Nephron Loss

Regardless of the type of initial injury to the kidney, glomerular hyperfiltration and tubulointerstitial damage are the final common pathways of glomerular destruction. Hyperfiltration occurs

as a response by the residual glomeruli to compensate for the loss of nephrons, as summarized in Figure 153.1. Reduced filtration results in increased production of renin and angiotensin-converting enzyme (ACE). The consequent vasoconstriction of the efferent arteriole increases the hydrostatic pressure on the capillary wall, resulting in a compensatory higher filtration rate per nephron but also increased protein transit across the wall. Proteinuria involves recruitment of inflammatory cells and upregulation of proinflammatory and profibrotic genes. Protein overload in tubular cells stimulates their differentiation into myofibroblasts, thus promoting fibrosis. Concurrently, the inflammatory cascade activates the complement system, resulting in additional damage to the kidney. Interstitial fibrosis impairs oxygenation of the tubular cells, and the resulting chronic hypoxia further activates the renin-angiotensin system. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers have antihypertensive properties; additionally, they may reduce intraglomerular pressure, proteinuria, and the consequent tubulointerstitial fibrosis, thus potentially slowing the rate of CKD progression.

Growth Failure

Multiple factors are involved in the pathogenesis of growth retardation in children with CKD, including deficient calorie and protein intake, decreased EPO production resulting in anemia, metabolic acidosis, drug toxicity (from corticosteroids) and alterations in the growth hormone (GH)-insulinlike growth factor (IGF)-1 axis. Growth hormone-IGF-1 alterations are characterized by peripheral resistance to GH secondary to decreased expression of GH receptors and decreased levels of the bioactive IGF-1, the primary mediator of somatic growth. This decrease in bioactivity results from the retention of IGF-1 binding proteins (BPs), which worsens as GFR declines. Additionally, renal osteodystrophy in children involves alteration of the growth plate-cartilage architecture, which further contributes to growth failure. Adynamic bone growth (ie, low bone turnover) and severe hyperparathyroidism increase the severity of growth retardation. Also contributing to growth failure is the hypogonadism associated with CKD. In teenagers with CKD, the loss of pulsatile secretion of gonadotropin-releasing hormone contributes to shortening of the pubertal growth spurt and reduced growth velocity.

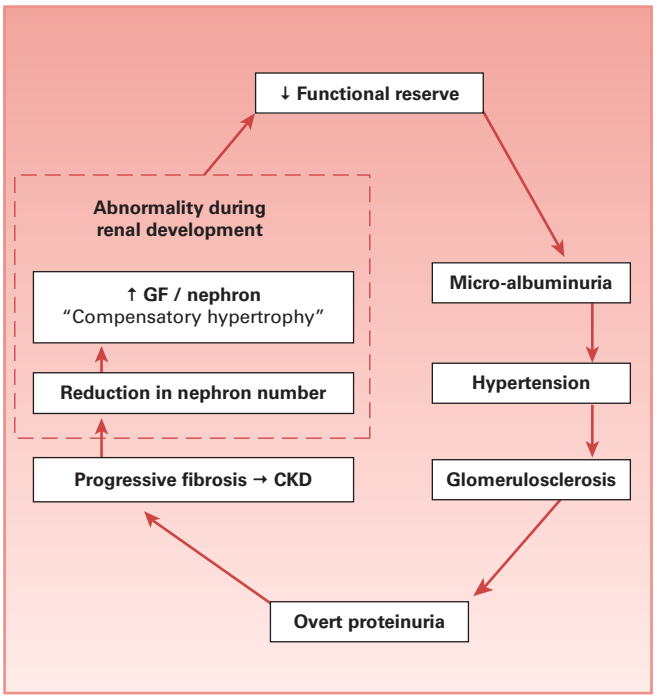

Figure 153.1. The consequences of reduction in nephron number in the pediatric patient.
Abbreviations: CKD, chronic kidney disease; GF, glomerular filtration.

Mineral and Bone Disorders Associated With Chronic Kidney Disease

The development of renal osteodystrophy is multifactorial. Reduced renal mass results in decreased synthesis of 1,25-dihydroxycholecalciferol; in turn, the stimulus to absorb calcium from the gut is decreased. The resultant hypocalcemia and lack of vitamin D feedback on the parathyroid glands stimulate the production of PTH, facilitating rapid mobilization of calcium from the skeleton, thus normalizing serum calcium at the expense of bone. With advancing CKD, skeletal resistance to PTH occurs, and circulating levels of PTH increase.

Hyperparathyroidism and the resultant high bone remodeling produces fibrosis in bone, a condition termed *osteitis fibrosa*. Administration of exogenous vitamin D and its derivatives can suppress such bone remodeling; however, without adequate monitoring, such administration can cause low bone turnover. The physician can monitor for adynamic bone by monitoring serum PTH and alkaline phosphatase levels, which usually are lower in these patients than in patients with secondary hyperparathyroidism and high bone turnover.

Hyperphosphatemia occurs when the few remaining nephrons lose the ability to excrete the daily load of phosphorus from the diet; it is a late phenomenon, usually occurring in CKD stages 4 and 5. Historically, aluminum-containing phosphate binders contributed to the pathogenesis of osteomalacia, a state characterized by poorly mineralized osteoid, and adynamic bone disease; currently, the use of large doses of calcium-based phosphate binders and active vitamin D sterols are implicated in the pathogenesis of osteomalacia. Biochemical abnormalities present in CKD-MBD, including abnormal calcium-phosphate metabolism, hyperparathyroidism, and increased levels of fibroblast growth factor 23 (FGF23), in association with traditional cardiovascular disease risk factors, such as hypertension, hyperlipidemia, hyperhomocysteinemia, anemia, and oxidative stress, contribute significantly to the development of cardiovascular disease, which is the leading cause of death in individuals with ESRD. In young adults with childhood-onset CKD, the prevalence of coronary artery calcification can be as high as 92% when evaluated by sequential computed tomography (CT) with electrocardiogram gating.

In the early 2000s, FGF23 was identified as the pathogenic hormone in various forms of hypophosphatemic rickets and tumor-induced osteomalacia. Secreted by osteocytes, FGF23 functions as a

phosphaturic hormone and as a suppressor of renal 1-α-hydroxylase. Circulating FGF23 levels have been observed to increase early in the course of CKD. Contributing to these elevated levels may be decreased FGF23 clearance, increased synthesis by osteocytes (a compensatory mechanism attempting to maintain normal phosphate levels) or an unintended response to treatment with active vitamin D analogs. In individuals with CKD, elevated FGF23 levels are associated with renal disease progression, cardiovascular morbidity, cardiovascular mortality, and all-cause mortality. In vitro and animal studies have shown that FGF23 may directly induce LVH.

Anemia

Chronic kidney disease anemia begins when the GFR falls below 30 mL/min/1.73 m^2 and is the result of multiple factors, including decreased EPO production, decreased red cell survival, bone marrow inhibition, iron deficiency, vitamin B_{12} and folate deficiency, inflammation, and osteitis fibrosa. Historically, aluminum toxicity was also implicated in CKD anemia. Blood loss during hemodialysis sessions may be contributory, as well. Recently, hepcidin, a hormone synthesized in the liver, was found to be central to the pathogenesis of CKD-associated anemia. Hepcidin causes the internalization of ferroportin, a protein that exports iron from the intracellular space to the extracellular compartment. Decreased hepcidin activity results in iron overload, whereas increased hepcidin activity is associated with anemia. Iron loading and inflammation increase hepcidin levels, and EPO treatment decreases hepcidin levels. As GFR decreases, hepcidin levels increase, resulting in ferroportin internalization, intracellular iron sequestration, and functional iron deficiency, thereby contributing to the anemia of CKD.

Differential Diagnosis

Initially, the main challenge for the physician is not determining a differential diagnosis but instead determining whether renal impairment is acute or chronic and, if chronic, the etiology. A variety of kidney problems, whether congenital, hereditary, acquired, or metabolic, may result in CKD. Although specific cures are not available for most of these renal conditions, a complete diagnostic workup is essential to determine the etiology of the renal disease. Such information may identify the presence of an inherited problem that may require genetic counseling and, in some cases, may aid in anticipating problems associated with renal transplantation. Some renal diseases, such as focal segmental glomerulosclerosis and atypical hemolytic uremic syndrome, may recur after renal transplantation, and the patient and family must be informed early about this possibility in preparation for renal transplantation. The different etiologies of CKD, as well as their prevalence in the 2008 NAPRTCS registry, are summarized in Table 153.2.

Table 153.2. Etiologies of Pediatric Chronic Kidney Disease According to the 2008 North American Pediatric Renal Trials and Collaborative Studies

Condition or Disease	*Disease*	*Percentage*[a]

Abbreviations: CAKUT, congenital abnormalities of kidney and urinary tract; GN, glomerulonephritis; MPGN, membranoproliferative glomerulonephritis.

[a] Total exceeds 100 because of rounding.

At initial presentation, it is necessary to distinguish acute from chronic renal failure because therapeutic strategies may differ and long-term renal prognoses can be quite different as well. Hereditary diseases commonly encountered include hereditary nephritis (eg, Alport syndrome), branchio-oto-renal syndrome, and juvenile nephronophthisis. Acquired diseases, such as chronic glomerulonephritis, membranoproliferative glomerulonephritis, and focal and segmental glomerulosclerosis, affect a large percentage of older children who progress to CKD. Whereas anemia, hypertension, and fluid and electrolyte abnormalities often are associated with both chronic *and* acute renal failure, suboptimal linear growth and signs

and symptoms of renal osteodystrophy manifest over time and occur in patients with chronic renal impairment.

Evaluation

A complete evaluation of the child presenting with renal failure must be performed, including careful history and physical examination, along with laboratory tests and appropriate imaging studies.

History

A thorough history must be obtained, including a complete and detailed family history, because this may aid in diagnosis (Box 153.3). A prenatal history, including possible drug exposures and results of antenatal imaging, may also provide useful information.

Physical Examination

A complete physical examination is required. Height and weight must be measured accurately, and the results should be plotted on the same growth curves used for healthy children. Weight may be overestimated if fluid retention is present. Blood pressure must be taken, using an appropriately sized cuff. Blood pressure measurements should be compared to the 50th percentile for age, sex, and height. The presence of tachycardia, heart murmurs, or adventitious heart sounds that may be indicative either of uncompensated anemia or of cardiac or pericardial involvement must be noted. Gross eye examination should be performed, including fundal examination, to assess for evidence of chronic hypertension. Macular abnormalities or hearing problems may be indicative of a heritable disease, such as Alport syndrome. Ear abnormalities (eg, preauricular pits, ear tags) accompanied by hearing deficits may be associated with renal disease (eg, branchio-oto-renal syndrome). Undescended testes may be evident in some children with urogenital problems.

Box 153.3. What to Ask

Chronic Kidney Disease

Child

- Were any abnormalities, such as hydronephrosis or polyhydramnios/oligohydramnios, noted on prenatal ultrasonography?
- Does the child have a history of prolonged illness, pallor, weakness, vomiting, or loss of appetite?
- Does the child have any history of headaches or visual or hearing problems?
- Does the child have any history of hematuria, proteinuria (evidenced by foamy or bubbling urine), urinary tract infections, or episodes of fever with unknown source?
- Does the child have impaired growth or development compared with siblings and other children?
- Does the child have any problems with micturition, such as dribbling or weak stream on urination?
- Does the child have increased passage of urine (ie, polyuria) or chronic excessive thirst and fluid intake (ie, polydipsia)?
- Does the child have daytime or nighttime urinary incontinence (ie, enuresis)?
- For any question to which the parent or guardian answered "yes," what was the age at presentation?

Family

- Does any family member have kidney disease, including hematuria, proteinuria, kidney cysts, or urinary tract infections, or has any family member undergone any urologic surgery?
- Does any family member have need of dialysis or kidney transplantation?
- Does any family member have a history of ear/hearing problems or eye abnormalities?

Laboratory Tests

For the initial laboratory workup, complete blood cell count, electrolyte levels, blood urea nitrogen level, creatinine level, calcium level, phosphorus level, and urinalysis should be obtained (Figure 153.2). Glomerulonephritis usually presents with numerous red blood cells, white blood cells, proteinuria, and a variety of casts in the urine. In the patient with proteinuria from whom a 24-hour collection is impossible, quantified excretion should be estimated by a protein-creatinine ratio in a spot urine sample. A ratio greater than 0.2 is abnormal and is well correlated with urinary protein excretion greater than 4 mg/m^2 per hour in a 24-hour urine collection. In nephrotic syndrome, the proteinuria is usually greater than 40 mg/m^2 per hour. Immunologic studies, including complement C3, complement C4, antinuclear antibody, and anti–double-stranded DNA, as well as a minimal infectious disease evaluation for hepatitis B and C, should be obtained if the renal disease is suggestive of an immune complex-mediated glomerulonephritis, such as systemic lupus erythematosus, postinfectious glomerulonephritis, or membranoproliferative glomerulonephritis.

Imaging Studies

Ultrasonography is by far 1 of the best imaging tools in the assessment of patients with CKD. Renal ultrasonography yields important information, such as kidney size, echogenicity, and the presence of hydronephrosis, cysts, or stones, that may help establish the diagnosis of the renal disease. The presence of small kidneys usually is indicative of chronic disease that may date to fetal development. Increased echogenicity with normal kidney size usually is indicative of medical renal disease.

Voiding cystourethrography is indicated in the patient with hydronephrosis and recurrent UTI to diagnose vesicoureteral reflux and evaluate the anatomy of the upper urinary tract. The use of spiral CT in the evaluation of patients with renal failure has increased in the past few years. This procedure requires relatively less time than standard CT and can be used to evaluate the kidney parenchyma as well as the upper and lower urinary tract.

Nuclear imaging of the kidneys has provided vital information in the workup of children with CKD. Generally, nuclear studies are not routinely done unless specifically indicated. A technetium Tc 99m mertiatide scan may be used to assess renal plasma flow. Technetium Tc 99m dimercaptosuccinic acid scanning may be used to assess

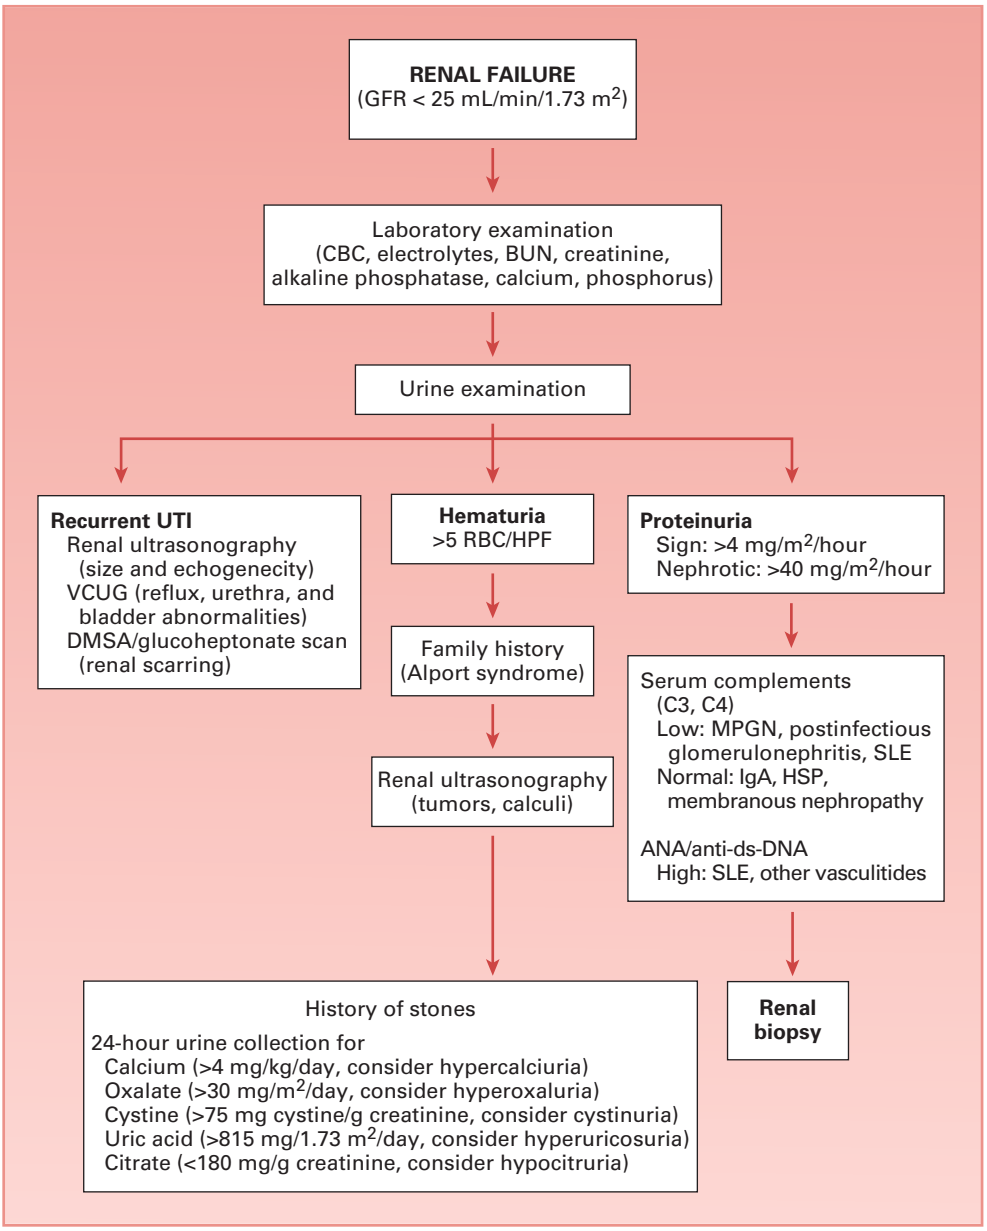

Figure 153.2. Initial diagnostic workup of a pediatric patient with chronic renal failure.

renal parenchymal involvement in the patient with acute pyelonephritis and/or recurrent UTIs. This nuclear imaging study provides excellent images of the renal parenchyma and often is used to detect renal scarring in the patient with recurrent UTI. Significant renal parenchymal scarring portends the development of hypertension later in life.

Management

The treatment of children with CKD has markedly improved over the last 2 decades and is summarized in Figure 153.3. Newer treatment options and earlier intervention strategies have greatly improved the lives of affected children. Care of these patients must be managed by multidisciplinary teams involving the primary care physician, nephrologists, nurses, social workers, nutritionists, and psychologists. Comprehensive management includes treatment of the primary disease and comorbid conditions, growth optimization, slowing disease progression, preserving residual renal function, preventing CKD-MBD and cardiovascular disease, and preparing for renal replacement therapy and renal transplantation as CKD progresses. To delay the progression toward ESRD and cardiovascular mortality, medical management of the patient with CKD includes strict control of hypertension; prevention of obesity; control of

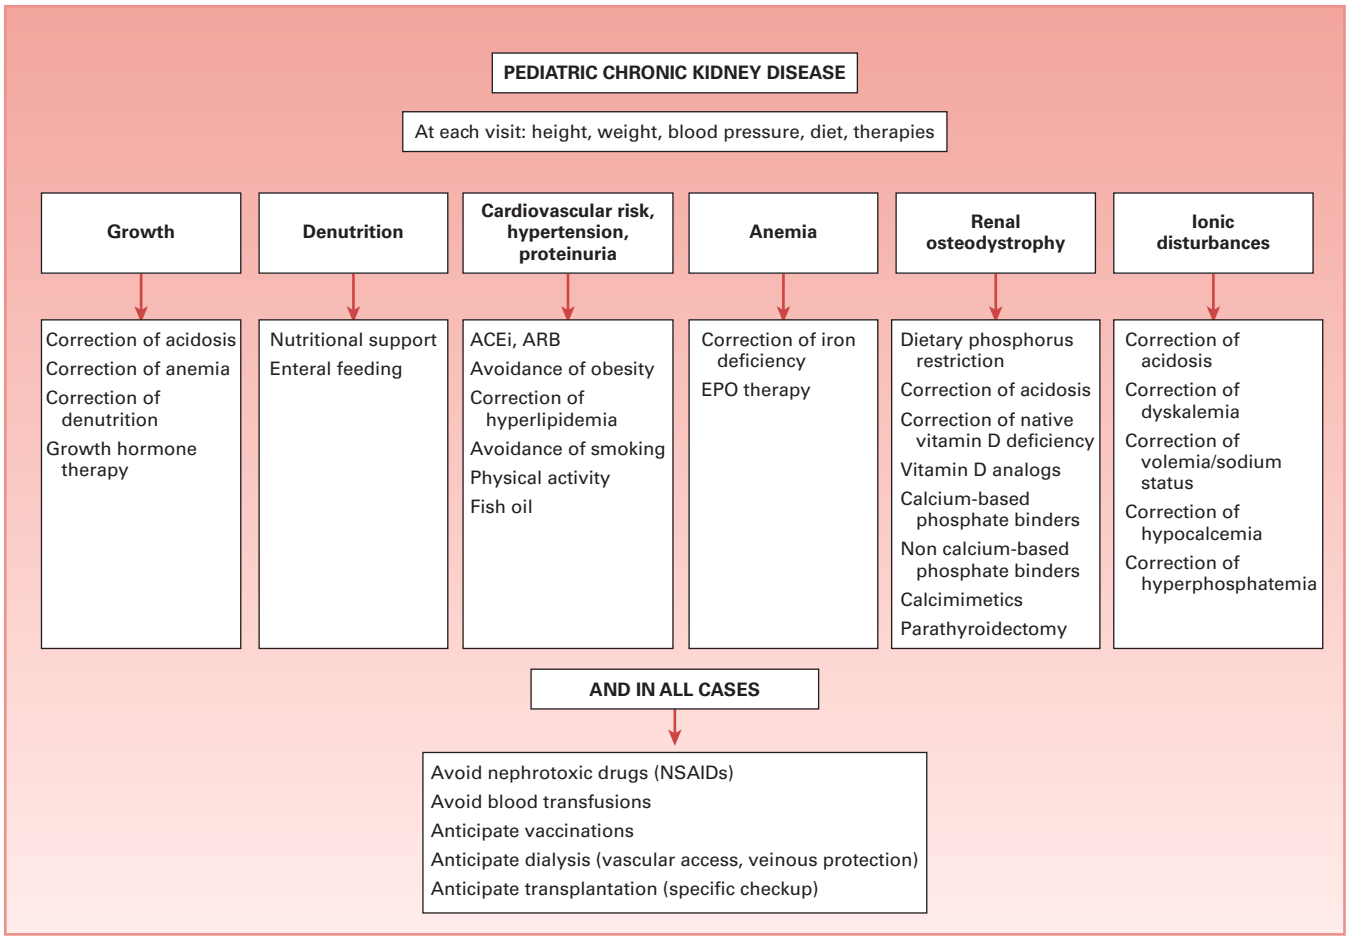

Figure 153.3. Overall management of pediatric chronic kidney disease.
Abbreviations: ACEi, angiotensin-converting enzyme inhibitors; ARB, angiotensin receptor blockers; EPO, erythropoietin; NSAIDs, nonsteroidal anti-inflammatory drugs.

proteinuria with ACE inhibitors or angiotensin receptor blockers; management of serum calcium, phosphorus, and PTH levels; anemia management; and prompt treatment of infections.

Malnutrition: Metabolic and Water/Electrolyte Abnormalities

Dietary management remains an important and challenging aspect of the overall management of the child with CKD. Frequently, these children are anorectic and require supplementation with fat, carbohydrates, and protein. Some patients, especially younger children, may require enteral feeding by nasogastric or gastrostomy tube to meet their daily nutritional requirements. The child with CKD should receive the recommended daily allowance for protein and calories according to age and sex, with adjustment made depending on weight gain. Protein restriction is not advised; studies have shown that restriction of protein intake does not delay the progression of renal failure in these patients. Close monitoring of nutritional status should be performed at each visit, with serial measurements of height and body weight; in children younger than 3 years, head circumference should also be measured.

Daily salt and fluid intake among patients may vary. The patient with hypertension may require relative dietary salt restriction. Conversely, the patient with congenitally obstructed, dysplastic kidneys or nephronophthisis often exhibits polyuria and salt wasting, requiring increased fluid intake and sodium supplementation.

Oral base therapy should be used to maintain bicarbonate levels above 22 mEq/L, as recommended by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative guidelines, because metabolic acidosis may have many deleterious effects, including worsening of bone disease, growth retardation, increased muscle wasting, decreased albumin synthesis, resistance to insulin, stimulation of inflammation, and increased overall mortality.

Most children with CKD do not develop hyperkalemia unless their renal function falls below 10 mL/min/1.73 m^2. Initially, dietary intervention may be sufficient, but this is difficult in infants and small children whose diet is limited to formula and only a few solid foods. Pharmacologic interventions, such as loop diuretic agents and polystyrene sulfonate, are used to manage hyperkalemia in these children. In situations of an acute rise in the serum potassium level, emergent measures must be implemented (Box 153.4). Sodium bicarbonate, insulin/glucose, and β_2 agonists (eg, albuterol) acutely decrease the serum potassium level by facilitating intracellular potassium uptake. If the hyperkalemia is unresponsive to conservative medical measures, dialysis must be performed immediately. In the setting of fluid overload and hyperkalemia, diuretic use may be indicated; potassium-sparing diuretics, such as spironolactone,

Box 153.4. Management of Hyperkalemia

- Calcium gluconate, 0.5 mL/kg of 10% solution, or calcium chloride, 0.2 mL/kg of 10% solution (IV).
- Sodium bicarbonate, 2 mEq/kg per dose (IV).
- Glucose-insulin solution, 0.5 g/kg glucose with 0.25 U of insulin per gram of glucose (IV; monitor serum glucose closely).
- Diuretic agent (loop type; potassium-sparing diuretic agents should not be used): furosemide, 1 mg/kg per dose (IV).
- Polystyrene sulfonate (eg, Kayexalate), 1 g/kg per dose orally (if awake) or rectally. (Do not use in patients with any gastrointestinal problems or anomalies.)
- Dialysis (if hyperkalemia persists despite previously noted measures).

Abbreviation: IV, intravenous.

should not be used. Additionally, in patients with impaired concentrating and diluting mechanisms, diuretic therapy should be avoided, because some of these children may have polyuria and become dehydrated on diuretic therapy.

Of increasing concern is the management of lipid disturbances in CKD because of the role of lipids in the progression of renal disease. The routine use of lipid-lowering agents in children with hypercholesterolemia and hypertriglyceridemia remains controversial because of reported liver and muscle toxicity associated with some of these medications. Further studies are warranted to test the efficacy and safety of these medications in the pediatric population.

Growth Failure

Use of recombinant human growth hormone (rhGH) therapy has improved the management of growth retardation in children with CKD; it should be considered in children with height below the fifth percentile. The 2012 KDIGO international guidelines recommend that children and adolescents with CKD stages 2 through 5 with related height deficits should be treated with rhGH when further growth is desired, after first addressing malnutrition and the biochemical abnormalities of CKD-MBD. In several studies, rhGH has been found to have a positive effect on linear growth, although results vary according to CKD stage at the initiation of rhGH. In the NAPRTCS database, catch-up growth after rhGH therapy was observed in 27% of children with chronic renal insufficiency, 25% of children who underwent renal transplantation, and only 11% of children undergoing renal replacement therapy. These findings highlight the need for early management of growth failure in pediatric patients with CKD. Moreover, the response during the first year of treatment correlates with final height. Growth hormone administration is continued until the patient reaches the 50th percentile for mid-parental height or renal transplant is achieved. Growth hormone therapy is contraindicated in the patient with a history of malignancy, hyperglycemia, hyperinsulinemia, or significant scoliosis.

A recent retrospective multicenter US study noted the underprescription of rhGH therapy in pediatric patients with CKD and reported that greater than 50% of short children with CKD did not receive rhGH. The most common reasons were family refusal, severe secondary hyperparathyroidism, and noncompliance; however, in up to 25% of cases, no evident rationale was determined. Waiting for insurance company approval resulted in a significant delay in the initiation of rhGH therapy in 18% of patients. Access to rhGH therapy should be a high priority. Newer treatment modalities targeting GH resistance (eg, recombinant IGF-1, recombinant IGFBP-3, IGFBP displacers) are under investigation for the management of growth retardation in pediatric patients with CKD.

Mineral and Bone Disorders Associated With Chronic Kidney Disease

For the management of renal osteodystrophy, dietary phosphorus restriction is reinforced in children with CKD; however, adherence to this dietary modification is generally poor secondary to unpalatability of the food. Additionally, many processed foods contain large amounts of phosphorus that are overlooked by caregivers despite appropriate nutritional counseling. These foods contribute considerably to phosphorus intake.

When dietary phosphorus restriction proves insufficient to maintain normal phosphate levels, phosphate-binding medications are necessary. Calcium-based binders are most commonly used; however, large doses of calcium-based binders have been associated with an increased risk of vascular calcifications. Thus, non-calcium-based binders, such as sevelamer carbonate and sevelamer hydrochloride, are being used more frequently. Currently, aluminum-containing phosphate binders are infrequently used because of the risk of aluminum toxicity and should be avoided as first-line therapies. If used, precautions must be taken in children who are concomitantly treated with citrate-containing medications, because citrate enhances aluminum absorption, thus enhancing toxicity risk.

Secondary hyperparathyroidism often manifests in children with CKD. The 2012 KDIGO guidelines recommend a serum PTH level within the normal range in patients with CKD stages 1 and 2, and a serum PTH level between 2 and 9 times the upper limit of normal in patients undergoing dialysis. Between 15 and 60 mL/min/1.73 m^2, the optimal level of PTH is unknown; however, a persistently elevated and/or progressively rising PTH level requires attention to modifiable factors, such as hyperphosphatemia, hypocalcemia, high dietary phosphate intake, and vitamin D deficiency, as the first step in management. Because of a lack of association with clinically relevant outcomes and a risk of hypercalcemia, the use of activated vitamin D sterols in the patient with predialysis CKD is recommended only as a means of maintaining age-corrected serum calcium levels. In the patient with CKD stage 5 on dialysis with sufficient vitamin D as well as normal calcium and phosphorus levels but with elevated PTH levels, treatment with activated vitamin D sterols (eg, calcitriol, doxercalciferol) may be warranted. The patient receiving activated vitamin D sterols should be frequently monitored for the development of hypercalcemia or hyperphosphatemia; in such cases, dose modification or phosphate binder adjustment may be necessary. Although calcimimetic agents (eg, cinacalcet) have been shown to be effective in reducing PTH and FGF23 levels in adults, the effects of these agents on the growing skeleton have not yet been well studied in pediatric patients. Thus, the child receiving cinacalcet should

be closely monitored, specifically for hypocalcemia, with appropriate dosage adjustments made as necessary.

If present, 25-hydroxyvitamin D deficiency may require treatment. Optimal levels of 25-hydroxyvitamin D are greater than 30 ng/mL (75 nmol/L). Vitamin D deficiency is highly prevalent in pediatric patients across the spectrum of CKD (40%–80%), resulting from several factors, such as low dietary intake, chronic illness, skin changes, and sometimes urinary losses in patients with proteinuria.

Anemia

The use of recombinant human EPO in the anemia associated with CKD has become a standard of treatment. The correction of anemia results in improved appetite, increased physical activity, and more important, avoidance of the risks associated with blood transfusion. Before the availability of EPO, most patients received frequent blood transfusions, increasing their risks of infection, transfusion reaction, and development of antibodies. The goal is to maintain hemoglobin between 11 and 12 g/dL. Iron stores are assessed by transferrin saturation and ferritin levels and should be maintained between 20% and 50% and between 200 and 800 ng/mL, respectively. The elucidation of the hepcidin pathway and an improved understanding of the pathophysiology of anemia has led to the development of new therapeutic modalities in adults, including prolyl hydroxylase inhibitors, EPO-receptor agonists (eg, Peginesatide), oxygen-carrier products, and *GATA* inhibitors. Trials using these agents in pediatric CKD-associated anemia have shown promising results.

Arterial Hypertension

For chronic management of hypertension in the pediatric patient with CKD, antihypertensive medications should be started if blood pressure measurements are consistently above the 90th percentile for age, sex, and height. The 2012 KDIGO CKD guidelines suggest that the blood pressure goal should be less than or equal to the 50th percentile for age, sex, and height unless achievement of this target blood pressure is limited by signs or symptoms of hypotension. Updates to pediatric hypertension thresholds and management are provided by the 2017 American Academy of Pediatrics "Clinical Practice Guideline for Screening and Management of High Blood Pressure in Children and Adolescents." Drugs currently used to manage hypertension in children with CKD include ACE inhibitors, diuretic agents, adrenergic blockers, peripheral vasodilators, and calcium channel blockers. Angiotensin-converting enzyme inhibitors are often used as first-line antihypertensive agents in children with CKD and, as mentioned previously, treatment with ACE inhibitors has been shown to be beneficial in reducing proteinuria, which may help inhibit proteinuria-associated tubulointerstitial inflammation and fibrosis. Angiotensin-converting enzyme inhibitors must be used with caution in patients with a solitary kidney and those with renal artery stenosis, because these medications may acutely decrease kidney function and precipitate hyperkalemia in patients with renal failure. Sexually active adolescent females must be informed about the adverse effects of ACE inhibitors in pregnancy, including renal tubular dysgenesis in the fetus. Calcium channel blockers, especially nifedipine, have been used in cases of severe hypertension because of their rapid onset of action. For patients with poor adherence to daily oral medications, clonidine is currently available in the form of transdermal patches. However, patients should be warned of central nervous system side effects, as well as rebound hypertension if the patch is removed abruptly. If hypertension is secondary to fluid overload and salt retention, aggressive fluid removal with diuretic therapy should be initiated. The patient with long-standing hypertension must regularly undergo echocardiography to assess for LVH and serial ophthalmologic examinations to assess for pathologic changes of the eye. The 2017 American Academy of Pediatrics pediatric hypertension guidelines also recommends strong consideration of routine ambulatory blood pressure monitoring in children with CKD to evaluate hypertension severity and abnormal circadian variations. For uncontrollable hypertension, which often occurs secondary to fluid overload, dialysis may be indicated (Box 153.5).

General Measures

In all cases, anticipation of dialysis or transplantation should begin early in the course of CKD, because many patients with CKD may progress to ESRD and require renal replacement therapy. Protection of upper extremity veins, in anticipation of the need for possible future vascular access, is important. Additionally, blood transfusions should be avoided to the extent possible to prevent the development of hyperimmunization, thereby potentially compromising a future transplant.

Children with CKD, as well as their siblings and household contacts, should receive all standard vaccines, including varicella, influenza, and *Streptococcus pneumoniae*. The patient on immunosuppressive treatment because of glomerulonephritis or after transplant should not receive live-virus vaccines. Every attempt to administer live-virus vaccines, such as measles, mumps, rubella, and varicella, should be done before transplantation. Because children with CKD have a decreased ability to mount an immunologic response, repeated vaccination to induce protective serum antibody titers may be necessary.

Box 153.5. Indications for Initiation of Dialysis

- Severe fluid overload
  - — Congestive heart failure
  - — Uncontrollable hypertension
- Uremic neuropathy
  - — Paresthesia
- Electrolyte abnormalities unresponsive to medical management
  - — Intractable metabolic acidosis
  - — Hyperkalemia
- Pericarditis
- Severe renal osteodystrophy
  - — Extraskeletal calcification
  - — Severe skeletal deformities
- Progressive malnutrition and severe growth retardation, especially in the first year after birth
- Severe anemia or bleeding diathesis

A review of all medications should be performed at every visit to adjust dosages according to kidney function, detect possible adverse effects, and identify any potentially dangerous drug interactions. Monitoring drug levels may be desirable when using antibiotics, anticonvulsant agents, digoxin, theophylline, and anticoagulant agents. To prevent toxicity, dosages of all medications should be altered based on estimated GFR. Special care should be taken when using antibiotics (eg, aminoglycosides, vancomycin) as well as nonsteroidal anti-inflammatory drugs, because of possible detrimental effects on residual kidney function, even in the early stages of CKD.

For contrast-requiring imaging studies in patients with GFR less than 60 mL/min/1.73 m^2 undergoing elective investigation involving the intravascular administration of iodinated radiocontrast media, the 2012 KDIGO CKD guidelines recommend avoidance of high osmolar agents; use of the lowest possible radiocontrast dose; withdrawal of potentially nephrotoxic agents before and after the procedure; adequate hydration with saline before, during, and after the procedure; and measurement of GFR 48 to 96 hours after the procedure.

As stated in the 2012 KDIGO CKD guidelines, indications for referral to a pediatric nephrologist include acute or chronic reduction in renal function, poorly treated or severe hypertension, severe electrolyte abnormalities, the finding of significant abnormalities in urinary tract structure, the presence of systemic diseases likely to produce renal effects, the need for education in progressive conditions, performance and interpretation of renal biopsies, and allaying parental/guardian or patient anxiety. Early referral may provide the opportunity to slow renal disease progression and may result in improved clinical outcomes.

Timing of Dialysis Initiation

For the pediatric nephrologist, the conversation with the patient's family about renal replacement therapy is initiated early in the CKD course. Timing of dialysis initiation is determined not by a certain GFR threshold but rather by multiple factors, including patient signs and symptoms, laboratory values, possibility of transplantation, and family circumstance. Generally agreed-on absolute indications for dialysis initiation include neurologic consequences attributable to uremia, hypertension unresponsive to antihypertensive therapy, pulmonary edema unresponsive to diuretic agents, pericarditis, bleeding tendency, and refractory nausea or vomiting. Relative indications may include less severe symptoms of uremia, hyperkalemia, hyperphosphatemia, malnutrition, and growth failure. Such indications for dialysis often occur when the GFR declines to less than 15 mL/min/1.73 m^2; however, some patients may remain asymptomatic despite a GFR below the aforementioned value, and other patients may warrant consideration for dialysis at higher GFRs.

Prognosis

The prognosis for children with CKD has changed in the last 2 decades. Options for dialysis (ie, hemodialysis, peritoneal dialysis) and kidney transplantation (ie, deceased donor, living-related donor) should be discussed before the occurrence of ESRD. Strategies such as preemptive transplantation (ie, transplantation before the need for dialysis) are likely preferred by the patient and family but may not be achievable because of the median time on the waiting list. Technical advances in dialysis allow the pediatric nephrologist to offer dialysis options to a child of any age and have made long-term survival possible while children await renal transplantation.

Kidney transplantation is the ultimate treatment for the child with CKD. Improvements in immunosuppressive medications and availability of other therapeutic strategies have considerably increased patient and graft survival after kidney transplantation. Full recovery and return to normal activities should be achieved after these children have undergone successful renal transplantation.

CASE RESOLUTION

The patient has a GFR of 30 mL/min/1.73 m^2. The initial evaluation reveals anemia (hematocrit 28% [normal: 36–48]), low serum bicarbonate (17 mEq/L [normal: 22–26]), hypocalcemia (8 mg/dL [normal: 8.6–10]), hyperphosphatemia (7 mg/dL [normal: 2.7–4.5]), and elevated PTH (700 pg/mL [normal: 10–65]). Ultrasonography reveals that both kidneys are small with increased echogenicity, and voiding cystourethrography reveals bilateral vesicoureteral reflux. Management of the primary disease is started with antibiotic prophylaxis to prevent further UTIs, and the patient is referred to pediatric urology. Measures to slow the progression to ESRD are initiated, involving dietary intervention and management of comorbid conditions. Bicarbonate is started for metabolic acidosis; iron and recombinant human EPO are started for anemia; and calcium carbonate is started as a phosphate binder/calcium supplement. The hypertension associated with proteinuria is best managed with an ACE inhibitor. Growth hormone will be considered after the acidosis, anemia, and hyperparathyroidism are corrected. Immunizations are current. An appointment with the pediatric nephrology team is scheduled.

CHAPTER 154

Diabetes Mellitus

Jennifer K. Yee, MD, and Catherine S. Mao, MD

CASE STUDY

A 10-year-old girl presents with a 3-week history of nocturnal polyuria. Her mother reports that her daughter, previously overweight, seems to have lost weight in the past 2 months after receiving nutrition education. Laboratory tests reveal that the girl's serum sodium level is 130 mEq/L; potassium, 3.2 mEq/L; glucose, 324 mg/dL; and 1+ ketones. Urinalysis reveals specific gravity of 1.025 and moderate glucose and ketones. Her height and weight are within normal ranges for her age, and the remainder of her physical examination is unremarkable.

Questions

1. What is the pathophysiology of type 1 and type 2 diabetes?
2. What are diagnostic criteria for differentiating type 1 and type 2 diabetes?
3. What are the objectives of therapeutic interventions in the child with diabetes?
4. What diagnostic evaluations are used in ongoing management of diabetes?
5. What are the acute and chronic complications associated with diabetes?
6. What is the role of "tight glycemic control" in children and adolescents?

Diabetes mellitus is the second most common chronic illness after asthma among children in developed countries. Diabetes mellitus is a metabolic imbalance that results from insulin deficiency, impairment of insulin action, or both. Advancement in the knowledge of the pathophysiology supports the assessment that diabetes is a heterogeneous disease involving immunologic, environmental, and genetic factors. This has led to a categorization of diabetes based on its pathophysiology rather than the therapeutic intervention. Diabetes associated with absolute insulin deficiency and impaired beta cell function is called type 1 (DM1) (previously juvenile onset or insulin-dependent), and diabetes associated with insulin resistance as well as impaired beta cell function is called type 2 (DM2) (previously adult onset or non-insulin-dependent).

Epidemiology

Overall, diabetes affects 9.4% of the population in the United States. The prevalence among adults age 18 years and older is 12.4%, while the prevalence among children and adolescents younger than 20 years is 0.23%. Diabetes mellitus type 1 and DM2 have been increasing in incidence among youth. From 2002–2003 to 2012–2013, DM1 increased from an incidence of 19.5 cases in 100,000 youths per year to an incidence of 21.7 in 100,000 youths per year. In the same time frame, DM2 increased from an incidence of 9.0 cases in 100,000 youths per year to 12.5 in 100,000 youths per year. Additionally, the populations affected by DM1 and DM2 seem to differ. Type 1 diabetes mellitus is seen equally among girls and boys, with the highest incidence among white youth. Type 2 diabetes mellitus is more prevalent among girls and has the highest incidence among black, Mexican American, and Native American populations. The peak age of presentation for DM1 is between 5 and 15 years. Less is known about DM2 in children, but previous studies show a mean age of 13.8 years at presentation.

The SEARCH for Diabetes in Youth Study is a population-based, observational study of physician-diagnosed diabetes among youth younger than 20 years from centers based in 5 states—South Carolina, Ohio, Colorado, California, and Washington. Much of the current epidemiologic data concerning DM1 and DM2 among youth in the United States has been determined from the data collected in this study.

Monogenic forms of diabetes are uncommon, comprising approximately 1% of all diabetes cases, which include neonatal diabetes (onset in the first 6 months after birth), and maturity-onset diabetes of the young.

Clinical Presentation

Children can vary in their clinical presentation from being asymptomatic to having fulminant metabolic imbalance (Box 154.1). Type 1 diabetes mellitus commonly presents with a classic triad of polydipsia, polyuria, and polyphagia. The most consistent presenting concern is increased urinary frequency, manifested as nighttime polyuria or secondary enuresis. Alterations in appetite and thirst are most commonly recognized when disease onset occurs in the preschool years, likely because parents and guardians are most able to monitor eating and drinking behaviors during the child's first few years. Weight loss can be variable but is more common in DM1 than in DM2. Recent trends indicate that diabetic ketoacidosis (DKA) occurs at the time of initial presentation in up to 31.1% in DM1 and

Box 154.1. Diagnosis of Diabetes Mellitus

- Symptoms (ie, polydipsia, polyuria, polyphagia) together with a random plasma glucose ≥200 mg/dL
- Fasting blood glucose ≥126 mg/dL (confirmed on a subsequent day)
- Oral glucose tolerance test with 2-hour peak plasma glucose ≥200 mg/dL
- Hemoglobin A_{1C} ≥6.5%

5.7% in DM2. Diabetic ketoacidosis presents with vomiting, polyuria, dehydration, and Kussmaul respirations. Children and adolescents with DM2 also report having the classic triad of symptoms but often are identified through screening urinalysis. Type 2 diabetes mellitus is strongly associated with obesity (body mass index ≥95th percentile [see Chapter 155]), acanthosis nigricans, and having a first-degree relative with DM2.

Pathophysiology

The patient with DM1 has an absolute insulin deficiency resulting from autoimmune destruction of the beta cells of the pancreas. The disease process is thought to be triggered by an environmental factor, such as a virus or toxin, in the genetically susceptible individual. Exposure occurs in early childhood, but disease progression can be variable. More than 90% of affected individuals carry human leukocyte antigen-DR3 or -DR4. Discordance of disease among twins supports the theory that DM1 involves an environmental exposure in genetically susceptible individuals. Twin studies show evidence of a preclinical autoimmune process, which also has predictive value in identifying susceptible individuals at risk for developing DM1. Immune changes include an increase in activated T-cells expressing human leukocyte antigen–DR, islet cell antibodies (ICA), insulin autoantibodies, glutamic acid decarboxylase (GAD) antibodies, and islet antigen 2 (Table 154.1).

Table 154.1. Predictive Tests for Individuals Susceptible to Type 1 Diabetes Mellitus[a]

Immunologic Marker(s)	*Risk of Developing DM1 (Within 5–8 years)*
ICA	25%–70%
Anti-GAD antibodies	68% among siblings of DM1 proband and 50% in the general population
IA-2 antibodies	58% among siblings of DM1 proband and 43% in the general population
IAA	Variable (may not be specific to islet cell tissue)
Reduced first-phase insulin release	100%
Anti-ICA and IAA	90%
Human leukocyte antigen with index case	25%–30%

Abbreviations: DM1, type 1 diabetes mellitus; GAD, glutamic acid decarboxylase; IA-2, islet antigen 2; IAA, insulin autoantibodies; ICA, islet cell antibodies.

[a] Individuals with first-degree relative with type 1 diabetes.

Disordered immune function, in which some antigenic components of pancreatic islet cells are not recognized as self, seems to be the pathogenic mechanism for the development of DM1. It is generally believed that at least 90% of beta cell mass must be destroyed before problems with glycemic regulation are manifest. Endogenous insulin deficiency, occurring as a natural consequence of islet cell destruction, results in the inappropriate use of carbohydrate. Cellular uptake of glucose by liver, muscle, and adipose tissue is blocked. Synthesis of glycogen, protein, and fat is reduced, and a catabolic state marked by lipolysis, proteolysis, and ketone body formation ensues. Increased serum glucose and ketones present an overwhelming osmotic load to the kidneys, resulting in urinary losses of volume and cations (Na^+, K^+, NH_4).

The autoimmune phenomena described previously are not evident in DM2 as demonstrated by the absence of ICAs, insulin autoantibodies, and GAD antibodies. This disease, which is characterized by resistance to insulin, may assume different presentations in childhood. The more traditional form of DM2 presents in older children and adolescents and is strongly associated with obesity and having a first-degree relative with DM2. Like adults with DM2, insulin resistance is present, but the existence of a relative insulin deficiency is necessary to develop DM2.

Differential Diagnosis

Diagnosis is usually straightforward given the symptomatology, except in children who present at a very young age. Although the onset of diabetes is rare before 1 year of age, the disease may present with nonspecific symptoms (ie, irritability, vomiting, tachypnea, poor weight gain). When diabetes presents before 1 year of age, or in a child with a strong family history of diabetes and no evidence of autoantibodies or insulin resistance, monogenic causes of diabetes warrant consideration. Chemotherapeutic agents (eg, L-asparaginase) and a variety of medications (eg, corticosteroids, diuretics, oral contraceptives, phenytoin, epinephrine) may induce glucose intolerance. Immunosuppressants taken by transplant recipients also cause hyperglycemia. Glycosuria without evidence of ketosis or elevated blood glucose occurs in certain renal conditions (eg, Fanconi syndrome, carbohydrate malabsorption syndromes, heavy metal intoxication). Transient hyperglycemia, with or without glycosuria, may occur in response to physiological stress (eg, burns, trauma, hyperosmolar dehydration). In most of these cases, glucose regulation returns to normal within several days.

Evaluation

Evaluation should focus on the diagnosis of diabetes (ie, hyperglycemia) and the category because DM1 and DM2 can have different treatment modalities and disease courses.

History

The history should focus on classic symptomatology and whether a family history of diabetes exists. Up to 80% of youth with DM2 will report a positive family history of diabetes, compared with 20% of

youth with DM1. Additionally, exogenous causes of diabetes should be ruled out. Obtaining a history of viral infections or chemical exposures during early childhood may be useful (Box 154.2).

Physical Examination

Growth parameters should be measured and plotted on standard growth curves. Obesity is present in 96% of youth with DM2, compared with 24% of youth with DM1. Although DM1 usually is associated with weight loss as part of the presenting symptomatology, even those patients with obesity and with DM2 may have lost weight prior to presentation. Youth with uncomplicated DM1 may have an unrevealing physical examination, whereas those with DM2 may have physical findings associated with obesity. One study demonstrated that 60% of adolescents with DM2 had acanthosis nigricans and 32% had hypertension at presentation. An intercurrent infection may trigger the symptomatology and should always be sought in cases of ketoacidosis. The child who presents with ketoacidosis may have evidence of vomiting, dehydration, Kussmaul respirations, or in severe cases, altered mental status.

Laboratory Tests

Initial laboratory tests should include evaluation of the serum and urine for glucose and ketones. For the patient presenting with DKA, evaluation should also include a full chemistry panel to assess for metabolic acidosis, hypokalemia, and serum osmolality. After the diagnosis of diabetes is suspected, further testing can assist in categorizing the type of diabetes. Tests include anti-GAD and anti-ICAs, the presence of which support the diagnosis of DM1 (Table 154.1) and insulin and C peptide levels, the latter of which is a marker of insulin levels. Insulin and C peptide levels are usually higher in patients with DM2 because they have insulin resistance rather than an absolute insulin deficiency. Insulin reserve can be measured by determining the basal and stimulated levels of C peptide (≥0.6 ng/mL basal level, ≥1.5 ng/mL 90 minutes after nutritional supplement such as Sustacal or Ensure High Protein). In categorizing diabetes, it is important to note that some individuals with DM1 can have insulin reserves up to 2 years after diagnosis.

Oral glucose tolerance tests may be necessary to confirm the diagnosis of diabetes in cases in which the onset of symptoms is not obvious. Two-hour postprandial values greater than or equal to 200 mg/dL or fasting glucose of 126 mg/dL or higher are evidence of diabetes. The introduction of the intravenous glucose tolerance test with measurement of first-phase insulin release has allowed early diagnosis of individuals at risk for the disease prior to development of symptoms.

Recently, the American Diabetes Association (ADA) added hemoglobin A_{1c} (HbA_{1c}) of 6.5% or greater as an additional criterion that may be used to diagnose diabetes. If such a value is found in a patient, a second test should be performed to confirm the result, and evaluation should proceed to assess for the presence or absence of ketones and type of diabetes.

To assess children who are at risk for DM2, screening may be done every 2 years starting at age 10 years or at the onset of puberty (whichever comes first) using fasting plasma glucose (as recommended by the ADA), oral glucose tolerance test (as recommended by the World Health Organization), or HbA_{1c} (as recommended by the ADA). Children who should be screened are those who meet criteria for obesity and have 2 or more of the following risk factors: family history of DM2 in first- or second-degree relatives, at-risk race/ethnicity (black, Asian/Pacific Islander, Native American, Hispanic), or associated signs and symptoms of insulin resistance (eg, acanthosis nigricans, dyslipidemia, hypertension, polycystic ovary syndrome).

Box 154.2. What to Ask

Type 1 Diabetes Mellitus

- Is the child having increased urination (eg, nighttime urination, unusual bed-wetting)?
- Is the child drinking or eating more than usual?
- Has the child experienced any weight loss?
- Has the child been taking or had access to any kind of medications (eg, corticosteroids, L-asparaginase, diuretic agents ["water pills"], birth control pills)?
- Are there any family members with diabetes (first- or second-degree relatives)?

Management

Early diagnosis together with a comprehensive program of education and aggressive management are essential to prevent acute and long-term complications. Long-term objectives of therapeutic intervention in the child with diabetes are to facilitate normal physical growth and psychological and sexual maturation, promote euglycemia through regulation of glucose metabolism, prevent acute complications (ie, hypoglycemia, ketoacidosis), prevent or delay long-term sequelae, and accommodate physiological changes that alter therapeutic needs (eg, exercise, adolescence, intercurrent illness).

Effective management requires a multidisciplinary team of professionals skilled in handling the myriad issues that arise for families and children with diabetes. Most clinics specializing in the care of children with diabetes include a nurse educator, dietitian, social worker, psychologist or behavioral health specialist, and pediatric endocrinologist. In settings in which such special care centers are available, the primary care physician serves as a key adjunct, underscoring the importance of ongoing patient-family involvement in disease management and ensuring optimal growth, development, and nutrition. In the absence of a special care center, the primary care physician assumes responsibility for all aspects of management, including management of acute complications, monitoring adherence and treatment effect, and surveillance for long-term complications.

Effective therapeutic intervention is based on individual needs for energy, insulin, and exercise. Several factors, including physical growth, insulin requirement, glycemic control, and activity level, influence those needs and must be assessed on a regular basis. For

DM1, insulin therapy is the mainstay of management, whereas DM2 therapeutic options include weight control through diet and exercise (see Chapter 155), oral hypoglycemic agents, and insulin. Oral hypoglycemic agents can decrease blood glucose by increasing insulin secretion, increasing insulin sensitivity, decreasing hepatic glucose output, or decreasing nutrient absorption. These agents include sulfonylureas and other insulin secretagogues, metformin hydrochloride, thiazolidinediones, and acarbose. Although DM2 may initially be managed with exogenous insulin, metformin is the oral agent prescribed most often for DM2 in children and adolescents because it has been approved by the US Food and Drug Administration for pediatric use. A newer class of medication acts by an incretin effect and increases glucose-dependent insulin secretion. This class includes exenatide (administered by injection). A complementary drug inhibits dipeptidyl-peptidase-4 (DPP-4), which cleaves the incretin. Therefore, the DPP-4 inhibitor prolongs the incretin effect to promote endogenous insulin release after a meal. Yet another new class of medications includes sodium-glucose cotransporter-2 inhibitors, which inhibit the reabsorption of glucose in the kidney. Similar to most drugs for the treatment of DM2, these newer drugs do not have a pediatric indication.

Insulin

The purpose of insulin therapy is to enable the affected child to approach euglycemia in response to adequate amounts of food, insulin, and exercise. The amount of daily insulin required is dependent on the child's age, weight, and development. On average for DM1, the child younger than 5 years requires 0.6 to 0.8 U/kg, the child between 5 and 11 years of age requires 0.75 to 0.9 U/kg, and the child or adolescent between 12 and 18 years of age requires 0.8 to 1.5 U/kg in a 24-hour period. Within 3 to 4 months of diagnosis, most individuals experience a partial remission, or honeymoon phase, during which time their insulin requirements decline dramatically. Conversely, illness, anxiety, and adolescence (ie, pubertal changes) may cause the insulin requirement to increase. Even under conditions of increased need, reported daily insulin dosages in excess of 2 U/kg of body weight should stimulate investigations into patient adherence.

Several insulin regimens currently in use take advantage of the variable onset of action of different insulin preparations (Table 154.2). The new insulin analogs are monomers of insulin rather than insulin aggregates. They provide a rapid onset and a shorter duration of action. This allows for easier adjustment of insulin dose depending on the child's appetite because the injection can be given immediately before the meal. The child with newly diagnosed diabetes should use a semisynthetic or recombinant human insulin preparation to minimize the possibility of allergic reaction. Any change in insulin preparation should be undertaken cautiously and only under medical supervision because brands vary in strength, purity, and glycemic response.

Morning hyperglycemia may result from 1 of 2 phenomena, which must be distinguished because the appropriate therapeutic responses are opposite. The *dawn phenomenon* likely involves a nocturnal surge of growth hormone, resulting in hyperglycemia that is present during the night (2:00–4:00 am) and is sustained until morning. Treatment involves increasing the evening dose of intermediate-acting insulin or moving the evening insulin to bedtime. In the *Somogyi effect*, morning glucose is high as a physiological response to nighttime hypoglycemia. Management of this condition requires decreasing the evening intermediate-acting insulin or increasing the carbohydrate content of a bedtime snack.

Adolescents require special consideration. The sexual maturation process occurs in the setting of relative insulin resistance, other hormonal alterations, and a burden of developmental tasks, which make glycemic control problematic at best. Daily insulin requirements may increase to 1.5 to 2 U/kg during adolescence but return to prepubertal levels at the end of the teenage years. Particular efforts must be made to ensure physical and psychological growth in the context of these special tasks. Dietary manipulation and consideration of alternative (usually more intensive) insulin and monitoring regimens is critical for successful glycemic control during this challenging period.

Continuous subcutaneous insulin infusion pumps afford the advantages of programmed variable basal rates and insulin dosing during specific times of the day. In a long-term study on outcomes among children with DM1, children on pumps had fewer hypoglycemic events and hospitalizations for DKA and improved HbA_{1c}. Although insulin pumps are not widely used in young children because of the potential risk of mechanical malfunction and catheter problems (resulting in hypoglycemia or hyperglycemia), they may be considered in children with unstable diabetes or to provide very low doses of insulin. Recent technologic advances have led to development of a hybrid closed loop system, which combines insulin pump and continuous glucose monitoring technology to allow continuous, automatic adjustment of insulin infusion based on the patient's blood glucose patterns.

Table 154.2. Commonly Used Insulin Preparations[a]

Type	*Onset of Action*	*Duration of Effect*
Rapid-acting analogs Lispro, aspart, glulisine	Within 15 minutes	≤5 hours
Short-acting Regular	Within 30 minutes	5–8 hours
Intermediate-acting[b] (zinc or protamine) Neutral protamine Hagedorn	1.5–2.5 hours	18–24 hours
Long-acting[b] Glargine Detemir Degludec	 70 minutes 1.5–2.5 hours 1 hour	 22–24 hours 20–24 hours ≥24 hours

[a] Twice-daily injections: Two-thirds of the total daily dose before breakfast made up of intermediate- and short-acting insulin in 2:1 ratio. One-third before dinner made up of intermediate- and short-acting insulin in 1:1 ratio.

[b] Bedtime dose: Intermediate- or long-acting insulin with regular insulin or short-acting insulin analog before each meal.

Glucose Monitoring

Self-monitoring of glycemic response through the in-home assessment of blood glucose levels is critical to effective therapy. The introduction of reflectance meters (ie, glucometers) has obviated the need for inaccurate, visually read strips of glucose-sensitive paper. The patient who is taking insulin should measure glucose 4 to 7 times daily. Most endocrinologists advocate testing before each meal and at bedtime during the first year after diagnosis. Testing may also be done at 2:00 am to test for hypoglycemia or hyperglycemia. Depending on the age of the child, an acceptable range for glycemic control is 80 to 150 mg/dL. Additional short-acting insulin may be given to correct for high blood glucose. Patients also need to monitor their urine for ketones whenever their blood glucose readings exceed 240 mg/dL.

Glycosylated HbA_{1c} measurements reflect glucose control over the preceding 2 to 3 months. The normal value is 4% to 5.6% of total hemoglobin, and the target value for individuals with diabetes is less than or equal to 7.5%. Glycosylated hemoglobin values less than 7% are excellent, between 7% and 8% are good, between 8% and 10% suggest need for improvement, and more than 10% are poor. The Diabetes Control and Complications Trial studied the effect of different levels of glycemic control on the complications of diabetes. Although the study only included pediatric patients 13 years or older, the study did show that patients with "tight glycemic control" had lower HbA_{1c} levels and fewer long-term complications than patients not tightly controlled. Adolescents with tight glycemic control had a greater risk of hypoglycemic events than the control group, a fact that must be taken into consideration in determining ideal glycemic control for a child. Generally, tight glycemic control is not recommended for children younger than 5 years; for older children, glycemic control should be individualized to the patient. Whenever a child's routines undergo dramatic change, stepped-up home monitoring and medical consultation are advisable. Caution should be used in interpreting HbA_{1c} values in infants and others in whom fetal hemoglobin or other hemoglobin variants are present because these hemoglobin variants may falsely elevate or lower the value of HbA_{1c}. Although compliance with intensive regimens is an indisputable challenge (particularly as responsibility for management shifts from parent or guardian to child), increasing evidence underscores the importance of tight glycemic control.

Since the turn of the 21st century, continuous glucose monitoring systems have become increasingly available to patients as a part of routine diabetes care. Continuous glucose monitoring involves placement of a sensor subcutaneously to measure blood glucose in the interstitial fluid. The advantages of this system includes production of more blood glucose monitoring data without adding to the burden of fingerstick blood glucose. Continuous glucose monitoring may be a highly effective tool alone or with an insulin pump device, to observe trends of low or high blood glucose, allowing the patient and health professional to adjust insulin dosing accordingly to prevent hypoglycemia and to decrease blood glucose excursions.

Nutrition

The timing, amount, and types of foods eaten for meals and snacks should be relatively consistent from 1 day to the next to match the relative constancy of the exogenous insulin. Standard daily caloric requirements are distributed in the following fashion: carbohydrate, 50% to 55% (≤10% in the form of sucrose); protein, 20% to 25%; and fat, 25% to 30% (6%–8% polyunsaturated, ≤7%–10% saturated). In DM2 with overweight/obesity, however, the patient may benefit from overall reduced calorie intake (carbohydrates ≥130 g/day). The distribution of calories should be approximately 25% for breakfast, 25% for lunch, 30% for dinner, and 20% for snacks. Snacks are an important part of the nutrition regimen for the child with diabetes. Most nutritionists recommend 3 snacks for young children (between meals and at bedtime) and 2 for older children. Dietary discipline is a tremendous challenge for many children. Introducing 1 change at a time may make such dietary manipulations more acceptable over the long term. Additionally, establishing healthy eating habits requires availability of healthy choices in the child's environment. Cooperation from the school and home enhances the likelihood of a child developing healthy eating practices.

Carbohydrate counting is an important part of matching insulin requirements to nutritional intake. For the patient on multiple daily insulin injection schedules, flexibility exists in tailoring each dose of insulin based on the carbohydrate content of each meal or snack. For the patient on a twice-daily insulin injection regimen, consistent carbohydrate content of meals and snacks is important in maintaining blood glucose levels. Learning carbohydrate counting takes time for patients and families, and ongoing nutrition support must be provided to help them become familiar and comfortable with how different foods affect patients' blood glucose levels.

Exercise

Exercise contributes to glucose control by facilitating the use of glucose without the assistance of insulin. If not carefully undertaken on a regular basis, exercise can precipitate acute hypoglycemia. Physical activity enhances the body's sensitivity to insulin and can even decrease the daily insulin requirement. Thoughtful planning of exercise involves compensatory changes in food intake and insulin doses. For example, extra energy intake at bedtime may offset the nighttime hypoglycemia that accompanies late afternoon exercise. Seasonal physical activities may necessitate an adjustment in the insulin regimen at certain times of the year.

Education

The role of education is pivotal to the successful management of diabetes in childhood and throughout life. During childhood, educational efforts must be focused on the entire family unit. The affected child must be involved as early as possible and in ways that are developmentally appropriate. The process should involve the early introduction of basic survival information, such as insulin therapy and management of complications. This can be followed by more detailed information, including strategies to reduce long-term sequelae.

Prognosis

Diabetic ketoacidosis is the major cause of morbidity and mortality in children and adolescents, followed by hypoglycemia. Clinical signs of hypoglycemia in older children include shakiness, blurred vision, and dysarthria. Concerns about the neurodevelopmental effect of hypoglycemia in young children have led to the recommendation of more liberal glycemic control in early onset disease. Diabetic ketoacidosis, precipitated by an intercurrent infection or poor compliance, is a metabolic derangement that always requires urgent medical attention and often necessitates hospitalization. Replacement of fluids, attention to electrolyte abnormalities, and insulin therapy are the mainstays of treatment in the face of this complication.

An increase in the number of pediatric patients presenting with hyperglycemic hyperosmolar state (HHS) has occurred. Because management of HHS differs from that of DKA, it is necessary for the physician to be aware of HHS. In fact, treatment for children with HHS may be different from treatment of this disorder in adults.

Long-term complications include proliferative retinopathy, nephropathy, peripheral and autonomic neurologic impairment, and early onset of cardiovascular disease. Ophthalmologic evaluation, overnight urine protein measurement, and a detailed neurologic examination should occur once or twice a year depending on the duration of disease. Intensive therapeutic intervention results in significant reduction in retinopathy, nephropathy, and cardiac and peripheral vascular disease. Preliminary evidence warrants consideration of such therapy with the expectation of benefit in long-term outcomes.

CASE RESOLUTION

With the presence of ketones, the girl is admitted to the hospital to initiate insulin treatment and determine appropriate dosing. Anti-GAD and anti-ICA levels are ordered to determine if she has autoimmunity, which would indicate DM1. She and her family require ongoing education. Careful management is necessary to optimize normal growth and development as well as to delay or prevent long-term sequelae.

CHAPTER 155

Childhood Obesity

H. Mollie Greves Grow, MD, MPH, FAAP

CASE STUDY

A 10-year-old girl is brought to the office by her mother to discuss concerns about the child's weight, which is 59 kg (130 lb). Her height is 140 cm (55 in), giving her a body mass index of 30 (>95th percentile for age). The remainder of the physical examination, including vital signs, is normal. The mother, who also has overweight, says she does not want her daughter to "end up like me." The patient says she gets teased at school about her weight. The history reveals that this patient is an only child who lives with her single mother in low-income housing in a large city. The mother works the day shift as a nurse's aide at a nearby nursing home. Because the mother is often tired, meals are simple and frequently consist of prepackaged foods, such as pastries for breakfast and frozen dinners for supper. At school, the girl buys her lunch, which usually includes whole milk, a processed entrée, and a dessert. After school, the girl goes home, where she watches television and snacks on chips and soda until her mother arrives home from work. The mother does not allow her daughter to play outside because the neighborhood is unsafe.

Questions

1. How is obesity defined and measured, and what are some pitfalls in measurement?
2. How do genetic susceptibility and environment interact to influence an individual's risk for obesity?
3. What are the complications of childhood obesity?
4. What is the role of the primary care physician in addressing childhood obesity?
5. How can obesity be managed in a supportive, nonstigmatizing way?

Childhood obesity is of significant concern because children with overweight are more likely to have overweight as adults and are at increased risk for multiple chronic conditions. Additionally, having obesity carries a psychosocial toll for affected adults and children, because it remains among the most stigmatized conditions. Children with obesity are often shunned by peers at school, feel isolated, and have fewer friends, whereas adolescents with obesity complete less schooling, go on to have lower household incomes, and are more likely to live in poverty than their counterparts without obesity. The primary care physician is usually the first (and often only) resource available to help patients and their families in screening, diagnosing, discussing, and managing childhood obesity.

Defining obesity presents certain challenges. Ideally, a measure of obesity would correlate with adiposity and predict morbidity and mortality. Body mass index (BMI) (weight in kilograms divided by height in meters squared) is the best and most widely used surrogate measure for obesity but does not completely correlate with adiposity for all individuals. Standards for adults have established a BMI of 25 or greater as overweight and 30 or greater as obese, based on increased risk of morbidity and mortality above these levels. Although BMI currently is the preferred method for assessing degree of obesity in children, other criteria are also used (Box 155.1). Experts classify children at the 85th to 95th percentile of BMI for age as having overweight and those greater than the 95th percentile of BMI for age as having obesity. Because BMI is not a direct measure of adiposity, it is important to recognize that not all children who meet the BMI criteria for overweight and obesity will have adverse health effects of their weight status. A helpful general rule is that the higher the BMI rises above the 95th percentile, the greater likelihood of adverse health effects. For BMI greater than the 99th percentile, which is associated with the most comorbidities, often a switch is made to using a BMI number, as for adults, or alternatively, the percentage above the 95th percentile. The BMI changes as children age because of changes in their proportion of bone mass and lean-to-fat tissue composition. After approximately 1 year of age, BMI-for-age values begin to decline and continue to do so during the preschool years until the BMI reaches a minimum at approximately 5 to 6 years of age, before rising throughout the remainder of childhood, into adolescence and adulthood. This phenomenon of increasing BMI after the nadir in the preschool years is referred to as *adiposity rebound*. Early adiposity rebound (age <4.8 years) is a predictor of later obesity and can be used clinically to identify children at risk.

Box 155.1. Diagnosis of Obesity

- Body mass index >95th percentile for age and sex (≥85th percentile is overweight)
- Body mass index >99th percentile or 120% above the 95th percentile is considered severe obesity
- Weight-for-height >95th percentile (typically used for children younger than 2 years)
- Greater than 120% of ideal body weight for height and age

Epidemiology

The prevalence of obesity is on the rise globally, especially in developed countries. Between 1980 and 2000, the percentage of overweight children and adolescents in the United States tripled, reaching 17.1% in 2003 to 2004. Since then, no significant increases have been seen overall among the US youth population, except for increases in the highest BMI group (>97th percentile). Severe obesity affects 4.5 million U.S. children and adolescents. Hispanic, black, and Native American individuals are disproportionately affected. People with lower education and those in poverty are at highest risk. Prevention and treatment of obesity is important to avoid health risks that affect the individual and are costly to society as a whole. In the United States, the overall spending associated with overweight and obesity was $93 billion in 2002 dollars, one-half of which was publicly financed through Medicare or Medicaid.

Clinical Presentation

The child with obesity usually presents to the physician in 1 of 2 ways. The parent(s)/guardian(s) or the child may come in concerned that the child has overweight (as in the case study). The physician must then consider the growth parameters and BMI for age to make an appropriate determination of the child's overweight status. The more common presentation is the parent who does not recognize that the child has overweight and who may believe that being big is a sign of health. The lack of awareness of the child's risk may particularly affect a parent during the time of the adiposity nadir (ie, the preschool and early school-age years when children are most lean), when early intervention to improve energy balance might yield the most benefit. Measurement of the child's height and weight and determination of BMI for age is important at all ages to identify the child who has overweight or obesity or is gaining weight more rapidly than expected; it is especially critical during early childhood when outward appearances may be most unreliable. Seeing change in percentiles is particularly helpful to differentiate children who may be healthy and grow steadily along a higher BMI curve, such as those 5% at the 95th percentile who are naturally in the high BMI range and are not adversely affected in their overall health.

Pathophysiology

Understanding of the pathophysiology of obesity continues to evolve. Certain neurohormones affect appetite, satiety, and the balance between fat storage and energy production. Ultimately, obesity results when energy intake exceeds expenditure. Historically, the storage of excess calories was an advantage to our ancestors who faced intermittent food shortage; however, this predisposition to store excess calories has contributed to increasing rates of obesity in our current setting in which the environment provides ubiquitous highly palatable, high-calorie, convenient foods and limited opportunities for physical activity.

It is known from studies of twins and family networks that susceptibility to obesity is influenced substantially by genetics; however, the magnitude of recent increases in obesity rates is suggestive of an interaction between genetic susceptibility and an obesogenic environment that facilitates unhealthy behaviors. National surveys indicate that individuals in the United States are consuming more calories now than they were decades ago. This trend is most related to increasingly widespread and easily available calorically dense foods in larger portions than ever before. A smaller but also important contribution of the population weight gain comes from less physical activity and more sedentary lifestyles. The reasons for this are myriad and include changes in transportation patterns, shifts in the workforce to jobs that involve less manual labor, and automation of household work. Children in particular have fewer opportunities for activity because of safety concerns; work habits of parents; the availability of television, computers, tablets, and smartphones; and reduced availability of physical education in school and after-school programs.

Differential Diagnosis

Most children who present to a physician with excess weight have primary obesity resulting from genetic susceptibility combined with an imbalance of caloric intake and activity levels. Only a small proportion of children have another cause, such as hypothyroidism, although many parents or guardians may initially inquire about another etiology. A thorough history, including review of systems, physical examination, and evaluation of growth parameters, helps confirm primary obesity in most cases. Whereas the child with primary obesity tends to have normal or increased height for age, the child with another etiology, such as hypothyroidism, typically is shorter than normal or has a delayed rate of linear growth. Certain genetic syndromes, such as Prader-Willi syndrome, pseudohypoparathyroidism, Bardet-Biedl syndrome, and Laurence-Moon syndrome, are associated with obesity. However, a child with any of these syndromes has other findings, such as developmental delay, dysmorphic features, and short stature, that are usually identifiable during the physical examination. Although initially another medical cause of weight gain may be lacking, evidence exists that weight gain can be exacerbated by an acquired diagnosis, such as sleep apnea, that manifests as a complication of obesity.

Evaluation

History

The history should include the age of the child, parental weight, and lifestyle information (Box 155.2). Knowledge of a child's birth weight and gestational age may be helpful. Term neonates weighing more than 4 kg (9 lb) are at increased risk of obesity. Preterm status is also a risk factor for subsequent obesity, possibly related to early metabolic effects of rapid catch-up weight gain after birth. Exclusive formula feeding may be a risk factor for obesity. A diet history, such as the 24-hour recall method or, alternatively, use of screening questions filled out by the parent or guardian in the waiting room, can be helpful to understand the dietary factors contributing to the child's overweight status, as well as to identify areas for potential change. Additionally, a history of signs or symptoms of complications of obesity should be elicited. For example, a teenager may complain of hip or knee pain

Box 155.2. What to Ask

Obesity

Open-Ended Questions to Engage Lifestyle and Family Changes Include

- What concerns do you have about your child's health? How do you feel about your child's weight?
- How has the current weight affected your child's life (eg, teasing, difficulty exercising or sleep)?
- What are you and your family already doing to support healthy habits for eating and activity?

Specific Probes to Learn More About the Child's Usual Daily Activities and Home Environment Include

- Who cares for your child during the day? (Home-based child care provided by grandparents or other family members is associated with increased risk of overweight.)
- How often does your child get to be physically active (eg, recess, physical education class, after school, on weekends)?
- Where are opportunities to add more activity (eg, to or from school, on weekends, playing sports or recreation, with parents)?
- How much time does your child spend in front of a screen, whether watching television or using a telephone, tablet, or computer? What are family guidelines for screen time? What media devices are in the child's bedroom?
- On a typical day, starting first thing in the morning, what does your child eat?
- How often does your family eat meals together? How often do you eat fast food or go out to eat?
- Who does the shopping and food preparation? Does the person who shops for food worry about food running out at home before there is money to buy more?
- How often does the child drink milk and water? How often does the child drink soda or juice drinks?
- What time does your child go to sleep and wake up? Does your child snore? Is your child rested during the day?

Questions to Set a Mutual Agenda

- What are some things you and your family would like to change for healthier eating and activity?
- Who might support you and your family in making changes?

Some Additional Questions for the Older Child or Adolescent

- Have you tried to lose weight before? How?
- Are you depressed?
- Have you participated in fad dieting? Fasting? Laxative use? Diuretic use?
- Have you used drugs, whether illicit, over the counter, or prescription, to lose weight?
- Have you used nutritional supplements for weight loss?
- Have you ever binged? Purged?
- Do you use tobacco? Alcohol?

suggestive of slipped capital femoral epiphysis (SCFE). The child may have a history of snoring, or apneic pauses followed by gasping for breath during sleep, and daytime sleepiness indicating obstructive sleep apnea (OSA). A history of irregular menstrual periods is useful in evaluation for polycystic ovary syndrome. A mental health history, including depression and anxiety symptoms, disordered eating, and history of bullying, is important to obtain. The family history, especially information on familial obesity, diabetes, hypertension, and early cardiac death, offers clues to the risk of obesity complications. Finally, a social history, including family social stressors, substance use, poverty, and food insecurity, is important to gauge the child's risks and the family's need for support to address obesity concerns.

Physical Examination

The accurate measurement of height and weight using appropriate equipment and plotting growth parameters on a BMI chart should be essential components of every well-child visit. For the child 2 years and older, the revised 2000 growth curves developed by the National Center for Health Statistics enable the physician and other health professionals to evaluate BMI for age relative to other children of the same sex. Before age 2 years, the World Health Organization weight-for-length curves should be used to assess proportional growth. Both sets of growth curves are available at www.cdc.gov/growthcharts. The child also should be examined for any dysmorphic features suggestive of an underlying genetic syndrome.

The physician should assess for potential complications of obesity when examining a child with overweight. Although many complications of obesity do not manifest until adulthood, the child with overweight is at risk for several conditions, including hypertension, hyperlipidemia, type 2 diabetes, nonalcoholic fatty liver disease, OSA, and orthopedic problems. Blood pressure should be accurately measured with an appropriate-sized cuff (larger cuffs are needed for youth with overweight) and compared with age-based standards. The skin should be examined for striae and acanthosis nigricans, the velvety pigmented lesion commonly found on the neck or axilla, which is associated with insulin resistance in children with overweight. Skin findings of hirsutism and acne in the adolescent girl with obesity may be indicative of polycystic ovary syndrome. The musculoskeletal examination should assess joint alignment and range of motion for Blount disease (ie, severe tibial bowing), SCFE, or other degenerative joint diseases. Tanner stage should be assessed for evidence of premature puberty.

Laboratory Tests

One-third to one-half of children with obesity have evidence of metabolic syndrome, a cluster of traits that includes hyperinsulinemia, obesity, hypertension, and hyperlipidemia. The higher the BMI for age, the greater the risk for metabolic complications. Laboratory studies to evaluate for potential complications of obesity are recommended starting at age 10 years, or earlier if specific concerns exist, such as severe obesity (ie, >99th percentile BMI for age) or a strong family history of type 2 diabetes or hyperlipidemia. Children age 10 years or older with a BMI above the 95th percentile (and those with BMI >85th percentile with family or other risk factors) are recommended to undergo fasting glucose and a fasting lipid panel. Some experts also recommend screening for fatty liver disease with an alanine transaminase test. The fasting glucose and/or the hemoglobin A_{1c} can help screen for diabetes or prediabetes. If results are abnormal, these tests should be repeated to confirm

diagnosis. Higher rates of nutritional deficiencies reported among youth with overweight include vitamin D, calcium, and iron; thus, screening for these should be considered based on dietary history and other risk factors.

If a genetic condition is suspected, an evaluation by a geneticist is indicated for high-resolution karyotype and other genetic tests, as directed by the suspected syndrome. For rare cases in which an underlying endocrine disorder is suspected, thyroid function studies or cortisol levels may be considered.

The child with a history of sleep-disordered breathing should be referred for a sleep study.

Imaging Studies

Radiologic studies are indicated when orthopedic complications of obesity, such as Blount disease or SCFE, are suspected. Echocardiography for evaluation of ventricular hypertrophy is a consideration in the child with long-standing hypertension, which is suggestive of left ventricle involvement, or OSA, which is suggestive of right ventricle involvement.

Box 155.3. Recommended Stages of Obesity Treatment

- Stage 1: *Prevention plus:* Initial treatment in the primary care office focuses on behavioral strategies for eating and activity changes to address causes of energy imbalance.
- Stage 2 (if no improvement within 3–6 months after stage 1): *Structured weight management* involving specific targeted goal behaviors for eating, activity, and reducing sedentary time; should include self-monitoring in the office or another setting for individual or group treatment.
- Stage 3 (if no improvement within 3–6 months after stage 2): *Comprehensive multidisciplinary management* in a pediatric weight management center or equivalent program.
- Stage 4 (for patients with body mass index >99th percentile or more severe comorbidities): *Tertiary care intervention* in a tertiary care facility that oversees more targeted medical weight loss and may offer surgical approaches.

Adapted with permission from Spear BA, Barlow SE, Ervin C, et al. Recommendations for treatment of child and adolescent overweight and obesity. Pediatrics. 2017;120(S4):S254–S288.

Management

Because not every child with obesity progresses to obesity in adulthood, a staged approach is recommended in managing childhood obesity. The pediatrician's first task is to help prevent obesity through identifying risk and using patient-directed counseling to promote healthy target behaviors and avoid unhealthy ones. Risk is largely determined by the child's age and history of parental/guardian obesity; however, race/ethnicity may also play a role. The child younger than 3 years with obesity but without an obese parent is at low risk for future obesity. These children should be monitored but, for the most part, do not require intervention. Between the ages of 3 and 5 years, parental obesity substantially increases the risk of a child having obesity as an adult. The chance of adult obesity in a preschool-age child with obesity with at least 1 parent with obesity is above 60%. In the older child, the child's own status of obesity is an increasingly important predictor of obesity in adulthood, regardless of whether a parent is obese. The probability that a child older than 6 years and with overweight will have obesity as an adult is 50%, regardless of parental obesity status. The child determined to be at high risk for future obesity requires close surveillance and intervention by the physician.

After a child has been identified as overweight, the physician is advised to follow the recommended stages of obesity treatment as shown in Box 155.3.

The core of child obesity treatment focuses on behavior and lifestyle modification, the aims of which are to improve health through increasing fitness, decreasing metabolic complications, and reducing or stabilizing BMI. The goal of treatment is sustainable and appropriate healthy eating and physical activities that do not result in disordered eating or inappropriate body image. Throughout assessment and management of obesity, the primary care physician should use supportive, nonstigmatizing language (eg, avoiding the terms "obese" and "obesity" and instead emphasizing "health" and "balance"). The physician should help families work together on physical fitness and overall health rather than focusing only on weight or body size. Involvement of the entire family in supporting healthy behaviors is necessary; the child who feels stigmatized or singled out within the family because of the child's weight may do worse overall with future weight-related health behaviors. Additionally, the physician should monitor children and teenagers for inappropriate focus on weight or engaging in unhealthy weight loss practices, including laxative abuse, induced vomiting, and fasting (see Chapter 64).

The initial weight change goal in caring for the prepubertal child with overweight is slowing weight gain or maintaining weight during normal linear growth. If more advanced treatment is indicated, the goal may include weight loss; however, loss of not more than 0.5 kg (1 lb) per month is recommended for children aged 2 to 5 years. Youth aged 12 to 18 years (or postpubertal individuals) may start at any of the 4 treatment stages, depending on severity and readiness to change. Initial treatment goals for children older than 5 years may be slowed weight gain or weight loss, with weight loss not more than 0.9 kg (2 lb) per month. As a quaternary intervention, surgical treatments for obesity are increasingly available for teenagers in select medical centers. Based on the latest policy guidance from the American Academy of Pediatrics (AAP), primary care pediatricians should recognize that severe obesity is a high-risk medical condition that is unlikely to resolve without intervention. Pediatric providers should refer patients who have severe obesity with comorbid conditions to comprehensive programs where surgery could be considered.

The physician can be most successful and efficacious in managing obesity by individualizing recommendations to the specific child and family and helping the child and family access available community resources. Motivational interviewing techniques can be helpful in determining and promoting a family's readiness to make changes to address weight concerns (Box 155.4). For the family that may not be ready to make changes, the physician can focus more on

Box 155.4. Brief Motivational Interviewing Approach to Management of Obesity in the Pediatric Patient

Goal: Through nonjudgmental questions and reflective listening, elicit a realistic plan for addressing the child's weight/health consistent with the family's values and goals.

Use: Basic motivational interviewing skills or OARS:

- O: Open-ended questions (eg, those starting with "How," "What," or "Tell me about . . .")
- A: Affirmations (eg, "You are already doing a good job with . . .")
- R: Reflections (eg, "It sounds as though you would like some help with changing . . .")
- S: Summaries (eg, "Let me see if I can summarize our discussion and plans between now and the next visit . . .")

Steps: Basic approach in 15 minutes

1. Assess BMI, inform parent or guardian and/or patient, elicit response.
   "Your child's BMI (ie, balance of weight to height) is in a range in which we start to be concerned about extra weight causing health problems. What concerns, if any, do you have about your child's weight?"
2. Set agenda: Assess what the parent or guardian and/or patient has already done, those individuals' goals for change, and possible target behaviors (Box 155.2).
3. Assess motivation and confidence to make the changes.
   "On a scale of 1 to 10, with 10 being highest, how important are the changes we have talked about for you? Why are you an "X" (ie, number chosen by the patient or family member) and not a "Y" (ie, lower number)?"
4. Ask about ways to implement the parent's or guardian's and/or patient's plans and/or goals.
   "Who can help you with your plans? What will help you be successful? How have you been able to make a change in the past?"
5. Summarize: Review plans (including follow-up), express confidence in the family, and offer further help.
   "Let's summarize our discussion today. You have planned to ____, and this is important to you because ____. You will get some help from ____ to be successful. This sounds like a plan that can work. I know you can do it if you set your mind to it. I suggest we meet again in 1 month to check in. I look forward to hearing about how well you are doing. At that time we can discuss other ways I might be able to help, such as a referral to a nutritionist or an exercise program."

Abbreviation: BMI, body mass index.

understanding values and current barriers, ordering appropriate testing to help the family assess risk, checking in frequently, and providing encouragement while respecting autonomy. For the family that is more ready to change, the physician can actively elicit from the patient and parent what those stakeholders consider to be important and feasible lifestyle changes and how they want to go about reaching their goals.

Modifying behaviors related to food and activity is difficult, and patients and their families require ongoing support and attention from their primary care physician as well as from additional clinical and community resources as they attempt to integrate and maintain healthy habits in their lives. Engaging with the family to elicit solutions and brainstorm solutions to barriers is more likely to yield positive results than blanket advice or recommendations. Even well-intentioned clinical recommendations are unlikely to be implemented if they are inconsistent with a patient's and family's values, culture, and resources. For example, a child's participation in an after-school sports program may not be a realistic option if a family cannot afford the fees or transportation to and from the program; instead, a school-based after-school program or an evening or weekend class at a community center with the parent might be an option.

In preventing and treating childhood obesity, the physician must also recognize the gaps between knowledge and behavior. That is, understanding that good nutrition and physical activity are important does not necessarily translate into healthy eating or regular exercise. For example, a parent may know to limit fat and sugar but may continue buying quantities of processed foods because of convenience or price or because of not knowing how to prepare healthier foods. Alternatively, some families may have food insecurity or periods with inadequate food that may result in overeating inexpensive, energy-dense foods. The physician should connect such families with nutrition assistance programs (eg, Special Supplemental Nutrition Program for Women, Infants, and Children [WIC], Supplemental Nutrition Assistance Program [SNAP]). Most families need additional education on appropriate serving sizes, preparation of healthful food, interpreting food labels, and making healthy food choices to counteract the mixed messages about nutrition in the media. Because time is limited in primary care office visits, referral to a dietitian or nutrition classes through WIC can be an initial step in providing families the necessary education and planning needed for changing their eating habits. For the motivated family, a dietitian can be particularly helpful for providing ideas to plan healthful daily meals and snacks.

Because the options for actively managing childhood obesity remain somewhat limited in the primary care setting, it is critically important for the physician to be aware and take full advantage of the available treatment programs in the local area. Increasingly, successful, evidence-based programs are available to help children attain a healthier weight. To date, the most efficacious programs are moderate-intensity, family-based behavioral treatment, generally of 3 to 12 months' duration. The physician can play an active role in referring to structured treatment programs by being a knowledgeable source of information and helping families learn about and become interested in these programs. Family participation in such programs often is dependent on support and encouragement from a trusted health professional. If structured overweight treatment programs are not available in the local area, the physician can recommend and refer to structured physical activity programs, such as those at local YMCAs or community centers. Physical activity programs can help a patient improve physical fitness and lower metabolic risks related to obesity, even if such programs do not result in weight loss.

A basic set of guidelines that physicians can use to help families move toward a healthier lifestyle is included in Box 155.5. Items on this list are evidence based from the standpoint that families who have implemented these generally have children with healthier weight. Some involve fairly simple changes, such as reducing intake of sugar-sweetened beverages or switching to lower-fat milk. Other suggestions may require more knowledge or motivation to implement successfully. Many websites provide excellent educational resources for families, including the US Department of Agriculture ChooseMyPlate.gov (www.choosemyplate.gov) and *Dietary Guidelines for Americans,* which is published every 5 years (www.health.gov/dietaryguidelines); Nemours KidsHealth (https://kidshealth.org); and the Let's Move! campaign initiated by former First Lady Michelle Obama (https://letsmove.obamawhitehouse.archives.gov).

Given the complexity of managing obesity, more clinical tools and additional training for pediatric professionals are available, including the AAP Section on Obesity (www.aap.org/obesity), AAP Institute for Healthy Childhood Weight (https://ihcw.aap.org/), and *We Can!* resources from the National Heart, Lung, and Blood Institute (www.nhlbi.nih.gov/health/public/heart/obesity/wecan).

Box 155.5. Ten Guidelines to Help Families Adopt a Healthier Lifestyle

1. Learn about the child's and family's usual diet and activity pattern to elicit ideas about helpful changes in which they are interested and are capable of making.
2. Promote simple "5210" guidelines for healthy living: 5 fruits and vegetables a day, ≤2 hours of screen time, ≥1 hour of physical activity, and 0 sugar-sweetened beverages a day.
3. Encourage intake of more "natural" foods, such as fruits and vegetables (fresh or frozen). Limit processed and prepackaged foods and snacks (which have added sugar and fat that children do not need) by keeping them out of the house as much as possible.
4. Set family guidelines on recreational screen time with a goal of <2 hours a day, including television, telephones, and tablets. Keep media devices out of children's and teenagers' bedrooms. (This is easier to do if the physician helps educate about not putting them there in the first place.)
5. Promote "fitness over fatness": every individual can be active and benefits from activity, regardless of the individual's weight. Explore ways for children and families to be active as part of their daily routine, with a goal of 60 minutes a day. Find sports or activities that the child enjoys and can master.
6. Teach healthy beverages for all ages: Milk and water is all we need. For children older than 1 to 2 years, change to 1% or fat-free milk. Limit milk to 16 to 20 oz per day after age 1 year. If the parent or guardian serves juice, limit the amount to <4 oz per day for toddlers and <6 oz for older children. Limit soda to special occasions (eg, birthdays).
7. Limit eating out, especially at fast-food restaurants. A goal is once a week or less. Find easy "make at home" versions of fast food, such as homemade pizza, sub sandwiches, and lean turkey burgers.
8. Promote regular family meals cooked at home. Make family mealtime a positive experience by turning off televisions and devices and instead talking together. Share stories about the day, "highs and lows," and/or something for which each person is grateful.
9. Encourage appropriate portion sizes for family members based on need. Teach parent(s)/guardian(s) "responsive eating" and how to respond to children's hunger cues during infancy and the toddler phase. Teach the "parent provides, child decides" approach to eating for children.
10. Promote healthy sleep, including regular bedtimes and adequate sleep (10–11 hours for school-age children; 8–9 hours for teenagers). Discuss how important it is to turn off devices at least 1 hour before bedtime.

Prevention

Prevention of obesity is the best option for reversing the growing epidemic of obesity and obesity-related comorbidities. Prevention of obesity should be a priority for all physicians who care for children and should focus on 3 broad areas: anticipatory guidance starting in infancy on healthful eating, adequate sleep, minimizing screen time, and providing access to regular physical activity with an emphasis on promoting overall health; early intervention for families with children who are at increased risk for developing obesity; and advocacy for public health measures to increase opportunities for healthful eating and regular physical activity within local communities. The pediatrician can take an active role in improving obesity trends by supporting changes in school and child care institutions, communities, and national policies (see resources available through the AAP and the Institute for Healthy Childhood Weight).

Prognosis

Without intervention, average life expectancy of individuals living in the United States is currently projected to decrease because of the increasing incidence of diseases associated with obesity, such as diabetes. Poor diet and sedentary lifestyles rival smoking as a preventable cause of premature death. Children with obesity who retain obesity into adulthood are at greatly increased risk for all the complications of obesity. Evidence suggests, however, that early intervention at the family and community levels can change this trajectory. Pediatricians continue to improve rates of BMI screening and referral, and those who have had training in obesity management are even more likely to implement current recommendations. Globally, more physicians and organizations are taking an active role in preventing and managing childhood obesity, and treatment options continue to evolve and improve, including the safety of bariatric surgery for youth with severe obesity. In most communities, there is a need for greater availability of all programs addressing child obesity, from prevention to treatment; pediatricians can be effective advocates for addressing this need. Childhood obesity rates in the United States have begun to stabilize, which may be a positive sign for the future.

CASE RESOLUTION

The case study describes a girl with obesity who is at substantial risk for retaining obesity into adulthood based on her present weight and her mother's history of obesity, as well as social and economic risk factors. Strengths for the family include a caring, engaged mother who recognizes her daughter's weight as a concern and is motivated to make changes. Working with a dietitian, the mother and daughter learn about simple changes for healthy diets. They begin to plan meals and snacks that include fruits and vegetables and can be prepared in advance. The daughter starts making her own lunch each night before school. The mother changes her grocery shopping: She buys 1% milk instead of whole milk and stops buying as many cookies, chips, and soda, except as an occasional treat. A social worker helps find an after-school program at the nearby YMCA. The patient starts attending and, with some special attention from the coach, finds she enjoys basketball and decides she would like to try out for the school team next year. The mother wants to exercise more, so she and her daughter plan after-dinner walks around the track at the local high school.

Over the next 6 months, you follow mother and daughter closely. The most recent growth parameters show that the girl has maintained her weight at 59 kg (130 lb) but has grown 5 cm (2 in) to a height of 145 cm (57 in), giving her a BMI of 28. The mother has lost 2.7 kg (5 lb) during this period, and both she and her daughter are excited about continuing their new lifestyle.

CHAPTER 156

Juvenile Idiopathic Arthritis and Benign Joint Pains of Childhood

Miriam F. Parsa, MD, MPH, FAAP, and Deborah McCurdy, MD, FAAP

CASE STUDY

A 4-year-old white girl is evaluated for limp. The parents are unclear about the duration of her symptoms, although they believe she began exhibiting knee problems after she was playing with her brother 3 months previously. The parents have observed the patient to walk "like her grandmother" every morning, with marked improvement in her gait after approximately 1 hour of movement. Her activity level has remained about the same, although the morning limp limits her ability to keep up with her siblings. She has no history of rash, fever, weight loss, severe pain, or other joint involvement. On physical examination, vital signs are normal; her left knee is swollen, with a 20° flexion contracture; and the left leg is 1.5 cm (0.6 in) longer than the right leg.

Questions

1. What findings are indicative of juvenile idiopathic arthritis?
2. What is the differential diagnosis for monoarticular arthritis?
3. Which laboratory tests are important in the diagnostic workup of a child with suspected juvenile idiopathic arthritis?
4. What are the most common complications of juvenile idiopathic arthritis?
5. What other organs are involved in juvenile idiopathic arthritis?
6. What are the long-term outcomes for the patient with juvenile idiopathic arthritis?
7. What types of agents are used in the management of juvenile idiopathic arthritis?

Joint pain is a common presentation in the pediatric population, and etiologies include trauma, infection, anatomic, and chronic inflammatory arthritis, such as juvenile idiopathic arthritis (JIA). Differentiating between a benign, self-limited etiology and a potentially destructive, chronic process is critical to the preservation of growing bones and cartilage. The etiology of joint pain may be roughly divided into 2 categories: mechanical and inflammatory. Mechanical or noninflammatory causes include pes planus, hindfoot valgus, and hypermobility. Inflammatory causes can be infectious, postinfectious (ie, immune complex mediated), or autoimmune mediated. Distinguishing between mechanical and inflammatory processes and determining the necessity of a pediatric rheumatology consultation may be straightforward after obtaining a detailed history and conducting a thorough physical examination and focused laboratory investigation.

Epidemiology

Juvenile idiopathic arthritis is the most common pediatric rheumatologic disease and among the more common chronic diseases of childhood. In the United States, the estimated annual incidence is 14 per 100,000 children, and the estimated prevalence is 96 per 100,000 children. The disease can occur in all racial and ethnic profiles with variable frequencies. Juvenile idiopathic arthritis is most prevalent among whites (typically oligoarticular JIA) and least prevalent in blacks and Asians. Consistent with most autoimmune diseases, females are affected more commonly than males.

Juvenile idiopathic arthritis is typically classified based on the International League of Associations for Rheumatology system. Juvenile idiopathic arthritis is an umbrella term for a set of diverse diseases with 1 common thread: chronic idiopathic inflammation of the joint space (Table 156.1). Juvenile idiopathic arthritis encompasses all of what historically was called "juvenile rheumatoid arthritis" and "juvenile chronic arthritis." The term "rheumatoid" was removed because rheumatoid factor (RF) antibodies are absent in most children with JIA. With increased knowledge of the genetics and inflammatory pathways in each subgroup of JIA, it is likely that the JIA nomenclature will be modified to further define the disease process and increase the homogeneity of each subgroup.

Table 156.1. International League of Associations for Rheumatology Classification of Juvenile Idiopathic Arthritis

JIA Subtype	*Peak Age of Onset (years)*	*Number of Joints Involved*	*Type of Onset*	*Sex Predilection*
Oligoarticular	4	≤4	Insidious	Girl > Boy
RF-negative polyarticular	2–5	≥5	Insidious	Girl > Boy
RF-positive polyarticular	12	≥5	Rapid	Girl > Boy
Systemic	Any, <16	Variable	Variable	Girl = Boy
Enthesitis related	12	Variable	Insidious	Girl < Boy
Psoriatic	3	Initially ≤4	Insidious	Girl > Boy
	11	≤4	Insidious	Girl = Boy

Abbreviations: JIA, juvenile idiopathic arthritis; RF, rheumatoid factor.

Data derived from Petty RE, Southwood TR, Manners P, et al; International League of Associations for Rheumatology. International League of Associations for Rheumatology classification of juvenile idiopathic arthritis: second revision, Edmonton, 2001. *J Rheumatol.* 2004;31(2):390–392; and Cassidy JT, Laxer RM, Petty RE, Lindsley CB. *Textbook of Pediatric Rheumatology.* 6th ed. Philadelphia, PA: Saunders Elsevier; 2011.

Clinical Presentation

Juvenile idiopathic arthritis presents with arthritis during the disease course. *Arthritis* is defined as joint edema on examination or a joint or joints with both pain on range of motion and limitation of range of motion. The onset of JIA may be insidious (eg, oligoarticular), rapid (eg, RF-positive polyarticular), or variable (eg, systemic) (Table 156.1). Adolescents 16 years and older with a new diagnosis of chronic idiopathic arthritis are considered to have adult rheumatoid arthritis, not JIA. The child with JIA may be observed to limp mostly in the mornings, have difficulty completing writing assignments, or exhibit regression of gross motor milestones. Complications of JIA, such as long-standing anterior uveitis, leg length discrepancy, and joint flexion contracture, may result in difficulties performing activities of daily living and at school. Leg length discrepancy is a product of chronic inflammation providing excess blood flow to an open epiphysis (eg, most obvious is the distal femoral epiphysis), causing premature and accelerated growth with eventual premature epiphyseal closure.

Oligoarticular JIA is the most common form of JIA, with approximately 50% of all JIA cases of this type, and peaks in the second and third years of life. It is defined by the presence of arthritis in fewer than 5 joints during the first 6 months of disease and most often involves the large joints; the knee is most commonly affected, followed by the hip. A child may present with single joint involvement. Oligoarticular JIA takes persistent and extended forms, the latter associated with a more severe disease course and mimicking adult polyarticular disease. Extended oligoarthritis remains asymmetric compared with rheumatoid arthritis, which is defined by symmetric disease. Up to 50% of children with oligoarticular JIA extend to involve 5 or more joints within several years of diagnosis (ie, extended oligoarthritis).

In addition to complications, such as leg length discrepancy and joint flexion contracture, the child with oligoarticular JIA is at increased risk for developing anterior uveitis. *Anterior uveitis* is inflammation of the anterior uveal tract and adjacent ciliary body, and it is not clear why the same types of inflammatory cells are targeting seemingly disparate targets (eyes and joints). Anterior uveitis may be a clinically silent component of the disease course in approximately 25% of all patients with oligoarticular JIA and, in a minority of affected patients, may cause blindness. Guidelines put forth by the American Academy of Pediatrics and American Academy of Ophthalmology define risk factors and ophthalmologic screening frequencies for the prevention of JIA-associated uveitis and are based on the age of onset of JIA and presence of antinuclear antibody (ANA) (Table 156.2). Screening recommendations are relevant for all children with oligoarticular, polyarticular, psoriatic, and undifferentiated JIA.

Polyarticular JIA is defined as arthritis of 5 or more joints during the first 6 months of disease and represents approximately 30% of JIA cases. The 2 peaks of disease incidence are suggestive of 2 different genetic interplays. Rheumatoid factor-negative disease is the more common subtype, often with a positive ANA test and increased risk for anterior uveitis, with a tendency to present in early childhood. Rheumatoid factor-positive disease most commonly presents in early adolescent girls with symmetric small joint disease and carries a worse prognosis in terms of joint damage. The arthritis is erosive and, if disease is uncontrolled, may result in *boutonnière deformity* (ie, proximal interphalangeal joint flexion and distal interphalangeal joint hyperextension) and *swan neck deformity* (ie, proximal interphalangeal joint hyperextension and distal interphalangeal joint flexion). Disease complications include flexion contractures, leg length discrepancy, uveitis, and temporomandibular joint arthritis.

Systemic JIA is present in 10% to 15% of patients with JIA and is associated with the greatest morbidity and mortality of all JIA subtypes. Systemic JIA lacks the autoantibody, sex, age, and human leukocyte antigen (HLA) associations seen associated with other

Table 156.2. Frequency of Ophthalmologic Examinations in Children With Juvenile Idiopathic Arthritis Based on Antinuclear Antibody Status and Age at Diagnosis[a]

Disease Subtype	*ANA*	*Age at Diagnosis (years)*	*Duration of Disease (years)*	*Risk Category*	*Frequency of Eye Examinations (months)*
Oligoarticular or polyarticular	+	≤6	≤4	High	3
	+	≤6	>4	Moderate	6
	+	≤6	>7	Low	12
	+	>6	≤4	Moderate	6
	+	>6	>4	Low	12

[a] Recommendations for follow-up continue through childhood and adolescence.

From Cassidy J, Kivlin J, Lindsley C, Nocton J; American Academy of Pediatrics Section on Rheumatology, Section on Ophthalmology. Ophthalmologic examinations in children with juvenile rheumatoid arthritis. *Pediatrics.* 2006;117(5):1843–1845.

JIA subtypes. It is characterized by fever, rash, lymphadenopathy, hepatosplenomegaly, and serositis. Classically, fevers are quotidian or daily in pattern and are accompanied by a migratory rash that consists of discrete salmon-colored macules seen predominantly on the trunk and proximal extremities (Figure 156.1). If arthritis is among the presenting symptoms, pain is worse during the febrile period. The arthritis is typically polyarticular, affecting large and small joints, and occurs within the first 6 months of symptoms. Patients are often initially categorized as "fever of unknown origin" because arthritis may be minimal or, more often, absent at time of presentation.

Macrophage activation syndrome is a rare but life-threatening complication of systemic JIA. Patients present with hepatosplenomegaly, lymphadenopathy, and purpura and may progress to multiorgan failure. A relative decrease in inflammatory markers (eg, erythrocyte sedimentation rate [ESR]) is observed in macrophage activation syndrome, which is in contrast to an elevation of these markers when systemic JIA exacerbates during disease exacerbation as liver and bone marrow function deteriorates. Treatment involves steroids and immunosuppressive therapy. In patients with systemic JIA, triggers to macrophage activation syndrome include viral infections and addition or change in medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs), sulfasalazine, and etanercept.

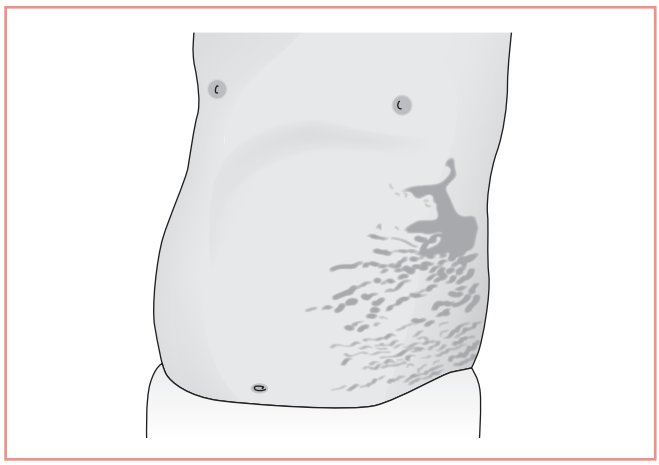

Figure 156.1. Salmon-colored rash seen in systemic juvenile idiopathic arthritis with Koebner phenomenon.

Enthesitis-related arthritis is characterized by typically lower extremity arthritis and inflammation of the insertions of tendons, ligaments, fascia, and joint capsule to bone (ie, *enthesitis*). Unlike oligoarticular and polyarticular JIA, in which autoantibodies are frequently present (eg, ANA, RF), enthesitis-related arthritis is generally seronegative with a strong association with HLA B27. Enthesitis-related arthritis most likely represents the earliest clinical stage of spondylarthritis, which is defined by inflammatory axial disease. Juvenile ankylosing spondylitis is an example of a spondylarthritis and generally affects boys aged 8 years or older. Extra-articular symptoms include anterior uveitis, which is acute and painful, in contrast with uveitis seen in oligoarticular and polyarticular arthritis, which is initially asymptomatic.

Psoriatic arthritis occurs in patients with chronic arthritis and psoriasis or those who meet 2 of the following criteria: dactylitis, nail pitting or onycholysis, and first-degree relative with psoriasis. The age at onset is biphasic, occurring at 3 years and 11 years of age. Clinical presentation of the younger cohort is similar to oligoarticular JIA, with the exception of higher frequencies of small joint involvement and dactylitis, with a sausage-like appearance of the digit. The older cohort resembles adult psoriatic arthritis and is characterized by axial skeletal involvement and enthesitis. The arthritis, which is

asymmetric, may present before the psoriatic rash, making diagnosis difficult. Similar to polyarticular JIA, the biphasic nature of psoriatic arthritis is suggestive of different genetic contributions. Up to 17% of patients have asymptomatic uveitis, similar to ANA-positive oligoarticular JIA, and require routine slit-lamp examination for diagnosis.

Differential Diagnosis

The differential diagnosis for joint pain in children is vast, including infectious, oncologic, immunologic, and autoimmune etiologies, and the pain can be characterized as self-limited or chronic based on a targeted history and thorough physical examination (Table 156.3) (Box 156.1). Joint pains of childhood may be self-limited in nature and include growing pains, postinfectious arthralgia, and pain amplification as well as mechanical abnormalities (eg, hypermobility syndrome) as causal.

Growing pains are a benign cause of pain in children and usually resolve within 1 to 2 years of onset (see Chapter 116). *Growing pains* are characterized by nocturnal pain without objective musculoskeletal manifestations. The pain generally is localized to the bilateral lower extremities and is relieved by massage, heat, or NSAIDs. The family history often is positive for growing pains. Additional workup is required in the patient with systemic symptoms (eg, fevers, weight loss), persistent pain during the day, objective musculoskeletal examination abnormalities, limping, or unilateral pain. *Osteoid osteoma* is a benign prostaglandin-producing bone tumor that typically involves the lower extremity, most commonly the proximal femur, and less commonly includes spinal involvement. Symptoms include unilateral, progressive pain that is worse at night, is unrelated to activity, and is improved with NSAIDs (ie, prostaglandin inhibitor). Physical examination may reveal point tenderness,

Box 156.1. Diagnosis of Juvenile Idiopathic Arthritis

- Systemic: arthritis + patterned fevers, rash, general malaise, and elevated inflammatory markers
- Oligoarticular: arthritis affecting ≤4 joints
- Polyarticular: arthritis affecting >5 joints
- Enthesitis related: arthritis + enthesitis, with or without human leukocyte antigen B27
- Psoriatic: arthritis + psoriasis *or* arthritis + dactylitis, nail abnormalities, family history of psoriasis

edema, or muscle atrophy. Diagnosis is made using a plain radiograph or, in select cases, computed tomography.

Mechanical or non-inflammatory causes of joint pain in children may include joint hypermobility (including genu recurvatum), hindfoot valgus or pronation, and pes planus. A typical presentation of a child with mechanical causes of joint pain includes a history of pain during or after activity, relief with rest, and typical physical examination findings. Further questioning may reveal a history of pain exacerbation of the knees, ankles, and feet when the child does not wear supportive shoes during physical activity. *Benign hypermobility syndrome* is defined as generalized joint hypermobility in the absence of other connective tissue abnormality or congenital syndrome. Although approximately 8% to 20% of whites meet criteria for this syndrome, many additional white individuals have hypermobility limited to a few joints. The patient with hypermobility syndrome commonly experiences fibromyalgia (a pain amplification syndrome) and patellofemoral syndrome as comorbid conditions. Joint edema can occur but is not persistent, as in chronic inflammatory arthritis.

Joint pain that is acute in onset, monoarticular, severe in quality, and accompanied by fever is suggestive of septic arthritis, an orthopedic emergency because of the rapid cartilage destruction if treatment is delayed. Monoarticular joint pain that is localized to the periarticular region, severe in quality, and accompanied by weight loss and abnormal complete blood cell count is suggestive of malignancy, such as acute lymphoblastic leukemia. Generally, joint pain that is persistent, daily, worse in the morning, not severe in quality, and known to improve with activity is suggestive of a chronic inflammatory arthropathy, such as JIA.

Pathophysiology

The exact pathogenesis of JIA is unclear, and a monogenetic inheritance pattern has not been observed. Autoimmune diseases result from an alteration in the selection, regulation, or death of T cells or B cells, which results in an abnormal response to a particular antigen. Genetic factors increase an individual's vulnerability but are not sufficient for disease expression. Clinical manifestations are believed to result from an interplay of environmental triggers, immune mechanisms, and largely specific HLA predisposition. Multiple HLA types have been associated with the development of JIA, with early-onset oligoarticular JIA having the most distinctive HLA associations. The level of risk to family members of a child with JIA seems to be only mildly increased compared with the general population.

The hallmark of chronic idiopathic arthritis is synovial cell proliferation with synovial fluid accumulation, also called pannus. The marked expansion of cells within a closed space results in stretching of periarticular ligaments and tendons. The cells responsible for inflammation (ie, lymphocytes [mostly T cells], macrophages, and dendritic cells) are recruited from the peripheral circulation and penetrate into the synovial membrane because of factors that include proangiogenic and vasoactive proteins. An aberrant immune system produces inflammatory cytokines that are found in large numbers within the synovial membrane or fluid (eg, tumor necrosis factor [TNF], interleukin [IL]-1, IL-6), enzymes that degrade collagen and articular cartilage, and signals that activate osteoclasts and result in bone erosion.

Evaluation

History

The history should clearly delineate the duration, severity, and extent of the symptoms (Box 156.2).

Physical Examination

The patient should undergo a complete physical examination that includes a full assessment of the skin, all joints (including the temporomandibular joint), flexibility of the spine (particularly cervical and lumbosacral), and evaluation for leg length discrepancy. Specific to the pediatric examination is the consideration of normal joint hypermobility when assessing for arthritis. Comparing bilateral joints is imperative in discerning subtle flexion contracture, which is suggestive of chronic arthritis. All patients suspected of having JIA should also undergo a slit-lamp examination of the eyes. However, any girl younger than 6 years and with a positive result on ANA testing should undergo an examination as soon as

Box 156.2. What to Ask

Juvenile Idiopathic Arthritis

- Has the child ever had any swelling, warmth, or redness of joints? Which joints have been involved and for how long?
- Does the child have difficulty walking or running? If so, does it occur at any particular time of day?
- Did the pain start acutely? Has the pain been persistent, intermittent, or migratory? Does the pain wake the child up from sleep?
- Are there other symptoms present, such as fever, rash, fatigue, gastrointestinal symptoms, and weight loss?
- Is there a history of other medical problems, such as gastroenteritis, inflammatory bowel disease, or psoriasis?
- Was there a precipitating event, such as trauma?
- Has the child traveled recently or been bitten by a tick?
- Is there a family history of growing pains, hypermobility, or autoimmune disease, such as juvenile idiopathic arthritis, psoriasis, or lupus erythematosus?

possible because uveitis activity is initially silent but can be progressive. Ocular examination should be performed by a pediatric ophthalmologist or uveitis specialist. Optometric examination or in-office funduscopy are not adequate substitutes for the specialty ocular examination.

Laboratory Tests

A diagnosis of JIA is primarily based on physical examination and history. A targeted laboratory investigation helps to evaluate for other etiologies. For example, a young child presenting with monoarticular arthritis and a marked elevation in acute phase reactants (ie, ESR >100) should be evaluated for malignancy and infection. Typically, the child with oligoarticular JIA has normal acute phase reactants, with any persistent elevation considered a poor prognostic factor (Table 156.4). In the older child, evaluating for the presence of RF, anti–cyclic citrullinated peptide antibody, ANA, and HLA B27 may help with diagnostic and prognostic assessment. The most important laboratory test in the diagnostic evaluation of a young child with chronic arthritis is for ANA. A positive ANA test result helps in the risk stratification of the child for the development of JIA-associated uveitis (Table 156.2).

Imaging Studies

Imaging is used to determine the extent and severity of joint damage and help exclude other diagnoses (eg, metaphyseal lines seen in leukemia, osteoid osteoma). Conventional radiography is used in the assessment of joint damage, such as bone erosion, joint space narrowing, joint subluxation, misalignment, and ankylosis. Synovitis on ultrasonography, as measured by excess synovial fluid, synovial hypertrophy, and joint space hyperemia, is diagnostic for JIA. Magnetic resonance imaging is the standard for detecting synovitis and enables assessment of all structures for active inflammation and joint damage. Ultrasonography and magnetic resonance imaging are more sensitive (eg, for detecting synovitis) than clinical examination in the assessment of arthritis.

Management

The objective of management for JIA is to control pain and inflammation while preserving function and normal growth, development, and well-being. Physical and occupational therapy are essential to maintain function but are of limited benefit in the setting of ongoing inflammation. The American College of Rheumatology published guidelines for the management of JIA that describe initiation and monitoring of therapeutic agents, including NSAIDs, disease-modifying antirheumatic drugs (DMARDs), and biologic drugs. Nonsteroidal anti-inflammatory drugs are first-line therapy for JIA, including several available in liquid formulations (eg, naproxen, meloxicam, ibuprofen). Methotrexate, a DMARD that has been used in distinctly different and significantly lower doses than for chemotherapy, has been used successfully for decades as a second-line arthritis agent. Biologics have greatly reduced the morbidity of disease, with fewer side effects compared with previously used therapeutic agents (eg, chronic steroids). Several biologics have been approved by the US Food and Drug Administration (FDA) for specific JIA subtypes, including anti-TNF (eg, etanercept, adalimumab), anti-IL-1 (eg, canakinumab), anti-IL-6 (eg, tocilizumab), and T-cell costimulatory blocker (eg, abatacept). Medication side effects are generally well tolerated by the pediatric population. The more common and relevant side effects include gastrointestinal with NSAIDs and oral methotrexate, as well as increased number and duration of upper respiratory and skin infections with methotrexate and biologics. No current evidence exists to suggest definitively that monotherapy with biologics increases the rate of malignancy in children with JIA.

Live vaccines should not be administered to individuals undergoing treatment with systemic immunosuppression. In the absence of systemic immunosuppression, routine vaccines should be administered to all children with JIA, regardless of disease activity.

Oligoarticular JIA is usually responsive to intra-articular steroids and/or managed with NSAIDs. Local steroid therapy has been shown to induce remission in select patients and may eliminate the need for systemic medication exposure. Methotrexate, a weekly DMARD, is used in patients with persistent disease despite joint injection and/or an adequate (2- to 3-month) trial of an NSAID. Anti-TNF therapy is introduced if a patient continues to exhibit moderate to high disease activity after 3 months of DMARD, more likely in the extended-oligoarticular subtype.

Initial management of polyarticular JIA is aggressive to reduce pain, inflammation, and the potential for joint damage. The patient with mild disease activity may initially be treated with NSAIDs; however, moderate to high disease activity warrants rapid initiation of methotrexate and anti-TNF agents. In addition to systemic medications, intra-articular steroid injections are used in the patient with 1 or 2 joints with particularly high disease activity. The belief that a child will "grow out of the disease" is not correct in polyarticular JIA, and families should be made aware of this prognosis, thereby improving their understanding of risk versus benefit of medications and therapeutic interventions.

Management of systemic JIA has progressed from steroid-predominant to steroid-sparing biologic therapy, specifically IL-6 and IL-1 antagonists. Interleukin-6 and IL-1 are 2 key inflammatory proteins found in systemic JIA inflammation. Tocilizumab (IL-6 inhibitory) and canakinumab (IL-1 inhibitor) have been FDA-approved for the management of systemic JIA. Nonsteroidal anti-inflammatory drugs, methotrexate, intra-articular steroid injections, and glucocorticoids may also be part of disease management.

Table 156.4. Typical Laboratory Evidence of Systemic Inflammation in Juvenile Idiopathic Arthritis

Juvenile Idiopathic Arthritis Subtype	*Acute Phase Reactants*
Oligoarticular	Normal
Polyarticular	Elevated
Systemic	Elevated
Macrophage activation	Relative decrease
Enthesitis related	Normal/mild elevation in polyarticular type
Psoriatic	Normal/mild elevation in polyarticular type

A pediatric ophthalmologist or uveitis specialist and pediatric rheumatologist are involved in the co-management of anterior uveitis. First-line therapy includes topical glucocorticoids and dilating drops. If eye disease is refractory to topical treatment or is steroid dependent, however, DMARDs (eg, methotrexate, anti-TNF therapy) are considered.

Prognosis

Among individuals with persistent oligoarticular JIA, 75% report disease remission, whereas only 12% of those with extended subtype report remission and the remaining 13% continue to experience symptoms into adulthood. Children with polyarticular JIA experience the same remission rates as those with the extended subtype (10%–15%). Features of poor prognosis include arthritis of the hip or cervical spine, evidence of bone erosion on imaging, persistently elevated ESR with wrist or ankle arthritis in patients with oligoarticular arthritis, and RF-positive or anti-cyclic citrullinated peptide antibodies in patients with the polyarticular type. Uveitis may continue even when the arthritis is improved or in remission. In systemic JIA, systemic features such as fever and rash tend to subside during the initial months to years of the disease but may flare, as in most autoimmune diseases. Approximately 40% of children with systemic JIA follow a monocyclic disease course and eventually recover. A small proportion of children have a polycyclic course characterized by recurrent episodes of active disease interrupted by periods of remission without medications, whereas more than 50% of children with systemic JIA have a persistent disease course.

The care of a child with chronic inflammatory arthritis also requires a multidisciplinary approach involving a primary care physician, rheumatologist, physical therapist, and subspecialists with expertise in affected organs. The primary care physician plays a vital role in monitoring for potential medication side effects (eg, infection) and disease activity, as well as ensuring optimal immunization for each child. Children with JIA are no exception when monitoring for appropriate growth at well-child and -adolescent examinations. High disease activity and high steroid burden can suppress growth initially; therefore, coordination of care to ensure appropriate nutrition and physical activity is vital. Supplementation with calcium and vitamin D is beneficial to prevent osteoporosis for all patients with chronic inflammation, in particular those on chronic steroids. Disease management for patients with chronic inflammatory arthritis is a balance of optimal function, minimal complications, and improved quality of life.

CASE RESOLUTION

The girl has a presentation consistent with oligoarticular JIA based on the number of involved joints with arthritis, the chronicity of her concerns by history, and abnormal physical examination. Testing for ANA was positive, which puts her at high risk of developing anterior uveitis (younger than 6 years at diagnosis, duration of disease, positive result on ANA test). She is referred to a pediatric ophthalmologist for uveitis screening every 3 months for the first 4 years following diagnosis and every 6 months for the next 3 years, followed by yearly screening thereafter. She is also referred to a pediatric rheumatologist for assistance in managing her disease and a physical therapist to address her limitation of motion and resultant weakness.

CHAPTER 157

Autoimmune Connective Tissue Diseases

Deborah McCurdy, MD, FAAP; Amy C. Gaultney, MD, MTS; and Miriam F. Parsa, MD, MPH, FAAP

CASE STUDY

A 14-year-old girl has a 1-month history of severe fatigue with difficulty sleeping and nonrestorative sleep, hand swelling, generalized aches, low-grade fever, weight loss, and face and leg rashes. She has not felt well enough to go to school for several weeks and states that her fingers are stiff and she cannot type. On examination, she appears tired and does not look well. Vital signs show a temperature of 38.1°C (100.5°F), blood pressure of 138/84 mm Hg, pulse of 98 beats per minute, and respiratory rate of 22 breaths per minute. Her eyes appear puffy, and her ankles and feet are swollen. She has swelling over the joints of her fingers and reports difficulty closing buttons.

Questions

1. What patient findings are concerning for an autoimmune disease?
2. How can the clinical history and laboratory evaluation assist in determining the diagnosis and treatment?
3. What would be your differential diagnosis for the patient in the case study, and what consultants might be helpful in diagnosing and managing the patient?
4. What are the criteria for the diagnosis of systemic lupus erythematosus? Based on the case study provided, does this patient meet criteria for systemic lupus erythematosus?
5. What therapies are used in patients with autoimmune connective disorders?

Although the diseases discussed in this chapter have been called "collagen vascular diseases" and "connective tissue diseases," their etiology is the result not of a gene mutation (as is the case with collagen gene mutations in osteogenesis imperfecta) but of inflammation and damage to connective tissues, blood vessels, and other organs resulting from aberrant immune responses in individuals genetically predisposed to autoimmunity. Significant progress has been made in classifying each disease with criteria for diagnosis, including clinical and laboratory findings. Most of the diseases discussed herein have associated autoantibodies that aid in diagnosis; however, these autoantibodies have not been definitively implicated in the disease pathogenesis.

Treatment algorithms for autoimmune connective tissue disorders have been proposed by the Childhood Arthritis and Rheumatology Research Alliance (comprising pediatric rheumatologists from Canada and the United States) and the Paediatric Rheumatology INternational Trials Organisation (a European organization). Generally, treatment for these diseases, which usually includes steroids and immunosuppressive therapies, must be started early and often aggressively to prevent organ damage. Although great progress has been made in the management of juvenile idiopathic arthritis (see Chapter 156) with the new biologic therapies, many other autoimmune diseases are still managed with medications used for the past several decades. One exception is belimumab (ie, Benlysta), a B lymphocyte stimulator-specific inhibitor approved in 2011 and used to treat systemic lupus erythematosus (SLE). Although belimumab appears to help with autoimmune rashes and arthritis, it does not appear to adequately treat lupus nephritis. Still, with the advent of the biologic therapies and enzyme inhibitors, steroid sparing, targeted therapies for these autoimmune diseases are under investigation.

Evaluation for Autoimmune Disease: General Considerations

History

Generally, the rheumatologic diseases are diagnoses of exclusion and warrant consideration in the context of a comprehensive differential diagnosis. The history is important to determine if an autoimmune disease is likely and should clearly delineate the onset (eg, whether a patient had a prior illness or injury), duration (eg, continuous or intermittent symptoms), and extent of the symptoms (eg, systems involved, severity of pain, swelling) (Box 157.1).

Physical Examination

A complete physical examination should be performed. The vital signs should be measured and noted if abnormal. The full physical examination must include complete examination of the skin;

Box 157.1. What to Ask

Autoimmune Disease

- Does the patient have a sleep disturbance not explained by poor sleep environment? Has the patient experienced fatigue that interferes with normal activities? Does this fatigue extend to the weekends?
- Does the patient have a history of rash? If so, what location? Does the patient experience photosensitivity (ie, does the sun make it worse)?
- Is the patient experiencing bruising or easy bleeding?
- Are visible changes in the joints present, such as swelling, erythema, or tightening of the skin? If so, at what location(s), and what is the extent of changes?
- Are the symptoms more pronounced at specific times of day (ie, morning stiffness, morning periorbital edema, swelling of the ankles at night)?
- Has the patient experienced weakness?
- What other symptoms, such as headache, fever, and weight loss, are present?

a thorough musculoskeletal examination, including assessment of spinal flexibility and muscle strength; and a neurologic and neuropsychiatric assessment. Lymphadenopathy should be noted as well as the presence of organomegaly. The presence of edema is noted by puffiness around the eyes in the morning and pitting edema of the feet, ankles, and even up to the knee at the end of the day. Pitting edema may be indicative of renal disease.

Laboratory Tests

Generally, laboratory tests should include a complete blood cell count, erythrocyte sedimentation rate, C-reactive protein, urinalysis, and other studies as determined by the differential diagnosis. The patient with suspected SLE should undergo an evaluation of autoantibodies, including antinuclear antibody (ANA), anti-dsDNA, anti-ribonucleoprotein (RNP)/anti-Smith (Sm), and anti-SS-A (Ro)/anti-SS-B (La). Low complement levels (resulting from consumption) are important indicators of active SLE. It is appropriate to obtain electrocardiograms (ECGs) and echocardiograms in the patient with SLE and with suspected cardiac involvement. Concern about vasculitis warrants antineutrophil cytoplasmic antibody (ANCA) testing. The renal system may be involved in many of the autoimmune diseases, and a urine protein/creatinine ratio can help quantify any existing proteinuria. Suspicion for inflammatory myopathies warrants measurement of creatinine phosphokinase, aldolase, and lactate dehydrogenase levels, and, if autoimmune myositis is suspected, myositis-specific antibodies. Magnetic resonance (MR) imaging of the muscle, electromyography, and muscle biopsy may be indicated if the diagnosis is not clear.

Imaging Studies

Radiography is helpful in the initial evaluation. Chest radiography might reveal an enlarged heart, pulmonary edema or other pulmonary lesions, or bony abnormalities. Additionally, radiographs reveal changes in the joints and help assess the acuity and chronicity of joint swelling. High-resolution chest computed tomography (CT) may show subtle changes in the lung parenchyma. Magnetic resonance imaging and MR angiography are helpful in the evaluation of central nervous system (CNS) lupus, and an MR image of the muscle may show inflamed joints in juvenile dermatomyositis (JDM).

Management

The management of autoimmune diseases is based on the diagnosis and disease severity.

Systemic Lupus Erythematosus

Systemic lupus erythematosus is a classic autoimmune disease, with most patients having 6 or more different autoantibodies. The disorder is characterized by multiorgan system involvement and a waxing and waning course. The clinical presentation is variable and may be mild, presenting primarily with rash and arthritis. In the pediatric population, however, the presentation often is more severe, with frequent renal and other organ system involvement. Systemic lupus erythematosus can present in any organ and should be considered in any child with multiorgan system symptoms. Antinuclear antibodies are present in greater than 90% of patients with SLE but can also be seen in many other diseases. Up to 20% of the healthy population has a positive ANA but have no SLE. Other, more specific autoantibodies usually are present and may be associated with disease manifestations. Studies have shown that symptoms of SLE may be present well before the diagnosis is made, and it may take time to see the full picture. The goal of treatment is to decrease the inflammation and bring the immune system into balance.

Epidemiology

Systemic lupus erythematosus is not a common disease, but those with Hispanic, African, Native American, or Asian ancestry have an increased incidence and prevalence. Approximately 20% of cases of SLE are diagnosed in the pediatric population (ie, <19 years of age). The prevalence is approximately 6 to 18.9 per 100,000 among white females, 20 to 30 per 100,000 among black females, 16 to 36.7 per 100,000 among Puerto Rican females (13 per 100,000 for Hispanics in general), and up to 31 per 100,000 for those of Asian descent. The female to male ratio varies from 4:1 to 13:1 depending on the ethnicity of the cohort. In the 1960s, before therapy was initiated early and aggressively, children with SLE lived for approximately 2 years after diagnosis. Currently, with early recognition and therapy, the 5- and 10-year survival rates for pediatric SLE have improved to greater than 95% and 92%, respectively. Survival is affected by socioeconomic status, access to health care, educational background, racial and ethnic background, endemic infection rates, disease activity, and renal or CNS involvement. In the first 2 years following diagnosis, mortality is often associated with severe disease, and death results from pancreatitis, pulmonary hemorrhage, infection, thromboembolic disease, and active neuropsychiatric disease. More than 5 years after diagnosis, causes of mortality include complications

of end-stage renal disease, atherosclerosis, suicide, and, less commonly, active SLE or infection.

Etiology and Pathogenesis

Systemic lupus erythematosus is the prototype of autoimmune disease with multiple autoantibodies. The current hypothesis is that a genetic predisposition to SLE exists that is activated by environmental factors. The genome-wide association studies done in 2008 and expanded on in subsequent studies have identified more than 50 robust susceptibility loci of genes associated with SLE. These candidate genes are mostly involved in a variety of pathways, including immune complex processing, toll-like receptor signaling, activation of adaptive immunity, and type I interferon production. In addition, there is a clear association with deficiencies in early components of complement and SLE. This association is noted in certain consanguineous populations in which there is a high prevalence of SLE that affects young children from families with these complement defects. Environmental factors include ultraviolet radiation, viral infections (a strong association exists between SLE and Epstein-Barr virus), and drugs and chemicals.

Additionally, a well-studied immune dysregulation exists that involves the innate and adaptive immune systems. The loss of tolerance in SLE results in recognition of a self-antigen as foreign, with subsequent autoantibody production (antibodies to DNA, histones, and small RNA proteins), increase in both proinflammatory cytokines and immune complexes. Theories include the generation of self-antigens on cell surfaces following apoptosis; abnormalities of innate immunity, including toll-like receptors; abnormalities of all arms of the adaptive immune system, including antigen-presenting cells, T cells, and B cells; and abnormal regulation of interferon-α.

The increased incidence of SLE in females has been attributed in part to an estrogen hormonal effect. Most children with SLE present around the time of puberty, which suggests that the increased estrogen may exacerbate the disease process. Additionally, there may be factors on the X chromosome that predispose to the lupus pathogenesis. For example, men with Klinefelter syndrome (XXY) have a 14-fold increased risk of developing lupus compared with XY men, whereas women with Turner syndrome (XO) have a decreased risk of lupus.

Clinical Presentation

In 1982, criteria for the diagnosis of SLE were established by the American College of Rheumatology and modified in 1997 to include antiphospholipid (aPL) antibodies. To fulfill the criteria for a diagnosis of SLE, 4 of the 11 clinical and laboratory findings must be present at some point during the disease. The criteria are approximately 95% specific and sensitive for diagnosis (Box 157.2). At the 2017 annual European Congress on Rheumatology, weighted criteria were proposed and are being evaluated to more specifically diagnose SLE.

Usually, patients present with constitutional symptoms such as fever, fatigue, and weight loss. Often, a history is present of a photosensitive rash and swelling of the joints. Additionally, the patient may exhibit systemic inflammation with lymphadenopathy and hepatosplenomegaly.

Box 157.2. Systemic Lupus Erythematosus Criteria for Diagnosis

Four of the following 11 clinical and laboratory findings are required for diagnosis:

- Butterfly rash
- Discoid rash
- Photosensitivity
- Oral ulcers
- Nonerosive arthritis
- Pleurisy or pericarditis
- Renal disorder
- Seizures or psychosis
- Hematologic disorder
- Positive autoantibodies (anti-dsDNA, anti-Smith, or antiphospholipid antibody/lupus anticoagulant)
- Positive antinuclear antibody

Adapted with permission from Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum.* 1997;40(9):1725.

In the pediatric population, more than 80% of patients have renal involvement at onset or at some point in the disease.

Mucocutaneous Involvement

Although the butterfly rash is strongly associated with SLE, only 60% of patients have this type of rash at onset, although up to 85% will have the butterfly rash at some point in their disease. This rash is usually photosensitive, crosses the nose, and is present on both cheeks but spares the nasolabial folds. Other photosensitive rashes exist, including palpable purpura. Less common in the pediatric population is the discoid rash, which involves the dermis and can result in scarring. The discoid rash most often occurs in blacks. Approximately 10% to 30% of patients will have painless oral and nasal ulcers. Raynaud phenomenon is noted in 15% to 20% of children, but it is not specific for SLE.

Musculoskeletal Involvement

Often from onset and throughout the course of the disease, most patients with SLE will experience arthritis, arthralgia, or tenosynovitis. Typically, the arthritis is a symmetric polyarthritis affecting large and small joints, especially the metacarpophalangeal and proximal interphalangeal joints of the fingers. The arthritis is nonerosive and usually responds to treatments administered to control other aspects of the disease. Myalgia, and more rarely myositis, occur in SLE and are usually responsive to treatment. Some patients, however, develop a myopathy related to steroid treatment itself. Up to 20% of patients with SLE may develop a secondary pain amplification syndrome (ie, fibromyalgia).

Renal Involvement

After skin and joints, the organ system most frequently involved in SLE in the pediatric population is the kidney. Approximately 50% of patients present with lupus nephritis, but by the end of the first year following diagnosis, 80% to 90% of patients with SLE manifest

renal involvement. Treatment and prognosis is based on the histologic classification of nephritis as established by the World Health Organization (WHO) using renal biopsy (class I–VI) (Box 157.3). The clinical markers (ie, proteinuria, hematuria, creatinine level) may not correspond to histologic classifications, but often WHO classes III and IV are associated with hypertension and impaired renal function and are managed with high-dose steroids and immunosuppression. The patients with WHO class III, IV, or V may also present with peripheral edema requiring steroid therapy. With more aggressive and consistent treatment, overall survival for patients with renal involvement has improved, with markedly increased 5- and 10-year survival rates.

Neuropsychiatric Involvement

Often, neuropsychiatric manifestations are underappreciated because patients often present with headaches, poor school performance, and features of depression. Involvement of the CNS or peripheral nervous system may be present in 20% to 95% of patients with SLE (thus, the term "neuropsychiatric SLE"). Headaches are the most frequent presentation, with a *lupus headache* defined as a migraine-like, unremitting headache requiring narcotic analgesics. Headaches refractory to treatment can be indicative of active CNS vasculitis, increased intracranial pressure, or cerebral vein thrombosis. Thrombotic events in the CNS or elsewhere often are associated with aPLs in patients with lupus, and a full workup with urgent imaging is indicated. In these cases, MR angiography often shows vasculitis or evidence of bleeding or ischemia. Psychosis manifested by visual and tactile hallucinations may be present in 30% to 50% of patients. Hallucinations are usually visual but may also be auditory. Imaging studies in patients with hallucinations may be normal, but often autoantibodies are found in the blood or spinal fluid. Psychosis in isolation warrants consideration of the secondary effects of glucocorticoids. More difficult to delineate is cognitive impairment, which may present as a broad range of symptoms from difficulty concentrating to confusion and coma. Other, less common neurologic symptoms include seizures, movement disorders (eg, chorea), and cranial nerve abnormalities. Imaging studies are an important part of the workup and may show vasculitis, hemorrhage or clot, or demyelination; alternatively, such studies may be normal in antibody-mediated CNS disease.

Hematologic Involvement

Anemia, thrombocytopenia, and lymphopenia may be present in 50% to 75% of patients. During active disease, a patient often has a normochromic, normocytic anemia typical of anemia of chronic disease.

Box 157.3. Lupus Nephritis: World Health Organization Classification

Class I: Normal or minimal mesangial proliferation
Class II: Mesangial proliferation
Class III: Focal proliferative, <50% glomeruli
Class IV: Diffuse proliferative, >50% glomeruli
Class V: Membranous, subepithelial immune deposits
Class VI: Sclerosing without active disease

The Coombs test is positive in 30% to 40% of patients, but only 10% to 15% of patients with SLE have significant hemolysis. Thrombocytopenia is present in 15% to 45% of patients. Patients with chronic autoimmune idiopathic thrombocytopenic purpura (AITP) and Evans syndrome (ie, AITP and Coombs-positive anemia) with a positive ANA test are more frequently diagnosed with SLE. Lymphopenia is thought to represent a general marker of disease activity.

Antiphospholipid Antibody Syndrome

The antiphospholipid antibody syndrome (APS) is a prothrombotic state that is secondary to acquired autoantibodies, including anticardiolipin (aCL) antibodies, the lupus anticoagulant (LAC; usually measured by partial thromboplastin time mixing studies or the dilute Russell viper venom time), and β2-glycoprotein I (β2GPI, apolipoprotein H). These aPL antibodies are directed against phospholipids that are found in cell membranes throughout the body and, as such, are composed of many different antibodies with different epitopes. The most common aPL antibodies are the aCLs and the LAC. The term "lupus anticoagulant" is a misnomer, however, and the condition is so called because the phospholipid-dependent partial thromboplastin time cascade is prolonged in the presence of aPL antibodies. In contrast, the affected patient is at risk for a thrombotic event because the aPL antibodies bind to the epithelial membranes of blood vessels and activate clotting mechanisms. Antiphospholipid antibodies alone may be associated with infection, malignancies, or autoimmune states; however, they are usually benign and transient. A risk of thrombosis is present with high titer aCL immunoglobulin (Ig) G or IgM, LAC positive status, or high titers of IgG or IgM β2GPI antibodies.

Antiphospholipid antibody syndrome can occur as a primary disease without an associated autoimmune disease but most often occurs patients with SLE. In children with SLE, aCL, β2GPI, occur in 44%, 40%, and 22%, respectively. The child may present with arterial, venous, or small vessel thrombosis. Although only 16% to 36% of children with aPL antibodies are at risk for a thrombotic event, those with LAC positivity have a 28-fold increased risk. The most frequent thrombotic event is deep vein thrombosis, followed by cerebral sinus vein thrombosis, portal vein thrombosis, thromboses in the deep veins of the upper extremities, and superficial vein thromboses. Thrombocytopenia and hemolytic anemia may also be secondary to aCL binding to the red cell and platelet membranes. Because children are at low risk for thrombosis, most are monitored without specific therapy. Some physicians start hydroxychloroquine sulfate (eg, Plaquenil, Quineprox), which has been shown to decrease erythrocyte aggregation on the endothelium. Low-dose aspirin is often used as an anticoagulant, but its efficacy is in question. In the patient with a documented thrombotic event, anticoagulation (eg, warfarin [Coumadin, Jantoven]) is used, but low-molecular-weight heparin (eg, Enoxaparin) or another anticoagulant can also be used, often for 6 months or longer.

Catastrophic APS is of concern because this is a life-threatening disease process in which 3 or more organ systems develop small vessel occlusions within 1 week in association with aPL. These children present with adult respiratory distress syndrome, hypertension, renal failure, and multiple other organ system involvement requiring intensive care therapies. Immediate and aggressive therapy,

including anticoagulation, plasmapheresis, and corticosteroids, is necessary to reverse the thrombotic storm, but the mortality rate is still high (up to 50% in some reports). After recovery from catastrophic APS, lifelong anticoagulant therapy is indicated.

Cardiac Involvement

Pericarditis is not uncommon in SLE (15%–25% symptomatic; however, ECG changes are noted in up to 68%), and the affected patient may be asymptomatic. The myocardium and pericardium may also be involved, as well as the valves (ie, aortic, tricuspid, mitral) with sterile verrucous vegetations or Libman-Sacks endocarditis. Libman-Sacks endocarditis may be associated with aPLs and increase the risk for subacute bacterial endocarditis. A patient may present with chest pain that is worse when lying down or taking a deep breath. Chronic inflammation is associated with an increased risk of premature arthrosclerosis, and myocardial infarction is a leading cause of death in young adults with SLE.

Pleuropulmonary Involvement

The lungs may be involved in 25% to 75% of patients with SLE, with higher numbers noted by abnormal findings on pulmonary function tests (PFTs) in an otherwise asymptomatic patient. Pleurisy is the most common manifestation and may be associated with pericarditis. Symptoms include chest pain, orthopnea, and dyspnea, and a chest radiograph may show a pleural effusion (frequently unilateral). The patient may present with pleuritic chest pain and respiratory distress associated with acute lupus pneumonitis or pulmonary hemorrhage or may have a more indolent course with interstitial lung disease and shrinking lung syndrome (ie, loss of lung volume resulting from diaphragmatic dysfunction or phrenic nerve dysfunction). Pulmonary hypertension may be insidious and is a life-threatening complication of pulmonary involvement. Because of the disease and medications, opportunistic infections are also problematic. Imaging studies, especially a high-resolution chest CT, as well as PFTs are indicated if pulmonary disease is suspected.

Gastrointestinal Involvement

Gastrointestinal (GI) involvement may be difficult to diagnose and differentiate from adverse effects from medication. The GI system is involved in approximately 20% of patients with SLE. During active inflammation, a patient often has hepatosplenomegaly. High transaminase levels are suspicious for lupoid hepatitis. Symptoms may include abdominal pain and diarrhea. Underlying pathology may be lupus peritonitis, enteropathy, or, in the setting of copious diarrhea, protein-losing enteropathy. Severe abdominal pain is seen with mesenteric vasculitis. Celiac disease has been associated with SLE and should be considered in the setting of severe weight loss. Pancreatitis may occur in association with active lupus or with steroid use and often presents with abdominal pain, nausea, and vomiting.

Endocrine Involvement

Antithyroid antibodies are common in SLE (up to 35%), and 10% to 15% of patients develop hypothyroidism. Thyroid-stimulating hormone should be checked annually in the patient with SLE. Diabetes can be associated with SLE, but more frequently, diabetes is induced by corticosteroid treatment. Growth failure is a consequence of active disease and corticosteroid therapy. The potential exists for a delay in puberty and menstrual abnormalities and, rarely, autoimmune ovarian failure. Ovarian failure may also occur as a result of immunosuppressive treatment with cyclophosphamide.

Ocular Involvement

Active disease with retinal vasculitis may cause cytoid bodies (cotton-wool spots) noted on retinal examination. Antiphospholipid antibodies may cause retinal vein occlusion and vision loss. Episcleritis and scleritis may occur. Keratoconjunctivitis sicca may occur in the patient with secondary Sjögren syndrome.

Autoantibodies in Systemic Lupus Erythematosus

Autoantibodies are the hallmark of SLE, and most patients have more than 6 autoantibodies (Box 157.4). A positive ANA is found in nearly all patients, but this is not specific for or associated with a certain disease manifestation. The antibodies of SLE are directed against histone, nonhistone, RNA-binding, cytoplasmic, and nuclear proteins. These include anti-DNA (65%–95%), anti–RNA-binding proteins, and anti-U1RNP (27%–34%) and anti-Sm antibodies (32%–34%). Anti–SS-A and anti–SS-B antibodies (27%–33%) are seen less frequently but are associated with skin disease and neonatal lupus. Anticardiolipin (19%–87%) and the LAC (10%–62%) are the most common aPLs.

Management

Treatment of children and adolescents with SLE must be started early to prevent organ damage. Treatments must be tailored to the symptoms, but young patients are reported to have more severe disease and often require aggressive therapy. A summary of treatments used in pediatric lupus and their most common adverse effects are enumerated in Table 157.1.

Vasculitis

Vasculitis is an inflammatory process involving the blood vessel wall; thus, any organ system may be involved. Vasculitis may be the primary disease process or complicate an autoimmune

Box 157.4. Autoantibodies Frequently Seen in Systemic Lupus Erythematosus

Autoantibodies (specific)

- Antinuclear
  - Positive in virtually every patient
- Anti-dsDNA
  - Fluctuate with disease activity
  - Increased with active renal disease
- Anti-Smith

Autoantibodies (seen in other disease but associated with a clinical sequelae)

- Coombs—hemolytic anemia
- Anticardiolipin or antiphospholipid—thrombosis, thrombocytopenia, hemolytic anemia
- Anti-ribosomal P—psychiatric disease

Table 157.1. Medications Frequently Used in Pediatric Systemic Lupus Erythematosus

Medication	*Uses*	*Adverse Effects*
NSAIDs	Treatment of arthritis/ arthralgia	Aseptic meningitis (ibuprofen) Gastritis
Corticosteroids	Treatment of skin disease, arthritis/ arthralgia	Poor wound healing Gastritis Osteonecrosis/osteoporosis Weight gain Myopathy Adrenal suppression
Hydroxychloroquine sulfate (eg, Plaquenil, Quineprox)	Prevention of autoantibody formation	Retinopathy
Methotrexate	Treatment of arthritis/ arthralgia	Nausea/vomiting Oral ulcers Hair loss Cytopenias/bone marrow suppression Transaminitis Teratogenesis Methotrexate-induced lung disease
Cyclophosphamide (eg, Cytoxan, Endoxan)	Treatment of refractory SLE nephritis	Cytopenias/bone marrow suppression Hair loss Amenorrhea Infertility Nausea/vomiting
Mycophenolate mofetil (eg, CellCept, Myfortic)	Treatment of SLE nephritis	Fever Hypertension Peripheral edema
Rituximab (eg, Rituxan)	Treatment of autoimmune hemolytic anemia, ITP	Cytopenias/bone marrow suppression
Belimumab (eg, Benlysta)	Treatment of skin disease/ musculoskeletal manifestations	Cytopenias/bone marrow suppression
ACE inhibitors	Treatment of proteinuria/ hypertension	Angioedema Cough

Abbreviations: ACE, angiotensin-converting enzyme; ITP, idiopathic thrombocytopenic purpura; NSAIDs, nonsteroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus.

disease, infection, or malignancy. Patients with SLE often have vasculitis.

In primary vasculitis, the disease is defined by the size of the affected vessels (Figure 157.1). Small vessel disease includes Henoch-Schönlein purpura (HSP). A small vessel vasculitis associated with granulomas is seen with granulomatosis with polyarteritis (GPA; formerly known as Wegener granulomatosis) and eosinophilic granulomatosis with polyangiitis (EGPA; formerly known as Churg-Strauss syndrome). Medium-sized vessel vasculitides include polyarteritis nodosa, cutaneous polyarteritis, and Kawasaki disease (KD). The large vessels are involved in Takayasu arteritis (Box 157.5).

Epidemiology

The prevalence of vasculitis is estimated to be 23 per 100,000. Henoch-Schönlein purpura and KD are the most common types, but the prevalence is difficult to determine because these diseases are self-limited. Childhood vasculitis occurs in individuals of all ethnic backgrounds. The prevalence of HSP is higher in children of European descent, the prevalence of KD is higher in children of Japanese descent, and the prevalence of Behçet syndrome is higher in children of Turkish ancestry. For HSP, the peak age is 4 to 6 years and boys are affected more frequently, with a female to male ratio of 1:2. Most children with KD are younger than 5 years, and the disease occurs more frequently in boys. The mean age for polyarteritis nodosa is 9 years, and the mean age for GPA is 14 years.

Etiology and Pathogenesis

The etiology of the vasculitides, as with other autoimmune diseases, likely has a genetic and an environmental component. Associations exist with the human leukocyte antigens (HLAs) and a familial inheritance is present, especially in Behçet syndrome (association with HLA-51). Studies have shown a familial link between GPA and rheumatoid arthritis, the association of the α_1-antitrypsin gene (*A1AT*) in GPA, and an association with the familial Mediterranean fever gene (*MEFV*) in Behçet syndrome and HSP.

The pathology includes inflammation of the blood vessels, either in segments or involving the entire vessel. Various degrees of cellular inflammation occur (often polymorphonuclear leukocytes or lymphocytes), along with necrosis in 1 or more layers of the vessel wall.

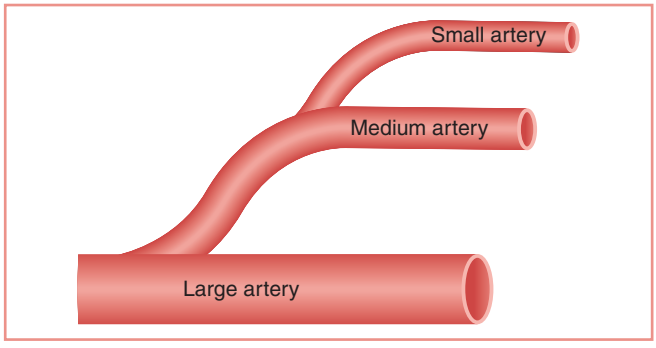

Figure 157.1. Various sized vessels associated with vasculitis.

Box 157.5. Classification and Criteria for Primary Vasculitis

Small Vessel

Henoch Schönlein purpura (IgA immune complex vasculitis)

Criteria[a]

- Purpura or petechiae with lower limb predominance and ≥1 of the 4 following criteria:
  - — Abdominal pain
  - — Histopathology
  - — Arthritis or arthralgia
  - — Renal involvement

ANCA associated vasculitis

Criteria for childhood granulomatosis with polyarteritis (formerly Wegener granulomatosis)[a]

- ≥3 of the 6 following criteria:
  - — Histopathology
  - — Upper airway involvement
  - — Laryngotracheobronchial stenosis
  - — Pulmonary involvement
  - — ANCA positivity
    1. Renal involvement

Medium Vessel

Polyarteritis nodosa

Criteria for childhood type[a]

- Histopathology or angiographic abnormalities plus 1 of the 5 following criteria:
  - — Skin involvement
  - — Myalgia/muscle tenderness
  - — Hypertension
  - — Peripheral neuropathy
  - — Renal involvement

Kawasaki disease

Criteria[b]

- Fever for ≥5 days (high, spiking fevers ≥40°C [≥104°F]) and 4 of the following:
  - — Bilateral conjunctival injection
  - — Mucous membrane changes of the lips and oral cavity
  - — Cervical lymphadenopathy
  - — Polymorphic exanthema
  - — Rash, swelling, and/or induration in the peripheral extremities or perineal area

Large Vessel

Takayasu arteritis

Criteria for childhood type[a]

- Angiographic abnormalities of the aorta or its main branches and pulmonary arteries showing aneurysm/dilatation plus 1 of the 5 following criteria:
  - — Pulse deficit or claudication
  - — Four limbs blood pressure discrepancy
  - — Bruits
  - — Hypertension
  - — Acute phase reactants

Abbreviations: ANCA, antineutrophil cytoplasmic antibody; Ig, immunoglobulin.

[a] Proposed by European League Against Rheumatism, Paediatric Rheumatology INternational Trials Organisation, and Paediatric Rheumatology European Society.

[b] Fewer than 4 criteria are required in the setting of fevers and characteristic coronary artery changes.

Inflammation in the media of a muscular artery tends to destroy the internal elastic lamina. Additional features in some types of vasculitis are giant cells in the vessel wall and the formation of granulomas.

Clinical and Laboratory Presentation and Treatment

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) is an IgA immune complex vasculitis that usually involves lower extremity purpura over the legs and buttocks. The purpura recur as cutaneous purpura "crops" in up to 33% of children, usually associated with running or jumping. Arthritis, usually of the knees and ankles, can be the presenting feature in approximately 50% of children and is present at some point in 75% of children. Lesions resembling cutaneous changes of HSP may be seen in the GI tract and can occur in 50% to 75% of children with HSP. Usually the children experience crampy abdominal pain. Typically, this is limited to bowel wall edema; however, the course may be complicated by bleeding, intussusception, and in severe cases necrosis of the bowel wall. Proteinuria is present in 20% to 60% of children with HSP and is concerning for renal involvement; however, ongoing renal disease is rare, and the risk of chronic renal impairment and end-stage renal disease is 2% to 15% and less than 1%, respectively. Occasionally, HSP can be associated with severe edema over the trunk associated with a low albumin level. Laboratory studies are usually normal, except for occasional increases in the acute phase reactant levels. It is important to test the stool for blood, which is indicative of bowel inflammation. With renal involvement, hematuria or proteinuria may occur. This should be monitored with urine dipstick assessments monthly for 6 months because renal disease may present late and after other clinical symptoms have resolved. Henoch-Schönlein purpura usually self-resolves in less than 1 month but may persist for 3 months. Management of HSP is generally supportive with analgesics and nonsteroidal anti-inflammatory drugs. In children with severe abdominal pain, corticosteroids (oral or, if the child is unable to eat, intravenous [IV] methylprednisolone [1–2 mg/kg per day in divided doses]) is used to prevent ongoing GI inflammation. Generally, HSP resolves and the outcome is good.

Kawasaki Disease

Kawasaki disease involves medium sized blood vessels, is the second most common childhood vasculitis, and can be associated with lifelong cardiac sequelae. Diagnostic criteria are enumerated in Box 157.6.

Box 157.6. Diagnostic Criteria for Kawasaki Disease

- Fever for ≥5 days
- Mucosal changes: strawberry tongue, fissured/erythematous lips, erythematous oropharynx
- Extremity changes: swelling of hands and feet, followed by desquamation and nail changes
- Bilateral conjunctival injection
- Polymorphous rash on the trunk
- Cervical lymphadenopathy (1 node must be >1.5 cm [>0.6 in])

Coronary dilatation and aneurysms may be detected during the acute phase but may develop during the convalescent phase in up to 20% of children, especially in very young children and children of any age for whom treatment was delayed. Multiple organ systems may be involved, including the GI tract (ie, vomiting, abdominal pain, hydrops of the gallbladder), the musculoskeletal system (ie, arthritis), and the CNS. Most of these children are quite irritable, which is suggestive of aseptic meningitis and headache.

Laboratory tests show high levels of acute phase reactants, a high white blood cell count with a shift to the left, and high platelet counts. Antineutrophil cytoplasmic antibodies may be positive as the disease progresses. Early treatment prevents cardiac complications in up to 80% of children.

The American Heart Association recommends treatment with high-dose aspirin (80–100 mg/kg per day) and IV Ig (IVIG; 2 g/kg) within the first 10 days of disease. Aspirin is decreased to an antiplatelet dose of 3 to 5 mg/kg per day after the child is afebrile for 48 hours. If the fever persists or returns, a second course of IVIG is warranted. Infliximab, an anti–tumor necrosis factor (TNF)-α agent (5 mg/kg) is used in some centers if the first dose of IVIG does not resolve the fever. Usually children recover from acute KD, but coronary aneurysms may result in long-term sequelae.

Antineutrophil Cytoplasmic Antibody Vasculitis

The 3 ANCA-associated vasculitides associated with small vessel inflammation are GPA, microscopic polyangiitis, and EGPA. The clinical features of each are enumerated in Table 157.2.

Management of the ANCA-associated vasculitides depends on the severity of the disease. For severe systemic disease, management usually includes a remission induction phase, using cytotoxic therapy (ie, cyclophosphamide) and corticosteroids, followed by a remission maintenance phase, using oral corticosteroids with an oral disease-modifying antirheumatic drug, such as methotrexate or azathioprine. Rituximab has also shown promise as an initial therapy. Some instances of local disease can be managed less aggressively, such as with methotrexate alone. Despite treatment, the rate of relapse is high. Depending on the extent of disease, prognosis is guarded.

Polyarteritis Nodosa

Polyarteritis nodosa is uncommon in children but can be life-threatening. The affected child tends to be ill with fever, malaise, and weight loss complicated by ischemia to involved organs. Often painful subcutaneous nodules develop along affected vessels and aid in the diagnosis. Laboratory findings are consistent with the inflammatory state, and the acute phase reactant levels are high, with a mild leukocytosis and anemia. The perinuclear ANCA may be positive. Corticosteroids are used initially, either oral or IV pulse methylprednisolone. Cyclophosphamide is indicated in severe life- and organ-threatening situations. Plasmapheresis has been shown to be helpful in some cases. Maintenance agents include azathioprine, methotrexate, IVIG, and mycophenolate mofetil (MMF). Recent studies suggest that rituximab may effectively treat this disease. The prognosis is guarded because of the severe organ involvement during the acute phase.

Childhood Primary Central Nervous System Vasculitis

Childhood primary CNS vasculitis may have an acute onset and can include neurologic and/or psychiatric symptoms. Imaging is the mainstay of diagnosis. The 2 types of childhood primary CNS vasculitis are angiography positive, which is seen on MR angiography and affects the medium and large vessels, and angiography negative, which affects the small vessels. To confirm the diagnosis of small vessel disease, angiography is required. Of note, the laboratory studies may be normal peripherally with no clues to the extent

Table 157.2. Antineutrophil Cytoplasmic Antibody–Associated Vasculitides

	Granulomatosis With Polyangiitis	*Microscopic Polyangiitis*	*Eosinophilic Granulomatosis With Polyangiitis*
Organ involvement	Upper/lower respiratory tract, kidneys	Kidneys (capillaritis and necrotizing glomerulonephritis)	Upper/lower respiratory tract, can present as prolonged asthma
Laboratory abnormalities	c-ANCA positive (80%–90% of patients) Elevated ESR/CRP Elevated rheumatoid factor (50% of patients)	p-ANCA positive (75% of patients) Elevated ESR/CRP	p-ANCA positive (<50% of patients) Elevated ESR/CRP Eosinophilia Elevated IgE

Abbreviations: c-ANCA, cytoplasmic antineutrophil cytoplasmic antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; Ig, immunoglobulin; p-ANCA, perinuclear antineutrophil cytoplasmic antibody.

of the CNS vasculitis. The CSF may show increased protein levels or may be normal. Imaging confirms the diagnosis. Therapy includes corticosteroids (oral or IV); however, typically cyclophosphamide is necessary to control the vasculitis. For maintenance therapy, azathioprine or MMF are used for therapeutic control.

Takayasu Arteritis

Takayasu arteritis is a granulomatous vasculitis affecting the large vessels, primarily the aorta and its branches. Diagnosis may be difficult because the symptoms are usually nonspecific. However, clinical clues include absent peripheral pulses, hypertension, CNS symptoms, and claudication. The laboratory tests may be normal, but more often increase of the acute phase reactant levels and anemia are evident. Imaging helps confirm the diagnosis. Corticosteroids are the mainstay of treatment and induce remission in up to 60% of patients. Other treatments include azathioprine, cyclophosphamide, and MMF. Infliximab and other anti-TNF biologics or tocilizumab, an anti-interleukin-6 biologic may be beneficial in these patients. Some of these children go into remission, but the ultimate prognosis depends on the severity of organ involvement during the acute phase.

Inflammatory Myopathies

Juvenile dermatomyositis is the most common pediatric inflammatory myopathy and primarily affects the striated muscles and skin. The prevalence is approximately 3.2 per 1 million children in the United States. Juvenile dermatomyositis is a vasculopathy involving the small arterioles and capillaries of the muscles and skin and results in inflammation and necrosis of muscle fibers. An acute inflammatory phase is associated with proximal muscle weakness. As healing occurs, laying down of calcium (eg, calcinosis) occurs in the areas affected by chronic inflammation. Polymyositis rarely occurs in children but presents in a manner similar to that of JDM, but without skin manifestations and a greater cellular inflammatory response. Myositis may be associated with other connective tissue diseases, such as SLE, mixed connective tissue disease, and scleroderma.

Epidemiology

Although JDM is not common, it is important to recognize the symptoms because early treatment can prevent sequelae. There is a bimodal age range of onset of dermatomyositis; in children the age range of onset is 5 to 14 years, with a peak at 7.6 years; in adults, the age range is 45 to 64 years. Dermatomyositis in adults may be associated with malignancy in up to 20% of patients, but in JDM there is no association with cancer. Juvenile dermatomyositis is more frequent in females, with an overall female to male ratio of 1.7-2.7:1.

Etiology and Pathology

The etiology of JDM is unclear, but several genetic associations are thought to contribute. Associations with both HLA class I, *HLA-B8*, and several class II genes have been found. The TNF-α 308A allele is noted in increased frequency in patients with JDM and is associated with the increased production of TNF-α that perpetuates the inflammatory response. In these susceptible individuals, infectious agents may increase the risk of inflammation. Often, an upper respiratory infection or GI illness precedes the onset of JDM. Infections, including coxsackievirus, influenza, group A streptococcus, toxoplasmosis, parvovirus, hepatitis B, *Borrelia,* and Leishmania, have been reported in association with JDM. Additionally, JDM has been reported after vaccinations. Several studies suggest that JDM may be a result of microchimerism, in which the mother's cells are present in the child's muscle tissue, resulting in an immune response.

The pathogenesis is that of an autoimmune vasculopathy with an immune attack on muscle arterioles, capillaries, and endothelium that results in vascular damage and vessel occlusion. Additionally, deposition of immune complexes may occur that contribute to vascular injury. The skin and muscle, primarily the striated muscles but also muscles of the GI tract, are involved. Muscle fibers near the affected vessels demonstrate atrophy or necrosis.

Clinical Presentation

The criteria in Box 157.7 are useful in making a diagnosis of JDM. These criteria have not been validated, however.

Muscle Involvement

Often, the child with JDM has an insidious progression over 3 to 6 months of malaise, low-grade fevers, and fatigue. Muscle pain or tenderness occurs in 25% to 75% of these patients, and edema over the affected muscles may be present. The predominant feature is proximal muscle weakness of the neck, abdominal muscles, and limb girdles. On examination, the child is unable to sit up from the supine position without rolling over and using the arms to push up into a sitting position, to rise from sitting to standing, or to squat or sit on the floor and get up without help. On getting up from the floor, the Gowers sign is often present, and on walking the child may exhibit a truncal sway and a positive Trendelenburg gait indicative of weakness of the hips.

Box 157.7. Criteria for the Diagnosis of Juvenile Dermatomyositis

- Symmetric proximal muscle weakness
- Characteristic cutaneous changes
  - Heliotrope rash: discoloration of the eyelids with periorbital edema
  - Gottron papules: erythematous, scaly rash over dorsal aspects of the metacarpal and proximal interphalangeal joints
- Elevated skeletal muscle enzymes: creatine kinase, aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, aldolase
- Electromyographic evidence of myopathy and denervation
- Muscle biopsy demonstrating necrosis and inflammation

Derived from Bohan A, Peter JB. Polymyositis and dermatomyositis (first of two parts). *N Engl J Med.* 1975;292(7):344–347; and Bohan A, Peter JB. Polymyositis and dermatomyositis (second of two parts). *N Engl J Med.* 1975;292(8):403–407.

Pharyngeal, hypopharyngeal, and palatal muscles can be affected, and such involvement must be recognized promptly to prevent aspiration or respiratory distress. It is important to evaluate this urgently with a barium swallow and PFTs.

Skin Involvement

More than 75% of children have cutaneous abnormalities that are pathognomonic of the disease at presentation. Cutaneous manifestations usually present at diagnosis and include the heliotrope discoloration around the eyes and edema of the eyelids. Other findings include *Gottron papules*—shiny, erythematous, scaly plaques that are symmetric over the proximal interphalangeal and metacarpophalangeal joints of the hand, extensor surfaces of the elbows and knees, and, more rarely, malleoli of the ankles. The findings result from the vasculopathy and subsequent ischemia. Less frequently appreciated but usually present is the inflammation and erythema of periungual skin and capillary nail bed that often show the presence of dilatation of vessel loops, thrombosis and hemorrhage, and, ultimately, loss of the capillary nail bed vessels. *Lipodystrophy* (ie, loss of fat from the body and extremities or local fat loss) occurs in 7% to 50% of affected children and can be associated with other metabolic problems.

Ulceration related to ischemic changes may occur. In the anatomic areas of chronic inflammation, calcification occurs in 12% to 43% of patients, sometimes within 6 months of onset. Calcification may occur in the skin or muscle belly or diffusely and is problematic because of recurrent skin ulcerations, limitation of motion, pain in the involved muscle, and increased risk of infection because of poor skin integrity. Management of calcinosis is difficult and may require surgical removal in some instances.

Gastrointestinal Involvement

The muscles of the GI tract may also be involved with inflammation throughout the bowel and microperforations when the disease is active. The child presents with progressive abdominal pain, melena, and hematemesis, or an ileus. Imaging studies may show free intraperitoneal air, but because the perforations are multiple and small, often no free air is noted radiographically. This is a medical emergency, and the affected child should be treated for sepsis and evaluated for possible surgical intervention.

Cardiovascular Involvement

Cardiac involvement is rare but may be life threatening. Myocarditis, conduction defects, or first-degree heart block may be delayed in presentation but can cause death. Hypertension can occur in 25% to 50% of patients, especially with glucocorticoid therapy. Prior to any surgery, the child with JDM should undergo a careful cardiac evaluation to ensure they are able to tolerate the procedure.

Involvement of Other Systems

Arthritis and arthralgia are frequent complications of JDM and may occur in 10% to 65% of children with the disease. Lymphadenopathy occurs early in the disease course in 10% to 65% of children and usually improves with treatment.

Laboratory Studies

Laboratory studies, including a complete blood cell count and inflammatory markers (ie, erythrocyte sedimentation rate, C-reactive protein), may be normal, but in the setting of marked inflammation in the skin and muscle the inflammatory markers may be elevated. Leukocytosis and anemia are rare except in the child with infection or GI bleeding. Urinalysis is usually normal. Because of the vasculopathy, factor VIII-related antigen (ie, von Willebrand factor) may be high in the child with active disease. Flow cytometry studies show increased numbers of $CD19^+$ B cells.

Muscle Enzymes

Serum levels of the sarcoplasmic muscle enzymes (ie, aspartate transaminase, creatine kinase, lactate dehydrogenase, aldolase) contribute to making the diagnosis and monitoring the effectiveness of therapy. Aspartate transaminase and lactate dehydrogenase correlate the best with active disease. Usually, creatine kinase level is elevated, but it may fluctuate and is the first to decrease with therapy. The other enzymes may remain high and decrease more slowly as the disease improves.

Autoantibodies

The ANA is positive in 10% to 85% of patients, and antibodies against small RNA antigens (ie, RNP, SS-A/SS-B) may be present. Traditional myositis-specific autoantibodies are rare in JDM, although anti-Jo-1 antibodies are seen in 2% to 5% of children with JDM, especially those with severe Raynaud disease and interstitial lung disease. Anti-Mi-2 is seen in 1% to 7% of those with milder disease. More recently, myositis specific autoantibodies have been associated with disease manifestations and commercial panels are now available. For example, anti-transcription intermediary factor 1-g autoantibodies (anti-p155) are associated with more severe cutaneous involvement and lipodystrophy and in adults increased cancer risk. Anti-nuclear matrix protein-2 autoantibodies (anti-p140) are associated with calcinosis and contractures and are identified in 13% to 29% of children with JDM. Anti-melanoma differentiation-associated protein 5 antibodies are associated with unique mucocutaneous features, severe lung disease, and minimal muscle involvement. The anti-signal recognition particle autoantibody level may be a clinically useful marker of disease activity.

Imaging Studies

Radiographs may show muscle edema and osteoporosis, but to determine the extent of muscle edema, MR imaging, especially the fat-suppressed T2-weighted or short T1 inversion recovery sequences, is required. Short T1 inversion recovery is optimal to show hyperintensity indicating muscle edema.

Electromyography and Muscle Biopsy

Electromyography showing a myopathic pattern and muscle biopsy with inflammation and loss of muscle fibers are rarely needed for the diagnosis. Usually, these are used in cases that are unclear and for which another criterion for diagnosis is needed.

Treatment

The use of corticosteroids has changed the prognosis for children with JDM. Corticosteroids decrease inflammation, improve skin manifestations and muscle strength, and prevent the chronic inflammation that results in calcinosis. Almost all children require corticosteroid therapy; if they have more severe disease, a methylprednisolone sodium succinate pulse (30 mg/kg with a maximum of 1 gm each day for 3 days) or a daily oral prednisone dose of 2 mg/kg is the first-line treatment. As strength improves and muscle enzymes return to normal, steroids are tapered. An adverse event of note with the use of corticosteroids is the onset of steroid-induced myopathy. However, in this case, muscle enzymes are not elevated. If the response to steroids is inadequate, methotrexate is generally the second-line treatment, and if this is not sufficiently effective, IVIG is used. Hydroxychloroquine is useful for skin manifestations and may decrease the risk of calcinosis. Immunosuppressants may be necessary to manage vasculopathy of the bowel or other organs. For severe involvement, cyclophosphamide is indicated, but in less severe cases, azathioprine or cyclosporine is used. More recently, rituximab has been found to reverse severe muscle disease. Most children with JDM benefit from physical therapy. It is important to protect the skin from ultraviolet light and prevent tissue injury. A proper diet and physical activity are important to promote optimal intake of calcium and vitamin D and prevent osteopenia, muscle atrophy, and contractures.

Scleroderma: Systemic Sclerosis, Localized Scleroderma, and Morphea

Scleroderma means "hard skin," and patients with this disease have increased skin thickening that can be systemic or localized. The current terminology classifies the systemic disease by the extent of the skin involvement into 2 categories: diffuse cutaneous systemic sclerosis (dSSc) and limited cutaneous systemic sclerosis (lSSc), which was previously called CREST syndrome (calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, telangiectasia). The localized scleroderma (LS) type includes morphea and linear scleroderma.

Epidemiology

Worldwide reports of dSSc exist with an annual incidence of 0.45 to 1.9 per 100,000 and a prevalence of 24 per 100,000. The disease is more common in African Americans and Choctaw Native Americans. The systemic form of the disease is rare in children, who comprise only approximately 1.2% to 9% of all cases. Morphea and linear scleroderma are seen predominantly in the pediatric population, with 67% of cases diagnosed before 18 years of age. The prevalence of morphea in children younger than 17 years is estimated to be 50 per 100,000. The prevalence of LS is approximately 2.7 cases per 100,000. Females are affected more often than males.

Etiology and Pathogenesis

Much remains to be learned about the scleroderma spectrum. The skin thickening is believed to be caused by a dysfunction of the immune system that activates the endothelium and fibroblasts that promote fibrosis. The genetic influence is not clear, but association exists with certain HLA markers. This is believed to be an autoimmune process because of the disease-specific autoantibodies and multiple abnormalities of T cell function (eg, cellular immunity) with increased cytokines, adhesion molecules, and growth factors resulting in endothelial injury and fibroblast proliferation. The signs and symptoms mimic graft-versus-host disease, with abnormalities of regulation of fibroblasts, production of collagen, and immunologic abnormalities. Some studies suggest microchimerism may play a role in the pathogenesis of the sclerodermas, as well as in the pathogenesis of dermatomyositis.

Clinical Manifestations

Systemic Sclerosis

The Pediatric Rheumatology European Society, American College of Rheumatology, and European League Against Rheumatism developed criteria useful in diagnosis and research. Juvenile systemic sclerosis involves children younger than 16 years with 1 major criterion (presence of skin sclerosis/induration proximal to metacarpophalangeal joints) and at least 2 of the 20 minor criteria (Box 157.8).

Because early on the course and progression of dSSc and lSSc may be insidious, the diagnosis may not be made for several years after the condition has had a significant effect on function or mobility. The characteristic presentation is a child with Raynaud phenomenon; tightening, thinning, and atrophy of the skin of the hands and face; or the appearance of cutaneous telangiectasias about the face, upper trunk, and hands. At the onset, edema of the skin may occur that persists for a few weeks or months, and this may offer a window of opportunity for treatment to decrease the inflammation and the resulting fibrosis. The next phase is the sclerotic phase, in which sclerosis is noticeable especially over the digits (ie, acrosclerosis, sclerodactyly) and face (ie, circumoral furrowing). Finally, atrophy of the skin occurs. Telangiectasia and calcinosis may be noted during this process. Arthritis may be a symptom in approximately 36% of children. Radiographs may show resorption of the distal tufts of the digits.

The greatest morbidity is related to involvement of the cardiovascular, pulmonary, renal, and GI systems. Pericardial effusions may be the initial presentation, but morbidity is from cardiac ischemia of the coronary arteries and cardiac fibrosis. Systemic hypertension may be a complication and must be monitored carefully, especially because it may be indicative of renal crisis. Pulmonary parenchymal disease often is asymptomatic early, but a patient may exhibit symptoms of a dry cough or dyspnea on exertion. The patient may eventually develop interstitial pneumonitis or pulmonary hypertension with significant morbidity and mortality. Pulmonary complications can be monitored by high-resolution chest CT and pulmonary PFTs. Renal disease is also an ominous complication of dSSc. A database of children with dSSc noted that 5% had renal involvement and 1% developed renal crisis. The presence of anti-topoisomerase and/or anti-RNA polymerase antibodies and rapidly progressing skin involvement are thought to be predictors of renal and cardiac involvement. Concern among rheumatologists caring for adults is the relationship between the use of high-dose steroids and the

Box 157.8. Criteria for Juvenile Systemic Sclerosis

Major Criterion

- Sclerosis/induration of the skin proximal to the metacarpophalangeal or metatarsophalangeal joints

Minor Criteria

Skin
- Sclerodactyly

Vasculopathy
- Raynaud phenomenon
- Nail fold capillary abnormalities
- Digital tip ulcers

Gastrointestinal
- Dysphagia
- Gastroesophageal reflux

Renal
- Renal crisis
- New-onset arterial hypertension

Cardiac
- Arrhythmias
- Heart failure

Respiratory
- Pulmonary fibrosis (high-resolution computed tomography/radiography)
- Decreased diffusion lung capacity for carbon monoxide
- Pulmonary hypertension

Musculoskeletal
- Tendon friction rubs
- Arthritis
- Myositis

Neurologic
- Neuropathy
- Carpal tunnel syndrome

Serology
- Antinuclear antibodies
- Systemic sclerosis selective autoantibodies (anti-centromere, anti-topoisomerase 1, anti-fibrillarin, anti-polymyositis-scleroderma, anti-fibrillin, or anti-RNA polymerase 1 or 3)

Adapted with permission from Zulian F, Woo P, Athreya BH, et al. The Pediatric Rheumatology European Society/American College of Rheumatology/European League Against Rheumatism provisional classification criteria for juvenile systemic sclerosis. *Arthritis Rheum.* 2007;57(2):203–212.

development of scleroderma renal crisis; thus, corticosteroids to reverse skin involvement must be used with caution and close monitoring is necessary. Gastrointestinal involvement is common, affecting one-third of patients during the disease. The oral cavity may have telangiectasia, and often patients report dry mouth or the sicca syndrome. Esophageal involvement may present early in the disease with heartburn and delayed gastric emptying that can result in aspiration. The small bowel is often involved with decreased motility and malabsorption and the large bowel with constipation.

Localized Scleroderma

The Pediatric Rheumatology European Society proposed a classification system for LS with 5 subtypes: circumscribed morphea, linear scleroderma, generalized morphea, pansclerotic morphea, and mixed morphea, in which a combination of 2 or more of the previous subtypes is present (Box 157.9).

Linear scleroderma is the most common subtype in children and adolescents, characterized by 1 or more linear streaks that typically involve an upper or lower extremity. With time, the streaks become progressively more indurated and can extend through the dermis, subcutaneous tissue, and muscle to the underlying bone. En coup de sabre involves the scalp and head and was named as such because it once was thought to look like the depression caused by the strike from a sword; progressive facial hemiatrophy may occur. Parry-Romberg syndrome is characterized by progressive facial hemiatrophy of the skin and tissue below the forehead. The patient with facial hemiatrophy may experience associated seizures and dental and ocular abnormalities.

Morphea, or areas of indurated, waxy skin with an ivory center and violaceous halo, are most commonly found on the trunk. The lesions may be small (<1 cm [<0.4 in]) and are called guttate or larger and may become confluent or generalized morphea. Deep morphea, in which the entire skin is thickened and feels bound down, includes subcutaneous morphea and eosinophilic fasciitis. This form is the least common and is considered the most disabling. Although LS involves primarily the skin, some patients develop musculoskeletal problems.

Laboratory Studies

In systemic sclerosis, the complete blood cell count shows anemia in approximately 25% of patients and may reflect anemia of chronic disease or may be caused by vitamin B_{12} or folate deficiency resulting from chronic malabsorption. Leukocytosis is rare, but eosinophilia occurs in approximately 15% of patients. Generally, these laboratory results are normal in localized scleroderma.

Autoantibodies

High titers of ANAs in the speckled pattern are frequently seen in approximately 80% of patients with systemic sclerosis. Anti-topoisomerase 1 (anti-sclerosis-70) autoantibodies are present in

Box 157.9. Classification of Juvenile Localized Scleroderma

1. Circumscribed morphea: round circumscribed areas
2. Linear scleroderma: affecting the trunk or limb, the head (en coup de sabre ["blow of a saber"]); Parry-Romberg syndrome or progressive facial hemiatrophy
3. Generalized morphea: induration of the skin that becomes confluent, eventually involving a large area
4. Pansclerotic morphea: circumferential involvement of limb(s) affecting the skin, subcutaneous tissue, muscle, and bone
5. Mixed morphea: combination of 2 or more of the previous subtypes

28% to 34% of patients and are usually seen in patients with dSSc with peripheral vascular disease, digital pitting, pulmonary interstitial fibrosis, renal involvement, and higher rate of mortality. Anticentromere antibodies occur almost exclusively in patients with lSSc in association with calcinosis and telangiectasias; they are seen less frequently in children. The anti-RNA polymerase III antibodies are associated with rapidly progressive skin disease and renal crisis.

In LS, ANAs are present in 23% to 73% of patients but are not predictive of the disease course. Anti-histone antibodies are detected in 47% of patients, are associated with more extensive localized disease, and may be useful in assessing disease activity.

Treatment

Treatment remains problematic for dSSc and lcSSc, and often, patients do not respond to therapies. Raynaud phenomenon and digital ulcers are managed with calcium channel blockers and sildenafil citrate. More recently, iloprost (synthetic analogue of prostacyclin prostaglandin I2) and competitive antagonists of endothelin-1 A, B (bosentan, macitentan) are used for severe digital ulcers. Iloprost and the endothelin inhibitors are useful in pulmonary hypertension to increase vascular dilatation and decrease pulmonary vascular resistance. To decrease inflammation in the lung, cyclophosphamide may be used in severe cases and other immunosuppression drugs (MMF or azathioprine) and hydroxychloroquine in more mild cases. Angiotensin-converting enzyme inhibitors play an important role in preventing renal crisis. In some cases, the skin disease is managed cautiously with low-dose steroids early in the disease during the edematous phase and with methotrexate during the sclerotic phase. Gastroesophageal reflux disease is managed with proton pump inhibitors. Supportive care is of great importance with attention to skin integrity, joint range of motion, and GI issues with weight loss. It is necessary for the physician to educate the family and child on the disease and its complications. The physician should inform the school of the child's potential needs while at school and any limitations. In addition, the physician can serve as a resource and source of information about dSSc and lcSSc for the community. Despite all treatment efforts, the prognosis is guarded.

Protocols have been proposed for the therapy of LS that include treatment with methotrexate in combination with corticosteroids. Linear scleroderma should be addressed early because it tends toward a progressive process. If lesions do not improve or if they expand, MMF is useful to inhibit further fibrosis. The difficulty in measuring lesion size makes it difficult to fully assess response to treatment.

Prognosis

Prognosis is improving for most autoimmune diseases because of the increased understanding of the pathogenesis. Criteria are being established and validated to aid in the diagnosis of each disease and optimize treatment. Consultation with rheumatologists, neurologists, nephrologists, and infectious disease specialists may be necessary to assist in the final diagnosis.

The care of a child with an autoimmune disease requires a multidisciplinary approach involving a primary care physician, rheumatologist, and subspecialists with expertise in affected target organs. The role of the primary care physician is to ensure routine care of the patient as well as prevent long-term sequelae of the disease and its treatment. Because many of the agents used to manage autoimmune disease have significant side effects, it is vital for the primary care physician to have a thorough understanding of the patient's medication regimen. The patient with autoimmune disease often experiences growth failure from the disease process or its treatment. Ensuring appropriate diet and physical activity is vital. Supplementation with calcium and vitamin D is beneficial to prevent osteoporosis. Periodic ophthalmologic screening, which is essential to assess for disease activity or adverse effects from medication, should be done at least annually. In the long term, the patient with autoimmune disease is at increased risk for cardiovascular disease secondary to chronic inflammation. An annual cardiovascular risk assessment may be required that includes a review of the diet and lipid profiles. The individual who has sustained a thrombolytic event or is at high risk for thrombosis may benefit from low-dose aspirin prophylaxis. As with any patient with a chronic disease, consideration of quality of life is essential. Disease management for the patient with autoimmune disease is a balance of optimal function, minimal complications, and improved quality of life.

CASE RESOLUTION

Initially criteria were insufficient for a diagnosis of SLE (ie, rashes, but not clarified if photosensitive; swelling and hypertension suggestive of renal disease; arthritis); however, it is clear that the adolescent has findings consistent with SLE. Additional questions about the history reveal that the sun made the girl's rashes worse, she had mouth sores, in the morning her eyes were puffy, and she sometimes had chest pain and trouble breathing. On physical examination, she was found to have a malar rash and a rash on the hard palate with other mouth sores, pitting edema of her feet and ankles, and mild hypertension. Laboratory results showed a mild anemia and lymphopenia, an ANA of 1:320 in a homogenous pattern, positive anti-ds-DNA antibodies, and low C3 (normal range: 87–158 mg/dL) and low C4 (normal range: 14–36 mg/dL). The urinalysis had 3+ protein and the protein/creatinine ratio was 1.0 (normal range: 0–0.4). With these additional findings the girl meets the criteria for a diagnosis of SLE with lupus nephritis. She is referred to a pediatric rheumatologist and nephrologist, and lupus nephritis (class III) is confirmed on renal biopsy. The girl is started on treatment with steroids and immunosuppression and improves over the next 6 months.

BERKOWITZ'S PEDIATRICS

A PRIMARY CARE APPROACH

6th Edition

Edited by Carol D. Berkowitz, MD, FAAP

The reference of choice for pediatricians, residents, medical students, and pediatric nurse practitioners, the newly revised and expanded sixth edition provides clear, practice-oriented guidance on the core knowledge in pediatrics. Edited by a leading primary care authority with more than 100 contributors, this edition provides comprehensive coverage of hundreds of topics ranging from temper tantrums and toilet training to adolescent depression and suicide.

More than 155 (**including 5 brand-new**) clinical chapters review pertinent epidemiology and pathophysiology and then give concise guidelines on what symptoms to look for, what alternative diagnoses to consider, what tests to order, and how to treat your patient.

This is an ideal reference for pediatricians, family physicians, medical students, residents, residency program directors, physician assistants, pediatric nurse practitioners, and nurses and perfect for use in continuity clinics.

This new edition brings you state-of-the-art expertise and insight by Carol D. Berkowitz, MD, FAAP, past president of the American Academy of Pediatrics. She is currently executive vice chair in the Department of Pediatrics at Harbor-UCLA Medical Center and distinguished professor of clinical pediatrics at the David Geffen School of Medicine at UCLA.

New in the sixth edition

- All chapters have been reviewed and updated to address current issues.
- Five new chapters, including Health Systems Science, Social Determinants of Health: Principles, and Adverse Childhood Experiences: Trauma-Informed Care.
- A newly created Instructor's Guide includes advice on how to best sequence topics in continuity clinics and provides answers to the text case study questions with an emphasis on applying chapter concepts and critical thinking to the case study.
- Case study questions have been enhanced and resources have been revised.
- This edition is completely reorganized into 15 parts using a systems-based approach.
