Most adolescent girls with severe bleeding and symptomatic anemia require a more extensive evaluation, and such patients usually are hospitalized for appropriate parenteral intravenous fluid therapy and possible blood transfusion. Occasionally, intravenous conjugated estrogens are required every 4 to 6 hours for the first 24 hours to stop severe acute hemorrhage. Most adolescents only require 1 or 2 doses. Intravenous estrogens should not be used in the patient with a contraindication to estrogen (eg, deep vein thrombosis) or who is not currently bleeding heavily. Otherwise, in cases of moderate to severe anemia, a COCP containing 30 or 35 mcg ethinyl estradiol is initiated 3 to 4 times a day; the progesterone component is necessary to stabilize the endometrium. Additionally, an antiemetic agent often is required 1 hour before the OCP during the first few days of therapy. After bleeding is controlled, the frequency of OCP administration can be tapered, and the adolescent can continue a monophasic COCP daily, skipping the placebo pills for at least the first cycle, and then switching to a lower-dose combination oral contraceptive for at least 6 cycles total. Studies have demonstrated that 20% to 25% of adolescents who require hospitalization for severe anemia within the first year after menarche have an underlying coagulopathy and therefore warrant a thorough hematologic investigation. In the case of excessive uterine bleeding in which oral contraceptives are used but the patient does not desire birth control, hormonal therapy should not be stopped until at least 3 months after the anemia has resolved to ensure restoration of iron stores.

Surgical treatment, such as dilatation and curettage, is rarely indicated in the adolescent patient and is reserved for individuals refractory to aggressive medical treatment.

Premenstrual Syndrome

The early identification of PMS or PMDD in the adolescent can be facilitated using screening questionnaires such as The Premenstrual Symptoms Screening Tool for Adolescents, a validated tool revised for use in teenagers that scores the severity of premenstrual symptoms

Table 61.2. General Guidelines for the Management of Abnormal Uterine Bleeding in the Adolescent

Factor	*Mild Anemia*[a]	*Moderate Anemia*[b]	*Severe Anemia*[c]
Hemoglobin (g/dL)	>11	8–11	≤7
Management	Reassurance, menstrual calendar, supplemental iron twice daily, COCP 1 pill daily (the latter if sexually active). Consider NSAID to help reduce blood loss.	Initially, 3–4 monophasic COCPs (30–35 mcg ethinyl estradiol and potent progestational agent[d]) every 6–8 hours for 2–3 days or until bleeding stops; take with antiemetic; taper to every 12 hours for 2–3 days, then every day after bleeding has stopped; skip placebos in first pill pack; then cycle for minimum of 3–6 months; prescribe oral iron supplementation. Consider NSAID to help reduce blood loss. Menstrual calendar.	Hospitalization if signs of hypovolemia or severe anemia; consider IV estrogen until bleeding stops; begin 3–4 monophasic COCPs (30–35 mcg ethinyl estradiol and potent progestational agent[d]) every day with antiemetic and taper as with moderate anemia over next 21 days; skip placebo pills for at least 1 month or until hemoglobin has normalized; then cycle with monophasic COCPs (30–35 mcg ethinyl estradiol) for 6–12 months; prescribe oral iron supplementation. Menstrual calendar.
Follow-up	2–3 months; repeat hemoglobin.	2–3 weeks for repeat hemoglobin, then every 2–3 months.	1–2 weeks for repeat hemoglobin, then every month.

Abbreviations: COCP, combination oral contraceptive pill; IV, intravenous; NSAID, nonsteroidal anti-inflammatory drug.

[a] Blood pressure and heart rate stable.

[b] Blood pressure and heart rate stable, moderate flow.

[c] Blood pressure stable, increased heart rate, heavy flow.

[d] Potent progestin: norgestrel or levonorgestrel.

and extent to which they interfere with work, relationships, and familial responsibilities. After the condition of PMS/PMDD is identified, the adolescent can be properly evaluated and educated about treatment options. Although various sources have advocated many different regimens for the management of PMS, no definitive findings have been reported, and no single effective treatment has been demonstrated. The overall goal of therapy is to improve the adolescent's quality of life by ameliorating the debilitating symptoms associated with PMS/PMDD.

Treatment involves education about the menstrual cycle and PMS, supportive self-care to reduce stress and the severity of symptoms, lifestyle modifications (eg, increasing exercise), dietary supplementation, and the initiation of specific medications (eg, selective serotonin reuptake inhibitors [SSRIs]) for severe PMS/PMDD symptoms. For example, therapies for mild to moderate symptoms include diet modification for the patient whose primary symptom is bloating, promotion of regular aerobic exercise, education about menstrual physiology and the relationship of changing hormones to symptoms, stress management, and cognitive-behavior therapy or group therapy. Calcium supplementation (1,200 mg daily in divided doses) and vitamin D are the only evidence-based dietary modifications that have been shown to consistently improve symptoms. Other vitamin and mineral supplements as well as certain herbal preparations require more definitive research before their use can be recommended. Some therapies that historically had been used extensively also have been associated with undesirable outcomes, such as the development of peripheral neuropathy with pyridoxine (vitamin B_6) at high doses.

Although it might be assumed that ovulatory suppression with COCPs in a conventional 21-day active/7-day placebo regimen would decrease PMS symptoms, their use has in fact been associated with incomplete suppression of ovulation and an exacerbation of PMS symptoms during hormone withdrawal. Lower estrogen dosing (eg, 20 mcg ethinyl estradiol), the use of the progestin drospirenone, and extended or continuous cycling of COCPs have been shown to reduce PMS symptoms in adult women with PMDD versus controls.

When mood symptoms predominate and significantly impair function, SSRIs are considered first-line treatment in adult women; however, this is not the case for teenagers. Fluoxetine, sertraline, and paroxetine are the only US Food and Drug Administration–approved SSRIs for use in the management of severe PMS/PMDD. Although fluoxetine is approved for use in children and adolescents, it is approved for only 2 conditions: major-depressive disorder and obsessive-compulsive disorder. Therefore, the decision to prescribe an SSRI in an adolescent with severe PMS/PMDD is at the discretion of the health professional because studies specific to adolescents are lacking and use of an SSRI in this age group requires diligent monitoring by a multidisciplinary team. Anxiolytic agents, specifically alprazolam, generally are not used in adolescents because of the possible development of drug dependency.

Vaginitis

See Chapters 59 and 60 for a discussion of the management of vaginal discharge in adolescents.

Prognosis

Most adolescents with common menstrual symptoms who receive aggressive, appropriate care are usually symptom-free after 3 to 4 months of continuous therapy. Complications associated with oral contraceptive use and NSAIDs are rare in this otherwise healthy patient population. Symptoms associated with an immature hypothalamic-pituitary-ovarian axis, such as anovulatory bleeding and abnormal uterine bleeding, may also resolve spontaneously but generally respond favorably to hormonal management. The prognosis for the adolescent with amenorrhea depends in part on the underlying etiology.

CASE RESOLUTION

More information should be obtained to exclude the numerous other causes of abnormal uterine bleeding in the adolescent before a diagnosis of anovulatory uterine bleeding can be made. Questions about breast tenderness, galactorrhea, weight loss, fatigue, visual changes, prolonged bleeding, and easy bruising can be particularly important. If the adolescent has no other symptoms, a hemoglobin or hematocrit as well as a complete blood cell count and a pregnancy test should be performed. An endocervical, vaginal, or urine specimen should be sent for nucleic acid amplification testing for gonorrhea and chlamydia. Depending on the severity of anemia and the desire for contraception, the adolescent should be placed on twice-daily iron supplementation and oral combined hormonal therapy for at least 3 months.

CHAPTER 62

Disorders of the Breast

Monica Sifuentes, MD

CASE STUDY

A 2-year-old girl is brought to the office for bilateral breast swelling first noticed 3 weeks previously by her mother. The swelling is nontender and does not appear to be increasing in size. No history exists of galactorrhea. The child is otherwise healthy, takes no medications, and is not using any estrogen-containing creams or other over-the-counter products or supplements.

On physical examination, vital signs are normal, and the child is at the 50th percentile for height and weight. A 1.5-cm, firm, nontender mass is palpated below her left nipple. Below the right nipple, a 1-cm, nontender mass of similar consistency is present. There is no discharge from either nipple and no areolar widening. The abdomen is soft, with no masses palpated. The genitalia are those of a normal prepubescent female with no pubic hair and vaginal mucosa that appears red and not estrogenized.

Questions

1. What is premature thelarche, and how can it be differentiated from true precocious puberty?
2. What are the most common causes of breast hypertrophy in the infant?
3. When does pubertal breast development normally occur in females?
4. What are the most common causes of breast masses in adolescent females, and how should they be managed?
5. How can physiologic pubertal gynecomastia be differentiated from pathologic causes of gynecomastia in adolescent males?

Breast disorders occur in all pediatric age groups and can become a cause for significant concern for both patients and parents or guardians. A neonate may present to the pediatrician with bilateral breast hypertrophy and galactorrhea or mastitis. Bewildered parents or guardians might bring in their young prepubertal daughter because of what appears to be early breast development. An anxious adolescent female may notice for the first time that her breasts are asymmetric, or she may feel a lump beneath the skin. An adolescent male can present with unilateral or bilateral gynecomastia that makes him uncomfortable and causes severe psychological distress. Whatever the underlying cause, breast problems can be disconcerting at any age. Primary care physicians should be equipped to differentiate between normal variants of growth and pathologic conditions in newborns, infants, children, and adolescents. Significant disorders are rare, but diagnosis is important so that appropriate management can begin.

Epidemiology

Breast problems range from congenital anomalies and benign disorders related to hormonal stimulation to breast masses and tumors. Serious disorders, such as primary breast cancer, are exceedingly rare in children and adolescents, although inappropriate breast enlargement or gynecomastia as a sign of another neoplastic process is not uncommon.

Benign breast hypertrophy can occur in 60% to 90% of newborns and occurs in both male and female term neonates. Presentation may be unilateral or bilateral. Occasionally nipple discharge occurs, particularly in the case of well-intentioned family members who try to extract the milk, inadvertently promoting the central secretion of prolactin and oxytocin via breast stimulation.

Congenital anomalies of the breast include polythelia, polymastia, amastia, and athelia. *Polythelia*, or extra accessory nipples, can occur anywhere along the embryonic mammary ridge (also called the "milk line") from the axilla to the groin and occurs in 2% of the general population (Figure 62.1). Reportedly, abnormalities of the urologic and cardiovascular systems have been associated with polythelia. *Polymastia* refers to supernumerary breasts along the milk line and occurs less frequently than polythelia. The usual locations for supernumerary breasts are below the breast on the chest or the upper abdomen. Polythelia and polymastia may be familial and can occur bilaterally or unilaterally. Problems associated with breast development, such as a tuberous breast deformity, also can be thought of as a congenital anomaly, although it does not manifest until later in puberty when breast growth is noted to be underdeveloped or abnormal in appearance. The breasts have the appearance of a tuberous plant root, with an elevated inframammary fold, narrow breast base, and "herniation" of glandular tissue through the areolae, which are unusually large.

Amastia (congenital absence of glandular breast tissue) and *athelia* (absence of a nipple) are rare, but their presence often is associated with other anomalies of the chest wall, such as pectus excavatum. Amastia also is seen in Poland syndrome, which includes absence of the ipsilateral pectoral muscles, various rib deformities and upper limb defects (eg, syndactyly [webbed fingers]), and radial nerve aplasia (Figure 62.2).

Premature thelarche is isolated unilateral or bilateral breast development in girls between 1 and 4 years of age without other signs of sexual maturation (eg, pubic hair, estrogenized vaginal mucosa, acceleration of linear growth). An estimated 60% of cases occur between 6 months and 2 years of age, and a diagnosis after 4 years of age is uncommon. In contrast, *precocious puberty* is the appearance of any sign of secondary sexual maturation before age 8 years in girls with a normal body mass index or age 9 years in boys. In young females, this involves breast or pubic hair development, and in males it involves pubic hair development or testicular enlargement. Despite well-documented ethnic variation among children, 7 years is considered the lower acceptable age limit for the onset of puberty in non-Hispanic black and Mexican American girls.

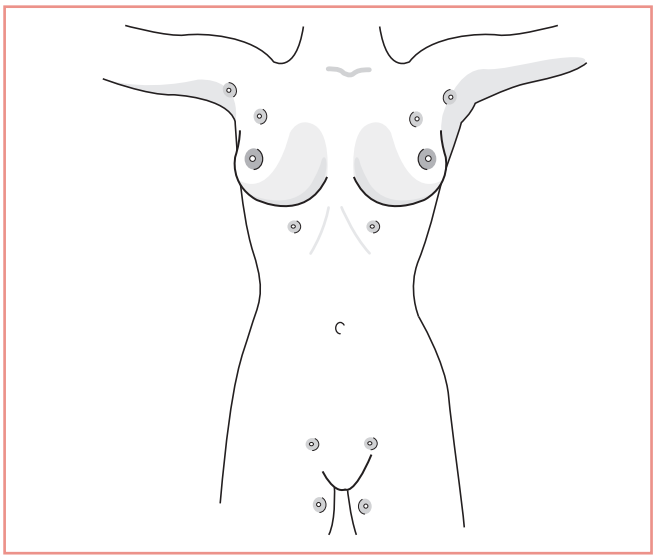

Figure 62.1. Polythelia. Supernumerary nipples along the embryonic mammary ridge (milk line).

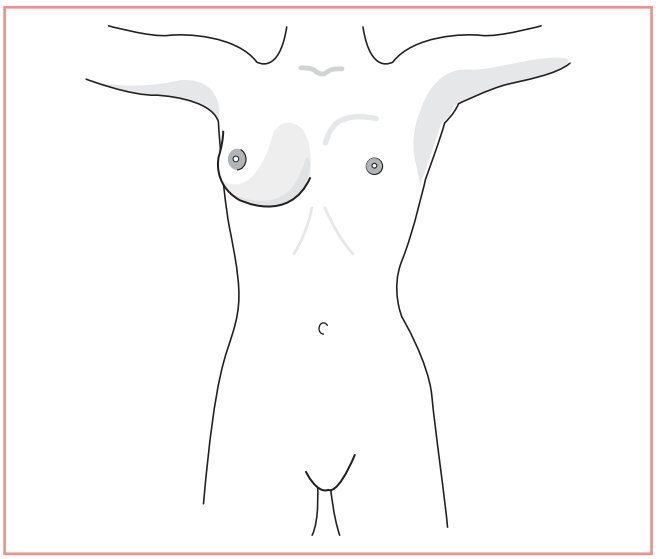

Figure 62.2. Amastia. Unilateral (left) complete absence of breast tissue.

Gynecomastia may occur in adolescent males as they progress through puberty and is often called "transient pubertal gynecomastia" or "physiologic pubertal gynecomastia." An estimated 60% to 70% of adolescent males are affected, with a peak incidence between ages 13 and 14 years or approximately 1 year after the onset of puberty. This generally corresponds to sexual maturity rating (SMR) (ie, Tanner stage) 3 to 4 genital and pubic hair development in the young male. Like breast development in the pubertal female, transient pubertal gynecomastia may be asymmetric and painful, although concurrent or sequential involvement of both breasts can occur. It is uncommon for pubertal gynecomastia to occur beyond age 17 or 18 years in the adolescent male.

In the adolescent female, breast masses are not uncommon; however, clinically significant lesions are rare. Breast cancer has an estimated annual incidence of 0.1 in 100,000 adolescents. In most studies of patients through age 20 years, the most common benign breast tumor is a fibroadenoma, which has been reported in 60% to 95% of biopsied lesions. Two-thirds of these lesions are located in the lateral quadrants of the breast, with most in the upper outer quadrant. The peak incidence of these lesions is in late adolescence (17–21 years of age), and they tend to occur more commonly in black females. Reportedly, 10% to 15% of cases are bilateral. Additionally, 25% of cases involve multiple fibroadenomas.

Fibrocystic changes are the second most common histologic diagnosis after fibroadenomas. Other breast masses include solitary cysts, abscesses, lipomas, and the *phyllodes tumor* (also known as *cystosarcoma phyllodes*), an extremely rare, rapidly growing, painless breast tumor that is nearly always benign and clinically can be confused with fibroadenoma, except for its aggressive growth. If malignant, however, cystosarcoma phyllodes can metastasize hematogenously to the lungs.

Malignancy is reported in less than 1% of excised lesions. Fewer than 50 cases of primary breast cancer in children and adolescents have been reported in the literature to date. Rhabdomyosarcoma and fibrosarcoma are among the other rarely reported primary tumors of the breast in adolescents. Metastatic cancer of the breast is more common than primary breast cancer and has been reported in children with primary hepatocellular carcinoma, leukemia, Hodgkin and non-Hodgkin lymphoma, neuroblastoma, and rhabdomyosarcoma. Of note is the increased lifetime risk for radiation-induced breast cancer in girls and adolescents who undergo mantle/chest wall irradiation during peak breast development (10–16 years of age); such irradiation typically is administered during treatment for Hodgkin lymphoma. The breast cancer risk for women who are survivors of Hodgkin disease is 75 times that of the general population. According to the literature, the cumulative risk for breast cancer during their lifetime exceeds 40% for girls who undergo chest irradiation for treatment of Hodgkin lymphoma.

Normal Breast Development

In the adolescent female, the first sign of puberty is breast development or thelarche. This begins with the appearance of a breast bud beneath the areola. Under the influence of estrogen, there is an increase in the adipose tissue along with the beginning of ductal and stromal growth. Progesterone initiates alveolar budding and lobular growth and contributes to the development of secretory lobules and alveoli. The alveoli are later lined by milk-secreting cells under the influence of prolactin when full maturation occurs during the first pregnancy.

The normal progression of breast growth is divided into 5 stages or SMRs. These descriptions are used to follow normal breast development, which occurs in parallel with and generally precedes pubic hair development. It usually takes 2 to 4 years for the completion of breast development, although, as in all aspects of puberty, variations do occur. The practitioner should keep in mind that many females remain in SMR 3 or 4 breast development until pregnancy. Additionally, especially between SMR 2 and 4, significant breast asymmetry can be quite common in the adolescent without indicating a pathologic process. After both breasts are fully mature and reach SMR 5, adequate catch-up growth usually has occurred.

Clinical Presentation

Neonates with breast disorders usually present in the first few weeks after birth with bilateral breast enlargement that may be asymmetric (Box 62.1). They may present with associated clear or cloudy nipple discharge. If an infection is present, the overlying skin may be warm and erythematous. Fever or other nonspecific symptoms, such as poor feeding and irritability, also may be present because mastitis involves the entire breast bud; although rare, septicemia can occur as well.

In prepubertal females, benign premature thelarche presents as unilateral or bilateral nontender subareolar swelling without the appearance of other secondary sexual characteristics. In contrast, girls with precocious puberty may have axillary hair, nipple and areola enlargement and thinning, and pubic hair in addition to early breast development. Adolescent females with a breast problem often report a unilateral breast lump noted incidentally by the teenager. It may be tender, fluctuant, firm, rubbery, or nodular. The adolescent also may report painful breasts (*mastalgia*) that can be cyclic in nature. For most breast masses, the overlying skin is normal, but occasionally skin changes do occur. Rarely, an associated nipple discharge may be present.

Because most breast masses occur in females, gynecomastia is particularly anxiety provoking in young adolescent males. It usually appears as a unilateral or bilateral 2- to 3-cm firm mass beneath the areola, which may or may not be tender. Irritation of the skin of the nipple may occur resulting from prolonged friction from clothing. Galactorrhea rarely accompanies pubertal gynecomastia and may be indicative of self-stimulation; illicit drug use, including cannabis, opiates, benzodiazepines, and amphetamines; or exposure to other medications, such as risperidone.

Box 62.1. Diagnosis of Breast Disorder From Birth Through Adolescence

Neonates, Infants, Prepubescent Children, and Adolescent Males

- Unilateral or bilateral subareolar mass
- Possible associated nipple discharge
- Overlying skin changes, such as erythema in neonates and infants

Adolescent Females

- Firm, rubbery, freely movable mass
- Possible tenderness
- Breast asymmetry
- Skin changes, such as shininess, venous distention, or dimpling (rare)
- Possible associated nipple discharge

Pathophysiology

Neonatal breast hypertrophy seemingly is a response to maternal estrogen exposure in utero. Constant stimulation can result in persistent swelling, galactorrhea, and overt infection (ie, mastitis). Of note, if galactorrhea is present, it should not persist beyond the first few weeks after birth. Generally, preterm neonates are less responsive to maternal hormones and, therefore, breast hypertrophy occurs less often in this age group and its appearance may be delayed for weeks.

Benign premature thelarche is a variation of normal pubertal development with transient elevations in estrogen levels from functional ovarian cysts or fluctuations in pituitary gonadotropin secretion. Often, the breast enlargement occurs without other estrogen effects, such as an increase in uterine size or changes in the appearance of the external genitalia. Typically, no linear growth or bone age advancement is associated with this condition. Current research is examining the potential role of leptin and its influence on sex steroids in the development of premature thelarche as well as pubertal gynecomastia.

Central precocious puberty is the result of early activation of the hypothalamic-pituitary-gonadal axis and the secretion of gonadotropin-releasing hormone (GnRH)-dependent pituitary gonadotropins in a pulsatile pattern. Although a search may be undertaken for an underlying central nervous system (CNS) or gonadal abnormality, most cases in females are idiopathic. In contrast, less than 10% of males with precocious puberty do not have an identifiable cause, and it has been reported that approximately 50% of boys with precocious puberty have an identifiable intracranial process. Central nervous system tumors cause precocious puberty by impinging on the neuronal pathways that inhibit the GnRH pulse generator in childhood. Cranial irradiation, received as a part of tumor therapy, also can cause central sexual precocity. Pseudo-precocious puberty is GnRH-independent and is caused by the extrapituitary secretion of gonadotropins or the secretion of gonadal steroids independent of pulsatile GnRH stimulation. (See the article by Long in Selected References for a general review of precocious puberty.)

The cause of fibroadenomas in adolescent females is postulated to be an abnormal sensitivity to estrogen. Observations supporting this hypothesis include the presence of estrogen receptors in the tumor and an increased incidence of this type of tumor during late adolescence. Thus, prolonged exposure to estrogen may play a role in the development of fibroadenoma. Enlargement can occur during pregnancy or toward the end of the menstrual cycle.

The definition of *gynecomastia* is an increase in the glandular and stromal tissue of the male breast. Physiologic gynecomastia is thought to occur from a transient imbalance between estrogen and androgens during puberty. Alterations in the ratio of these hormones results in an increase in estrogen relative to testosterone. Certain medications can cause elevations in serum prolactin and lead to gynecomastia or galactorrhea (Box 62.2). Some illicit drugs, such as marijuana, contain phytoestrogens that can mimic estrogen or stimulate estrogen receptor sites. Specific medications, such as spironolactone and cimetidine, interfere with androgen receptors or induce inhibition of enzymes necessary for steroid synthesis.

Differential Diagnosis

The differential diagnosis of breast disorders in children and adolescents depends on sex and age at onset. In addition, the presence or absence of other secondary sexual characteristics is helpful to differentiate between a variation of normal pubertal development and a pathologic process.

Infants and Children Younger Than 9 Years

In prepubertal children, the differential diagnosis of isolated early breast development includes exposure to exogenous sources of estrogen, such as skin creams that may contain tea tree or lavender oil, makeup, and medications (eg, oral contraceptives).

Box 62.2. Causes of Galactorrhea

- Mechanical stimulation of the nipple
- Medications
  - Opiates
  - Estrogens
  - Digitalis
  - Butyrophenones (haloperidol)
  - Phenothiazines
  - Risperidone
  - Metoclopramide
  - Isoniazid
  - Reserpine
  - Cimetidine
  - Benzodiazepines
  - Tricyclic antidepressants
- Illicit drugs
  - Marijuana
  - Heroin
- Hypothalamic-pituitary disorders

For patients with suspected precocious puberty, other etiologies must be considered in addition to exogenous hormones (Box 62.3). Central nervous system tumors, lesions, and vascular insults are among the most common causes. Congenital tumors, such as hypothalamic hamartomas, are especially important to rule out because they often present before age 3 years. Other CNS tumors to consider are neurofibromas, optic gliomas, astrocytomas, and ependymomas. Specific CNS lesions include cysts in the area of the third ventricle and congenital brain defects. Hydrocephalus, postinfectious encephalitis or meningitis, head trauma, and static cerebral encephalopathy also can cause sexual precocity. Endocrine disorders include primary hypothyroidism, estrogen-producing tumors of the ovary or adrenal gland, and ovarian cysts.

Adolescents

The differential diagnosis of breast masses in adolescent females is extensive (Box 62.4). Conditions can be distinguished from one another based on the location of the lesion; its texture, mobility, and size; and the speed at which it is enlarging.

Box 62.3. Differential Diagnosis of Precocious Puberty

- Central (true)—GnRH–dependent
- Idiopathic
- Central nervous system
  - Tumor
    - Optic and hypothalamic gliomas (often associated with neurofibromatosis), hypothalamic hamartoma, astrocytoma, ependymoma, craniopharyngioma
  - Lesion
    - Congenital defects, hydrocephalus, cyst in the third ventricle
  - Insult
    - Postinfectious encephalitis or meningitis, static encephalopathy
  - Infection
    - Abscess, tuberculous granulomas of the hypothalamus
  - Head trauma
  - Sequela of cranial radiation
  - Sarcoid granuloma
- Endocrine
  - Hypothyroidism
  - Secondary to GnRH-independent precocious puberty (21-hydroxylase deficiency, Albright syndrome)
  - Peripheral (pseudo-)—GnRH-independent
  - Adrenal
    - Tumor
    - 21- or 11-hydroxylase deficiency
- Gonadal
  - Tumor
    - Albright syndrome
    - Familial testotoxicosis
  - Ectopic human chorionic gonadotropin–secreting tumor
  - Exogenous steroids

Abbreviation: GnRH, gonadotropin-releasing hormone.

Box 62.4. Causes of Breast Masses in the Adolescent Female

- Fibroadenoma
- Breast abscess
- Breast cyst
- Juvenile (giant) fibroadenoma
- Cystosarcoma phyllodes (benign)
- Fat necrosis (secondary to trauma)
- Lipoma
- Hematoma
- Intraductal papilloma
- Adenocarcinoma
- Rhabdomyosarcoma
- Angiosarcoma
- Lymphoma
- Cystosarcoma phyllodes (malignant)

According to some authors, gynecomastia can be classified as type 1, 2, or 3 based on physical examination findings. Type 1 is consistent with benign pubertal hypertrophy. The differential diagnosis for types 2 and 3 includes physiologic gynecomastia (no evidence of an underlying disease process); organic disorders, such as hyperthyroidism, liver disease, and testicular or adrenal neoplasms; rare genetic syndromes, such as Klinefelter syndrome; and side effects of certain prescription medications, over-the-counter supplements, or drugs of abuse (Box 62.5).

Persistent galactorrhea can be caused by several conditions in addition to excessive stimulation of the nipple from sexual activity or constant friction to the area. Other etiologies include neurologic, hypothalamic, pituitary, and endocrine disorders. Common causes in the adolescent female are prolactin-secreting tumors and hypothyroidism. The same drugs that induce galactorrhea in females can cause gynecomastia in males (see Boxes 62.2 and 62.5).

Evaluation

History

In the infant or child, the history should focus on endogenous as well as exogenous sources of estrogen (Box 62.6). Additionally, it is important to ascertain from the parent or guardian whether a growth spurt has occurred as well as if other physical features of puberty have appeared. With teenagers, it is important to inquire about medications; complementary and alternative therapies, including herbal remedies, supplements, and illicit drug use; and a history of systemic illness. All adolescent patients should be interviewed alone, especially when discussing illicit substance use (see Chapter 63). The adolescent male may feel particularly embarrassed and self-conscious given the nature of his visit; thus, the physician should be especially patient and supportive during both the interview and the physical examination.

Box 62.5. Causes of Type 2 Gynecomastia in the Adolescent Male

- Idiopathic
- Hormone-secreting tumors
  - Seminomas (account for 40% of germ cell tumors)
  - Leydig cell tumor
  - Teratoma
  - Feminizing adrenal tumor
  - Hepatoma
  - Bronchogenic sarcoma (ectopic human chorionic gonadotropin production)
- Thyroid dysfunction (hyperthyroidism and hypothyroidism)
- Renal failure and dialysis
- Chronic liver disease/cirrhosis of the liver
- Klinefelter syndrome (XXY)
- Testicular feminization syndrome (partial androgen insensitivity syndrome)
- Drugs (prescription medications and substances of abuse)
  - Marijuana, amphetamines, heroin, methadone
  - Alcohol
  - Anabolic steroids/androgens
  - Estrogens, testosterone
  - Growth hormone
  - Cimetidine, ranitidine
  - Omeprazole
  - Digitalis
  - Spironolactone
  - Phenytoin
  - Tricyclic antidepressant agents
  - Anxiolytic agents: diazepam, buspirone
  - Risperidone
  - Selective serotonin reuptake inhibitors
  - Cancer chemotherapeutic agents: alkylating agents, methotrexate
  - Isoniazid
  - Ketoconazole
  - Highly active antiretroviral treatment
- Over-the-counter herbal supplements or skin care products containing lavender, tea tree oil, or other oils with estrogen-like actions
- Pseudogynecomastia (adipose tissue in male with obesity)

Physical Examination

The physical examination includes an assessment of the patient's linear growth, especially in cases of suspected precocious puberty. The height and weight should be plotted on the growth curve and compared with previous measurements. Accelerations in height occur in sexual precocity. Excessive weight gain also should be noted; obesity can simulate breast enlargement in young females and gynecomastia in males, and adipose tissue can be mistaken for breast development if the tissue is not palpated correctly.

The extent of the breast examination depends on the age of the patient. In infants and young children, the breast tissue should be

Box 62.6. What to Ask

Breast Disorder

Prepubertal Children

- At what age was the breast mass first noted?
- Does it seem to be increasing in size?
- Is it tender or erythematous?
- Is there associated discharge from the nipple?
- Has the child been exposed to any estrogen-containing skin creams, medications, or other products?
- Is the child or adolescent using any herbal supplements, such as ginseng or fennel, or products that contain tea tree or lavender oil?
- In the male patient, is he taking any medications known to cause gynecomastia, such as digoxin, omeprazole, or isoniazid?
- Is the child experiencing any neurologic symptoms, such as headache, ataxia, or visual disturbance?
- Is there a history of head trauma, central nervous system infection, or cerebral insult?
- Has the parent noted any other signs of early pubertal development (eg, pubic hair, acne, sudden increase in height)?

Adolescent

- When was the breast mass first noticed, and where is it located?
- Does it seem to be increasing in size?
- Is the lesion tender?
- Is there a history of trauma to the breast?
- Is there any discharge from either nipple?
- In the female, when was the last menstrual period?
- Is there a history of headache or visual disturbances?
- Are there any signs or symptoms of systemic illness, such as weight loss?
- Is there a family history of breast cancer in a first-degree relative, particularly the mother? If so, what was her age at diagnosis?
- Is there a history of chest wall radiation or treatment with chemotherapeutic agents?
- In the male, is he taking any medications that can cause gynecomastia, such as cimetidine?
- Is the adolescent male using anabolic steroids, supplements, or topical oils?
- Is the adolescent using any other illicit substances, such as marijuana or heroin?
- Is there a family history of gynecomastia or abnormal sexual development?

measured and the size recorded so that growth can be monitored over time. Consistency of the tissue and mobility also should be evaluated. Breast growth as a result of neonatal breast hypertrophy and benign premature thelarche is nontender, firm, and freely mobile. The nipple should be examined for a clear or cloudy discharge by gently compressing each nipple separately.

In the adolescent female, the breast examination should include visual inspection of the breasts as well as palpation of any lesions and axillary nodes. Ideally, this would be performed in the sitting and supine positions, as is done in adult women. Most adolescent females, however, may be uncomfortable with so extensive an examination. The physician must take the time to explain the reasons for the examination to help the patient feel less self-conscious. All physicians and other health professionals should ensure that a female staff member is present to chaperone during the breast examination.

Visual inspection should assess for SMR, appearance of the skin, breast symmetry, and evidence of trauma. Shiny skin or superficial venous distention on 1 breast would indicate the possible presence of an underlying large mass. A peau d'orange (ie, orange peel) appearance of the skin or erythema and warmth should be noted as a sign of an infiltrative lesion or infection, respectively.

Palpation of the breast mass can be accomplished with the patient in the supine position using 1 of 3 methods. Using the second, third, and fourth fingers of 1 hand, the examiner should gently palpate each breast in a pattern of concentric circles, spokes of a wheel, or vertical and horizontal lines. The location of the mass should be noted; a mass beneath the areola might indicate an intraductal lesion, whereas the upper outer quadrant is the classic location for a fibroadenoma. The consistency of the lesion is important. Is it firm, rubbery, and fluctuant, or irregular and lumpy? Is it freely movable or attached to the chest wall? Fibroadenomas tend to be nontender, firm, discrete, freely movable, and rubbery. A tender, poorly defined mass is consistent with a contusion; a hematoma is more sharply defined with associated skin ecchymoses. Fat necrosis can occur after trauma and is painless, firm, well circumscribed, and mobile. The size of the mass should be measured and recorded. It is important to remember that tumor size does not generally correlate with malignant potential. Tender, diffuse, cord-like thickening, which may feel like a beanbag, may be indicative of fibrocystic breast changes. The mean age at presentation of fibrocystic breast changes is mid-adolescence. This condition may involve 1 or both breasts, is more apparent around the time of menses, and may be exacerbated by the consumption of caffeinated beverages. Limiting caffeine consumption may provide symptomatic relief. Finally, each nipple should be gently squeezed to check for a discharge. If present, whether it is clear, milky, or bloody should be noted. A serosanguineous or sanguineous discharge is indicative of an intraductal mass. Additionally, a retracted nipple is indicative of involvement of the areolar area.

In the adolescent male, the breast tissue should be gently palpated in the supine position to distinguish between fat deposition without glandular proliferation in the overweight patient (ie, pseudogynecomastia, adipomastia) and true gynecomastia. Type 1 gynecomastia presents as a unilateral or bilateral freely mobile subareolar nodule, which is generally up to 3 cm in size. Enlargement beyond the areolar perimeter is consistent with type 2 gynecomastia. Type 3 resembles SMR 3 breast development in girls. The breast tissue associated with types 1 and 2 also is firm and rubbery and may be tender to palpation, whereas type 3 has a consistency similar to female breast tissue.

The examiner should palpate for axillary lymphadenopathy. Although most physicians associate it with breast cancer, it also may be found with infection or necrosis of a benign tumor. In the

adolescent male, in addition to palpation of the breast tissue, it is important to evaluate liver size and texture as well as define the SMR of the genitalia to determine whether pubertal development is consistent with the gynecomastia. The testicles should be palpated carefully for size and consistency and the presence of masses, nodules, or asymmetry. Any evidence of atrophy (ie, decrease in testicular size) should be noted. Additionally, findings suggestive of hypothyroidism or hyperthyroidism, liver disease, or other stigmata suggestive of a syndrome must be investigated.

A detailed neurologic examination, including examination of the fundi, should be performed—especially in children with sexual precocity—to confirm or detect a CNS disorder.

Laboratory Tests

The laboratory workup for breast disorders is dictated by the findings on history and physical examination. Isolated neonatal breast hyperplasia and premature thelarche require no laboratory studies. Although serum gonadotropin concentrations (ie, luteinizing hormone, follicle-stimulating hormone) and estradiol levels can be obtained in girls with precocious puberty, definitive demonstration of an activated hypothalamic-pituitary axis generally requires the administration of a GnRH stimulation test by a pediatric endocrinologist. In addition, a morning testosterone level should be ordered in boys. Based on these results, further studies may be indicated, such as a serum human chorionic gonadotropin (hCG) level.

For most breast lesions in adolescent females, no laboratory studies are needed. Ultrasonography-guided fine-needle aspiration of the mass may be performed in patients with an apparent discrete collection of fluid. The aspirated fluid should be sent for culture and antibiotic sensitivities. Sometimes, to relieve patient and parental anxiety or to better identify the etiology of the mass, it is necessary to perform another procedure (eg, core needle biopsy) if imaging features are atypical or the lesion has undergone rapid growth. Excisional biopsy of the mass allows for more accurate histologic information but is rarely indicated for most lesions.

In the healthy adolescent male with gynecomastia and no evidence of systemic illness, no history of medication use or illicit substance abuse, and an otherwise normal physical examination (including the testicular examination), no further laboratory studies are necessary. If pubertal gynecomastia and other systemic illnesses are ruled out, an endocrine workup is appropriate to elucidate the cause of nonpubertal gynecomastia. This should begin with morning serum levels of hCG, luteinizing hormone, follicle-stimulating hormone, and serum testosterone and estradiol because circadian variation may affect their interpretation. Dehydroepiandrosterone sulfate, thyroid function tests, renal function studies, and liver enzymes also may be useful. If these laboratory studies are normal, the diagnosis is idiopathic gynecomastia. If they are abnormal, consultation with a pediatric endocrinologist or adolescent medicine specialist should occur.

A pregnancy test and serum prolactin level should be ordered in the adolescent female with galactorrhea, regardless of the menstrual history.

Imaging Studies

Left hand and wrist radiographs to determine the child's bone age should be obtained in children with a diagnosis of precocious puberty. Additionally, magnetic resonance imaging of the brain should be obtained in boys to evaluate for a CNS lesion or structural abnormality in the hypothalamus or pituitary gland. Depending on the history, magnetic resonance imaging may be indicated in some girls. Pelvic ultrasonography, although rarely necessary, can be performed to rule out the presence of an ovarian tumor or cyst in girls with precocious puberty.

Mammography is not recommended as part of the evaluation of a breast mass in the pediatric age group. Particularly in female adolescents, mammograms can be very difficult to interpret because of the dense fibroglandular breast tissue, which reduces the overall sensitivity of the examination. Exposing developing breast tissue to ionizing radiation and the associated cellular changes that may result in future malignancy is also a consideration. Additionally, the risk for primary breast cancer in an otherwise healthy adolescent girl with no risk factors is extremely low. Breast ultrasonography is generally the primary imaging modality for the evaluation of a breast mass for several reasons. It accurately confirms the presence of the mass and helps distinguish between a cystic lesion and a solid mass. Ultrasonography is noninvasive and causes no pain for the anxious teenager. It can also provide more accurate measurement of the size of the lesion and its location prior to an image-guided biopsy. Finally, specific characteristics of the lesion, such as the shape, margins, and presence of microcalcification, can help differentiate benign and malignant lesions.

Testicular ultrasonography to search for a tumor is indicated in the adolescent male if the level of serum hCG or estradiol is elevated or if a testicular mass is noted on physical examination. Other imaging studies for the evaluation of gynecomastia generally are not useful.

Management

In neonates, mastitis most often is caused by *Staphylococcus aureus* and group B streptococcus. Gram-negative bacilli also have been reported. Parenteral antibiotics should be initiated when the diagnosis is made. Incision and drainage of a breast abscess is rarely indicated and should only be undertaken by an experienced surgeon familiar with the anatomy of the breast to minimize the likelihood of injury to the affected breast bud.

Congenital anomalies, such as polythelia and polymastia, do not require any treatment. If, however, the patient or parent/guardian wants the tissue removed for aesthetic or psychological reasons, it is recommended to do so before puberty. Reconstructive surgery for amastia, as in Poland syndrome, is typically delayed until late adolescence to allow full development of the unaffected breast.

Although no treatment is required for benign premature thelarche, parents and guardians need to be reassured that the condition is self-limited. The patient should be reexamined periodically to check for any further progression of puberty, such as persistent breast growth, the appearance of pubic hair, or a growth spurt.

If no underlying medical condition has been discovered, the treatment for most children with central precocious puberty is directed at controlling the secondary sexual development with GnRH agonists/analogue therapy. When GnRH is administered on a routine basis or continuously, gonadotropin secretion decreases, which delays further pubertal development. Leuprolide acetate is the GnRH agonist most often prescribed in the United States. Children should be followed every 1 to 3 months in conjunction with a pediatric endocrinologist to monitor their progression and response to therapy. The child continues to receive the medication until they reach the normal age of puberty, at which point the medication is discontinued and the process of puberty begins again.

Unless otherwise indicated by the type of tumor, children with a CNS lesion as a cause of precocious puberty usually do not require neurosurgical intervention. Therapy should focus on minimizing the degree of growth acceleration and the development of secondary sexual characteristics.

Most breast masses in adolescent females are small, well demarcated, firm or rubbery, and nontender and can be managed with the "wait and watch" approach. The patient should be followed every 3 to 4 months, preferably allowing a few menstrual cycles to pass between each visit. If there is no change in the lesion or just a small increase in its size, no studies or procedures are indicated because it is most likely a fibroadenoma. As previously noted, a core needle biopsy may be requested to relieve the anxiety for the parent/guardian and the teenager that accompanies the presence of a breast lesion and to confirm the diagnosis. Total excision of the tumor mass and a careful histologic evaluation may be warranted in some cases, especially if the mass is painful or rapidly enlarging and exceeds 3 cm; however, excision is unnecessary in most instances. According to the literature, if findings on physical examination, imaging, and biopsy are consistent with a benign lesion, the diagnosis of a benign mass can be made with 99% accuracy. If this is the case, no further procedures are indicated and follow-up with the patient every 6 months to 1 year is sufficient. Surgical removal of a tumor that progressively enlarges over several months (eg, giant fibroadenoma) is important. This type of fibroadenoma is greater than 5 cm in size at onset or appears soon after menarche and accounts for 4% to 10% of fibroadenomas of the breast. When the lesion becomes very large, an acceptable cosmetic result is more difficult. Accordingly, surgical removal of a giant fibroadenoma shortly after the time of diagnosis rather than watchful waiting is warranted. It is important to note that any adolescent patient with a palpable breast mass and a past history of malignant disease or family history of breast cancer should be evaluated aggressively and referred to a pediatric surgeon or breast surgeon directly for a diagnostic excisional biopsy.

The primary treatment for physiologic pubertal gynecomastia, or type 1, is reassurance for the adolescent male and his family that the condition is self-limited in 75% to 90% of adolescents and should regress spontaneously within 1 to 2 years, although some sources report up to 3 years. In most cases, the boy should be reexamined periodically (ie, every 6 months) until resolution occurs. Type 2 gynecomastia may require surgical reduction of the mammary gland, although some studies have shown success with medical therapy. The off-label use of 10 to 20 mg of tamoxifen orally twice daily for 3 months has been shown in some cases to decrease breast tenderness and pain, followed by a decrease in breast tissue. Surgical intervention may be warranted after a period of observation for at least 12 months in cases of nonobese males with intractable breast pain or tenderness, persistent breast growth, and/or significant psychological distress. Surgery currently involves a combination of ultrasonic liposuction and direct excision of the breast tissue beneath the nipple and areola. The adolescent male may benefit from concurrent psychological counseling as well.

Other underlying causes for gynecomastia should be treated accordingly, and any drugs or medications contributing to the condition or associated galactorrhea should be discontinued, if possible.

Prognosis

The prognosis of a breast disorder in the child or adolescent depends on the particular lesion. Generally, most lesions, such as neonatal breast hyperplasia and premature thelarche, are self-limited and resolve spontaneously. Breast development persists for 3 to 5 years in 50% of cases of premature thelarche, but in 1 retrospective study, most cases regressed within 6 months to 6 years after the diagnosis. Aside from the short stature that may accompany idiopathic central precocious puberty, these females also tend to have a good prognosis. Fibroadenoma in the adolescent female can recur but typically is benign and has no direct association with the development of breast cancer. Most cases of pubertal gynecomastia in adolescent males resolve within 1 to 3 years.

CASE RESOLUTION

The child has a diagnosis of premature thelarche. She has no known exposure to exogenous sources of estrogen or alternative therapies that are associated with breast growth and has isolated breast tissue development with no other secondary signs of pubertal maturation. Her parents should be informed of this diagnosis and reassured that the condition is self-limited and does not indicate that the child is starting puberty. The child should be scheduled for a follow-up visit in 3 to 4 months to remeasure the breast buds and reexamine the genitalia for the appearance of pubic hair as well as to monitor the patient's linear growth.

CHAPTER 63

Substance Use/Abuse

Monica Sifuentes, MD

CASE STUDY

A 17-year-old male is brought to your office by his father with a chief report of chronic cough. You have followed this patient and his siblings for several years and know the family quite well. The father appears very concerned about "this cough that just won't go away." The adolescent is not concerned about the cough, however, and reports no associated symptoms, such as fever, sore throat, chest pain, or sinus pain. You ask the father to step out of the room for the rest of the interview and the physical examination.

On further questioning, the patient reports that he vapes (ie, smokes electronic cigarettes) daily and has tried marijuana as well as cocaine. He denies regular use of these substances but reports exposure to these drugs at parties and when he spends time with "certain friends." The adolescent is now in the 11th grade, attends school regularly, and thinks school is "OK." His grades are average to above average, but he thinks he might fail 1 class this semester. Although he formerly played baseball, he stopped last year. He hopes to get a part-time job at a local fast-food restaurant this summer. Currently, he is sexually active with only females of his age and uses condoms occasionally. He denies suicidal ideation and exposure to any firearms.

On physical examination, he appears healthy with an occasional dry cough. He is afebrile, and his respiratory rate, heart rate, and blood pressure are normal. Pertinent findings on examination include slight conjunctival injection bilaterally, nasal turbinate erythema and edema, and mild erythema of the posterior pharynx. The patient is negative for tonsillar hypertrophy. The remainder of the examination is within normal limits.

Questions

1. What are the most common manifestations of substance use/abuse in adolescents?
2. What are the risk factors associated with substance use/abuse in adolescents?
3. What other conditions must be considered when evaluating adolescents with a history of chronic substance use/abuse?
4. What laboratory evaluations, if any, should be performed for the adolescent with suspected substance use/abuse?
5. What are the specific consequences of short- and long-term use/abuse of substances such as alcohol, marijuana, cocaine, opiates, and hallucinogens?

Primary care physicians are in a unique position to educate their patients, particularly young teenagers, about alcohol and substance use/abuse through primary prevention and anticipatory guidance. Ideally, this should begin before the teenager has first tried a cigarette or alcoholic drink, with the physician gradually introducing each topic as the preteen enters middle school and becomes accustomed to speaking to his, her, or their physician alone. Opportunities for education include health maintenance visits, the preparticipation sports physical evaluation as the teenager enters high school, and medical encounters for an acute injury or illness. More importantly, if a primary care physician is fortunate enough to have a long-standing relationship with the teenager, the physician can identify, evaluate, and manage a substance use disorder as soon as it develops and assist the patient and family proactively with appropriate referrals and local resources, thereby improving the adolescent's overall outcome.

Ideally, all preteen and adolescent patients would be questioned and counseled about the use of illicit substances, alcohol, and tobacco at each health maintenance visit (see Chapters 4 and 38). Unfortunately, this does not occur consistently because some health professionals do not feel comfortable opening that avenue of conversation or simply do not have the time and resources to inquire and intervene. Time constraints, unfamiliar billing codes, and difficulty maintaining confidentiality for sensitive services in a busy office or clinic make screening for substance use challenging. As a result, primary care physicians miss valuable opportunities to adequately assess adolescents for alcohol and substance use disorders and provide them with the necessary guidance to ensure their future health, safety, and well-being.

Substance use is use of or experimentation with illicit drugs, prescription medications, alcohol, or tobacco. Illicit drugs include marijuana; cocaine; amphetamines; hallucinogens, such as lysergic acid diethylamide (LSD), mescaline, and psilocybin, which is found in *Psilocybe mexicana* mushrooms; opiates; and phencyclidine hydrochloride (PCP). *Substance abuse* refers to the chronic use of mind-altering drugs despite adverse effects. *Addiction*, a chronic relapsing disorder, is the term applied to compulsive and continued use of a substance despite adverse consequences. Because addiction is neurologically based, the substance may produce physical dependence or symptoms of withdrawal when it is discontinued.

Epidemiology

Current Trends and Prevalence Rates

Adolescents in the United States currently use a wide range of substances. Alcohol, tobacco, and marijuana are by far the more common and most popular substances and can serve as gateway drugs to more serious illicit drug use. Several surveys tracking substance use/abuse among adolescents are conducted annually in the United States to identify the magnitude of high-risk behavior among those in 8th through 12th grade. The most well-known of these surveys are Monitoring the Future, which is administered annually to students in 8th, 10th, and 12th grade by the University of Michigan for the National Institute on Drug Abuse; the Youth Risk Behavior Surveillance System (YRBSS) survey, conducted biannually by the Centers for Disease Control and Prevention (CDC) of students in grades 9 through 12; and the National Survey on Drug Use and Health, a computer-assisted interview of residents 12 years and older conducted in the home. It is important to remember that most statistics do not include the estimated 15% to 20% of students who drop out of high school before their senior year.

In a 2017 survey of graduating high school seniors, approximately 60% admitted to alcohol use at some time during their life. Almost 30% of students reported drinking alcohol during the month preceding the survey. Binge drinking likely has contributed most to the overall morbidity and mortality associated with alcohol use in adolescents and young adults. Among high school seniors in the class of 2017, approximately 20% reported having 5 or more drinks in a row within a couple hours on at least 1 day during the 30 days before the YRBSS was administered. Although tobacco use among adolescents decreased from 1999 to 2017, data from the CDC indicate that in 2017 approximately 10% of teenagers nationwide reported current cigarette use and another 10% percent smoked at least one-half pack of cigarettes per day. Nationwide, the current rates of smokeless tobacco use (eg, chewing tobacco, snuff, dip) and cigar or cigarillo use are 6% and 8%, respectively. As expected, use of smokeless tobacco is much higher among males than females. Electronic vapor products (ie, electronic [e-] cigarettes, e-cigars, and e-pipes; vape pipes, vaping pens, hookahs), which were introduced in the US market in the middle of the first decade of the 21st century, have become the most commonly used tobacco product among youth in the United States, with many adolescents and young adults later transitioning to traditional cigarettes. In 2017 alone, greater than 40% of high school students reported ever having used an electronic vapor product. E-cigarette advertising aimed at teenagers and marketing strategies promoting flavored solutions have contributed greatly to the popularity of e-cigarettes among this age group. By 2019, there were an increasing number of reports of deaths related to vaping, and a number of states issued a ban on vaping product marketing, issued a ban on flavored vaping solutions, or withdrew vaping products from the market.

Marijuana is the most commonly used illicit psychoactive substance. In 1993, 35% of high school seniors reported ever having used marijuana; in 1997, this figure increased to greater than 50%. Per current estimates from the 2017 YRBSS, this figure is approximately 36%, with nearly 20% of high school seniors reporting marijuana use 1 or more times during the month preceding the survey. Daily use of marijuana has been reported in 6% of high school seniors.

The use of other substances among adolescents was generally on a downward trend in the late 1980s and early 1990s; however, use is once again on the rise. This phenomenon is known in the substance use/abuse literature as "generational forgetting," which occurs as acknowledgment of adverse effects of specific drugs fade over the years. Reportedly, approximately 9% of high school graduates in 1997 tried cocaine, with approximately 4% having used it in the previous month. These figures remained essentially unchanged until 2007, when cocaine use declined; currently, use of this substance is at an historical low of 1% among 12th-graders. The 1991 prevalence rate for LSD usage was 5%, and its use also remained stable over in the next 10 years until 2001, when the rate increased to 8% and became more widespread than cocaine use among high school students. According to the 2017 YRBSS survey, 9% of 12th-graders nationwide tried LSD or another hallucinogenic drug. Lifetime amphetamine use among 12th-graders was 3% in 2017, with a range of 2.3% to almost 8% across state surveys. Additionally, nationwide ecstasy use was reportedly approximately 4%.

Concurrently, the reported use of over-the-counter (OTC) nonprescription stimulants that contain caffeine has increased, with popular energy drinks now sold in many convenience stores and supermarkets. Other substances used to "get high," such as inhalants (eg, aerosol spray paints, hair sprays, paint thinners, whipped cream containers), are often used by younger students (ie, preteens) and unfortunately can be found in many garages, workrooms, and basements. Although the rate has decreased from 1997, in 2017 7% of early adolescents (ie, ninth graders) reported sniffing or inhaling substances to become intoxicated. Dextromethorphan also has become popular as an OTC product used/abused by adolescents secondary to its hallucinogenic effects and easy accessibility in cough syrups. Studies confirm an increasing trend in its use/abuse, particularly in teenagers younger than 18 years.

The nonmedical use/abuse of prescription drugs, such as Oxycontin, Percocet, Vicodin, Adderall, Ritalin, and Xanax, has increased more than that of most illicit drugs in the past 2 decades. Many teenagers report the ease by which prescription drugs can be obtained, resulting in continued use/abuse and future dependence as an adult. In 2017, nonmedical prescription drug use was reported by up to 17% of teenagers 1 or more times during their life. Certain prescription drugs, namely opioids, stimulants, sleeping pills, and anxiolytics, now represent the third most widely used/abused substance in adolescents after alcohol and marijuana.

Although not everyone considers them an illicit substance, anabolic steroids are used/abused by some adolescents, mostly males, to increase muscle size and strength. In 1997, approximately 3% of adolescent males admitted to using them at some time in their life. More recently, studies indicate as many as 5.5% of high school students participating in sports use anabolic steroids (6.6% males, 3.9% females). The 2017 nationwide figure per the CDC is almost 3%; however, state and local surveys indicate a range of 2% to 7% for use of anabolic steroids.

Demographics

Generally, adolescent males use illicit drugs more than females do, with a few exceptions. Males are more likely to use anabolic steroids, but females reportedly use amphetamines, barbiturates, tranquilizers, and OTC diet pills more than their male counterparts. Additionally, although annual prevalence rates for overall alcohol use show little difference by sex, adolescent males have a higher rate of heavy or binge drinking compared with adolescent females. Tobacco usage is essentially the same for both sexes, except for smokeless tobacco and cigars, with more boys using these products.

Adolescents who do not plan to attend college are more likely to use illicit substances than their college-bound counterparts, and these adolescents and young adults also are more likely to use illicit drugs more frequently. No difference between the 2 groups exists, however, in the rates of ever having tried illicit substances. Binge drinking also continues to escalate among older adolescents and young adults attending college. The specific influence of parental education, socioeconomic status, and race or ethnicity on the use/abuse of illicit substances is difficult to determine because many other factors, such as genetics and the environment, contribute to heavy drug use and addiction.

Risk Factors and Behaviors

Although alcohol and tobacco are considered licit or lawful drugs, it is illegal for minors to purchase and use alcohol and tobacco in the United States. Use of these substances often begins during adolescence, however, including during the preteen years. The strongest predictor of drug use by youth is having friends who regularly use drugs, that is, alcohol, tobacco, or other substances (eg, marijuana). Additionally, it has been shown that the more risk factors identified, the greater the risk of substance use/abuse in the teenager.

Several factors are important precursors to (ie, risk factors for) drug use during adolescence. These risk factors include association with drug-using peers; attitudinal factors, such as favorable attitudes toward drug use in the family; low religiosity; poor school performance or academic failure, often beginning in the late elementary years; young age of initiation of alcohol or drug use; presence of a conduct disorder; environmental factors, such as the prevalence of drug use in a given community; history of child abuse; family history of alcoholism or drug use; poor parenting practices; high levels of conflict within the family; minimal bonding between parents and children; family disruption; and early and persistent problem behaviors during childhood, such as untreated attention-deficit/hyperactivity disorder (ADHD).

It is well documented in the literature that early age of onset of alcohol and tobacco use is predictive for the use of other drugs, a greater variety of drugs, and more potent agents. Additionally, the use of alcohol at an early age is associated with future alcohol-related problems, such as lifetime alcohol dependence and use/abuse. The early initiation of alcohol also results in increased sexual risk-taking behavior during adolescence (ie, unprotected sexual intercourse, exposure to multiple sexual partners, being drunk or high during sexual intercourse, increased risk of pregnancy) as well as academic problems and delinquent behavior later in adolescence. Long-term effects during young adulthood include difficulties with employment, criminal and aggressive behavior, and continued substance use/abuse. Potential long-term health risks associated with the early initiation of alcohol, tobacco, and substance use/abuse depend on the specific exposure but include conditions such as pulmonary disease, chronic liver disease, cardiovascular complications, and cancer.

The role of the media and technology in adolescent alcohol and tobacco use has been the subject of much discussion in the past 20 years. Previous studies confirmed that exposure to smoking on television and in movies was 1 of the key factors that prompted teenagers to smoke and that preteens whose parents forbad them from viewing R-rated movies were less likely to begin smoking or drinking. One prospective study reported that exposure to R-rated movies or having a television in the bedroom significantly increased the risk of initiating smoking for white teenagers. Additionally, watching more movie depictions of alcohol use is strongly predictive of drinking onset and binge drinking in adolescents in the United States. Advertising also contributes to the depiction of alcohol and tobacco use as normative activities. In fact, it has been reported that advertising may be responsible for up to 30% of alcohol and tobacco use among adolescents. The influence of advertising on adolescents is now even more apparent with the current marketing of electronic vapor products to attract teenage consumption.

Clinical Presentation

Adolescents who are consuming alcohol or are involved in drug use may present to the health professional in several different ways. Illicit substance use might be uncovered during a routine confidential interview at an annual health maintenance visit, preparticipation sports physical evaluation, or urgent care appointment. Alternatively, the adolescent might have physical symptoms including chronic cough, persistent allergies, chest pain, and fatigue. Chronic conditions, such as asthma, may continue to worsen despite appropriate therapy in the adolescent smoking tobacco or marijuana or using e-cigarettes.

Abdominal tenderness may be noted on physical examination and found to be associated with gastritis, hepatitis, or pancreatitis. The adolescent also may have been in a recent motor vehicle crash or involved in other trauma, or their parent or parents may report that their teenager exhibits frequent mood swings, irritability, or erratic sleep patterns.

Pathophysiology

Although several theories have been proposed to explain why casual substance use develops into use/abuse and addiction in some adolescents and young adults and not others, the most critical factor seems to be the presence of underlying psychopathology. Adolescents who have untreated major depressive disorders, ADHD, or schizophrenia, for example, may use mood-altering substances to manage unpleasant feelings of dysphoria and low self-esteem. Initially used as a

temporary measure, this method of self-medication increases the likelihood of chronic substance use/abuse.

It is well known that genetic influences also play a major role in adult use/abuse of alcohol; however, less evidence exists for adolescent drug use. What is known is that families and parental attitudes play a significant role in the development of alcohol and other drug use in teenagers. Permissive attitudes toward alcohol and drug use by parents or guardians and parental or older sibling drug use in the setting of other environmental risk factors are predictive of increased drug and alcohol use in the adolescent.

Differential Diagnosis

The differential diagnosis for symptoms and behaviors associated with substance use/abuse includes underlying psychiatric disorders. Affective, antisocial, and conduct disorders as well as ADHD can be the primary or secondary condition in adolescents who are abusing drugs. Like adults, adolescents may use illicit drugs to self-medicate associated depression, anxiety, or auditory hallucinations. The pharmacology and toxicity of the illicit substances most commonly used by adolescents are summarized in Table 63.1.

Evaluation

History

The interview should be conducted in a private, quiet area to minimize interruptions. If parents or guardians have accompanied the adolescent, they should be politely asked to leave the room after they have had an opportunity to express their concerns and after issues of confidentiality are addressed in the presence of both parties. Doing so helps avoid future uncomfortable moments when a parent or guardian returns and asks what was disclosed in their absence. After parents or guardians have left the room, issues addressing confidentiality and privacy should be reviewed once again with the patient. Special circumstances, such as a disclosure of sexual or physical abuse or possible suicidal ideation or homicidal intent, that dictate that confidentiality be broken also should be discussed with the teenager before proceeding with the interview (see Chapter 4).

The interview should proceed in a casual, non-pressured, nonjudgmental fashion. Initial inquiries should address less threatening general topics, such as school, home life, and outside activities, including activities with friends. Use of the HEADSS (home, employment and education, activities, drugs, sexuality [including a history of sexual abuse or assault], suicide and/or depression) assessment allows for a thorough review of the essential components of the psychosocial history (see Chapter 4). Another interview tool, the SSHADESS (strengths, school, home, activities, drugs and alcohol, substance use, emotions and depression, sexuality, safety) assessment, has been developed to emphasize and review positive components in an adolescent's life in addition to any high-risk behavior.

Some practitioners prefer to use questionnaires or other formal validated screening tools to initially obtain this background information. A questionnaire is given to patients to fill out while they are waiting to be seen, and responses are reviewed privately with the health professional during the actual visit. Some questionnaires address only issues concerning substance use/abuse, whereas others are more general but also include questions about alcohol, tobacco, and drugs (Figure 63.1 and Box 63.1). Controversy exists about the role of such questionnaires, primarily concerning the truthfulness of answers, because parents or guardians may be with teenagers as they are attempting to complete the form. Administering questionnaires via technology and in a designated, private space can help improve honesty.

More specific questions about the use of alcohol and tobacco as well as illicit substances should be asked after general subjects have been discussed (Box 63.2). If adolescents seem wary of answering these questions, it may be helpful to initially inquire about their friends. Questions should be phrased with the assumption that the responses will be affirmative (eg, "How many beers do your friends drink in a week? And do you drink the same amount?"). It is hoped that this less-threatening approach invites more honest answers. An assessment of the risk of suicidal behavior is also indicated.

Because many physicians lack unlimited time to interview adolescents and obtain all the details in a single visit, various standardized methods have been developed to efficiently screen teenagers for substance use in the context of health supervision visits. Brief screening tools that are both self- and interviewer-administered can be used to glean important information even in a busy practice. For example, 1 screening tool uses the following 3 questions: During the past 12 months, have you smoked marijuana? Have you drunk any alcohol? Have you used anything else to get high? If an adolescent answers "no" to all 3 questions, the patient should still be asked if he or she have ridden in a car with a driver who was high or had been using alcohol or drugs. Additional screening is recommended for any teenager who answers "yes" to any of the 3 initial screening questions. Six questions, known as the CRAFFT screening tool, are then reviewed with the adolescent to further identify drug and alcohol risk or problems associated with their use. The teenager receives 1 point for each "yes" answer; a total score of 2 or more indicates a positive result and high risk for a substance use disorder. It also indicates the need for additional follow-up as well as referral to a mental health professional or therapeutic treatment program. The validity of this brief, developmentally appropriate tool for screening adolescents has been reported in the literature and is well supported by experts in the field of adolescent and addiction medicine for use by primary care physicians. Another screening tool, funded by the National Institute on Drug Abuse, is the Screening to Brief Intervention tool (S2BI). It is used to assess the frequency of past-year substance use for tobacco, alcohol, marijuana, and 5 other classes of substances (Figure 63.1). Depending on the results of the S2BI tool, motivational intervention is recommended as the next step.

Physical Examination

Positive findings on physical examination are rare, especially in adolescents who consume alcohol or other substances only occasionally. In adolescents with a history of chronic substance use/abuse, however, certain physical findings may be present.

Table 63.1. Pharmacology and Toxicity of Substances Commonly Used by Adolescents

Substance	*Pharmacology*	*Effects*	*Toxicity*
Nicotine	Potent psychoactive drug that acts on receptors in the CNS to produce effects	Stimulation, relaxation, focused attention	Nontolerant individuals: weakness, nausea, vomiting, feeling unwell
Marijuana	Active ingredient (ie, delta-9-tetrahydrocannabinol) is rapidly absorbed into the bloodstream from inhaled smoke	Low dose: euphoria, relaxation, time distortion, auditory and visual enhancement High dose/toxic: mood fluctuations, hallucinations, paranoia, psychosis	Acute: panic attacks, psychosis (rare) Chronic: short-term memory impairment, amotivational syndrome, reduced sperm counts
Alcohol	Causes nerve cell membranes to expand and become more "fluid," thereby interfering with neuronal conduction Interference of neurotransmitters	Mild: disinhibition, euphoria, mild impaired coordination, mild sedation Moderate: increased sedation, slurred speech, ataxia	Severe: confusion, stupor, coma, respiratory depression
Cocaine	Increased release and decreased reuptake of biogenic amines causing CNS and peripheral nervous system stimulation Local anesthesia Vasoconstriction	Produces a sense of well-being and heightened awareness, decreased social inhibition, and intense euphoria	Delirium, confusion, paranoia, hypertension, tachycardia, hyperpyrexia, mydriasis
Stimulants (eg, amphetamines, crystal methamphetamine, ecstasy)	CNS stimulation (ie, sympathomimetic)	Heightened awareness; restlessness and agitation, decreased appetite Low doses increase ability to concentrate	Hypertension, hyperthermia, seizure, stroke, coma, arrhythmia
Hallucinogens (eg, LSD, mescaline, mushrooms)	Inhibits release of serotonin	Distortions of reality—perceptual alterations, synesthesia common (eg, "hearing" smells)	Paranoia, flashbacks, psychosis, depression
PCP	Dissociative anesthetic with analgesic, stimulant, depressant, and hallucinogenic properties	Dissociative anesthetic Dose-dependent euphoria, dysphoria, perceptual distortion	Psychoses; aggressive, violent behavior; depression; seizure, rhabdomyolysis
Opiates (eg, opium, heroin, methadone hydrochloride)	Binds to opioid receptors in CNS, causing CNS depression	Sedative analgesics Euphoria followed by sedation, somnolence	Respiratory depression, CNS depression, miosis, bradycardia, hypotension, arrhythmia, seizure, rhabdomyolysis
Sedatives (eg, benzodiazepines, barbiturates)	CNS depression, binds to specific receptor that potentiates GABA	Sedation, anxiety reduction	Similar to opioid intoxication
Anabolic steroids	Bind to androgen receptors at the cellular level, stimulate production of RNA and protein synthesis	Euphoria; increased irritability and aggressiveness; at high doses, induction of mental changes	Psychosis
Inhalants	CNS stimulation and excitement, progressing to depression	Euphoria, hallucinations, psychosis	Respiratory depression, arrhythmia, seizure, sudden sniffing death syndrome (ie, sudden death secondary to arrhythmia)

Abbreviations: CNS, central nervous system; GABA, γ-aminobutyric acid; LSD, lysergic acid diethylamide; PCP, phencyclidine hydrochloride.

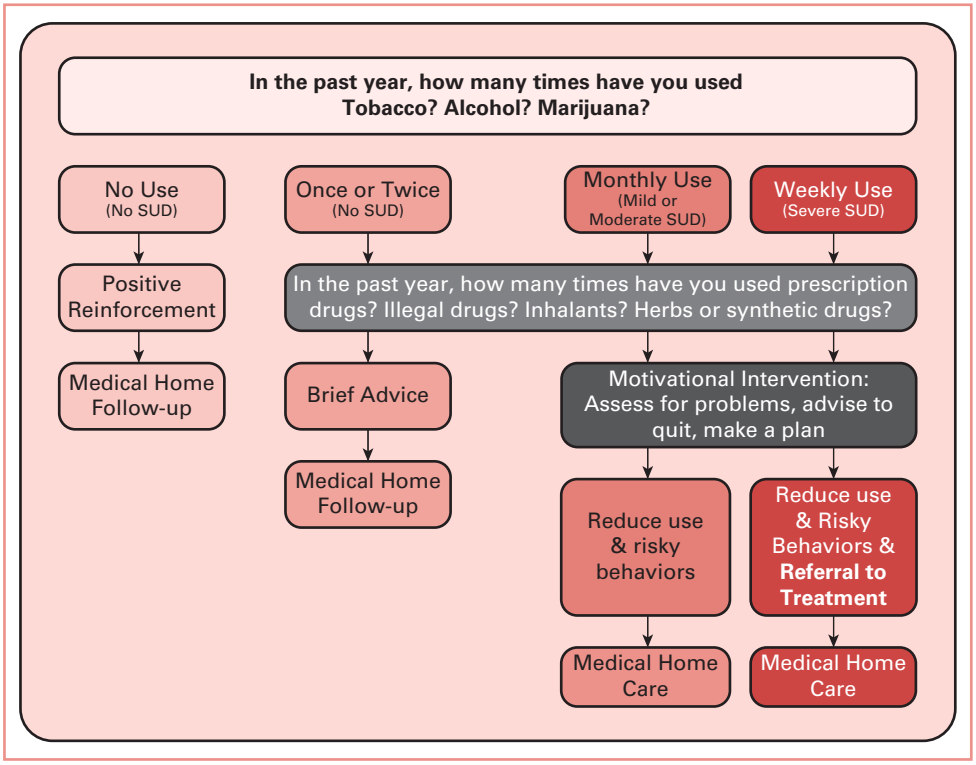

Figure 63.1. The Screening to Brief Intervention tool approach to clinical screening, brief intervention, and referral to treatment.

Abbreviation: SUD, substance use disorder.

Reprinted from S Levy, L Shrier. 2014. Boston, MA: Boston Children's Hospital. Copyright 2014, Boston Children's Hospital. Reprinted under Creative Commons Attribution-Noncommercial 4.0 International License.

All vital signs should be reviewed. Tachycardia and hypertension occur primarily with acute intoxication with cocaine or stimulants (eg, amphetamines). The current weight also should be recorded and compared with previous values, and any significant weight loss should be noted. The skin should be examined closely for track marks, skin abscesses, or cellulitis, especially if the patient admits to using drugs intravenously. The skin should also be examined for evidence of self-injurious behaviors, such as cutting. Findings consistent with hepatitis (ie, hepatomegaly, jaundice) may be present in these individuals. The presence of diffuse adenopathy, thrush, leukoplakia, seborrheic dermatitis, or parotitis should raise the suspicion of HIV infection. A nonspecific maculopapular rash also may be seen during the acute viremic phase of an HIV infection. Upper respiratory symptoms, such as chronic nasal congestion, long-lasting "colds" and "allergies," and epistaxis can occur with chronic inhalation of cocaine or another illicit substance. Signs of nasal congestion, septal perforation, and wheezing also may be noted on examination. Additionally, smoking crack cocaine can cause chronic cough, hemoptysis, and chest pain. Smoking marijuana over long periods can result in similar findings. Gynecomastia can occur with use of anabolic steroids, marijuana, amphetamines, and heroin. The adolescent female using anabolic steroids may exhibit signs of virilization, such as a deep voice, hirsutism, and male pattern baldness. The detailed neurologic evaluation is arguably the most important aspect of the examination. Any abnormalities in memory, cognitive functioning, or affect should be noted. Chronic marijuana use is sometimes accompanied by amotivational syndrome.

Acute intoxication with some drugs (eg, cocaine) may result in delirium, confusion, paranoia, seizures, hypertension, tachycardia, arrhythmias, mydriasis, and hyperpyrexia. Acute PCP intoxication produces abnormal neurologic signs, tachycardia, and hypertension. Findings such as central nervous system and respiratory depression, miosis, and cardiovascular effects (eg, pulmonary edema, orthostatic hypotension) are consistent with opiate overdose. Signs and symptoms of acute intoxication generally are seen in the emergency department setting rather than in the primary care physician's office or clinic.

Laboratory Tests

In the clinic setting, routine drug screening as part of the initial evaluation of substance use is not recommended and generally not indicated to initiate treatment. Specific laboratory studies should be performed, however, in those patients with a history of known substance use/abuse and who are enrolled in a drug treatment program to monitor for abstinence; in patients who are required by court order; and in patients who exhibit acute altered mental status, intoxication, or abnormal neurologic findings, such as may be seen in an emergency department setting. In the office setting, these symptoms are frequently absent, and urine or serum studies to "check" for drug use are not particularly useful.

Box 63.1. Rapid Assessment for Adolescent Preventive Services

1. In the past 3 months, have you taken diet pills or laxatives, made yourself vomit (throw up) after eating, or starving yourself to lose weight?
2. Do you eat some fruits and vegetables every day?
3. Are you active after school or on weekends (walking, running, dancing, swimming, biking, playing sports) for at least 1 hour, on at least 3 or more days each week?
4. When you are driving or riding in a car, truck, or van do you always wear a lap/seat belt?
5. Do you always wear a helmet when you do any of these activities: ride a bike, rollerblade, or skateboard; ride a motorcycle, snowmobile or ATV; ski or snowboard?
6. During the past month, have you been threatened, teased, or hurt by someone (on the internet, by text, or in person) causing you to feel sad, unsafe, or afraid?
7. Has an adult ever physically injured you (by hitting, slapping, kicking) or has anyone ever forced you to have sex or be involved in sexual activities when you didn't want to?
8. Do you carry a weapon (gun, knife, club, other) to protect yourself from another person?
9. In the past 3 months, have you used any form of nicotine including vaping (e-cigarettes, Juul, RUBI, Suorin, Blu, hookah, vape pens), smoking (cigarettes, cigars, black and mild) or chewing tobacco (dip, chew, snus)?
10. In the past 12 months, have you driven a car while texting, drunk or high, or ridden in a car with a driver who was?
11. In the past 3 months, have you drunk more than a few sips of alcohol (beer, wine coolers, liquor, other)?
12. In the past 3 months, have you used marijuana (weed, pot, cannabis, THC) in any form such as vaping, smoking, edibles, drinks, pills, oil, or any other type?
13. In the past 3 months, have you taken a prescription medication (codeine, OxyContin, Norco, Vicodin, Adderall, Ritalin, Xanax, other) without a prescription, taken more than the prescribed amount or continued to take it after you no longer needed it?
14. Have you ever had any type of sex (vaginal, anal, or oral sex)?
15. Are you physically attracted to people who are the same gender as you (girl if you are a girl/guy if you are a guy) or do you feel that you are gay, lesbian or bisexual?
16. If you have had sex, do you always use a condom and/or another method of birth control to prevent sexually transmitted infections and pregnancy?
17. During the past month, did you often feel sad or down as though you had nothing to look forward to?
18. Do you have any serious problems or worries at home or at school?
19. In the past 12 months, have you seriously thought about killing yourself, tried to kill yourself, or have you purposely cut, burned, or otherwise hurt yourself?
20. Do you have at least one adult in your life that you can talk to about any problems or worries?
21. Do you destroy things, hurt yourself, or hurt other people when you are angry?

Box 63.2. What to Ask

Adolescent Substance Use/Abuse

- Do any of your friends drink alcohol, smoke marijuana or tobacco, or use any other drugs?
- What drugs, including alcohol and tobacco, are you currently using? For how long and how frequently?
- In what environments do you use these substances?
- Have you ever blacked out or been arrested while under the influence of drugs or alcohol?
- Has drug or alcohol use ever interfered with school, work, or other social activities?
- Has drug or alcohol use adversely affected relationships with family, friends, or romantic partners?
- Have you ever had sexual encounters while under the influence of drugs or alcohol?
- Do you ever use drugs or alcohol to feel better or to forget why you feel sad?
- Do your parent(s) or guardian(s) use alcohol, tobacco, or illicit drugs?
- Is there a f amily history of alcoholism, addiction, or mental health issues?

If these tests are performed in an ambulatory setting and the patient is awake and alert, the adolescent's consent is recommended despite adamant requests from a parent or guardian. The results should not be shared with anyone other than the patient, unless the patient gives permission or the test was ordered while investigating the cause of an acute medical condition. According to the American Academy of Pediatrics and the Society for Adolescent Health and Medicine, obtaining a urine drug test without the consent of the adolescent undermines the physician-patient relationship and the development of a meaningful, trusting relationship at this critical time in the patient's life. Drug testing should not be performed simply to allay parental anxiety or confirm suspicions about possible substance use/abuse for a parent, teacher, or athletic coach unless previously authorized by the adolescent.

If urine is obtained for drug testing, it is critical that the sample be collected in a controlled manner and not contaminated, diluted, or altered in any way. The physician should also be familiar with the particular laboratory performing the drug test as well as the reported sensitivity and specificity of each test. Urine testing is available to detect marijuana and its metabolites, cocaine, amphetamines, PCP, opiates, barbiturates, and benzodiazepines. Blood levels can be obtained for alcohol, marijuana, cocaine, amphetamines, barbiturates, and benzodiazepines. Although salivary or urinary concentrations of cotinine and nicotine concentrations can also be performed, these measurements are used mainly in research studies.

Testing for specific inhalants is not routinely done. The deleterious effects of these substances on the hematologic, hepatic, and renal systems can be evaluated by performing a complete blood count, liver function tests, prothrombin time and partial thromboplastin time, and blood urea nitrogen and creatinine; however,

results are generally nonspecific. Testing for synthetic cannabinoids, dextromethorphan, and 3,4-methylenedioxymethamphetamine (ie, ecstasy) is not typically included in drug panels.

Management

The clinical approach to the management of substance use in the adolescent is dependent on the patient's degree of risk-taking behavior and drug involvement (ie, experimentation, limited use, problematic use, abuse, or addiction/dependence); the physician's relationship with the adolescent and family; the adolescent's desire to change his or her their behavior; and the family's involvement and awareness of the extent of the problem. A more detailed discussion is found in the 2016 policy statement, "Substance Use Screening, Brief Intervention, and Referral to Treatment," by the American Academy of Pediatrics Committee on Substance Use and Prevention.

Anticipatory Guidance

If preteens (ie, middle school students) or adolescents and their peers are not participating in any high-risk behaviors, including tobacco, alcohol, or drug use (ie, the answers to all 3 CRAFFT screening questions are "no"), pediatricians should provide patients with both positive reinforcement for their abstinent behavior and age-appropriate anticipatory guidance. This should include advice and information on safety issues; consequences of alcohol and tobacco use, including use of e-cigarettes; and exposures to peers who may be using illicit and prescription drugs. Adolescents should be praised for making smart choices and encouraged to continue their current behavior but should be invited to return to the office if they have any questions or concerns. This may be particularly helpful for patients whose daily environment exposes them to high-risk situations for alcohol and drug use. The pediatrician should encourage an open dialogue about substance use/abuse between adolescents and their parents or guardians to assist teenagers in developing strategies for drug avoidance.

Early Intervention

Primary care physicians should provide early intervention guidance to preteens and adolescents who have begun or are engaging in occasional high-risk behavior and are considered to be at moderate risk for substance use–associated problems. These are patients who have started using alcohol or drugs and score 0 or 1 on CRAFFT screening. Such use implies only occasional or casual use of illicit substances by patients or peers. This scenario is the most challenging because many adolescents, as well as their parents or guardians, perceive occasional alcohol or drug use as "experimental" or a phase of "normal teenage behavior" and therefore may trivialize any advice given by the pediatrician. Interventional guidance involves clear advice to stop alcohol and other drug use and a discussion of potential risks created by the adolescent's current behavior. For example, individuals who drink alcohol or smoke marijuana at parties are at increased risk for involvement in a motor vehicle crash afterward as the driver or passenger. Another common scenario involves alcohol intoxication and poor judgment about sexual behavior. All teenagers should be made aware of the possible consequences of their unsafe behavior, especially if their occasional drug use has progressed to more regular use in risky situations. Furthermore, they should receive educational counseling about the unhealthy effects of alcohol use in adolescence (eg, the deleterious effects of alcohol on developing brain cells). Experts also recommend including strength-based counseling to recognize the positive qualities of the adolescent.

Specialized Programs

Preteens or adolescents who are routinely using drugs, alcohol, or tobacco but are clearly motivated to stop often can be treated solely by their primary care physician or collaboratively with child and adolescent mental health specialists. Teenagers who began using illicit substances at an older age, have a fairly good relationship with their families, have supportive relationships with friends who do not use drugs, and who continue to do well in school and participate in other outside activities are more likely to be successful than teenagers who start at a younger age. The physician initially should identify the problem and establish whether the adolescent desires to change his, her, or their behavior. After obtaining the patient's consent, the physician should meet with the family, develop an appropriate strategy for treatment intervention, and follow the adolescent periodically in the office. Timely and consistent reinforcement by the primary care physician is necessary, especially in the beginning of treatment. Referral to an outpatient program, such as Alcoholics Anonymous, Alateen, or Narcotics Anonymous, also may be indicated. Appropriate community resources for the teenager and family should be reviewed. Continued coordination of services by the pediatrician is challenging but essential to ensure adherence by the adolescent and cooperation by the family to maximize the adolescent's chance for a full recovery.

Mental Health or Treatment Programs

Referral to a mental health or addiction specialist or a specialized treatment program (eg, drug detoxification center) is indicated for the adolescent who displays clear signs of dangerous behavior and continues to use drugs despite office treatment by the primary care physician and adverse effects on the adolescent's daily life and relationships. Immediate intervention is also necessary for the adolescent who is using intravenous drugs, combining sedative drugs, or consuming large quantities of alcohol. Additionally, the teenager with a suspected concomitant psychiatric condition should be referred immediately for psychiatric evaluation. Other criteria for specialty treatment programs include a chronic history of substance use/abuse, a serious life-threatening event in conjunction with substance use/abuse (eg, attempted suicide, motor vehicle crash), familial strife, or persistent involvement with a drug-dependent crowd. Primary care physicians should become familiar with local inpatient programs and residential treatment facilities in their community and partner with mental health and addiction specialists to provide the patient and family with optimal services. Although the selection of a program may be influenced by financial resources and insurance coverage options, it is quite important to try to select the most appropriate program for the individual adolescent and family. Guidelines

exist to aid the physician in the selection process for public and private facilities. These guidelines include total abstinence, appropriate professionals with expertise in drug addiction, familial involvement in the program, family therapy, and appropriate outpatient follow-up. Regardless of the final course of action of the patient, it is important for the primary care physician to remain involved with the family while making these difficult decisions and support their experience throughout the recovery process.

Prevention Programs

Prevention programs have been developed to assist young people from preteens to young adults and influence their decisions about the use of alcohol, tobacco, and other illicit substances. Current programs focus on multiple aspects of the lives of children and adolescents. Programs may involve individual decision-making, self-esteem, and basic education about alcohol, tobacco, and drugs. These programs frequently emphasize positive communication skills, strong family values and dynamics, influential parenting skills, and positive peer associations. Structured curricula also have been created for use in the schools, and community outreach programs have been organized by groups such as local police departments. The effectiveness of each type of program is a subject of controversy, but each is aimed at preventing the initial or continued use of illicit substances among children, preteens, and adolescents. *Reaching Teens: Strength-Based, Trauma-Sensitive, Resilience-Building Communication Strategies Rooted in Positive Youth Development,* is an excellent resource and guide for parents and health professionals.

Prognosis

It is difficult to assess the exact outcome for the adolescent who undergoes treatment for substance use/abuse, because definitions of success vary. For some teenagers, success implies periods of sobriety; for others, it means complete abstinence; and for still others, it is abstinence in addition to recovery from other contributing psychological problems. Specific outcomes data indicate that abstinence rates are positively correlated with regular attendance in a support group and parental participation in these groups. Additionally, general success rates range from 15% to 45%, depending whether the tool assesses short- or long-term outcomes. A lifetime potential exists for relapse among all adolescents with a history of substance use/abuse.

CASE RESOLUTION

The adolescent is at high risk for continued substance use/abuse because of his association with friends who use drugs as well as his own ongoing tobacco use, possible school failure, and recent change in extracurricular activities (ie, dropping out of baseball). The physical examination findings also are consistent with his smoking history. The physician should review these risk factors with the teenager in private and acknowledge the difficulty in removing oneself from such an environment. The adolescent's motivation to change his behavior should be assessed, and referrals to special intervention programs can be discussed. Regardless of the outcome, the physician should continue to see the teenager at an agreed-on interval to monitor his ability to quit smoking and change his high-risk behavior.

CHAPTER 64

Eating Disorders

Monica Sifuentes, MD

CASE STUDY

A 16-year-old girl is brought to the office by her mother because the mother feels that her daughter is too thin and always appears tired. The mother reports that her daughter does not eat much at dinner and generally says she is not hungry. Recently, the girl bought diet pills that were advertised online. The teenager claims that she has not taken the pills, so she does not understand why her mother is so upset. She says she feels fine and considers herself healthy because she has recently become a vegetarian.

The girl is a 10th-grade student at a local public school and attends classes regularly, although her friends are occasionally truant. She is involved in the drill team, swim team, and student council. She has many friends who have "nicer" figures than she does. Neither she nor her friends smoke tobacco or use drugs, but they occasionally drink alcohol at parties. The girl is not sexually active and denies a history of abuse. Her menstrual periods are irregular, with the last occurring approximately 3 months prior to this office visit.

She currently lives with her mother, father, and 2 younger siblings. Although things are "OK" at home, she thinks her parents are too strict and do not trust her. They have just begun to allow her to date, but she dislikes that she has a curfew.

The physical examination is significant for a thin physique, and vital signs are normal. On the growth chart, her weight is at the 15th percentile and her height is at the 75th percentile; her body mass index is 17 (10th percentile). Her weight at a previous visit was at the 40th percentile. The remainder of the physical examination is unremarkable.

Questions

1. What are the common characteristics of disordered eating in adolescents?
2. What are the important historical points to include when interviewing the patient with suspected eating disorder? Which teenagers are considered at risk?
3. How is the diagnosis of anorexia nervosa and bulimia nervosa made?
4. What is the treatment plan for the adolescent with eating disorder?
5. What are the medical complications of anorexia nervosa and bulimia nervosa?
6. What is the prognosis for these conditions? How can the primary care physician help improve the outcome?

Basic characteristics of eating disorders are summarized in Box 64.1. For more stringent criteria, refer to *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*) criteria. An adolescent may have an atypical presentation, a history of anorexia nervosa (AN) and bulimia nervosa (BN), or an underlying affective component that confuses the issue. The adolescent may not display a blatant refusal to eat but may instead exhibit subtle characteristics of disordered eating, such as constant dieting, obsession with a certain physical exercise, or irregular menstruation. Additionally, preoccupation with physical appearance and weight currently is not uncommon or necessarily pathologic in Western society. The fashion industry and social media promote the idea that thinness and beauty are interrelated. Thus, the typical adolescent who longs to be accepted by peers and who is learning to develop a sense of independence and control is a prime target for the development of disordered eating. The primary care physician is in a unique position to recognize individuals at risk, appropriately screen teenagers with specific behaviors, and provide early diagnosis of and intervention for patients with disordered eating to prevent the development of potentially lethal complications associated with these conditions. The overall goal is to decrease the lifelong medical and psychological morbidity and mortality associated with AN and BN to enhance the long-term health and emotional well-being of affected individuals.

Epidemiology

Historically, eating disorders predominately affected white adolescent females in more affluent communities. Although disordered eating currently occurs in many other settings, historically, AN and BN were rare among persons of lower socioeconomic status, among ethnic/racial minorities, and in children younger than 12 years of age. Currently, these conditions are diagnosed in individuals of all ethnic, cultural, and socioeconomic backgrounds in the United States as well as in other developed countries. Additionally, males make up an estimated 5% to 10% of all patients with eating disorders and tend to be younger, malnourished, or medically unstable when they present for treatment, which is suggestive of delayed evaluation and diagnosis.

Although dieting behavior among adolescents and young adults is not uncommon, true AN has a prevalence of approximately 0.5%

Box 64.1. Criteria for Anorexia Nervosa and Bulimia Nervosa

Anorexia Nervosa

- Caloric intake below caloric requirements (low weight for age, sex, developmental stage, physical well-being)
- Fear of weight gain or becoming overweight/obese
- Distorted body image
- Failure to recognize dangers of low weight
- Types:
  - *Restricting type:* Characterized by dieting, fasting, and/or excessive exercise.
  - *Binge-eating/purging type:* Characterized by binge eating associated with self-induced vomiting or the misuse of diuretics, laxatives, suppositories, or enemas.

Bulimia Nervosa

- Binge eating
- Eating larger than normal amounts of food
- A sense of being out of control and using other behaviors to restrict weight gain (eg, excessive exercise, fasting, vomiting, laxatives, diuretics, or other medications)

Derived from *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition.

to 1% in these individuals. Estimates have ranged from 1% to 10% in high-risk groups, such as upper- and middle-class white females. Less than 5% of these cases are males, with a female-to-male ratio of 9:1, although this prevalence has been disputed to be an underestimate of young males with AN. The age of onset historically was reported to occur during middle adolescence (age 14–16 years). It has become increasingly more common, however, for school-age children and younger teenagers to be dissatisfied with their weight and concerned with body image. Studies of middle-income elementary school girls have reported significant body and weight dissatisfaction. Skipping meals and desserts, fasting, and vomiting all have been reported specifically to lose weight. For many of these young girls, the goal is not to maintain a normal weight but to be underweight by standard growth charts.

The prevalence of BN is approximately 1% to 4%, although some studies report that as many as 8% of adolescent and college women and 0.5% of men have bulimia. The age of onset of BN tends to be later than for AN, with symptoms beginning during late adolescence and young adulthood (age 17–20 years). Several behavioral and affective disorders have been associated with the development of AN and BN. These include comorbid psychiatric conditions, such as depressive, bipolar, and anxiety disorders; alcoholism and substance use; other addictive behaviors (eg, laxative abuse); poor impulse control; and obsessive-compulsive personality. Girls who are obese or experience early puberty also are at increased risk for developing an eating disorder, with symptoms starting in the context of dieting. A history of sexual abuse may be present among patients with eating disorders. Additionally, suicidal behavior (ie, attempts) is more likely in individuals with BN, as are reports of an increased incidence of family members with substance use and dependence disorders. Generally, eating disorders occur with increased frequency in patients with a family history of eating and mood disorders as well as obesity.

Variants of eating disorders, which do not meet full diagnostic criteria based on previous guidelines but cause significant distress and impairment in social, occupational, or other important areas of functioning, are not uncommon in preteens and adolescents. Exact numbers are uncertain because many of these patients remain "under the radar" and the consequences of their eating behaviors are not fully recognized. Additionally, more than one-half of junior high and high school girls have dieted at some time, many of them repeatedly. For this reason, the revised *DSM-5* criteria for both AN and BN are less restrictive. New diagnostic categories now include the spectrum of patient behaviors: avoidant/restrictive food intake disorder, atypical AN, and binge-eating disorder.

Clinical Presentation

The patient with eating disorder may present with general symptoms related to weight loss and nutritional or volume deficiencies, such as fatigue or syncope. Such a patient also may exhibit minimal weight gain according to standard growth charts or a delay in the onset of puberty or progression of pubertal development. More importantly, female adolescents also may present with primary or secondary amenorrhea noted incidentally during an annual health maintenance or sports physical examination. Sometimes an underlying psychiatric condition, such as obsessive-compulsive disorder or anxiety, is the impetus for the medical referral. Occasionally, a patient with undiagnosed eating disorder is hospitalized because of complications related to the condition, such as electrolyte disturbances associated with diuretic use, hematemesis from induced vomiting, or syncope from hypovolemia. Finally, the preteen or adolescent may be referred to the primary care physician by a concerned parent, well-intentioned friend, informed coach, or astute school personnel who notice significant weight loss or restrictive eating patterns.

Pathophysiology

Anorexia Nervosa

Although several risk factors predispose an individual to the development of AN, this condition, like other eating disorders, has no single cause (Box 64.2). Longitudinal studies clearly point to a significant role for inappropriate dieting behavior in the pathogenesis of an eating disorder. Because not all dieters develop an eating disorder, however, other contributing risk factors must be involved. Current theory suggests that the etiology of AN is multifactorial and precipitated by a complex interaction between genetic, environmental/cultural, and psychological risk factors, along with the adolescent's personal experiences and individual personality traits.

Biologic Factors

It has been postulated that the normal increase in adipose tissue with the onset of puberty creates special challenges for some girls. An eating disorder may develop as an attempt to control or combat this

Box 64.2. Risk Factors for the Development of an Eating Disorder

- Family history of an eating disorder or obesity
- Affective illness or alcoholism in a first-degree relative
- Specific activities/sports: ballet, gymnastics, modeling, dance, figure skating, long-distance running, wrestling, lightweight rowing, pole vaulting
- Personality characteristics (eg, perfectionism)
- Parental eating behavior and weight
- Low self-esteem
- History of physical or sexual abuse
- Body image dissatisfaction
- History of excessive dieting, frequently skipped meals, compulsive exercise

Adapted from Rome ES, Ammerman S, Rosen DS, et al. Children and adolescents with eating disorders: the state of the art. *Pediatrics.* 2003;111(1):e98–e108.

normal pubertal weight gain with the initiation of dieting behavior. Preexisting hypothalamic dysfunction also has been implicated as a contributing factor to AN. Additionally, changes in neurotransmitter levels have been shown to occur with initial vomiting or dieting. These changes may result in specific psychiatric symptoms that may perpetuate disordered eating. Recent data obtained with neuroimaging studies have shown that most of the physiological disturbances resolve with normalization of the patient's body weight, however. Additionally, a premorbid disturbance in the neurotransmitter serotonin has been speculated to be a risk factor for the development of AN and BN. Serotonin controls appetite by creating a sensation of fullness or satiety. It is also known to affect sexual and social behavior, mood, and stress responses. Although further studies are needed to confirm the exact role of this hormone in the development of an eating disorder, it has been shown that decreases in this brain neurotransmitter have been associated with impulsivity, aggression, and depression.

Leptin, a circulating hormone produced in adipose tissue, also seems to have a significant role in mediating the neuroendocrine effects of AN. Decreased concentrations of leptin are seen with reduced body fat stores as a result of decreased caloric intake and energy deficits. Paradoxically, leptin levels also appear to contribute to physical hyperactivity (eg, compulsive exercise, restlessness), which is often seen in patients with AN despite their inadequate metabolic intake.

Genetic Factors

A genetic predisposition to anorexia has been shown in studies of monozygotic twins. The incidence of the disorder is increased in sisters and other female relatives of patients with AN.

Personal Characteristics

Generally, patients with AN are described as obsessive-compulsive personality types, perfectionists, and overachievers, particularly in academics and sports. They also display low self-esteem and high anxiety levels despite their perceived successes by others. In the case of girls, they are the "model daughters" who have never caused any previous problems because of their compliant, self-sacrificing, dutiful, nonassertive nature.

An increased association exists between AN and major depression, and many studies of women have shown that first-degree relatives of patients with AN have higher rates of depression than the general population. Many depressive symptoms in patients with AN improve with restoration of body weight, however. Therefore, some of these clinical features of depression also may be secondary to the adolescent's state of severe malnutrition or starvation.

Familial Influences

Researchers have noted that certain family dynamics may serve to initiate and perpetuate AN, although it is no longer believed that family dysfunction is the main cause of disordered eating. Typically, however, the family is overprotective and rigid, with the mother often enmeshed in her daughter's life. Conflict resolution tends to be poor, and an inability to express feelings within the family is often evident. Diagnosis of an eating disorder often causes additional stress in the family, thus contributing to more difficulties in their relationships. Multiple case-control studies have shown an increased rate of AN and BN in relatives of patients with eating disorders. This may be the result of inheritance patterns of personality traits as well as comorbid mood and anxiety disorders. Although there is limited research, studies suggest that there is no difference in familial or genetic factors between males and females with eating disorders.

Social/Environmental Pressures

The media as well as postindustrial, high-income societal standards are believed to play a role in setting the stage for the development of eating disorder. Individuals in affluent communities are especially at risk if thinness, food, eating, and obsessive exercise become the prime focus of daily activity. In addition, young women become caught in what has been labeled a "slender trap," in which thinness is equivalent to attractiveness and success. Food restriction or purging is a means of attaining thinness. An inability to maintain thinness equals failure. Role models in the media, such as fashion models and actors, also serve as ideals by which young people create their physical standards.

Other Influences

Involvement in particular extracurricular activities that promote leanness and endurance, such as ballet, gymnastics, figure skating, cheerleading, and running, may contribute to the development of AN in females. For male athletes, such influences include participation in sports such as wrestling, lightweight rowing, pole vaulting, and long-distance running, in which maintaining a low weight is important and dieting and/or fasting is used to achieve that weight limit. Chronic medical conditions, such as diabetes mellitus or inflammatory bowel disease (IBD), also may contribute to the development of an eating disorder.

Bulimia Nervosa

Several theories have been proposed to explain the etiology of BN but, similar to AN, no single etiology has been confirmed. Most likely, multiple factors contribute to the development of this eating

disorder, and it is the complex interaction between these factors at a particular developmental point in an older adolescent's life that results in this condition.

Biologic, psychological, familial, and societal influences are thought to contribute to the development of BN in older teenagers and young adults. Among other issues, adolescent and parental obesity are risk factors for BN, as are early menarche, early sexual experiences, posttraumatic stress disorder, and a history of childhood sexual or physical abuse that occurs in conjunction with a comorbid psychiatric condition. More important, dieting has been documented as an important risk factor in this age group.

Familial dysfunction and high levels of conflict also have been associated with BN. Unlike with AN, conflict might be discussed openly but negatively within the family, and the existence of inadequate expression of emotions may result in a lack of parental warmth and concern. As a result, the relationship between the parent and teenager is distant rather than enmeshed. The adolescent generally has a low level of self-esteem, high impulsivity, perfectionist temperament, and body image dissatisfaction. Additionally, parents and relatives have a high rate of affective and eating disorders as well as alcoholism.

Differential Diagnosis

It is important to differentiate AN from BN, although occasionally this distinction may be difficult to make if a patient displays behaviors consistent with both conditions. Additionally, approximately 50% to 60% of patients with eating disorders have associated comorbid psychiatric disorders. Major affective disorders to consider include depression, bipolar disorder, and obsessive-compulsive disorder. Anxiety disorders and substance use also are commonly seen, although the latter is more strongly associated with BN.

Weight loss, loss of appetite, and refusal to eat can be associated with many medical conditions. Therefore, other diagnoses to consider when evaluating patients for AN include IBD, malabsorption, celiac disease, diabetes mellitus, occult malignancies, AIDS, Addison disease, hyperthyroidism or hypothyroidism, hypopituitarism, tumors of the central nervous system, and chronic substance use, particularly with amphetamines and cocaine. Superior mesenteric artery syndrome is another important condition to consider in the differential diagnosis; however, it also can be a consequence of an eating disorder, specifically AN.

Evaluation

History

A complete medical history, including a detailed review of systems, should be obtained from all adolescents and young adults with suspected eating disorder to rule out the multiple other conditions in the differential diagnosis of decreased appetite and weight loss. The primary care physician then should interview the patient alone and focus on establishing the diagnosis of disordered eating by addressing more specific issues related to changes in food preferences (eg, vegetarian, vegan, low-fat diet), eating behaviors, dieting, calorie counting, weight history, exercise routine, and body image concerns (Box 64.3). The 2008 article titled "Interviewing the Adolescent With an Eating Disorder" includes a detailed discussion of interviewing techniques to use on patients with a suspected eating disorder. The severity of the medical and nutritional aspects of the condition should be determined, after which a thorough psychosocial

Box 64.3. What to Ask

Eating Disorders Generally

- Have there been any changes in the adolescent's weight? What is the most and least the adolescent has ever weighed? When did these weights occur and for how long?
- How does the adolescent feel about how they look? Is there anything they would like to change? How long have they been feeling this way?
- How much does the adolescent want to weigh or think they should weigh?
- How often does the adolescent weigh themselves?
- How much of the day is spent thinking about food?
- What is a typical day of eating like, including eating times, types of foods, beverages, amount consumed, and portion size? Do they have a mealtime ritual?
- What did they eat yesterday (24-hour dietary recall)?
- Does the adolescent have any food restrictions? Is the teenager a vegetarian? Do they count calories, fats, and carbohydrates? Binge eat?
- Does the adolescent hide or throw away food?
- Do they feel guilty about eating?
- How do the adolescent and the adolescent's friends manage weight control?
- What does the adolescent do when he, she, or they feels "fat"? Does the adolescent vomit to lose weight? How often does this occur? Are there particular triggers?
- Has the adolescent or any of the adolescent's friends ever used diuretics, diet pills, coffee, enemas, or laxatives to lose weight or compensate for overeating?
- Does the adolescent exercise? If so, what type and how often? Does the adolescent feel stressed if a workout is missed or delayed?
- In what sports or dance activities, if any, does the adolescent participate?
- For females, are menstrual periods regular? Last menstrual period? Age at menarche?
- Does the adolescent have any other symptoms associated with complications of eating disorders?
- Does the adolescent have any depressive symptoms, such as sleeping problems or fatigue that can accompany eating disorders?

For Patients with Bulimia Nervosa Specifically

- When do binges occur? With what foods?
- How much does the adolescent binge, and how often?
- What are the precipitating factors?
- What happens specifically during a typical episode?
- Does the adolescent vomit? How often?
- Does the adolescent use drugs or alcohol?
- Is there a history of depression or attempted suicide? Self-injurious behavior? Sexual or physical abuse?

evaluation should be conducted. Inquiries should focus on symptoms associated with complications of eating disorders, such as dysphagia secondary to esophagitis from recurrent vomiting, constipation from fluid restriction, and muscle weakness associated with emetine toxicity from chronic ipecac use. Because ipecac is no longer readily available, this adverse effect is seen less frequently than in the past. Although rarely seen by the primary care physician at the initial visit when the diagnosis of an eating disorder is made, recognition of serious medical complications is paramount to determining the type and urgency of further care.

Interviewing an adolescent with an eating disorder can be quite challenging; however, a thorough psychosocial assessment should be performed after a discussion about confidentiality has occurred with the adolescent and the parent. The HEADSS assessment (home, employment and education, activities, drugs, sexuality, suicide/depression) is useful to direct the psychosocial interview from general topics to more sensitive ones (see Chapter 4). Particular attention should be paid to the adolescent's overall functioning at home, with friends, and at school; the presence of other comorbid psychiatric disorders (eg, depression, anxiety); and a history of suicidal ideation or sexual and/or physical abuse. Out-of-control behavior as a result of substance use also should be assessed. The use of psychological testing or questionnaires to assess cognition, anxiety, and depression may be beneficial, depending on the comfort level of the primary care physician with these tools. Several validated screening tools specific for eating disorders also exist, including the Eating Disorders Examination Questionnaire (EDE-Q), Eating Disorder Inventory-3 (EDI-3), Eating Attitudes Test (EAT), and the Female Athlete Screening Tool (FAST). If the primary care physician is unfamiliar or uncomfortable with these tools, consultation with a mental health professional is warranted.

A detailed menstrual history also must be obtained from females because secondary amenorrhea is frequently an early sign of AN secondary to decreased body fat. Primary amenorrhea in the context of pubertal delay also can occur with AN. With BN, menses may be irregular or absent. A family history of eating disorders, substance use, or psychiatric disorders should be reviewed with the teenager and confirmed by the parent or guardian.

A dietary history should be obtained from the adolescent as well as the parent or guardian independently and should focus on any dietary restrictions or aversions. This may be difficult initially because the patient often does not believe he, she, or they has a problem with food. A 24-hour dietary recall can be an important place to begin the assessment. The presence of dieting or calorie counting, binge-eating and purging behaviors, amount of food consumed, and the frequency and duration of these behaviors should be documented by the physician or a registered dietician.

Physical Examination

In both AN and BN, the patient should undress, wearing only undergarments, for the physical examination. This prevents hiding the true body habitus with bulky clothes. The current height and weight should be plotted on a growth chart and the body mass index calculated (weight [kg]/height [m^2]). Delayed growth or short stature should be noted, because it can occur with severe malnutrition as well as other systemic conditions. Vital signs, including blood pressure, should be recorded and compared with previous measurements. Evidence of cardiovascular instability can be manifested by tachycardia, bradycardia, or orthostatic hypotension. The patient also may be hypothermic as a result of overall malnutrition. The general appearance and affect of the patient must be noted. The adolescent with typical AN is often emaciated, with an obvious loss of subcutaneous tissue, and may appear apathetic or anxious or have a flat affect. The patient with BN may have mild obesity or normal weight with a full-appearing facies secondary to parotid and submaxillary swelling, which is a complication of frequent purging. In most cases, however, the teenager appears "normal" at the initial visit.

Characteristic physical findings in patients with AN are consistent with a "state of hibernation," because the body adapts to starvation by slowing metabolism and decreasing energy requirements to a minimum. Hypothermia, orthostatic hypotension, bradycardia, and lanugo (ie, downy hair) on the arms and back are seen in patients with restrictive AN. The palms and soles may be yellow secondary to hypercarotenemia, and pigmentation of the chest and abdomen may be increased as a result of malnutrition. Thinning or loss of pubic and scalp hair as well as dry or pale skin also may be seen. The breasts should be examined carefully for sexual maturity rating (ie, Tanner stage) as well as galactorrhea. The presence of galactorrhea, along with a history of amenorrhea, warrants further investigation for a prolactinoma. The patient with AN may have interrupted or delayed pubertal development. A cardiac murmur must be noted and evaluated further, because one-third of patients with anorexia have mitral valve prolapse. The abdomen should be palpated for tenderness or masses and may be scaphoid in appearance. Bowel sounds are often decreased in the patient with anorexia, and stool may be palpated secondary to constipation. The presence of pubic hair (ie, genital sexual maturity rating) also should be noted. A rectal examination should be performed for the patient with a history of bloody stool, which is a finding consistent with IBD, or evidence of rectal prolapse. The extremities should be evaluated for coldness, mottling, or edema. They also should be palpated for tenderness because fractures may be present resulting from loss of bone mineralization. The skin, particularly the forearms, should be examined for any evidence of self-injurious behavior (eg, cutting). Finally, a complete neurologic examination, including a mental status evaluation and fundoscopic examination, should be performed to exclude a central nervous system lesion or endocrine disorder.

In the patient with BN, specific physical findings, if any, often are associated with dehydration and electrolyte imbalances that occur as a result of chronic vomiting or laxative abuse. Vital signs should be reviewed for tachycardia, sinus bradycardia, and orthostatic hypotension; the presence of any of these signs is indicative of hemodynamic instability. The patient also may have hypothermia. The skin should be inspected on the dorsum of the hand over the knuckles

for scratches, scars, or calluses from self-induced vomiting (Russell's sign). Periorbital petechiae and subconjunctival hemorrhages also may occur as a result of recurrent or severe retching. The oropharynx should be inspected for dental caries, enamel erosion, or discoloration as well as for parotid hypertrophy. Additionally, palatal scratches or mouth sores are evident. The abdomen should be palpated for epigastric tenderness, fullness, or midabdominal pain. Positive findings may be the result of esophagitis, gastritis, or pancreatitis.

Any muscle weakness or cramping should be appreciated and may be indicative of an electrolyte abnormality. Edema of the extremities may be noted in the patient who abuses laxatives.

Laboratory Tests

Box 64.4 lists the laboratory studies necessary in the evaluation of the patient with AN and evidence of malnutrition or purging behaviors. A complete blood cell count may be helpful because leukopenia, anemia, and, rarely, thrombocytopenia can occur with this disorder. Electrolytes (ie, sodium, potassium, chloride, carbon dioxide) and blood urea nitrogen are important, especially if the patient uses diuretics, laxatives, or ipecac. Serum magnesium, calcium, and phosphorous must be monitored, especially in the refeeding phase of treatment. The erythrocyte sedimentation rate may be low with anorexia and high with IBD or other inflammatory process. Normal liver function tests aid in excluding other causes of weight loss. Normal serum amylase and lipase levels rule out other etiologies for recurrent vomiting, such as pancreatitis. Serum tissue transglutaminase and immunoglobulin A levels can be obtained if concern exists for celiac disease. Other urine and serum tests (eg, thyroid function tests) help differentiate an endocrine disorder from AN, especially in the patient with primary or secondary amenorrhea (Box 64.5). Electrocardiography is used in diagnosis of QTc prolongation, heart block, and arrhythmias. Additionally, electrocardiography is indicated for the patient with electrolyte abnormalities or a history of significant purging or weight loss.

Laboratory abnormalities in BN reflect the type and extent of purging behavior of the adolescent with this diagnosis. Box 64.4 summarizes the necessary laboratory studies for the patient with BN.

Box 64.4. Initial Laboratory Assessment for the Patient With an Eating Disorder

Anorexia Nervosa

- Complete blood cell count, erythrocyte sedimentation rate
- Serum electrolytes (sodium, potassium, chloride, carbon dioxide)
- Blood urea nitrogen/creatinine
- Serum glucose
- Serum calcium, phosphorous, magnesium, zinc
- Serum protein, albumin, cholesterol
- Liver function tests
- Endocrine laboratory tests (perform in patients with amenorrhea)
  - Urine pregnancy
  - Follicle-stimulating hormone
  - Luteinizing hormone
  - Estradiol
  - Thyroid function: thyroid-stimulating hormone, thyroxine 4, thyroxine 3
  - Prolactin
- Urine pH and urinalysis
- Electrocardiography

Bulimia Nervosa

- Serum electrolytes (sodium, potassium, chloride, carbon dioxide)
- Serum glucose
- Serum calcium, phosphorous, magnesium, zinc
- Blood urea nitrogen/creatinine
- Serum amylase
- Urine pH and urinalysis
- Electrocardiography

Box 64.5. Medical Complications of Eating Disorders

Associated with Purging Behavior

- Fluid and electrolyte imbalances (from laxative abuse and vomiting)
- Irreversible cardiac muscle damage (from ipecac toxicity)
- Esophagitis, dental erosion, Mallory-Weiss tearing (from chronic vomiting)
- Renal stones (from dehydration)
- Amenorrhea, hypoestrogenemia, osteopenia (from decreased body mass index)

Associated with Caloric-restrictive Behavior and Weight Loss

- Abnormalities on electrocardiography: QTc prolongation, low voltage, sinus bradycardia, sinus tachycardia, segment depression (from electrolyte abnormalities)
- Cardiac arrhythmias, including supraventricular beats and ventricular tachycardia, with or without exercise
- Mitral valve prolapse
- Pericardial effusion
- Delayed gastric emptying, slow gastrointestinal motility, constipation, bloating, fullness, abnormal liver function tests (from fatty infiltration of the liver)
- Increased blood urea nitrogen, increased risk of renal stones, total body depletion of sodium and potassium
- Refeeding syndrome (from extracellular shifts of phosphorous)
- Leukopenia, anemia, thrombocytopenia
- Amenorrhea, hypoestrogenism, osteopenia (from decreased body mass index)
- Growth retardation, pubertal delay
- Cognitive deficits
- Cortical atrophy, seizures

Modified from Rosen DS; American Academy of Pediatrics Committee on Adolescence. Identification and management of eating disorders in children and adolescents. *Pediatrics.* 2010;126(6):1240–1253, and Goldstein MA, Dechant EJ, Beresin EV. Eating disorders. *Pediatr Rev.* 2011;32(12):508–521.

Radiologic studies, such as computed tomography of the head or magnetic resonance imaging of the brain, are indicated if the diagnosis of an eating disorder is uncertain or the neurologic examination is abnormal. Bone density studies, such as dual-energy x-ray absorptiometry scanning, are not performed routinely except in adolescents with sustained amenorrhea for longer than 6 months. If amenorrhea persists, annual dual-energy x-ray absorptiometry scanning is recommended. An upper and lower gastrointestinal series may be warranted in the patient with esophageal symptoms or in whom IBD is a strong consideration. The performance of other procedures, however, should be based on the individual case and associated symptoms.

Management

It is the role of the primary care physician to recognize when inappropriate dieting and weight loss become an obsession for an adolescent and when abnormal and unhealthy behaviors develop for maintenance of obvious malnutrition. When treating the patient with eating disorder, the physician must first establish trust; in doing so, the patient should be reassured that the physician is not attempting to remove all control by trying to make the adolescent "fat." The goal is to create a therapeutic alliance between the physician, adolescent, and family to restore and maintain the patient's health and emotional well-being as well as promote recovery and prevent acute and long-term complications. Depending on the severity of symptoms and the comfort level of the physician to monitor early medical, nutritional, and psychological issues, the adolescent may continue to be followed by the primary care physician in conjunction with a registered dietitian, family therapist, and mental health professional, such as a psychologist and/or psychiatrist. Early in the treatment course, the primary care physician must be willing to follow the patient frequently—as often as once or twice a week, if necessary—depending on the medical and psychological stability of the patient. If the physician wishes to refer the patient to an experienced multidisciplinary team of specialists, it is important that the primary care physician remain informed and involved in the care of the teenager.

Numerous studies have shown that eating disorders are best managed by an interdisciplinary professional team experienced in providing developmentally appropriate care for children and adolescents with eating disorders. This team generally consists of the primary care physician, an adolescent medicine specialist, a psychologist and/or psychiatrist, a registered dietician, and a social worker or case manager. Ideally, the team is available to offer both inpatient and outpatient services, although most mild to moderately affected teenagers can be treated in an outpatient setting. Criteria for inpatient admission should be established by the team and reviewed with the patient and family at the onset of therapy.

Particularly for the patient with restrictive eating disorder, consensus must be reached between the adolescent, parent or guardian, and multidisciplinary team about the minimum acceptable weight for the patient's age, height, pubertal stage, premorbid weight, and previous growth trajectory. Attaining such consensus should be done in conjunction with a registered dietitian. Unlike with adults, weight restoration in the adolescent also must take into account the requirements for normal pubertal growth. An agreement that includes the goals of treatment, parameters for weight gain, and maintenance of health should be established between the adolescent and all members of the treatment team. Refeeding/nutritional rehabilitation must be the initial priority, especially in the adolescent with AN, as long as the patient is otherwise medically stable and does not require inpatient psychiatric hospitalization. Details about the proposed nutritional regimen, which includes a stepwise increase in daily caloric intake, calculated amount of protein to be ingested, daily fat intake, vitamin and mineral requirements, and treatment goal weights, should be developed by the dietitian and reviewed with the adolescent and the family in conjunction with mental health support and close medical follow-up. (See Rome and Strandjord, and Garber and Kohn, in Selected References for a discussion of traditional and newer approaches to refeeding and refeeding syndrome.) Early nutritional rehabilitation and timely medical stabilization are essential to correct the cognitive deficits associated with disordered eating, especially severe restrictive AN.

Historically, adolescent-focused individual therapy with some family support was the cornerstone of treatment for the patient with an eating disorder, particularly AN. Studies in the past 10 years, however, have shown that family-based therapy (FBT), also known as the Maudsley approach, is both effective and superior to individual therapy for AN. Consisting of 10 to 20 family meetings over a 6- to 12-month treatment course, FBT is an outpatient form of family therapy that empowers parents to take charge of their adolescent's weight restoration. Patients with disordered eating often try to hide or minimize their illness and generally have difficulty acknowledging their abnormal eating behaviors, associated patterns, and degree of weight loss. Parents, too, may be in denial or may be unaware of the extent of their teenager's condition. Family-based therapy emphasizes the role of the parents in taking the lead in managing their adolescent's eating, particularly in the early stages of treatment. Therapists assist the family to problem-solve factors that may be perpetuating the eating disorder behaviors and thus interfere with improvement of the adolescent's nutrition and weight restoration. Family-based therapy does not blame the parents for causing the eating disorder; rather, solutions are sought for moving forward. Through a distinct 3-phase structured process, FBT initially focuses on refeeding and weight restoration (phase 1); followed by gradually allowing the adolescent to have more responsibility for eating and weight gain (phase 2); and finally addressing the psychological aspects of the eating disorder in the context of adolescent development and treatment termination (phase 3). It has been reported that weight gain in the first month of FBT is predictive of success with this approach. The primary care physician must work cooperatively with mental health colleagues to provide the necessary structured psychological services for the patient and family. Although the

process is difficult, the patient must begin to acknowledge his or her behaviors and accept the need for assistance before effective mental health interventions can occur.

For those who are not able to participate in FBT, individual therapy, such as cognitive behavioral therapy, should be provided for both the patient and family. Support groups also may be beneficial and frequently are an important component of a day treatment program (eg, day hospitalization, partial hospitalization) for the adolescent with eating disorder who requires more intensive outpatient care but not an inpatient hospitalization or residential program. Day treatment programs are generally less costly and may be more accessible than traditional hospital-based programs. According to the American Academy of Child and Adolescent Psychiatry, psychiatric hospitalization, day programs, partial hospitalization programs, and residential programs should be considered only when outpatient interventions have been unsuccessful or are unavailable. (See Golden et al in Selected References for a discussion of the role of the medical provider at each level of care.)

Pharmacotherapy with agents such as selective serotonin reuptake inhibitors are generally not prescribed for the adolescent with AN except to manage comorbid conditions, such as depression and anxiety disorders. Several studies have shown, however, that these same medications can be effective in patients with BN by decreasing binge-eating and purging behaviors. Randomized controlled trials support the use of fluoxetine, tricyclic antidepressants, or topiramate in the management of BN. Additional benefits are achieved when medication is combined with cognitive behavioral therapy, dialectical behavior therapy, or FBT.

Medical complications of eating disorders are well established (see Box 64.5). Inpatient treatment is required for less than 75% ideal body weight for age, sex, and stature; continued weight loss despite intensive outpatient treatment; or a history of rapid weight loss. Refusal to eat and body fat less than 10% also are criteria for hospital admission. Other indications include cardiovascular compromise, such as bradycardia (<50 beats/minute during the day or <40 beats/minute at nighttime), orthostatic hypotension (changes in blood pressure >10 mm Hg, or pulse >20 beats/minute), or altered mental status; evidence of persistent hypothermia (<35.6°C [<96.1°F]); suicidality (ie, ideation, plan, or attempt) or out-of-control behavior; intractable vomiting; electrolyte disturbances or uncompensated acid-base abnormalities (serum potassium <3.2 mEq/L or serum chloride <88 mEq/L); hematemesis; and significant dehydration as evidenced by systolic blood pressure lower than 90 mm Hg or syncope. Cardiac arrhythmias, including prolonged QTc, also require inpatient monitoring. Rarely does confirmation of the diagnosis warrant an inpatient stay. The goal of hospitalization is to correct medical complications, document appropriate weight gain, and establish healthy and safe eating habits with the assistance of the parent or guardian.

Prognosis

Overall, the outcome for the patient with an eating disorder is variable, with some patients recovering after minimal intervention and with other patients developing more chronic problems. Binge eating, for example, may replace food restriction. Most studies report the prognosis as more favorable if the patient's condition is identified early and treated rapidly and aggressively. Predictors of poor outcome for AN include very low body weight at the time of initial treatment, long duration of illness, a psychiatric comorbidity, a dysfunctional parent-child relationship, and purging behaviors. For BN, factors found to be predictive of poor outcome include longer duration of illness at presentation, severity of eating pathology and frequency of vomiting, premorbid obesity, associated comorbid disorders (eg, personality disorder, substance use), and suicidal behavior. A family history of alcoholism also has been reported as a poor prognostic factor for BN.

According to current literature, eating disorders have the highest mortality of any mental illness. The mortality rate for adolescents with AN is approximately 2%. Higher numbers were previously reported when adult and adolescent data were combined. Exact figures for BN have not been determined, although the mortality rate has been quoted as being similar to that of AN. The most common cause of death in both disorders is suicide. Medical causes are often the result of cardiac arrhythmias from electrolyte abnormalities.

CASE RESOLUTION

Although the adolescent may not currently meet strict criteria for the diagnosis of AN, her preoccupation with dieting in the context of weight loss and a BMI of 17 is worrisome. Your concerns about the patient's documented weight loss, menstrual dysfunction, and current eating and dieting behaviors should be discussed openly with the teenager and her family. General laboratory tests should be performed. The adolescent should be referred to a mental health professional and registered dietician with experience in the management of eating disorders for further evaluation. The emphasis should be on the teenager's overall health and well-being. She should be followed frequently until her weight and eating behaviors have reached the mutually agreed-on goal by all professionals involved in her care, after which she should continue to be seen at regular intervals by her primary care physician.

CHAPTER 65

Body Modification: Tattooing and Body Piercing

Monica Sifuentes, MD

CASE STUDY

A 16-year-old girl comes to your office for her annual physical examination. Although the girl was previously healthy, her mother is concerned that the girl seems irritable and unwilling recently to participate in family events. The adolescent is currently in 10th grade at a local public school, gets As and Bs in most subjects, is a member of the volleyball team, and has just begun working part-time at a movie theater. Both her parents are employed, and the girl gets along well with her 19-year-old sister, who is currently in college, and her 14-year-old brother. She has many friends in the neighborhood as well as at school.

You interview the adolescent alone and learn that she occasionally smokes marijuana, has tried cocaine on 1 occasion, and attends parties at which many people are drinking alcohol. She has been sexually active in the past but is not currently. She denies depression and describes her mood as generally happy, except when she is forced to spend what she believes is excessive time with her family instead of with friends.

On physical examination, the adolescent's height and weight are in the 50th percentile for age. Her body mass index is 21. Vital signs are normal. You note a small tattoo at her right hip area. The girl's mother is unaware of its presence, according to the teenager. She obtained it a few months prior while visiting her sister in college.

Questions

1. What is the epidemiology of body modification in adolescents and young adults?
2. What is the motivation for obtaining tattoos and body piercing in this age group, and is there an association with high-risk behavior?
3. What techniques are used to place tattoos and perform body piercing?
4. What are possible adverse consequences of body modification, and what should be done to manage them?
5. How can the primary care physician assist an adolescent in making a safe and healthy decision about body modification?

Body modification is the practice of permanently altering one's appearance, and it has been practiced in many cultures worldwide for millennia. Such modification includes tattooing, body piercing, and scarification. Although much less common than tattooing and body piercing, scarification uses various techniques to intentionally irritate the skin to produce a permanent pattern of scar tissue. It is described as a more intense form of body modification and is reportedly appealing to individuals seeking a more dramatic result.

Historically, body modification, particularly tattooing, was associated primarily with the military and with disenfranchised individuals, such as criminals and gang members. Currently, however, it is considered mainstream among many individuals in US society, with people of all ages as well as socioeconomic and educational backgrounds sporting tattoos and piercings. Body art is seen in most clinical settings serving youth and young adults as well as in middle schools and high schools and on college campuses. Additionally, it is not uncommon to encounter a teenager with multiple tattoos and body piercings or to evaluate an adolescent for a possible complication of the procedure. Whether described as a rite of passage, an expression of their own individuality, or a desire to join a particular peer group, obtaining a tattoo or body piercing has become a widespread experience during adolescence and young adulthood and therefore should be added to the primary care physician's list of issues to review with the teenager during the routine health maintenance visit.

The practice of typical body modification should be distinguished from more intense nonsuicidal self-injurious behaviors, such as cutting, scratching, burning, and hitting oneself. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*) describes *nonsuicidal self-injury disorder* (NSSID) as a mental health disorder associated with self-injury that can manifest in impulsive or compulsive adolescents suffering from anxiety, depression, personality disorders, or psychotic disorders. Adolescents engaged in self-injury expect to gain relief from their negative emotions through physically hurting themselves and may use this behavior as a means of coping with personal emotional issues. Consultation with a mental health specialist is warranted for these challenging cases.

Epidemiology

It was previously estimated that 13% to 25% of the general population in the United States had a tattoo. Because tattooing has grown in popularity and become a fast-growing retail business, however, these figures are likely a gross underestimation. Surveys conducted in outpatient clinics and on high school and college campuses confirm that more than 10% to 15% of teenagers aged 12 to 18 years have a tattoo. In a study of more than 2,000 US high school students, 55% expressed interest in obtaining a tattoo regardless of its permanence or the students' academic success in school. Additionally, it has been reported in the literature that one-half of new tattoos are obtained by women and that many are obtained during the college years. Surveys conducted in the last 10 years reveal that approximately 20% to 25% of college students have a tattoo.

Body piercings are more common than tattoos among adolescents and young adults, and some experts speculate that this may be because the procedure is not permanent, allowing the individual to remove the jewelry at any time. In a study of college students, 45% had undergone body piercing and 22% had tattoos with and without piercings. Other studies that include younger adolescents attending an outpatient adolescent clinic report body piercing in approximately 27% and tattoo in approximately 13%. Most studies also confirm that females are more likely to obtain a piercing than males; male athletes are more likely to obtain a tattoo than their nonathlete male counterparts.

The motivation for obtaining body art also has been studied, with most of the literature confirming adolescents' search for uniqueness and desire to enhance their independence and self-identity. For some teenagers, body art is considered a form of decoration or an opportunity to be creative; alternatively, it fulfills a desire for peer acceptance and solidifies group membership. Attainment of body art for the purpose of peer acceptance or solidifying group membership has been documented by studies demonstrating that friends or peers provide the strongest influence for youth pursuing body art. Tattoos in particular can be a means of permanently documenting a relationship with an individual or group. Despite popular belief, studies do not confirm that most adolescents obtain a tattoo or body piercing impulsively while under the influence of illicit drugs or alcohol. In fact, many older teenagers and young adults report taking considerable time to decide whether to obtain a tattoo or piercing.

The extent to which parents or guardians are involved in the adolescent's decision to have a tattoo placed or body piercing performed is variable for many teenagers and depends on their particular relationship, whether the adolescent is a minor, and state parental consent requirements. In some cases, parents are not consulted before the procedure, although in many states the law requires parental consent and presence, and tattooing of minors is prohibited. Current laws are not consistently enforced, however, and in many states tattooing and body piercing have different regulations. Health professionals are therefore encouraged to become familiar with their individual state laws related to minors obtaining tattoos and piercings to counsel their patients appropriately.

Clinical Presentation

Tattoos can be found on any area of the body and, depending on the talent of the artist and the desire of the client, can be simple and 1 color or quite elaborate and multicolored. Generally, amateur tattoos (ie, those performed by a nonspecialist or friend) are less intricate and are considered more risky because often they are not performed under ideal circumstances, using antiseptic techniques, or with conventional pigments and applicators. Unconventional pigments include charcoal, India ink, and mascara. Pencils, pens, sewing needles, and other sharp objects, including guitar strings, may be used to apply the dye for a self-administered or amateur tattoo.

The most common site for piercing is high on the pinna of the ear. Regular lobular ear piercings are not generally included in the context of body modification because they occur commonly at any age. Other body sites that are pierced include the tragus of the ear, eyebrows, tongue, nose, nasal septum, cheek, lip, navel, and nipples. Intimate or genital piercings also can be seen in males and females. The foreskin, penis, scrotum, clitoris, perineum, and labia are all common areas for intimate piercings. Although specific data by sex are not available, it is reported that more men than women obtain genital piercings.

Technique, Application, and Safety Standards

Tattoos

The process of applying a professional or commercial tattoo is relatively standardized, although different tattoo parlors may have their own individual practices. Generally, the client selects a design from flash sheets in the shop or an individualized design by the artist, and the tattoo is stenciled or drawn on clean-shaven skin. The skin is cleansed again with an antiseptic solution, and a thin layer of ointment, such as petroleum jelly, is placed on the site. Most professionals in the United States use a motorized, electric-powered tattoo gun, which is similar to a dental drill, that holds 1 or several needles in a needle bar that is dipped in ink and that punctures the skin a few millimeters deep, up to several thousand times a minute. In Europe, small amounts of ink are applied directly to the skin and the needle is used to push the ink into the skin. Regardless which method is used, the pigment reaches the level of the dermis via the solid-bore needle or needless, while blood and serosanguineous fluid are wiped away as tattoo placement continues. When the tattoo is completed or the session is finished, an antibiotic ointment is applied and a bandage is placed over the site.

The client is instructed to remove the dressing 24 hours later and keep the area moist with an antibiotic ointment. Additionally, clients are instructed to place an emollient or vitamin E oil over the healing tattoo several times a day. The area is to be cleansed with a mild soap and patted dry or blotted (not rubbed). If aftercare instructions are followed carefully, most tattoos heal in approximately 2 to 3 weeks, with superficial crusting and "shedding" of epidermis as part of the natural course of tattoo placement. Sunscreen should be worn if sun exposure cannot be avoided in the ensuing weeks.

Swimming, soaking in water, and direct shower jets to the area are discouraged for several weeks.

Ideally, the application process uses inks that are poured into single-use disposable containers and sterile needles that are disposed of after each client. Although the tattoo ink pigments are considered cosmetics and are subject to US Food and Drug Administration regulation, however, neither the tattooing process itself nor the use of the inks is regulated. Additionally, certain pigments may not be approved for intradermal use and have been known to contain low concentrations of metal salts, such as lead, iron, mercury, or aluminum.

The practice of universal precautions is required by state and local regulatory agencies and advocated by specific educational groups, such as the Alliance of Professional Tattooists (APT), a nonprofit organization established in 1992 to promote standards for professional and associate tattooists and develop guidelines for consumers to evaluate the safety of individual tattooing establishments. The organization also sponsors regular educational seminars for tattoo artists on the prevention of disease transmission in tattooing. Membership in APT is voluntary and requires that the professional tattooist pay annual dues, participate in a health and safety seminar, and have at least 3 years of full-time experience at a consistent location. Other membership levels are available, with variable costs for annual dues and requirements for membership (eg, <3 years' experience and/or apprenticing associates). Despite APT efforts and standards, however, specific areas of concern about the tattoo industry remain, including unlicensed tattoo artists and establishments, the presence of unregulated ingredients in the pigments, inconsistent cleaning of equipment between clients, an inability to reliably sterilize all parts of the equipment despite good efforts, and infrequent inspections of tattoo parlors by regulatory agencies.

Body Piercing

The process of body piercing is generally less complicated than tattooing and depends, in part, on the anatomic site to be pierced. The client chooses the jewelry and body part to be pierced, the area is cleaned with a topical antiseptic, and a large hollow needle is brought through the skin. The jewelry is then brought through the hole following the needle, and the hole is sealed with a bead, bar, or metal disc. Because the procedure is relatively quick, topical anesthetics are generally not required.

Although earlobe piercing is a relatively straightforward procedure, it is commonly performed using a piercing gun at a local mall, cosmetic shop, or kiosk. Because the stud is driven through the earlobe via the gun rather than through a hollow tube manually, the tissue is torn or crushed rather than pierced. Additional concerns about the piercing gun include inconsistent and informal training of personnel, an inability to sterilize all parts of the gun between procedures, and embedded earrings and ear backs. The gun cannot be adjusted for the thickness of other tissues, so although it is a popular method for earring placement, this tool is not recommended for sites other than the earlobe.

The immediate aftercare of piercing varies by the site pierced. For example, local skin discoloration and a nonmalodorous serous exudate can occur with piercings of the nares or navel. Tongue or lip piercings have been associated with significant swelling for several days after the procedure. Additionally, a yellow-white fluid secretion can occur that, to the unfamiliar examiner, appears to mimic an infection. Clients with oral piercings are generally instructed to dissolve ice in their mouth immediately after piercing to help with pain and swelling, manage further discomfort with a nonsteroidal anti-inflammatory drug, and elevate the head when sleeping.

Healing times vary considerably depending on the anatomic site of the piercing. Generally, sites with increased vascularity and exposure (eg, face, tongue) tend to heal faster than those involving cartilage, which is poorly vascularized. Areas of the body that are subject to movement also heal more slowly. For example, healing time may be 1 to 2 months for the tongue, 1 to 1.5 months for the nasal septum, 2 to 3 months for the nostril, and 2 to 4 months for the tragus of the ear. High-ear piercings through the cartilage also may require 2 to 4 months for healing. Navel piercings have the longest healing time (up to 9–12 months) because of friction and moisture from clothing and often are associated with the most complications.

As with tattooing, not all states have regulations and safety standards in place for body piercing, and if such regulations and safety standards do exist, local governing bodies do not consistently enforce them. Universal precautions should be strictly practiced, and the adolescent should be familiar with these guidelines and know how to find a reputable piercer before obtaining body art.

Because no formal training programs exist for piercers, many learn by video or apprenticeship. Generally, practitioners in studios have completed an apprenticeship and have more training than those in cosmetic shops, malls, or ear-piercing kiosks. They also are more experienced in piercing sites other than the ears and may be members of the Association of Professional Piercers (APP). Established in 1994, the APP is a nonprofit organization dedicated to the education, health, and safety of body piercing for the public. It has developed self-regulatory policies for the industry, standards for membership in the organization, and annual conferences on health and safety issues. Members must have at least 1 year of piercing experience, documented training in blood-borne pathogens and cardiopulmonary resuscitation, and certification in first aid. Members also must show photographic proof of a medical-grade autoclave in the piercing studio and send in spore test results from the autoclave. To help document this, a detailed video of the studio is required, along with copies of all aftercare education given to clients. After this process is completed, the member receives a certificate to mount in the studio.

Current legislation addressing minors and piercing is regulated by individual states; in some states, such as California, ear piercing performed with piercing guns is excluded from the definition of body piercing. Concerning minors, the APP requires that the parent or legal guardian as well as the minor show proof of identification before signing the consent form for body piercing. Additionally, nipple or genital piercings are not performed on anyone younger than 18 years.

Evaluation

History

All teenagers should be interviewed alone, after their parent or legal guardian has had an opportunity to discuss their concerns with the health professional (see Chapter 4). A visible tattoo or body piercing allows the physician to inquire about the circumstances surrounding the body art at the beginning of the interview, in contrast to body art noted in an inconspicuous area of the body during the physical examination. Whether parental consent was obtained before the procedure should be addressed directly, because this issue could be a basis for current as well as future familial conflict. The type of facility in which the tattoo or piercing was obtained should be discussed, along with whether the adolescent recalls whether universal precautions were followed. A general review of systems should be performed to exclude systemic conditions, such as viral hepatitis, as well as any other complications related to obtaining the tattoo or piercing in a nonprofessional environment. Specific questions about the area of the body that is pierced also should be reviewed (Box 65.1). For example, the teenager with a tongue piercing should be asked if he, she, or they has problems with mastication, swallowing, loss of taste or movement, or permanent numbness.

It has been reported that amateur or self-administered tattoos are associated with increased high-risk behaviors, including substance abuse at a younger age, illicit drug use, lower academic achievement, and an increased number of tattoos overall. Recent studies have shown, however, that not all adolescents and young adults with multiple tattoos or body piercing(s) engage in high-risk behavior (Box 65.2). Successful academic achievement and close family support have been reported in tattooed and nontattooed college students. Although tattoos are permanent, more than 50% of academically successful high school students with consistently good grades have reported an interest in them.

Box 65.1. What to Ask

Tattoos and Body Piercing

- When was the tattoo or body piercing placed?
- Did the teenager obtain consent from the parent or legal guardian before getting the tattoo or piercing?
- Is the adolescent satisfied with the tattoo or piercing?
- Was the tattoo or body piercing placed by a professional or by a friend, acquaintance, or relative?
- If the tattoo or body piercing was obtained in a studio, where was the studio located? Was it licensed? Was it clean, "like a medical facility"?
- Did the tattooist or piercer wash his, her, or their hands before gloving? Use new disposable gloves? Open all equipment in front of the teenager?
- For tattoos, did the tattooist remove a sterile needle and tube set from a new envelope? Did the tattooist pour fresh ink in a new disposable container?
- For body piercing, did the piercer use individually wrapped sterile needles? Did the piercer use a piercing gun?
- Did the teenager receive aftercare education, including written material?

Box 65.2. The Association Between Body Modification and High-Risk Behavior in Teenagers[a]

- Adolescents with tattoos or body piercings were found to be more likely to have engaged in risk-taking behaviors than those without either type of body modification. Risk-taking behaviors included disordered eating behavior, gateway drug use (ie, cigarettes, alcohol, marijuana), hard drug use (ie, cocaine, crystal methamphetamine, ecstasy), sexual activity, and suicide. Additionally, aggressive and violent behavior was associated with males having tattoos and with females having body piercings. Gateway drug use was associated with younger age of tattooing and body piercing.[b]
- Adolescents with body modification had 3.1 times greater odds of problem substance use compared with those without body modification.[c]
- Tattooing was significantly associated with older age, living in a single-parent household, and lower socioeconomic status. Such adolescents also exhibited greater involvement in sexual intercourse, higher levels of substance abuse themselves as well as among their peers, increased violent behaviors, and school problems.[d]
- A correlation was found between body piercing in teenagers and increased rate of sexual intercourse, smoking, marijuana use, school truancy, running away, suicidal ideation or attempts, and peer substance use.[e]

[a] Many studies have been conducted to explore the association between high-risk behavior and body modification in adolescents. No definitive answers exist, but this box presents published findings from the early 2000s.

[b] Carroll ST, Riffenburgh RH, Roberts TA, Myhre EB. Tattoos and body piercings as indicators of adolescent risk-taking behaviors. *Pediatrics.* 2002;109(6):1021–1027.

[c] Brooks TL, Woods ER, Knight JR, Shrier LA. Body modification and substance use in adolescents: is there a link? *J Adolesc Health.* 2003;32(1):44–49.

[d] Roberts TA, Ryan SA. Tattooing and high-risk behavior in adolescents. *Pediatrics.* 2002;110(6):1058–1063.

[e] Armstrong ML, Roberts AE, Owen DC, Koch JR. Contemporary college students and body piercing. *J Adolesc Health.* 2004;35(1):58–61.

Whether body art is considered an expression of individuality, rebellious behavior, or succumbing to peer pressure, the presence of a tattoo or body piercing on an adolescent warrants an in-depth psychosocial assessment and review of systems for possible exposure to viral infections, such as hepatitis C.

Physical Examination

In most adolescents with a tattoo or body piercing the routine physical examination is generally normal, unless either a past complication with the tattoo or piercing occurred or a current problem exists. Poor aftercare and hygiene can prolong healing time in body piercings. Additionally, smoking can delay the healing time associated with oral piercings. If the teenager has recently undergone a tongue piercing, a larger barbell will be seen through the tongue. Larger barbells initially are placed with tongue piercing to accommodate the swelling associated with the procedure. Later, the barbell is replaced with a shorter rod.

Infectious and noninfectious complications from tattoos and body piercings are listed in Box 65.3. Local infection occurs in only

Box 65.3. Complications of Tattoos and Body Piercing: Infectious and Noninfectious

Tattooing Complications

Infectious

Bacterial etiologies

- Local skin infections
  - — Superficial pyoderma
  - — *Staphylococcus aureus*
  - — *Streptococcus pyogenes*
- Systemic infections
  - — Deep or severe pyoderma
  - — Syphilis
  - — *Mycobacterium tuberculosis*
  - — *Mycobacterium leprae*
  - — Nontuberculous mycobacteria
  - — *Mycobacterium chelonae*
  - — *Mycobacterium abscessus*
  - — Chancroid
  - — Tetanus
  - — Endocarditis

Viral etiologies

- Human papillomavirus
- Hepatitis B and C
- HIV

Noninfectious

- Hypersensitivity to dyes or pigments
- Allergic granulomas
- Malignant melanoma and basal cell carcinoma at tattoo site
- Keloid formation
- Swelling and burning during magnetic resonance imaging

Body Piercing Complications

Infectious

Bacterial etiologies

- *S aureus*
- *Pseudomonas aeruginosa*
- Group A β-hemolytic streptococcus
  - — Cellulitis
  - — Septic arthritis
  - — Acute glomerulonephritis
  - — Erysipelas
  - — Endocarditis
- *M tuberculosis*
- *Clostridium tetani*

Viral etiologies

- Hepatitis B and C
- HIV

Noninfectious

Body jewelry, in general

- Artifact on radiographs

High-ear piercing

- Pinna deformity

Tongue piercing

- Airway obstruction
- Chipped/cracked teeth
- Interference with mastication/swallowing
- Permanent numbness
- Articulation disorders
- Loss of taste/movement
- Oral mucosa inflammation

Lip piercing

- Injury to salivary ducts
- Aspiration of jewelry

Navel piercing

- Allergic dermatitis

Nipple piercing

- Trauma/avulsion of nipple

Genital piercing

- Tissue inflammation in sexual partner
- Scarring
- Interruption of urinary flow in males

approximately 5% of tattoos, but infectious complications have been reported in as many as 30% of body piercings. Acute signs of infection include erythema, warmth, swelling, and pain at the site, in addition to drainage in some cases. Rarely, a fluctuant, fluid-filled mass is evident if an abscess has developed.

Because some of the noninfectious complications can be related to the type of metal found in the jewelry, knowledge of this specific information is useful in individuals with body piercing. Only jewelry made from surgical stainless steel, titanium, solid 14- or 18-karat gold, or solid platinum should be used in healed piercings to avoid allergic dermatitis. Certain metals, such as nickel, cobalt, and chromium, have been associated with the development of contact dermatitis in sensitive individuals. Initially, during the healing phase of piercings, however, surgical stainless steel and 14-karat gold jewelry should be avoided because they may contain trace amounts of nickel. Permanent makeup also has been reported to cause severe allergic contact dermatitis that can take months to years to completely heal. The reported reactions included tenderness, itching, and "bumps" at the site of the permanent makeup application. Hypersensitivities to dyes or pigments from a professional tattoo also can appear as an erythematous outline of the original work. This inflammatory reaction can also occur with temporary tattoos created with henna, which is approved as a hair dye but is not approved for use on the skin. Use of henna has been associated with severe contact dermatitis, especially if an additive containing paraphenylenediamine is mixed with the henna to give the normal red-brown paste an additional black-and-blue color. The addition of paraphenylenediamine to the henna mixture also speeds drying time and prolongs skin pigmentation.

Keloids and hypertrophic scars can appear as a flesh-colored mass at the area of the tattoo or piercing and differ in their timing and resolution. A hypertrophic scar generally appears within 6 weeks of the tattooing or piercing, is confined to the wound margins, and has a tendency for spontaneous regression. In contrast, keloid formation may occur as late as 1 year after the initial wound, often grows beyond the border of the wound, and persists. Keloids occur primarily in black and Asian patients and can cause an itching or burning sensation that may warrant a prompt referral for removal.

Laboratory Tests

Generally, laboratory studies are not necessary if the adolescent is not engaged in high-risk behavior and is certain that universal precautions were followed when the tattoo or piercing was placed. In most cases, however, the teenager may be uncertain or may not remember the details. In such cases, a serum test for viral hepatitis B and C should be obtained, because hepatitis C virus is found in approximately 30% of people with tattoos, compared with 3.5% of people without them. An antibody test for HIV should be sent for the high-risk teenager who is being screened for other sexually transmitted infections; however, the test is not necessary if the patient has a tattoo or body piercing and no other indications for HIV screening.

No definitive documented cases of HIV transmission from tattooing or body piercing have been reported to date.

A serum test for syphilis should be done because, unlike HIV, transmission of this and other sexually transmitted infections has been reported from tattooing or piercing, albeit rarely.

If evidence exists of abscess formation, such as may be seen with perichondritis, a specimen of the purulent fluid should be obtained and sent for culture and antimicrobial sensitivities.

Management

Although tattoo removal or modification is not ordinarily requested by most adolescents, it is available for the patient who no longer wants the tattoo or is unhappy with its current appearance. Recent studies have examined the motivation for tattoo removal after a duration of at least 10 years. Reasons for removal are varied and include embarrassment, a need to disassociate from the past, improved self-esteem, being tired of the tattoo, and negative social remarks about the tattoo. Professional employment or job advancement was not consistently cited as a common reason for removal, although some surveys attribute tattoos in certain visible locations as career limiting.

Historically, tattoo removal was quite difficult, and only approximately 70% of tattoos could be completely cleared because of impurities in tattoo pigments, different ink densities and depths, and the presence of certain metals in the dyes. *Selective photothermolysis*, which is a newer technology that uses a selective type of laser to target specific color pigments, is quite effective in removing several ink colors. Using a quality-switched laser system, the wavelength of the laser is set to match the specific absorption pattern of the different color pigments in the tattoo and a pulse is delivered over nanoseconds with extremely rapid heating. Fragmentation of the tattoo pigment occurs and, upon releasing it into the skin, an acute inflammatory process follows along with phagocytosis of fragmented pigment particles. Subsequent laser treatments can be performed 4 weeks later, although longer intervals between treatments may reduce the risk of permanent changes to the pigment of the skin. No laser method is completely successful in removing all evidence of the tattoo, especially intricate and colorful ones, and in most cases, immediate lightening of the skin occurs with subsequent hypopigmentation. Hyperpigmentation, allergic reactions, and scarring resulting from thermal burn injury may also occur after laser treatment. Although these complications are usually transient, they can be permanent, and the patient must be made aware of the risks associated with each process. Tattoo removal can be costly. Whereas the average cost for tattoo placement may be $50 to $100 per hour of service, removal may cost several thousands of dollars depending on the size, complexity, and number of colors in the tattoo. Other, less popular techniques for tattoo removal include dermabrasion, which is less desirable because of concerns for infection and its variable effectiveness; *salabrasion* (ie, use of a salt solution to abrade the skin); scarification; and surgical excision, with or without the use of tissue expanders and grafting. Camouflaging also can be performed; with this technique, either a new pattern is made using skin-toned pigments or the tattoo is modified and made into another design. For instance, the name of a person can be incorporated into a new tattoo of an animal or object. Certain nonprofit organizations also offer tattoo removal to former gang members as a part of their preparation for employment and educational services.

Although it seems counterintuitive, in most cases removal of jewelry is not recommended if a piercing appears infected. The concern is that, without a wick or surgical drain, any potential space left at the site after the jewelry is removed could result in the development of an abscess. Instead, the adolescent should be instructed to leave the jewelry in place to allow drainage of the wound, use warm compresses, and clean the area with an antimicrobial soap and water. The use of topical antibiotic ointments is controversial because they can be occlusive and contribute to delayed healing. Certain individuals with specific medical conditions are at increased risk for infections after body piercing, including patients with diabetes mellitus, systemic lupus erythematosus, and conditions requiring chronic corticosteroid use. In such cases, if infection occurs it may be necessary to remove the jewelry early in the course of the infection and initiate appropriate antibiotic coverage.

Oral antibiotic coverage against skin staphylococcal and streptococcal species should be administered if the tattoo or piercing appears superficially infected and other measures have not been effective. More aggressive treatment is required if the piercing site involves the cartilage, such as with high-ear piercings, or if the patient is immunocompromised. Auricular infections can occur even after the use of strict antiseptic techniques and may appear a few weeks after the initial piercing. The cartilaginous helical area of the ear is particularly prone to infection because it is poorly vascularized and is slow to heal. Additional antimicrobial coverage against *Pseudomonas aeruginosa* is essential in these cases, along with diligent follow-up to monitor the initial response to oral antibiotic therapy. Currently, oral fluoroquinolones offer good antipseudomonal and antistaphylococcal coverage and penetrate cartilage well. Inpatient hospitalization for intravenous antimicrobial therapy and subsequent drainage of the site may be necessary for moderate or unresponsive infections. Early recognition of perichondritis and appropriate management of it are essential to prevent the development of a persistent infection and to minimize the risk of a permanent auricular deformity. Additionally, timely consultation with a plastic surgeon or otolaryngologist early in the course of the suspected infection is recommended for early incision and drainage of a perichondral abscess, appropriate wound care, and possible reconstruction of any disfigurement. Additional information about body piercing complications and their management in adolescents and young adults can be found in the 2017 American Academy of Pediatrics Committee on Adolescence article on tattooing, piercing, and scarification in that population.

Role of the Primary Care Physician

Education is essential for the adolescent who has not yet obtained a tattoo or piercing or who already has one and is contemplating the placement of another. The physician should inquire where the

adolescent plans to have the procedure performed and educate the patient on what key questions to ask and how to find a reputable studio. Additional information, such as the APT (www.safe-tattoos.com) and APP (www.safepiercing.org) websites, should be shared with the patient, and written materials that contain safety guidelines should be provided to the adolescent at the visit. Teenagers are often reluctant to ask their health professionals for information about obtaining tattoos and piercings and almost never contact a health professional if they believe they may have a complication associated with tattooing or piercing. Instead, they tend to ask their peers or contact the establishment at which the tattoo or piercing was initially obtained. Primary care physicians should be a nonjudgmental resource during health maintenance visits to ensure the adolescent's continued health and safety. Additionally, the appearance of an uncommon medical condition, such as unexplained hepatitis, endocarditis, or toxic shock, in the adolescent patient or young adult warrants careful consideration for a possible complication related to tattooing or body piercing.

Prognosis

Most teenagers and young adults experience no adverse effects from body modification. Complications are uncommon with the placement of a professional tattoo but can occur with body piercing and usually are amenable to medical management. Risk-taking behavior that may occur in conjunction with body modification can carry long-term sequelae, but the association between defiant behavior and having a tattoo has changed over time. Although body modification has become more widespread and generally is acceptable based on public opinion, any decision to pursue body modification should be made in the context of the adolescent's long-term and professional career goals, because studies have documented negative repercussions in some areas of employment.

CASE RESOLUTION

Because the presence of 1 tattoo may be associated with a likelihood to obtain another tattoo, the primary care physician should review safety guidelines for obtaining a tattoo and body piercing with the adolescent and offer the teenager educational material or refer her to select websites to reinforce the discussion. The immunization status of the teenager also should be assessed, with particular attention to tetanus and hepatitis A and B. Additionally, in private discussion with the teenager, the physician should reiterate any concern about the adolescent's current high-risk behavior and its possible consequences. It also may be worthwhile to discuss with the teenager the pros and cons of telling her parents about the tattoo before they find out inadvertently.

CHAPTER 66

Depression and Suicide in Adolescents

Monica Sifuentes, MD, and Robin Steinberg-Epstein, MD

CASE STUDY

A 15-year-old girl is brought to your office by her mother with the chief report of easy fatigability. The mother is concerned because her daughter is always tired, although several other physicians have told her that the girl is healthy. The adolescent, who states no complaints or concerns, appears quite shy. She is currently in the 10th grade, likes school, receives average grades, and speaks English and Spanish. The mother, a single parent, moved to the United States from El Salvador approximately 2 years ago with her 2 daughters. Currently, they are living with relatives in a two-bedroom apartment. The mother is employed as a housekeeper, and the patient and her sister help their mother clean homes on weekends. During the week they make dinner for the rest of the family as a means of contributing to the rent. When you speak to the girl alone, she acknowledges she has a few friends at school and adamantly denies any drug, alcohol, or tobacco use. She has never been sexually active and reports no history of sexual or physical abuse. She scores 11 on the 9-item Patient Health Questionnaire. The physical examination is entirely normal, although the girl's affect appears somewhat flat.

Questions

1. What is the significance of nonspecific symptoms, such as fatigue, during adolescence?
2. What factors contribute to depression in the adolescent?
3. What are the classic signs and symptoms of depression in the adolescent?
4. What are some important points to cover in the history when interviewing the adolescent with suspected depression?
5. What is the purpose of the depression/suicide screening tool (eg, Patient Health Questionnaire-9)? How should the results be interpreted and used?
6. How is the risk of suicide assessed in the adolescent patient?
7. How should suicidal behavior (ie, suicide attempts) be managed in the adolescent?

The number of people in the United States with mental health concerns, including depression and suicidality, far surpasses the number of mental health specialists. For this reason, the American Academy of Pediatrics recommends that primary care physicians take an active role in the identification and early management of uncomplicated mental health concerns in children and adolescents. Furthermore, the importance of primary care physicians in this arena is emphasized by research findings. Patients who ultimately die by suicide visit primary care physicians more than twice as often as mental health clinicians in the months leading up to their death. A review of studies analyzing this clinical scenario estimated 45% of those who died by suicide saw their primary care physician in the month before their death, whereas only 20% saw a mental health professional in the preceding month. Women and older patients are more likely to have sought care in the month before their suicide compared with men and younger patients. Those who practice general medicine (ie, internists, pediatricians, family physicians) write most of the antidepressant prescriptions in the United States.

Depression and suicidality are common in the pediatric and adolescent population. Thus, it is important to remain cognizant of their clinical presentation and to diligently screen and probe for their presence.

Depression is among the multiple risk factors that predispose adolescents to suicide. Not all teenagers who attempt suicide are depressed, however; conversely, not all depressed adolescents attempt suicide. This distinction is important to keep in mind when evaluating any adolescent for depression or suicidal behavior. Early identification of risk factors in the susceptible adolescent along with early intervention for those with depressive symptoms will, it is hoped, benefit the teenager at risk for suicide and allow the primary care pediatrician to provide first-line intervention for the adolescent patient experiencing emotional distress.

Epidemiology

Depression

The exact prevalence of depression in adolescents is difficult to determine because depression is often underreported. It is considered 1 of the main psychiatric conditions affecting children and adolescents, however, along with anxiety. Depressive symptoms have been reported in as many as 50% of girls and 40% of boys in the 14- to 15-year age group. The overall prevalence of depression as an illness is approximately 5%; mild depression is reported in 13% to 28% of teenagers, moderate depression in 7%, and severe depression in 1.3%. Depression occurs more commonly in adolescents than in prepubertal children and is more frequent in females than males after puberty.

Several risk factors contribute to the development of depressive disorders in adolescents (Box 66.1). Certain psychiatric conditions also are associated with depression, including generalized anxiety disorders, eating disorders, substance abuse, conduct disorders, and borderline personality disorders.

Suicide and Suicidal Behavior

Suicide is the second-leading cause of death in the United States in individuals 10 to 24 years of age; only motor vehicle crashes result in more deaths in young people. In 1960, the annual suicide rate in this age group was 5.2 per 100,000. The suicide rate has continued to rise over the past 50 years. According to the Centers for Disease Control and Prevention, the suicide rate in 2017 was 11.8 per 100,000, with 6,241 completed suicides in 15- to 24-year-olds. It has been stated that for every suicide that is completed successfully, 50 to 100 suicides are attempted. More than 75% of teenagers who committed suicide had not been on medication and were not under treatment for depression or suicidal concerns.

According to the 2017 Youth Risk Behavior Survey of the Centers for Disease Control and Prevention, 17.2% of all students in grades 9 to 12 nationwide had seriously considered attempting suicide during the previous 12 months. Approximately 14% of students nationwide had made specific suicide plans, more than 50% of students with suicide plans reported attempting suicide, and 2.4% of the individuals who attempted suicide required medical attention. The prevalence of developing a suicide plan was higher among gay, lesbian, and bisexual students (38.0%) and "not sure" youth (25.6%) than among heterosexual students (10.4%). Rates also differ by race and ethnicity, with black and Asian teenagers having lower suicide rates than white teenagers, and black females having the lowest suicide rate of all adolescents. American Indian/Alaska Native males have the highest suicide rate among this age group.

In discussing adolescent depression and suicide, it is important to clarify the meaning of specific terms. *Suicidal ideation* is thoughts of engaging in suicide-related behavior. *Suicidal intent* is having the aim or resolve to follow through with a plan. *Suicidal behaviors* are behaviors related to suicide, including preparatory acts, suicide attempts, and death. *Suicide attempt* is a nonfatal, self-directed, potentially injurious behavior with any intent to die as the result of the behavior. A suicide attempt may or may not result in injury. *Suicide* is death caused by self-directed injurious behavior with any intent to die as the result of the behavior.

Several risk factors associated with adolescent suicide have been identified (Box 66.2). Suicide is rarely associated with depression but is most often associated with a recent, abrupt crisis (eg, breakup of

Box 66.1. Risk Factors Associated With Depressive Disorders in Adolescents

- Family history of psychiatric illness (eg, parent with an affective condition, another family member with a bipolar or recurrent unipolar disorder)
- Age at onset of depression in the affected parent; the earlier the age of onset, the greater the likelihood of depression in any children
- Exposure to an unexpected suicide attempt or completion in the school or community
- History of environmental trauma (eg, sexual or physical abuse, loss of a loved one)
- Chronic illness
- Certain medications (eg, propranolol, phenobarbital, prednisone)

Box 66.2. Risk Factors Associated With Suicide in Adolescents

- History of a previous suicide attempt (most important)
- Male sex
- History of adoption
- Lesbian, gay, bisexual, or questioning sexual orientation
- Transgender identification
- History of physical and/or sexual abuse or exposure to violence
- Family history of psychiatric disorders, especially depression, substance abuse, and suicidal behavior
- Personal mental health problems
  - Sleep disturbances
  - Psychological characteristics, such as aggression, impulsivity, and hopelessness or severe anger
  - Preexisting psychiatric condition (eg, depressive/bipolar disorder, conduct disorder, posttraumatic stress disorder)
  - Alcohol and illicit substance abuse or dependence
  - Pathologic internet use
- Social and environmental issues
  - Family disruption or stressful life event, including violence, divorce, or death of a loved one
  - Impaired parent-child relationship
  - Living outside the home (eg, homeless, corrections facility, group home)
  - Bullying
  - Exposure to an unexpected suicide attempt or completion in the school or community
  - Availability of firearms in the home

a romantic relationship, accusation, failure). Although adolescent females are more likely to attempt suicide than males (22% and 12%, respectively), males are more likely to succeed (male-to-female ratio, 4:1). This fact may result from the lethality of the methods, such as firearms or hanging, that males usually choose. Although females are more likely to ingest pills, the role of firearms in suicide attempts or completion in females is increasing. The availability of firearms and alcohol, which varies from state to state, greatly contributes to the occurrence of suicide. Up to 45% of individuals who have committed suicide show some evidence of intoxication at the time of death. Although most suicide attempts are impulsive, studies have shown that adolescents often have communicated their suicidal intent or ideation to someone before the attempt. Approximately 50% of adolescents who attempt suicide have sought medical care within the preceding month and 25% within the preceding week. In contrast, only one-third have previously received mental health care.

Clinical Presentation

The depressed or suicidal adolescent may visit a physician for a variety of clinical reasons, but rarely do they seek professional assistance for feeling "depressed." Some adolescents have a difficult time accurately understanding and communicating their emotions. A depressed teenager often presents as irritable, argumentative, or angry rather than sad. Teenagers may exhibit diminished interest or pleasure in activities or relationships and changes in cognitive functioning (eg, concentration), sleep, appetite, or energy, which results in impairments in multiple activities of daily living. They also may present with seemingly nonemergent complaints and a flat affect or with multiple somatic concerns and an anxious appearance. Additionally, the teenager may have frequent visits to the primary care physician's office for acute conditions that on first glance seem unrelated but later indicate possible substance abuse or a mood disorder. Some adolescents are accompanied by a family member or friend, which initially may make the teenager reticent to discuss psychosocial issues with the physician. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Text Revision* (*DSM-5*), major depressive disorder (MDD) is diagnosed when at least 5 of 9 listed symptoms or signs occur for a duration of at least 2 weeks. At least 1 symptom must be sadness or loss of interest for most of every day, and a significant change in function must exist. Changes can manifest as poor academic performance; school attendance issues, including truancy and disruptive behaviors; and difficulties with peer and familial relationships (Box 66.1).

Pathophysiology

The exact neurobiologic etiology of depression remains elusive. It is believed to involve impaired serotonin and norepinephrine transmission in critical areas of the brain, most notably the frontal lobes. Like other complex psychiatric conditions, the etiology of depression seems to be multifactorial, with a strong genetic and psychosocial/environmental basis. The genetic basis of depression is suggested by statistics that indicate, for instance, that 25% of children who commit suicide have a family member or close relative who has committed suicide. Similarly, a family history of major depression is a significant risk factor for depression in children and adolescents. Studies suggest the incomplete penetrance of a dominant gene as a possible etiology for this finding. Regardless of the exact mechanism, genetic influences can increase the adolescent's vulnerability for depression. Specific environmental events can occur in an adolescent's life that may precipitate a depressive episode, such as the loss of a loved one or parental divorce. Other events, such as physical or sexual abuse, also can trigger depression in a susceptible teenager.

Differential Diagnosis

The differential diagnosis of depression includes any condition that may alter an individual's cognition or affect. For example, if a disease alters one's nutritional status and leads to malnourishment, this may alter affect and energy, which may resemble depression (Box 66.3). Examples of such diseases include cancer, tuberculosis, and eating disorders (eg, anorexia nervosa). Endocrine disorders, such as hypothyroidism, hyperthyroidism, and Addison disease, can mimic depression. Central nervous system (CNS) pathology, although rare, includes tumors, infections, postconcussion syndromes, and cerebrovascular accidents. Concomitant systemic illnesses, such as systemic lupus erythematosus, diabetes mellitus, and AIDS, can have CNS manifestations that may be mistaken for an isolated episode of depression. Although these diseases can occur, their prevalence pales in comparison to the prevalence and significant contribution of substance and alcohol abuse. It is also important to recognize that many chronic conditions are stressful and can place patients at risk for comorbid depression. Other mental

Box 66.3. Diagnosis of Depression in Adolescents

SIGE CAPS Mnemonic

S: Sleep changes
I: Interests—decreased interest in school or activities
G: Guilt, helpless, hopeless
E: Energy (decreased), fatigue
C: Concentration decreased
A: Appetite (increased or decreased)
P: Psychomotor agitation and retardation
S: Suicidal ideation

Criteria for Major Depressive Disorder

- Depressed or irritable mood most of the day, nearly every day
- Decreased interest in most daily activities, including school
- Significant weight changes
- Sleep problems (insomnia or hypersomnia)
- Psychomotor agitation or retardation
- Low energy or fatigue
- Feelings of worthlessness or guilt
- Diminished ability to concentrate or think
- Preoccupation with death or suicide

health conditions, such as early-onset bipolar disorder, can present initially with depressive symptoms. Approximately 20% to 40% of children with MDD eventually develop bipolar disorder. In contrast, longitudinal studies have found that very few individuals diagnosed with bipolar disorder as children meet criteria for the condition as adults. Another disorder to consider in children with depressive symptoms is disruptive mood dysregulation disorder, which was introduced in 2013 to identify those children with irritability and persistent, prolonged tantrums. Additionally, children with autism spectrum disorder often develop comorbid depression during adolescence as a manifestation of their isolation and poor coping skills. Other *DSM-5* psychiatric diagnoses to consider include adjustment disorders, uncomplicated bereavement, separation anxiety, and dysthymia, which is more chronic and sometimes less severe than major depression. Finally, side effects of prescribed and over-the-counter medications may produce clinical symptoms consistent with depression and therefore should be considered in the differential diagnosis.

Evaluation

History

The assessment of an adolescent for depressive symptoms is an important part of any routine encounter. At all visits a standardized screening tool should be given to the patient to complete before seeing the medical professional. These are short, quick assessments that provide an additional means by which a teenager can communicate depression or suicidality to the health professional before the start of the in-person encounter. Two such validated questionnaires are the Patient Health Questionnaire-9 (PHQ-9), which is a self-report survey with 9 questions based on *DSM-5,* and the *Columbia-Suicide Severity Rating Scale*. The PHQ-9 is composed of 9 questions with a score that ranges from 0 to 27. A score of 5 to 9 corresponds with mild depression, 10 to 14 with moderate depression, 15 to 19 with moderately severe depression, and 20 and above with severe depression. A positive result on either the PHQ-9 or the *Columbia-Suicide Severity Rating Scale* warrants a more comprehensive and complete conversation, especially if the screening tool for suicidality raises concern based on the validated scoring criteria.

A diagnosis of depression may be difficult to make after just 1 interview. At the initial visit, along with use of a depression/suicide screening tool, a complete psychosocial or HEADSS assessment (home, employment and education, activities, drugs, sexuality [including a history of sexual abuse or assault], suicide/depression) should be performed on all adolescents (see Chapter 4). The parent(s) or guardian(s) should be included during the first part of the interview to review their observations and concerns about their adolescent's behavior and mood, after which the teenager should be interviewed alone and a thorough history of recent feelings, behaviors, and attitudes should be obtained (Box 66.4). Mood changes should be noted; a labile affect can be a symptom of ongoing depression. The physician should keep in mind that malnourishment can result in a depressed or seemingly flat affect.

Box 66.4. What to Ask

History of Depression in an Adolescent

- Does the adolescent occasionally feel sad or "blue" and not understand why?
- Does the adolescent have unexplained crying spells?
- Does the adolescent feel "mad," "bored," or "grouchy"?
- Does the adolescent seem inappropriately jovial?
- Have any recent losses occurred in the adolescent's life that may explain his, her, or their feelings?
- Is the adolescent having trouble with concentration or memory?
- Does the adolescent have trouble falling asleep at night or have early morning awaking?
- Has the adolescent lost weight recently or shown any disinterest in food?
- Does the adolescent have any self-harm (eg, cutting) behaviors?
- Does the adolescent have feelings of hopelessness and have any desire to cause self-harm? Has the adolescent made any previous suicide attempts?
- Do the parents or siblings have a history of drug or alcohol use?
- Is there a family history of affective disorders? What has been their response to treatment?
- Is there a history of family violence?

A full psychiatric assessment also should be completed to obtain information about a possible comorbid condition, including features of psychosis, anxiety disorders, disruptive behaviors, and mania. It is important to note, however, that severe depression may be accompanied by symptoms of psychosis. Information about a family history of psychiatric illness or substance abuse, including alcohol abuse, also should be reviewed with the teenager as well as the parent(s) or guardian(s).

To identify youth at risk for suicide, health professionals must inquire about specific areas of adolescents' lives. Questions should be posed in an open and direct manner, such as, "Sometimes when people are very sad or upset they think of hurting themselves. Have you ever felt this way?", not, "You don't want to hurt yourself, right?" The health professional also should probe for a history of or ongoing sexual or physical abuse, assault, violence, or neglect as well as current interpersonal conflicts, such as fights, punishments, breakups, or traumas. An early history of sexual abuse has a strong association with the manifestation of suicidal ideation by age 15 years. Feelings of hopelessness, agitation, and impulsivity should be identified, along with frequent thoughts of suicide or death. It has been reported that having frequent thoughts of suicide is the best predictor of suicide attempts. Use of any illicit substance also raises the risk for suicide attempts. The adolescent who is suspected of being at risk for suicide must be questioned directly about suicidal ideation, specifically whether the teenager has a plan in mind and access to firearms, medications, or other means of suicide. Previous suicide attempts also must be reviewed with the teenager, because 35% to 45% of adolescents who complete suicide have a positive history of a previous attempt. Nonlethal suicide gestures or other methods

of self-inflicted harm should never be taken lightly or minimized. Initial questions should be nonspecific and become more specific as the interview proceeds, especially if answers to previous questions are positive (Box 66.5).

Promises to maintain confidentiality with the depressed adolescent who is considered at risk for suicide are discouraged because parental or guardian involvement is strongly advised. Precipitating and motivating factors for any previous suicide attempts should be determined before a treatment plan is developed. More important, the lethality of previous attempts must be evaluated.

Physical Examination

A thorough physical examination and review of systems should be completed to rule out a chronic medical condition, such as hypothyroidism, inflammatory bowel disease, lupus, or anemia, or an organic etiology for nonspecific symptoms. For the patient with a history of sexual abuse or assault or of sexual activity, a genital examination should be performed to evaluate for sexually transmitted infections, taking great care to avoid further trauma to the patient. In most cases, the physical examination may be of little yield in the adolescent with a true affective disorder; however, careful examination may reveal findings such as cut marks, track marks, skin picking, or loss of tooth enamel, any of which may be helpful in diagnosing a comorbid condition, such as substance abuse or an eating disorder. A careful detailed neurologic examination, including a mental status examination evaluating eye contact, rate of speech, spontaneity in conversation, thought content, affect, and processing, is essential in differentiating various psychiatric conditions (eg, bipolar disorder, schizophrenia).

Box 66.5. What to Ask

History of Risk for Suicide in the Adolescent

- Is the adolescent on any prescribed medications (eg, isotretinoin)?
- Is the adolescent experiencing any psychiatric difficulties, social maladjustments, or family or environmental challenges (eg, recent parental divorce or separation, school expulsion)?
- Does the adolescent have a history of symptoms of depression, conduct problems, or psychosis?
- How is the adolescent progressing in school?
- Does the adolescent have a history of substance abuse?
- Does the adolescent have any legal problems?
- Does the adolescent suffer any social isolation or have interpersonal conflicts with family or friends?
- Has the adolescent suffered any personal losses recently?
- Has a suicide recently occurred in the school or community?
- Are there any family problems, such as abuse or neglect?
- Has the adolescent ever thought that life was not worth living?
- Does the adolescent ever feel hopeless?
- Has the adolescent ever thought of causing self-harm?
- Does the adolescent have a previous history of suicide attempts?
- Does the adolescent currently have a plan for suicide?
- Does the adolescent have access to firearms, medications, or other means of suicide?

Laboratory Tests

Although no routine laboratory studies are regularly recommended, several laboratory tests warrant consideration in evaluating for physiologic contributions to depression. Such tests include a thyroid panel, fasting blood glucose level, complete blood count, electrolyte test, and urine or serum toxicology screening. Laboratory studies are also important screening measures prior to pharmacotherapy; thus, in addition to the aforementioned tests, the physician also should consider a blood urea nitrogen and creatinine test, liver panel, electrocardiography, and, in females, a pregnancy test. Psychometric testing may help rule out a concomitant learning disability or attention-deficit/hyperactivity disorder.

Imaging Studies

Radiologic imaging, such as computed tomography of the head or magnetic resonance imaging of the brain, is indicated if either the history or the physical examination is suggestive of a CNS process.

Management

Depression

Management of depression typically consists of psychotherapy, pharmacotherapy, or a combination of both. The National Institute of Mental Health supports psychotherapeutic intervention for mild depression. The types of therapy shown to be most effective for adolescents with depression include cognitive behavioral therapy and interpersonal therapy. For more severe depression or depression with suicidal ideation, the current first-line medical treatment in the primary care setting involves the use of selective serotonin reuptake inhibitors (SSRIs). Pharmacotherapy may be used with the aforementioned psychotherapies. Not all therapists are trained in the delivery of these therapeutic methods, however, and in many communities these interventions are not readily available. When psychotherapy is not available or is not effective, SSRIs may be necessary.

If depressive symptoms are associated with a specific adjustment disorder, such as divorce, a recent move, or death, and if family, peers, or school factors are affected, supportive counseling is indicated. The duration and depth of counseling depends, in part, on the comfort level of the primary care physician performing this task and how receptive the adolescent and family are to this intervention. Identification of the specific problem, exploration of the teenager's response to the problem, and development of a reasonable solution with the adolescent and parent(s) or guardian(s) may be helpful to improve adherence to psychotherapy. Regardless of the existence of a clear trigger for a depressive episode, medication may still be necessary when the symptoms impair daily functioning.

If family difficulties or dysfunction is the major issue, the family, adolescent, and physician or counselor should meet to assess the magnitude of the problem and the motivation required to address it. The physician should use this opportunity to educate the adolescent and the family about the signs and symptoms of depression and

the significant effect of depression on school functioning, family and peer relationships, and social interactions. Cognitive behavioral therapy is a specific type of therapy that has been found to be particularly helpful in adolescents with depression. The need for individual cognitive-behavioral or family therapy should be discussed as well as the effectiveness of psychiatric medication in the appropriate setting. Attention to parental mental health and understanding the strategies necessary to manage the adolescent's irritability and isolation also are extremely important. Psychological referral should be initiated if the patient requires more prolonged or intensive psychotherapeutic treatment, the severity of depression seems to worsen, suicidal behavior becomes an issue and additional mental health consultation is necessary, or a comorbid psychiatric condition is suspected.

Immediate psychiatric consultation and referral are indicated if an adolescent has severe depressive features that interfere with daily functioning or if the patient is experiencing suicidal intent, homicidal intent, or psychosis. Ensuring the adolescent's safety is the priority. A mental health referral is also appropriate if supportive counseling by the primary care physician has been ineffective or in cases of recurrent or chronic depression.

Psychiatric intervention generally includes pharmacotherapy in conjunction with psychotherapy, because most cases of depression include psychological, social, and environmental components. Although much attention has been given to safety concerns about the use of antidepressant medications among children and adolescents, SSRIs are considered first-line medications for the management of moderate to severe depression in teenagers. Two SSRIs, fluoxetine hydrochloride (eg, Prozac, Sarafem) and escitalopram oxalate (eg, Lexapro), have been approved by the US Food and Drug Administration (FDA) for managing depression in adolescents, but several other antidepressants are commonly prescribed in an off-label manner. Side effects of this class of medication tend to be dose related, and most subside with time (1–2 weeks) or with dose reduction. Common adverse effects include headache, abdominal pain, diarrhea, sleep changes, and jitteriness or agitation. Serious behavioral symptoms, such as aggression, hostility, and impulsivity, must be reviewed with a psychiatrist.

In 2004, the FDA added a black box warning for antidepressant medications stating that on rare occasions children and adolescents treated with these drugs have an increased likelihood for displaying suicidal behavior; however, no increase in the risk of completed suicides was noted in a meta-analysis conducted by the FDA. Subsequently, physicians wrote fewer prescriptions for antidepressants, which resulted in an increased rate of completed suicides. It now is generally accepted that although a small risk of suicidal behavior may exist, as long as patients are appropriately monitored the benefits of prescribing antidepressants outweigh the risks. This caution should be presented in context with the risks of untreated depression and discussed openly with the parent or guardian and the adolescent. Before starting the medication, informed consent must be obtained from the parent or guardian and assent must be attained from the teenager. Patients should be observed closely for worsening of symptoms, suicidal behavior, or unusual changes in behavior. Families should be educated on the importance of close follow-up and immediate, open communication with the physician should these symptoms occur. Initially, the adolescent should be seen or the family contacted frequently during the first 6 weeks of such treatment. Improvements in vegetative functions, such as sleeping and eating, often occur within the first 3 weeks. Family observations are initially more telling than self-observation. Often, the last feature to improve is the patient's self-report of mood elevation. An adequate trial of SSRIs is reported to be at least 4 to 6 weeks. Frequent medication adjustments are not advised, and abruptly stopping SSRIs is not recommended because of the possibility for a withdrawal syndrome. Stopping medication after several weeks should include a slow taper.

Suicide and Suicidal Behavior

Adolescents who are considered at risk for suicide must be asked directly at every visit if they are suicidal and if they have a plan (Box 66.5). Past suicide attempts are the most robust predictor of a future suicide attempt. Inquiry should include probes for thoughts of death, suicidal ideation, plan for suicide, means available, and intent. The teenager should be interviewed alone in an empathic and open-ended fashion. The parent or guardian also should be interviewed separately. Positive responses to this inquiry determine whether the adolescent will be treated on an inpatient or outpatient basis. The health professional should assess for protective factors as well (Box 66.6).

A suicide risk assessment and triage resource should be used, such as the SAFE-T suicide risk assessment (Table 66.1). In most cases, the adolescent with no previous suicide attempts, who exhibits ambivalence about suicidal thoughts, with no real intent to die, and with a good family support system may be treated as an outpatient. A safety plan must be devised, however. The patient is asked to agree to contact the clinician, parent, or another responsible adult if the patient feels a suicidal urge or experiences suicidal intent. The precipitants for possible suicidal behavior must be reviewed, and alternative methods for coping should be rehearsed with the teenager. Additionally, all potential means of suicide, particularly firearms and toxic medications, must be removed from the home or place of residence. It is not enough to "secure" firearms; they must

Box 66.6. Protective Factors

- Intact reality testing
- Children in home
- Spiritual beliefs and/or practices
- Moral beliefs
- Social stigma
- Future-oriented thought
- Presence of positive social relationships
- Fear of death and/or suicide
- Problem-solving skills
- Goals and/or aspirations

Table 66.1. Suicide Threat Assessment

Risk Level	*Risk/Protective Factor*	*Suicidality*	*Possible Interventions*
High	Psychiatric disorders with severe symptoms, or acute precipitating event; protective factors not relevant	Potentially lethal suicide attempt or persistent ideation with strong intent or suicide rehearsal	Admission generally indicated unless a significant change reduces risk. Suicide precautions
Moderate	Multiple risk factors, few protective factors	Suicidal ideation with plan, but no intent or behavior	Admission may be necessary depending on risk factors. Develop crisis plan. Give emergency/crisis numbers
Low	Modifiable risk factors, strong protective factors	Thoughts of death, no plan, intent or behavior	Outpatient referral, symptom reduction. Give emergency/crisis numbers

be removed. Increased supervision must be implemented by parents or guardian as well as peers. Random room checks must be agreed on as well as an open-door policy until the therapist clears the patient for more privacy. The family also must agree to find a therapist and begin treatment immediately. An emergency plan must be developed, including "permission" to call 911. Resources should be provided. A crisis prevention card might be created that includes items such as identification of common triggers, an outline of coping skills, identification of a support system complete with telephone numbers, and the therapist's telephone number as well as a suicide hotline telephone number. Referral to a therapist is recommended as soon as possible. Preferably, this should be arranged while the adolescent is in the office, and the patient should be given a definite time and date for the appointment. Ideally, the therapist should meet with the family before the first appointment with the adolescent alone. Detoxification from drugs or alcohol, if necessary, also should be addressed with the family and teenager.

Because all suicidal threats, gestures, or ideations by adolescents must be taken seriously, emergent psychiatric referral is required for most of these individuals. The adolescent deemed to be at serious risk for suicide should be treated as an inpatient and admitted to a pediatric or adolescent unit for 72 hours of observation. The purpose of this brief hospitalization is 3-fold: to stabilize the patient medically, if necessary; to observe and evaluate patient-family dynamics; and to impress on the patient and family that the attempt has been recognized and taken seriously. Intervention requires the involvement of mental health professionals and social services. Referral to the emergency department for any patient considered to be of moderate to severe risk or anyone who concerns the health professional is crucial. It is not the role of the primary care physician to clear someone of the need for emergent psychiatric intervention.

Prognosis

The risk of recurrence of major depression in adolescents who have recovered is substantial. One study reports that 5% of patients relapse within 6 months of recovery, 12% within 1 year, and an estimated 33% within 4 years. Higher rates of recurrence have been reported, however, with approximately 70% of teenagers with MDD experiencing another depressive episode within 5 years. Additionally, youth with a depressive disorder have a 4-fold risk for experiencing the same disorder as an adult. Prepubertal-onset depression is associated with an approximately 30% risk for future bipolar disorder or mania.

The risk of repeated suicidal behavior seems to be greatest within the first 3 months after the initial attempt. Reported reattempt rates are 6% to 15% in the first 1 to 3 years after the initial attempt.

CASE RESOLUTION

The girl's symptoms may be indicative of depression, because she has a flat affect and seems to be somewhat isolated (ie, insufficient time for friends, recent move to the United States). After much inquiry, she seems to be at low risk for suicide; however, her PHQ-9 score of 11 indicates that she is at moderate risk of depression. The physician should continue to inquire about symptoms of depression and ask her directly about suicidal behaviors, then arrange for cognitive behavioral therapy and close follow up. If depression is confirmed and does not improve with therapy, medication may be indicated. If the girl becomes suicidal, she and her family should be referred to an emergency department for an emergent mental health evaluation and possible intervention, including hospital admission.

PART 5

Acute and Emergent Problems

CHAPTER 67

Fever and Bacteremia

Eric R. Schmitt, MD, MPH, FACEP, FAAP

CASE STUDY

An 8-month-old girl is brought to the emergency department with a 2-day history of fever and increased fussiness. She is irritable but consolable by her parents. Her parents believe that her immunizations are current, but they do not have the immunization record with them. On examination, she has a rectal temperature of 39.5°C (103.1°F). The rest of the physical examination is within normal limits, and no source for the fever is apparent.

Questions

1. What are the serious bacterial infections in febrile newborns and infants?
2. What has been the effect of conjugated vaccines against *Haemophilus influenzae* and *Streptococcus pneumoniae* on the incidence of bacteremia and meningitis in febrile newborns and infants?
3. What are the challenges in differentiating between serious and benign febrile illnesses in young children?
4. What diagnostic studies are recommended in the evaluation of febrile newborns, infants, and children?
5. When are empiric antibiotics indicated, and when should febrile newborns and infants be hospitalized?

Fever is among the most common chief complaints among pediatric patients seeking medical attention in physician offices, urgent care centers, and emergency departments and accounts for up to 30% of these visits. Most such patients have a benign, self-limited viral illness. Some patients, however, have a serious bacterial infection (SBI), such as meningitis, urinary tract infection (UTI) and/or pyelonephritis, pneumonia, bacteremia, septic arthritis, osteomyelitis, cellulitis, or deep tissue infection. *Bacteremia* is a bacterial infection within the bloodstream; it is considered occult in the absence of an apparent source of infection after a thorough physical examination in an otherwise healthy-appearing child.

Epidemiology

Historically, management decisions about febrile children have been largely dictated by age. Patients are typically divided into the following age-defined categories: newborns and infants younger than 90 days, infants and young children 3 to 36 months of age, and children age 3 years and older. Febrile newborns and young infants (ie, younger than 90 days) have higher rates of SBI than older children and often represent a diagnostic challenge. They have relatively immature immune systems, which renders them particularly susceptible to bacterial infections and have not yet received most of their immunizations. They often have limited responses to bacterial infections and exhibit relatively nonspecific signs and symptoms. In addition, newborns and young infants have different bacterial pathogens that can cause these serious infections, including *Escherichia coli*; *Streptococcus agalactiae* (group B streptococci); less commonly, *Streptococcus pneumoniae*; and, rarely, *Listeria monocytogenes* and other gram-negative organisms (Box 67.1). The overall prevalence of SBI among febrile newborns and infants younger than 90 days with a temperature of 38.0°C (100.4°F) or higher is approximately 10%; the rate approaches 20% in newborns younger than 28 days. Urinary tract infections are by far the most common source of SBI, with a smaller percentage having pneumonia, bacteremia, or meningitis. Contemporary studies have demonstrated that febrile newborns and young infants with diagnosed viral infections have lower rates of SBI than those without viral infections (4% and 12%, respectively). In these studies, none of the febrile newborns and young infants with viral infections confirmed on diagnostic testing had meningitis, but some did have UTIs and, rarely, bacteremia.

Febrile infants and children age 3 to 36 months are at a higher risk for bacteremia than older children but less so than newborns and young infants. Although the physical examination is more reliable in this age group than in newborns and younger infants, in many patients the examination is normal without any localizing source of infection. These individuals may, in turn, have occult bacteremia. Vaccine development and widespread immunization programs have dramatically changed the epidemiology and clinical course of bacteremia in this age group within the United States over the past several decades. Before the introduction of the *Haemophilus influenzae* type b (Hib) and pneumococcal vaccines, the prevalence rates of bacteremia were approximately 3%. During this time, *Haemophilus* was considered the most significant organism causing bacteremia because of its invasiveness and ability to cause localized infection, particularly meningitis. In the mid-1980s, the Hib vaccine was introduced, which has nearly eliminated this particularly invasive organism. In the post-Hib but prepneumococcal conjugate vaccine era, the rates of occult bacteremia ranged from 1.6% to 1.9% in children with a

[a] Hib disease has been nearly eliminated with the routine use of Hib conjugate vaccines.

temperature of 39.0°C (102.2°F) or higher and no obvious source of infection. More than 90% of cases of occult bacteremia in this age group were caused by *S pneumoniae*, with the remainder being caused by *Salmonella, Neisseria meningitides, Staphylococcus aureus,* and a few other rare organisms. Pneumococcus is not as virulent a microorganism as some other bacteria, and many cases of occult pneumococcal bacteremia resolved spontaneously without any intervention. Left untreated, a small percentage (3%–5%) went on to develop pneumococcal meningitis, which has the most serious complication and fatality rate. In 2000, the heptavalent pneumococcal conjugate vaccine was licensed by the US Food and Drug Administration for use within the United States. This vaccine provided coverage against the 7 main serotypes of *S pneumoniae*, which were responsible for approximately 80% of the cases of invasive pneumococcal disease in the United States and Canada at the time. Following the introduction of this vaccine, the rate of invasive pneumococcal disease (including bacteremia) and carriage for the serotypes covered by the vaccine dropped considerably. Additionally, there was evidence suggestive of herd immunity, in that a decline in invasive pneumococcal disease was noted among older individuals who had not received the vaccine. Consequently, a selective pressure has increased the prevalence of invasive pneumococcal disease caused by strains not covered by the heptavalent vaccine, although the overall magnitude of this effect appears to be relatively small. Additionally, other bacteria, such as *E coli, Salmonella,* and *S aureus*, appear to have increased in relative frequency as a source of bacteremia. In 2010, a new 13-valent pneumococcal conjugate vaccine (PCV13) was licensed and expanded coverage to include 6 different serotypes that have emerged with increasing frequency as a cause of invasive pneumococcal disease following the introduction of the heptavalent vaccine. The American Academy of Pediatrics and the Advisory Committee on Immunization Practices currently recommends the pneumococcal conjugate vaccine (ie, PCV13) for all infants in a 4-dose regimen to be given at 2, 4, 6, and 12 to 15 months of age. A pneumococcal polysaccharide vaccine (PPSV23) was approved in late 2014 that provides even broader protection. The addition of PPSV23 is recommended for children older than 2 years with certain high-risk chronic medical conditions after they have received PCV13. Continued surveillance of invasive disease is necessary to ascertain what effect the changes in epidemiology of these newer vaccines may have on the diagnosis and management of bacteremia in young febrile children. Preliminary data have shown a 42% decrease overall in the incidence of invasive pneumococcal infection in 2011 after the implementation of routine PCV13 immunization and a 53% decrease in the incidence in children younger than 24 months compared with years 2007 through 2009.

Clinical Presentation

In many children, fever is the only symptom or manifestation of disease and no other signs or symptoms may be apparent. These children may look well and behave normally. Young children, especially newborns and infants younger than 3 months, are likely to have fewer and more subtle behavioral signs with bacterial infections. Physicians must, therefore, maintain a high index of suspicion for the presence of an SBI, even in the absence of localizing signs (Box 67.2). Occult bacteremia, by definition, has no abnormal physical manifestations aside from fever.

Pathophysiology

Fever is an elevation in the thermoregulatory set point of the body. The thermoregulatory center is located in the preoptic region of the anterior hypothalamus, and an elevation in the hypothalamic set point above the normal body temperature initiates the physiologic changes that result in fever. Exogenous pyrogens (eg, bacteria, viruses, antigen-antibody complexes) stimulate host inflammatory cells (eg, macrophages, polymorphonuclear cells) to produce endogenous pyrogens. Interleukin-1 is currently regarded as the prototypical endogenous pyrogen. Endogenous pyrogens cause the hypothalamic endothelium to increase intermediary substances, such as prostaglandins and neurotransmitters, which then act on the preoptic neurons of the anterior hypothalamus to produce an elevated set point. The body uses physiologic mechanisms (eg, peripheral vasoconstriction, shivering) and behavioral actions

Box 67.2. Diagnosis of Serious Bacterial Illness in Children

- Lethargy, irritability, or change in mental status
- Tachycardia disproportionate to the degree of temperature elevation
- Tachypnea or labored respirations
- Bulging or depressed anterior fontanel
- Nuchal rigidity
- Petechiae
- Localized erythema, tenderness, or swelling
- Abdominal or flank tenderness
- Fever

(eg, bundling up, drinking hot tea) to increase body temperature to reach and maintain this higher set point, thus producing fever (Figure 67.1).

This contrasts with hyperthermia, in which the thermoregulatory set point of the body is normal. Because of abnormal physiologic processes, heat gain exceeds heat loss, and the body temperature rises despite efforts to return to the control set point.

Differential Diagnosis

In most cases, the duration of fever in children is short, and signs and symptoms are localized. Fever without a source involves an acute episode of fever that lasts 1 week or less in children in whom history, physical examination, and laboratory tests do not reveal a source. Most affected children are eventually diagnosed with an acute, generally benign, infectious illness. Occult bacteremia remains a major concern in young children, primarily in infants younger than 3 months. High-risk factors for occult bacteremia are presented in Box 67.3. *Fever of unknown origin* is fever of at least 8 days' duration in infants or children in whom routine history, physical examination, and laboratory assessment do not reveal a source.

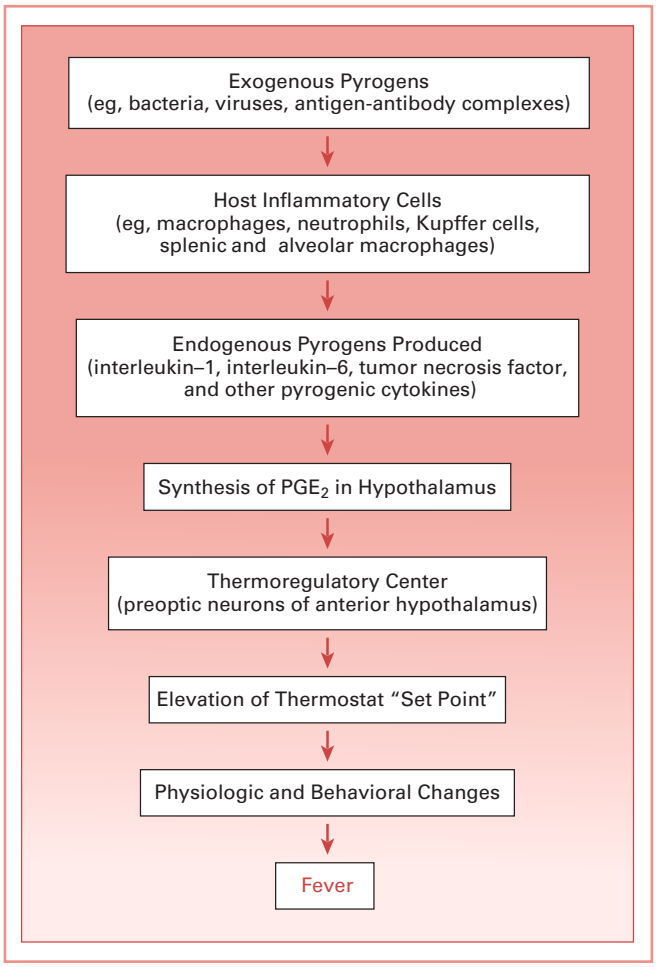

Figure 67.1. Pathophysiology of fever production. Antipyretic agents work by blocking the synthesis of prostaglandin E_2 (PGE_2).

The differential diagnosis of children with an acute febrile illness is primarily infectious (Box 67.4), including benign and generally self-limited illnesses (eg, upper respiratory infections) and less common but more serious illnesses (eg, meningitis, osteomyelitis). Occasionally, a child with a fever without a source has a

Box 67.3. Risk Factors for Occult Bacteremia

- Age 36 months or younger
- Temperature ≥39.5°C (≥103.1°F)
- White blood cell count ≥15,000 cells/mm^3 or ≤5,000 cells/mm^3
- Total band cells ≥1,500 cells/mm^3
- Erythrocyte sedimentation rate ≥30 mm/hour
- Underlying chronic disease (eg, malignancy, immunodeficiency, sickle cell disease, malnutrition)
- Clinical appearance (eg, irritability, lethargy, toxic appearance)

Box 67.4. Common Infectious Causes of an Acute Episode of Fever in Children

Upper Respiratory Tract
- Upper respiratory infection (ie, common cold)
- Otitis media
- Sinusitis

Pulmonary
- Bronchiolitis
- Pneumonia

Oral Cavity
- Gingivostomatitis
- Pharyngitis
- Dental abscess

Gastrointestinal Tract
- Acute gastroenteritis (bacterial or viral)
- Appendicitis

Genitourinary Tract
- Urinary tract infection
- Pyelonephritis

Musculoskeletal
- Septic arthritis
- Osteomyelitis

Central Nervous System
- Meningitis
- Encephalitis

Miscellaneous (Including Noninfectious Causes)
- Bacteremia
- Immunization reaction
- Viral exanthems (eg, chickenpox, measles)
- Neoplasia
- Collagen vascular disease

noninfectious illness, such as collagen vascular disease or neoplasia. By comparison, the differential diagnosis of children with fever of unknown origin is quite broad and includes infectious and noninfectious disorders (Box 67.5).

Evaluation

History

The medical history provides a great deal of valuable information in the evaluation of children with fever (Box 67.6). The history should focus on the duration and severity of the fever as well as the presence of associated symptoms that may localize an infection to a specific organ system. Additionally, caregivers should be specifically asked about infectious risk factors, such as potential sick contacts, immunization status, and chronic medical conditions.

Box 67.5. Common Causes of Fever of Unknown Origin in Children

Infectious Diseases

Bacterial
- Localized infection: mastoiditis, sinusitis, pneumonia, osteomyelitis, pyelonephritis, abscess (eg, abdominal, pelvic)
- Systemic: tuberculosis, brucellosis, salmonellosis, leptospirosis, tularemia

Viral
- Hepatitis viruses
- Cytomegalovirus
- Epstein-Barr virus (infectious mononucleosis)
- HIV

Fungal
- Disseminated coccidioidomycosis
- Disseminated histoplasmosis

Miscellaneous
- Malaria
- Rocky Mountain spotted fever
- Syphilis
- Lyme disease

Neoplasia
- Leukemia
- Lymphoma
- Hodgkin disease
- Neuroblastoma

Collagen Vascular Diseases
- Juvenile idiopathic arthritis
- Systemic lupus erythematosus
- Rheumatic fever

Miscellaneous
- Inflammatory bowel diseases
- Kawasaki disease
- Thyroiditis
- Drugs
- Factitious fever

Box 67.6. What to Ask

Fever and Bacteremia
- How long has the child had fever? How high has the temperature been?
- Does the child have any other symptoms, such as rash, vomiting, diarrhea, abdominal pain, or dysuria; cough, rhinorrhea, or other respiratory symptoms; lethargy, irritability, or change in mental status?
- Is anyone sick at home?
- Has the child's activity level changed (eg, more sleepy than usual), or is the child more irritable than usual?
- What immunizations has the child received?
- Is the child taking any medications?
- Do any pets live in the house?
- Has there been any history of recent travel, especially outside the country?
- Has the child ever been hospitalized for an infectious illness?
- Does the child have any medical problems, especially asthma, sickle cell anemia, congenital heart disease, or immunodeficiency?

Physical Examination

Rectal temperature should be obtained in all newborns, infants, and young children. Temperatures obtained by other routes (eg, axillary, oral, cutaneous) are less reliable. An elevation in rectal temperature in a newborn or an infant should not be attributed to overbundling. Other vital signs may also provide important diagnostic clues. Tachycardia disproportionate to the degree of temperature elevation may be suggestive of dehydration or sepsis. Tachypnea may be the only sign of a respiratory infection, and it also can occur in response to metabolic acidosis (eg, secondary to sepsis or shock). These changes may suggest an occult focus of infection. Response of the temperature and other vital signs to antipyretic agents should be noted; the physician must remain cautious, however, because a clinical improvement in response to antipyretic agents can occur even in the setting of an SBI. Newborns and young infants with recorded fevers at home but who are afebrile on physician evaluation should be treated as if they have a fever. The report of a tactile fever without a recorded temperature is sensitive, but not specific, and therefore overestimates the true likelihood of a fever. In newborns and young infants in whom the risk of SBI is relatively high, however, the report of a tactile temperature should be taken seriously, and these patients should be managed as though the fever were documented.

Observation of the overall hydration status and activity of the patient is extremely important. An attempt should be made to determine whether the patient is behaving and responding in an age-appropriate fashion. Physicians should look for eye contact,

spontaneous motor movements, negative responses to adverse stimuli, and positive responses to pleasant stimuli.

All febrile children should undergo a complete physical examination. This is important even when the history may suggest involvement of only 1 organ system. For example, in young children vomiting and fever may be signs of a viral illness, but they also may signal a more serious infection such as a UTI or meningitis. The underlying condition may go undiagnosed unless a thorough examination and appropriate diagnostic evaluation are performed.

The anterior fontanel should be palpated. It may be normal, bulging as a result of CNS infection, or depressed secondary to dehydration. The ears should be examined carefully and pneumatic otoscopy performed to evaluate for otitis media as the source of fever, especially in children younger than 3 years. The occurrence of otitis media should not preclude further workup for invasive bacterial disease in children who do not appear well (see Chapter 87). The oropharynx also should be examined. Dry mucous membranes may indicate dehydration. Enlarged, inflamed, or exudative tonsils may signal the presence of a viral infection or group A streptococcal infection in older children. Respiratory symptoms, such as retractions, nasal flaring, grunting, stridor, rales, rhonchi, and wheezing, may all be clues to respiratory tract infections. Enanthems on the buccal mucosa or exanthems on the skin are often signs of viral infections. The presence of petechiae in association with fever is usually benign; in rare cases, however, it may indicate a serious underlying infection, such as meningococcemia. The capillary refill time, quality of peripheral pulses, and the general temperature of the extremities can be used to assess perfusion. Localized areas of tenderness, erythema, swelling, induration, or fluctuation may point to cellulitis, septic arthritis, osteomyelitis, or the presence of an abscess. Nuchal rigidity can be an important clue to the presence of meningitis. This clinical finding is rarely present in children younger than 15 to 18 months, and physicians must rely on other clinical factors and maintain an index of suspicion for meningitis in febrile children of this age. Newborns and infants with meningitis may display paradoxical irritability, which is when crying is made worse by holding and trying to console the child.

Laboratory Tests

Newborns and Infants 90 Days or Younger

The physical examination alone cannot reliably identify an SBI in newborns and infants 90 days or younger. For all patients with a temperature of 38.0°C (100.4°F) or higher, a thorough evaluation for a bacterial source of infection is therefore required. This evaluation includes a complete blood cell count (CBC) with differential, urinalysis with microscopic evaluation, and blood and urine cultures. Cerebrospinal fluid studies and cultures should be performed on all newborns and infants younger than 29 days and strongly considered for those aged between 29 to 90 days. Peripheral white blood cell (WBC) counts, although possibly helpful in older infants and children, do not reliably predict UTIs, bacteremia, or meningitis in febrile newborns and young infants. Decisions about whether to send blood and urine cultures or to perform a lumbar puncture should not be based on the screening peripheral WBC count in this age group. Additionally, the standard urinalysis has a sensitivity of only approximately 85% in this age group and should not be used to determine the need for urine culture.

Rapid viral diagnostic techniques that can reliably identify several of the more common viral pathogens (eg, respiratory syncytial virus, influenza, adenovirus, parainfluenza) are becoming increasingly available. The presence of a positive viral test result, however, does not automatically preclude further diagnostic testing in this age group. Studies have identified a small but significant number of patients with UTIs who also happen to have a positive viral test result, and for this reason, urine culture should still be routinely obtained. The risk of bacteremia and meningitis is significantly decreased, however, and in well-appearing patients older than 1 month with a positive viral test result further testing may not be indicated or cost effective.

If empiric antibiotics are to be administered, a lumbar puncture must be performed so as not to obscure the possibility of partially treated meningitis should pleocytosis be discovered on a subsequent cerebrospinal fluid specimen. Stool analysis and culture should be reserved for febrile newborns and young infants with diarrhea. Routine diagnostic radiographic studies (eg, chest) are not necessary and should be reserved for infants with respiratory symptoms or examination findings (eg, tachypnea, hypoxia, rales, wheezes, increased work of breathing).

Infants 3 to 36 Months of Age

The diagnostic approach to older infants and young children has changed following the introduction of pneumococcal conjugate vaccines. Before widespread vaccine use, the standard of care involved an aggressive diagnostic approach looking for occult bacteremia in febrile children 3 to 24 months of age with temperature higher than 39.0°C (102.2°F) and in febrile children 2 to 3 years of age with temperature higher than 39.5°C (103.1°F) without any apparent source of infection. This historical approach included a screening CBC, blood cultures, and empirically treating infants and children with an elevated WBC count greater than 15,000 cells/mm^3 or an absolute neutrophil count (ANC) greater than 10,000 cells/mm^3 because they were at higher risk for occult bacteremia. The ANC was generally considered to be the best predictor of risk for occult bacteremia. More recently, other acute phase reactants, such as erythrocyte sedimentation rate, C-reactive protein, and procalcitonin, have been studied. These levels are all commonly elevated in serious infections but have inadequate sensitivity and specificity and have not been shown to be reliably better predictors for occult bacteremia than the peripheral WBC count or ANC. At this time other laboratory tests, including antigen testing, serum cytokine measurements, and polymerase chain reaction (quantifying the patient's molecular response to infection), are not particularly useful because of their limited availability, relatively high false-positive rates, or cost. However, there is significant interest and ongoing study of these technologies and it is probable that they will be part of patient care in the future, but currently there is no single test that has reliably identified all young febrile children with occult bacteremia.

With the declining prevalence of invasive pneumococcal disease postlicensure of the heptavalent conjugate vaccine and the further decrease with PCV13, the need for routine screening, culturing, and selective antibiotic use for occult bacteremia has been challenged. The peripheral WBC count has become a less useful screening tool in an era of such low rates of invasive disease. Additionally, the rates of contaminated blood cultures are now much higher than actual cases of bacteremia, which often results in unnecessary additional testing, hospitalization, antibiotic administration, and family stress. *Infants and children who have received at least 2 doses of the PCV13 vaccine can be safely managed without blood tests, because this is no longer a cost-effective strategy.* Individuals who are at increased risk because they are unimmunized, whose vaccine status is uncertain, or who have received only 1 dose of the vaccine may need screening evaluation with CBC, blood, and urine cultures and expectant antibiotics if they are found to have an elevated WBC count or ANC. The increase in herd immunity and change in epidemiology of bacteremia following the widespread use of the pneumococcal vaccine may warrant reconsideration of this in the future following long-term surveillance of invasive disease.

Infants with temperature higher than 39.0°C (102.2°F) warrant urine testing, especially in girls younger than 2 years, uncircumcised boys younger than 12 months, and circumcised boys younger than 6 months. Chest radiography should be considered in infants with significant respiratory symptoms or auscultatory findings suggestive of pneumonia. In infants with temperatures higher than 39.5°C (103.1°F) and WBC counts greater than 20,000 cells/mm^3, chest radiographs should also be obtained to detect occult pneumonia, which is reported in up to 25% of these patients, even in the absence of significant respiratory symptoms or auscultatory findings.

Children Older Than 3 Years of Age

The laboratory evaluation of children older than 3 years is individualized and influenced by the history and physical examination; most patients do not need any testing. Healthy children in this age group are not at high risk for occult bacteremia. The physical examination of children this age is more reliable, and they are better able to communicate their symptoms than younger children. Routine screening tests are not generally indicated in healthy individuals and should be reserved for those who appear toxic or have an underlying disease that puts them at increased risk for bacterial infections (eg, sickle cell disease, cancer, immunodeficiency, nephrotic syndrome).

Imaging Studies

As noted previously, chest radiography is the most common imaging study done in the routine evaluation of a newborn, infant, or child with fever and symptoms consistent with lower respiratory infection or with fever and no apparent source. Other imaging studies, such as bone scanning, gallium scanning, magnetic resonance imaging, and computed tomography, are indicated if infection is suspected, such as an occult abscess or osteomyelitis, and if positive imaging findings will change patient management. Brain computed tomography is not needed prior to lumbar puncture in young children without focal neurologic deficits.

Management

Management of children with fever includes controlling the fever and managing the underlying process causing the fever. No evidence exists that fever itself is harmful. To the contrary, animal studies have suggested that fever may have some survival advantage. Despite the possible beneficial effects of fever, febrile children may feel uncomfortable, and fever should be reduced to relieve the associated discomfort and malaise. Antipyretic agents, such as acetaminophen and ibuprofen, can be used. The use of both of these medications concurrently can result in dosing errors; therefore, in most cases, families should be advised to use only a single medication. Aspirin should not be used for fever control in children because of the association with Reye syndrome and viral illnesses. Sponging or bathing with tepid water and unbundling children aid in fever reduction. Ice water or alcohol baths should be avoided to prevent inadvertent hypothermia.

All toxic-appearing febrile newborns, infants, and children, regardless of age, require hospitalization and administration of broad-spectrum antibiotics. Hospitalization and the initiation of empiric intravenous (IV) antibiotics are recommended for all febrile newborns 28 days or younger pending culture results. Ampicillin and gentamicin are the most commonly used initial antibiotics within this age group; however, use of these antibiotics must be considered carefully in the context of resistance patterns and local practice within a geographic region. With the onset of standard group-B streptococcus surveillance during pregnancy and the use of intrapartum antibiotics, more gram-negative organisms and increased gentamicin resistance have been reported, necessitating the use of a third-generation cephalosporin, such as cefotaxime, for initial empiric coverage. Ceftriaxone is generally avoided in this age group, particularly among jaundiced newborns, because of its ability to displace bilirubin from albumin, thereby increasing the risk of kernicterus. The addition of empiric vancomycin and/or acyclovir should be considered for patients at risk for resistant gram-positive organisms or congenital *Herpes simplex* infection.

Well-appearing febrile infants aged 29 to 90 days may be treated on an outpatient basis with antibiotics (ceftriaxone 50 mg/kg intravenously or intramuscularly) or close observation alone, provided they meet established low risk for SBI criteria (Box 67.7). For this approach to be safe, however, parents or guardians must be reliable and have means of communication and transportation in the event of a positive culture result so that they can be notified to return the infant for reevaluation and possible admission. All febrile infants aged 29 to 90 days need very close follow-up, typically within 24 hours. Most pathogens are isolated from cultures within the first 24 hours, and hospitalization with IV antibiotics is generally warranted for any young infant with a positive culture result consistent with a pathogen. The addition of vancomycin must be considered if resistant pneumococcus is a possibility.

The management of well-appearing febrile infants and children between 3 and 36 months of age is dependent on the identification of a focal infection on physical examination or diagnostic studies. Antibiotics should be administered if a bacterial infection is identified. Well-appearing infants who are tolerating oral fluids

Box 67.7. Low-Risk Criteria for Serious Bacterial Infection in Young Febrile Infants

1. Well-appearing
2. No focal bacterial infection apparent on examination
3. Previously healthy term infant with unremarkable neonatal course
4. WBC count between 5,000 and 15,000 cells/mm^3
5. Absolute band cell count <1,500 cells/mm^3 or a band-to-neutrophil ratio of ≤0.2
6. Normal cerebrospinal fluid examination with <8 WBCs per high-power field and negative Gram stain
7. Normal urinalysis with <10 WBCs per high-power field
8. Stool studies with <5 WBCs per high-power field (if diarrhea present)
9. Normal chest radiograph (if respiratory signs/symptoms present)

Abbreviation: WBC, white blood cell.

well and have no significant respiratory distress or hypoxia can be managed on an outpatient basis, even if they have a UTI or pneumonia. Clinicians may administer a dose of ceftriaxone for the first 24 hours and transition to an oral antibiotic thereafter. Continued close follow-up is necessary, usually within 24 to 48 hours. Infants who have received 1 dose or less of the pneumococcal vaccine can receive a dose of ceftriaxone pending culture results if the WBC count is greater than 15,000 cells/mm^3 or the ANC is greater than 10,000 cells/mm^3.

Healthy and well-appearing febrile children older than 3 years can be treated on an outpatient basis if they are well hydrated and have no respiratory distress or hypoxia. Children with underlying medical conditions or who are at risk for bacterial infections may require treatment in the hospital with IV antibiotics regardless of age, depending on their individual circumstances.

Children with occult pneumococcal bacteremia who are afebrile and well-appearing at follow-up likely can continue to be treated on an outpatient basis. Additional dosing of ceftriaxone may be necessary; transition to an oral antibiotic can be considered if sensitivity testing has been performed. Repeat blood cultures likely are not necessary if the child is afebrile, because the likelihood of persistent bacteremia is low. Those who are younger than 90 days, are still febrile at follow-up, or have clinically worsened warrant hospitalization and IV antibiotics. Additionally, a lumbar puncture should be considered if not previously performed in a child with a positive blood culture. All individuals with occult *N meningitides* bacteremia warrant hospitalization and IV antibiotics. A lumbar puncture also should be strongly considered if not previously performed because of the substantial risk for meningitis with this particular microorganism. In general, most other cases of occult bacteremia warrant hospitalization and IV antibiotics. Consultation with an infectious disease specialist may be indicated to determine appropriate antibiotic selection and duration of therapy.

Prognosis

Occult bacteremia may resolve without therapy and have no sequelae, but it may persist or produce localized infections, such as meningitis or septic arthritis. In children with bacteremia who do not undergo antimicrobial therapy, the risk of persistent bacteremia is approximately 20% and the risk of meningitis is approximately 5% to 10%. These risks vary depending on which organism is isolated from the blood. In general, the risk of developing serious sequelae is greater with bacteremia caused by *H influenzae* than *S pneumoniae* (25% and 5%, respectively). Currently, concern about SBI related to either of these organisms is significantly diminished with the introduction of the conjugate vaccines.

CASE RESOLUTION

The infant is irritable and has a high fever of unknown source. Her vaccine status is uncertain. No source of her infection is revealed on physical examination. Because her fever is 39.5°C (103.1°F), she is irritable, and her immune status is uncertain, a complete laboratory assessment, including a lumbar puncture, should be performed. Management should be determined after all laboratory data are available. If laboratory assessment reveals a focus of infection, such as a UTI, she should be managed with antibiotics. If laboratory assessment does not reveal a source for the fever and her WBC count is greater than 15,000 cells/mm^3 or her ANC is greater than 10,000 cells/mm^3, she can be administered an intramuscular injection of ceftriaxone as expectant management for occult bacteremia and undergo reevaluation in 24 hours or undergo treatment without antibiotics.

CHAPTER 68

Emerging Infectious Diseases

Christian B. Ramers, MD, MPH, AAHIVS, and Thomas R. Hawn, MD, PhD

CASE STUDY

A previously healthy 8-year-old boy is brought to his pediatrician's office in late August with 2 days of fever, fatigue, headache, myalgias, nausea, and gingival bleeding. On the morning of the visit his mother noted a rash on his legs. He lives with his family in the Northeastern United States but recently returned from a 1-week vacation in Key West, Florida. He engaged in extensive outdoor activities, including snorkeling, hiking, and several evening boat trips, and he sustained multiple mosquito bites during the trip. He received all routine childhood immunizations, denies any allergies, and takes no medications. No other family members are ill.

On physical examination, his temperature is 38.7°C (101.7°F) and he is generally ill-appearing. He has photophobia and mild meningismus, and a petechial rash is noted on his trunk and lower extremities. Laboratory studies sent from the office reveal microscopic hematuria, leukopenia (white blood cell count 2,800 cells/mm^3), and thrombocytopenia (platelet count 85,000 platelets/mm^3).

Questions

1. What is an emerging or reemerging infection?
2. What pathogens are associated with emerging infections?
3. What are some common or emerging infectious diseases that may cause the clinical syndrome in the case scenario?
4. How does recent travel influence the differential diagnosis?
5. What resources can a primary care physician access to help in making a diagnosis?

Emerging and reemerging infectious diseases are defined as those for which the incidence in human populations has increased in the past 2 decades or threatens to do so in the near future. They may represent the resurgence of an ancient human scourge, a novel zoonosis that has broadened its host range, a common pathogen that has acquired a new antimicrobial resistance profile, or more rarely a previously unidentified or unknown microorganism. A startling diversity of organisms has met these criteria, including viral, bacterial, fungal, and parasitic pathogens. Likewise, a variety of factors affect the emergence or reemergence of these pathogens, including range and susceptibility of human hosts, evolution and antigenic shift of the pathogen, and ecological and environmental changes, such as vector amplification or breakdown of public health measures. Although a select few of these emerging pathogens represent malicious propagation or bioterrorism, most appear spontaneously at ambulatory or emergency health facilities and thus are relevant to the practicing primary care physician. It has only been through astute clinical observation, targeted outbreak investigation, and a coordinated public health response that many emerging infectious diseases have been identified.

In this chapter we review the factors involved in the emergence and reemergence of infectious diseases of public health significance, discuss several specific examples that are likely to be most relevant to pediatric practice, summarize regional and global outbreaks of emerging infectious diseases, and provide practical steps for the primary care physician to access local diagnostic and public health support.

Contributing Factors

The spectrum of infectious diseases has always changed and evolved along with societal and environmental changes. Literature supports the supposition that throughout human history, several general driving forces influence the emergence or reemergence of certain infectious diseases. The most important factors are human migration, environmental and ecological changes, changing patterns of human host susceptibility and immunity and, more recently, the use and overuse of antimicrobial agents. Table 68.1 shows some of the mechanisms identified in recent emerging infectious diseases and provides illustrative examples from the United States and abroad. In reality, many simultaneous contributing factors often are at play, and diseases may emerge or retreat within human populations without clear drivers. Common themes that result in recognizable emergence events typically couple a vulnerable host population with a pathogen to which that population lacks immunity or prior exposure.

Pediatric populations are particularly susceptible to emerging and reemerging diseases in several of these categories. The recent Zika virus epidemic has also shed light on the particular risks to the fetus in the setting of a newly emerging or reemerging infection. After immunity from acquired maternal antibody wanes, children

Table 68.1. Factors Contributing to Infectious Disease Emergence/Reemergence

Contributing Factor	*Examples*	*Illustrative Pathogens*
Societal change	Economic impoverishment Population growth or migration Globalization of food distribution Urban decay	Cholera, malaria, salmonella
Advances in health care	New medical devices Organ transplantation Drugs causing immunosuppression Use of antimicrobial agents	Aspergillosis, cytomegalovirus, methicillin-resistant *Staphylococcus aureus*
Human behavior	Worldwide travel Injection drug use Sexual activity Outdoor recreation activities	HIV/AIDS, hepatitis C virus, histoplasmosis
Environmental changes	Deforestation/reforestation Flood/drought Global warming	*Cryptococcus gattii*, dengue, *Burkholderia pseudomallei*
Public health infrastructure and control	Reduction of prevention programs Inadequate surveillance Waning immunization rates	*Mycobacterium tuberculosis* (multidrug-resistant and extensively drug-resistant), measles, mumps, pertussis
Microbial adaptation and change	Antigenic drift/shift Changes in virulence factors Development of drug resistance	H1N1, H5N1, and H7N9 influenza; chloroquine-resistant malaria; vancomycin-resistant enterococci

Derived from Morens DM, Folkers GK, Fauci AS. The challenge of emerging and re-emerging infectious diseases. *Nature*. 2004;430(6996):242–249.

develop adaptive immunity on their own and may experience up to 12 upper respiratory and/or diarrheal diseases per year. In some cases an unexplained increase in pediatric mortality from a typical clinical syndrome, such as upper respiratory or flu-like illness, may be the harbinger of an emerging pathogen. Large institutional settings, such as child care centers and schools, place children at high risk for exposure to infectious agents via close contact, and respiratory and droplet spread. Similarly, differing hygiene practices, such as handwashing, cough etiquette, sharing of fomites, and fecal/urinary incontinence, place infants and children at particular risk of exposure.

Antimicrobial agents are commonly prescribed in the primary care setting for otitis media, pharyngitis, and respiratory infection, and overuse of antibiotics in this setting has been associated with an increased risk of colonization and infection with drug-resistant organisms. In many cases, what was once a first-line therapy for a particular clinical syndrome must be reconsidered because of the emergence of altered antibiotic susceptibility patterns. Advances in medical care has resulted in growth in the number of vulnerable hosts through increased survival of preterm infants, cancer chemotherapy, organ transplantation, and the use of immunosuppressive or immunomodulatory agents. Additionally, because of parental belief systems, personal choice, and lack of access, immunization rates in certain regions remain suboptimal, placing children at risk of acquiring vaccine-preventable disease.

Special Situations

Increasingly, primary care physicians are required to carefully consider the risks of emerging or reemerging infectious diseases. Some of the unique clinical settings in which less common or emerging infectious diseases warrant consideration include expanded international travel, immigration and international adoption, immune suppression and immunomodulation, and the unvaccinated or undervaccinated child.

Expanded International Travel

With the increasing accessibility of long-distance international travel, children are more frequently being included in tourist trips or, in the case of immigrant families, visits to friends or relatives in their home country. Children are less likely to seek pretravel advice and consequently are less likely to adhere to recommended travel guidelines. A report from GeoSentinel, a large group of worldwide travel clinics, found that only 32% of children visiting friends and relatives in developing countries received recommended travel vaccines or prophylactic medications even though they were more likely to present with illness and require hospital admission after travel. Primary care physicians evaluating returning travelers must consider detailed travel history, prophylaxis or protective measures taken (if any), risk profile of the region visited, and incubation period of

the suspected pathogen. Although by far the most common travel-related illnesses are self-limited diarrheal disease, emerging infections, such as Ebola, Zika, dengue, chikungunya, and H5N1, H7N9, or H1N1 influenza, must be considered along with other infectious diseases, such as malaria and tuberculosis.

Immigration and International Adoption

Increasing rates of international adoption or recent immigration may result in evaluation by primary care physicians of children with unknown or unavailable birth, early childhood, or immunization histories (see Chapter 37 and Chapter 39). Vaccine schedules vary by country of origin, including some vaccines that are no longer given in the United States (eg, bacille Calmette-Guérin, live oral polio virus vaccine). Considerable variation exists in reliability of medical reporting in these situations, with some countries achieving or exceeding developed world standards but most providing reports of dubious quality. Many physicians who specialize in "adoption clinics" or work in settings with large immigrant populations obtain serologic evidence of prior immunization (eg, measles, mumps, varicella, polio, diphtheria, tetanus). Physicians must also be aware of infections with clinically silent latent phases (eg, viral hepatitis, latent tuberculosis, intestinal helminth infections, HIV). Several emerging or reemerging infectious diseases in the United States may be endemic in the countries of origin of adopted or recently arrived immigrant children.

Immune Suppression and Immunomodulation

Therapeutic advances in pediatric oncology, organ transplantation, rheumatology, and care of chronic congenital conditions have resulted in an increasing population of children with immunosuppression. Although typically under the care of specialists, these children may have a medical home in a primary care facility and thus can present with an opportunistic or emerging infectious disease to their primary care physician. The spectrum of risk for infectious diseases varies considerably depending on the type of immunosuppression. For example, tumor necrosis factor-α inhibitors, which are commonly used in the management of juvenile idiopathic arthritis, convey a particularly high risk of fungal and mycobacterial infection. Neutropenia from cytotoxic chemotherapy is associated with an increased risk of bloodstream bacterial infection among others. Similarly, lymphopenia related to solid organ transplantation portends a particular vulnerability to viral infections, ranging from widespread community respiratory viruses to reactivation of common agents, such as varicella-zoster virus. Emerging infectious diseases, such as new coronaviruses (Middle East respiratory syndrome coronavirus [MERS-CoV], severe acute respiratory syndrome [SARS]), human metapneumovirus, or H1N1 influenza, may have particularly severe clinical manifestations in children with immunosuppression compared with the general population.

Unvaccinated or Undervaccinated Child

Despite the ongoing efforts of public health authorities, some regions have noted a worrisome downward trend in immunization rates. Although the most widely cited study linking autism to measles, mumps, rubella (MMR) vaccination was retracted by the *Lancet* in February 2010, several recent parental surveys indicate persistent beliefs about a suspected vaccine–autism link. In 2004, the Institute of Medicine Immunization Safety Review Committee published a comprehensive report that found no convincing evidence of a causal link between the MMR vaccine or any thimerosol-containing vaccine and autism. In a survey of 1,552 parents conducted in 2009, however, 25% agreed with the statement, "Some vaccines cause autism in healthy children." Decreasing vaccination rates have resulted in increased risk for outbreaks of reemerging infectious diseases. Measles was officially declared "eliminated" (defined as the absence of endemic measles transmission for >12 months) in the United States in the year 2000. During the first 8 months of 2019, however, more than 1,200 cases of measles were reported in more than 30 states; 75% of the cases occurred in New York State, where individuals had not been vaccinated. This is the greatest number of cases reported since 1992. This compares with a median 60 cases reported annually every year from 2001 through 2011. Similar to resurgent measles outbreaks, a 2010 to 2011 pertussis epidemic in California became the largest since 1955, affecting more than 9,000 individuals and causing 10 infant deaths. Thus, it is crucial for physicians to include vaccination status and exposure history when evaluating children with an infectious syndrome. Increasingly, the differential diagnosis and diagnostic workup must include emerging and reemerging diseases, some of which may be unfamiliar to physicians from their training or clinical experience.

Select Emerging Pathogens

Major emerging and reemerging infectious diseases of the past 20 years are shown in Figure 68.1 and Table 68.2. The table is not meant to be an exhaustive list, but rather a sampling of emerging pathogens most likely to present to a primary care physician.

Viruses

Zika

Zika is a flavivirus that was initially isolated from a monkey in the Zika forest in Uganda in 1947. The geographic distribution was previously thought to be limited to Africa with mild clinical manifestations. From 2007 to 2014, however, Zika caused outbreaks in several of the Pacific Islands, after which a major epidemic emerged in Brazil in 2015 with rapid spread throughout the Americas, with outbreaks in the United States in 2016. Currently, Zika is present in more than 80 countries in Africa, Asia, and the Americas. *Aedes aegypti* as well as other *aedes* species are the primary vectors with a predilection for urban environments, similar to dengue, chikungunya, and yellow fever. Non-vector routes of transmission include blood transfusions and sexual contact.

Major features of the reemergence of Zika include both the expanded geographic distribution and discovery of its cause of severe fetal neurologic infections. Zika is neurotropic and targets neural progenitor cells in the developing brain. The resurgence of Zika in

Bethesda, MD: National Institute of Allergy & Infectious Diseases; 2017. https://www.niaid.nih.gov/news-events/three-decades-responding-infectious-disease-outbreaks

the Americas has included clinically devastating congenital central nervous system (CNS) malformations, including microcephaly, ventriculomegaly, cerebral calcifications, and ocular abnormalities. In adults, approximately 50% of infected individuals have no symptoms, with the remaining developing a rash, fever, conjunctivitis, and arthralgias. Uncommon manifestations include Guillain-Barré syndrome. The cause of the apparent shift to more prominent CNS clinical manifestations of the recent epidemics is not known. Genetic data indicate that Zika acquired a single amino acid mutation in a surface protein that causes increased neurovirulence, viral replication, and rates of microcephaly in cellular and animal models. This mutation appeared in approximately 2013 and has been stably transmitted during the epidemic. Although this genetic change may explain the new clinical manifestations, it remains possible that neurologic involvement was not previously apparent because of a lower disease incidence.

Several issues are important for clinical management of Zika, including transmission prevention, evaluation and treatment of pregnant women, and treatment of infected neonates. Prevention of vector-borne transmission includes mosquito precautions as well as avoiding or postponing travel during pregnancy. Travel-related precautions pertaining to sexual transmission extend to the post-travel time period because Zika can persist in bodily fluids (eg, RNA is detected for approximately 2 weeks in plasma, 6 weeks in urine, and up to 6 months in semen). Currently, the CDC recommends that men wait at least 3 months before engaging in unprotected sex if they are planning to conceive with their partner and may have had a Zika virus exposure. Previously, the waiting period was 6 months, but the recommendation was updated based on data indicating that the longest period from symptom onset to potential sexual transmission was 32 to 41 days. Evaluation of pregnant women for possible Zika infection includes exposure risk assessment, symptom assessment, and diagnostic testing options that are tiered based on time from exposure and stage of pregnancy. Potential diagnostic tests include nucleic acid tests in serum and urine, immunoglobulin (Ig) M serology, and a plaque reduction neutralization test. For pregnant women diagnosed with acute Zika virus infection, further diagnostic testing in the form of ultrasonography and amniocentesis can be performed to assess for fetal infection and complications. Currently, no specific treatment or vaccine is available for Zika virus.

Table 68.2. A Sampling of Recent Emerging Infectious Diseases

Pathogen	*Clinical Syndrome*	*Diagnosis*	*Management*
Zika virus	Adult: asymptomatic or viral exanthem with arthralgias Fetal: severe CNS malformations	Exposure/symptom assessment, IgM, PCR	Supportive
Ebola virus	Hemorrhagic fever	Clinical case definition Confirm on serology, PCR testing	Supportive Experimental therapies: convalescent serum, monoclonal antibodies, experimental antiviral agents, preventive vaccine
Measles virus	Measles Pneumonia Postinfectious encephalitis	Clinical Confirm with IgM	Supportive Consider antibiotics for bacterial superinfections
Mumps virus	Parotitis Orchitis Encephalopathy	Serology Culture PCR testing	Supportive NSAIDs
Dengue virus	Unspecified febrile illness Dengue fever Dengue hemorrhagic fever	Serology	Supportive Aggressive fluid management
Influenza virus (H1N1 [2009], H5N1 [2007], H7N9 [2013])	Fever, respiratory symptoms	PCR or antigen testing	Oseltamivir phosphate, zanamivir, amantadine hydrochloride, rimantadine hydrochloride
Coronavirus (ie, SARS, MERS-CoV)	Fever, respiratory symptoms	PCR testing	Supportive
Chikungunya virus	Febrile syndrome with arthralgias, rash, conjunctivitis	Clinical Confirm with serology, viral culture, or PCR testing	Supportive, NSAIDs
WNV	Asymptomatic West Nile fever West Nile encephalitis (flaccid ascending paralysis)	Serology WNV antigen or PCR testing IgM in CSF	Supportive (ribavirin and interferon-α-2b are experimental)
MRSA	Skin and soft tissue infections, bacteremia, pneumonia	Culture and susceptibility	Antibiotics
Resistant gram-negative bacteria	Pneumonia, UTI, bacteremia, sepsis	Culture and susceptibility	Antibiotics
Resistant *Streptococcus pneumoniae*	Pneumonia, meningitis, otitis media	Culture and susceptibility	Antibiotics
Ehrlichiosis/anaplasmosis	Fever, headache, myalgia, rash	PCR testing or peripheral blood smear	Doxycycline
Cryptococcus gattii	Pneumonia, meningitis	Culture or cryptococcal antigen testing	Amphotericin, 5-FC, fluconazole

Abbreviations: 5-FC, 5-fluorocytosine; CSF, cerebrospinal fluid; CNS, central nervous system; Ig, immunoglobulin; MERS-CoV, Middle East respiratory syndrome coronavirus; MRSA, methicillin-resistant *Staphylococcus aureus*; NSAIDs, nonsteroidal anti-inflammatory drugs; PCR, polymerase chain reaction; SARS, severe acute respiratory syndrome; UTI, urinary tract infection; WNV, West Nile virus.

Ebola

First described near the Ebola river in Zaire (now the Democratic Republic of Congo [DRC]) in 1976, Ebola virus is a member of the genus *Filoviridae* of hemorrhagic fever viruses. Although until recently only seen in sporadic and remote outbreaks in sub-Saharan African villages, Ebola's reputation has far outpaced its reach because of a case fatality rate of 88% in early descriptions of the first outbreaks. Four species are known to cause disease in humans, with variable geographic footprints and virulence. *Sudan ebolavirus* has a case fatality rate of approximately 50% and has caused several moderate-sized outbreaks in the border region of Sudan, Uganda, and the DRC. *Zaire ebolavirus*, the most lethal species, has caused most of the sporadic outbreaks throughout sub-Saharan Africa, including the largest outbreak ever recorded in 2014 to 2016 that engulfed several West African countries, with approximately 28,600 cases and more than 11,000 deaths. *Bundibugyo ebolavirus* is a third species discovered in 2007 that has caused 2 well-documented outbreaks in the DRC and along the border of the DRC and Uganda. Finally, *Taï*

Forest ebolavirus has been identified in a single case in Côte d'Ivoire in West Africa. At the time of publication, an ongoing outbreak of the *Zaire ebolavirus* is occurring in the North Kivu and Ituri provinces of DRC, with at least 129 confirmed or probable cases and 89 deaths.

Although the reservoir of Ebola is unknown, scientists suspect a fruit bat or non-human primate may serve as the natural host, with uncommon "spillover events" occurring after direct human-to-animal contact. Human-to-human transmission can occur after 1 of these events via direct contact (through broken skin or mucus membranes) with infected blood or body fluids, including urine, saliva, sweat, feces, vomit, human milk, and semen. Importantly, human-to-human transmission does not occur in the absence of symptoms. No evidence exists indicating that mosquitos or other insects can transmit Ebola, and secondary foodborne transmission is not thought to occur except from direct consumption of the meat of an infected primate.

After an incubation period of approximately 8 to 10 days (range, 2–21 days), Ebola causes an array of nonspecific systemic symptoms, such as fever, nausea, vomiting, diarrhea, weakness, severe headaches, myalgias, and abdominal pain. The diagnosis should be suspected in cases with both a combination of suspected symptoms and a possible exposure to Ebola virus within the previous 21 days. Isolation of "patients under investigation" and strict contact precautions are necessary to contain outbreaks and prevent spread to health care personnel. Specialized molecular testing for viremia is available in public health laboratories and is typically positive within 3 days of the onset of symptoms.

The pathophysiology of Ebola virus disease (formerly Ebola hemorrhagic fever) involves massive fluid, electrolyte, and protein wasting as well as capillary leak and hemorrhage with resultant blood loss, dehydration, oliguria, circulatory collapse, and respiratory failure. In a well-studied case series of 27 patients evacuated from the West Africa outbreak to the United States or Europe, peak plasma viral RNA levels occurred at a median of 7 days and was cleared a median of 17.5 days after onset of symptoms. With maximal supportive care as well as experimental therapies in 85% of patients, the case fatality rate in this cohort was 18.5%, which was lower than previously reported.

Postmortem human-to-human transmission of Ebola has occurred as well, particularly related to burial rituals such as cremation, cleansing of bodies, and postmortem autopsy evaluations. The CDC has developed guidelines for safe handling of human remains focusing on the use of personal protective equipment as well as proper disposal of medical equipment and safe interment of the body. In survivors who recover from the infection, ocular complications and lingering arthralgias have been described. Persistence of virus has also been observed in immune-privileged sites, such as aqueous humor, cerebrospinal fluid (CSF), and semen; however, the transmission dynamics of convalescing patients are poorly understood.

The foundation of managing Ebola virus disease is supportive care, principally intravenous hydration and electrolyte replacement, oxygen and mechanical ventilation as necessary, renal replacement therapy, blood pressure and blood product support, and antibiotic treatment for any suspected secondary infections. After intensive ethical discussions, experimental treatments were mobilized during the 2014 to 2016 West Africa outbreak, including transfusions using convalescent serum of survivors, monoclonal antibody combinations (ie, ZMapp, ZMab, MIL77), antiviral drugs thought to have inhibitory activity against Ebola (ie, TKM-Ebola, favipiravir, brincidofovir, amiodarone), and agents purported to counteract capillary leak (ie, FX06, melanocortin). No agents have been approved by the US Food and Drug Administration for use in individuals with Ebola virus disease, and each of these cases underwent considerable ethical scrutiny and evaluation.

Prevention of Ebola virus disease has relied mainly on early diagnosis as well as strict isolation and infection control procedures. An experimental vaccine was developed and preliminarily tested in 2015 in Guinea during the large outbreak in that country. In a small trial, the vaccine appeared to be highly protective against Ebola virus disease. The National Institutes of Health is conducting an ongoing open label, pre-exposure clinical trial in adults at potential occupational risk.

Measles

Measles, which is caused by a virus from the Paramyxoviridae family, began to decline as a major threat in the United States after a safe and effective vaccine was developed in 1963. A significant resurgence occurred between 1989 and 1991, however, largely because of a pool of vulnerable, unvaccinated preschool-age children. Nearly 55,000 cases and 130 deaths occurred in the United States, prompting a renewed effort at prevention through vaccination. A second dose of vaccine for school-age children was also recommended after this outbreak. Another resurgence of new cases occurred after 2004, but with new epidemiologic features; 90% of the cases were either directly imported from travelers or immigrants, or were associated with importation from outside the United States. Large outbreaks in the United States have been reported in 2008, 2011, 2013, 2014, and 2019.

Measles is a highly contagious pathogen passed via respiratory droplets. Secondary transmission is thought to be greater than 90% among susceptible household contacts. Approximately 10 days after exposure, clinical illness is characterized by a distinctive febrile prodrome (ie, conjunctivitis, coryza, cough), followed by Koplik spots (blue-gray enanthem on buccal mucosa) and, ultimately, the classic maculopapular erythematous eruption. Diagnosis is usually ascertained based on clinical evidence alone given the distinct clinical presentation; however, for confirmatory testing, the immunoglobulin (Ig) M serology is nearly 100% sensitive if performed after the onset of rash. Respiratory droplet isolation should occur until 4 days following appearance of the rash in immunocompetent patients and until the clinical illness resolves in those who are immunocompromised. Treatment is largely supportive; however, respiratory and neurologic complications can occur in 6% and 0.1% of patients, respectively. Further control of this reemerging infectious disease will likely depend on renewed attention to domestic vaccination efforts and the roll-out of vaccination worldwide.

Mumps

Although the clinical syndrome of the mumps virus is distinct from that of measles, the 2 members of the Paramyxoviridae family share

a similar history of initial control and recent reemergence. A live, attenuated mumps vaccine was licensed in 1967 and incorporated into the Advisory Committee on Immunization Practices recommended schedule by 1977. Due to high vaccination rates, mumps had declined by more than 99% by 2005. However, there have been 2 major resurgences in the United States. In 2005 to 2006 a total of 6,584 cases were reported in a multistate outbreak in the Midwestern United States. Although numerically most of these cases occurred among college students who had been previously vaccinated, attack rates were considerably higher in unvaccinated individuals. Equally large outbreaks involving more than 6,000 cases were reported in 2016 and 2017. During the first 8 months of 2019, there were more than 2,360 reported cases in 47 states.

The clinical presentation of mumps typically involves fever, malaise, and parotitis. Complications are rare, but in some studies up to 10% of patients had aseptic meningitis, of which hearing loss is an important sequela. Up to 37% of adolescent and adult males can present with orchitis, which may result in sterility. Diagnosis is typically made based on a compatible clinical syndrome with confirmation by isolation or polymerase chain reaction (PCR)-based detection of the virus from saliva, CSF, urine, or semen. Immunoglobulin M serology is also a useful confirmatory method.

Management is generally supportive, with analgesics used for the pain of parotitis and/or orchitis. For severe cases, intravenous Ig has been used to mitigate immune-mediated postinfectious complications, and interferon-α-2b has been used to alleviate orchitis.

The previously discussed outbreaks have been the focus of considerable scrutiny as indicators of vaccine effectiveness and community vaccination rates. Based on extensive analyses, MMR vaccine is still considered to be 80% to 90% effective after 2 doses. However, a significant portion of the population remains vulnerable to occasional outbreaks. No change was made to immunization schedules or interim recommendations after these outbreaks.

Dengue

Dengue fever virus is a member of the Flaviviridae family and is known to occur in 4 serotypes. It is transmitted via a vector, usually *A aegypti,* and is present in more than 100 countries throughout the Americas, Asia, and Africa. Although historically dengue fever virus was confined to tropical and subtropical regions roughly overlapping with malarial zones, its range is expanding. In the United States, no cases of locally acquired dengue were reported between 1946 and 1980. Since 1980, sporadic cases have been reported along the United States–Mexico border, but in 2009 to 2010 a small outbreak of locally acquired dengue occurred in Key West, Florida. During the first 8 months of 2019, 408 cases were reported in the United States, with 6 additional cases in US territories. The worldwide incidence of dengue has increased at least 4-fold in the past 3 decades for unclear reasons.

Clinical manifestations occur over a wide spectrum, from asymptomatic seroconversion to severe, even fatal disease. Headache and petechial rash are common. Classically the disease is thought to occur in 3 forms: undifferentiated febrile illness, dengue fever, and dengue hemorrhagic fever. In reality, however, clinical manifestations are diverse and may include hepatitis, myocarditis, pericarditis, and encephalopathy. Leukopenia and thrombocytopenia are common laboratory findings, and in severe cases, a coagulopathy and bleeding manifestations seem to be the most dangerous sequelae. Diagnosis can be made with a compatible clinical history and confirmed on serologic testing. No direct-acting antivirals exist, nor is a vaccine available. Care is generally supportive.

Influenza Viruses

In 2009, a novel strain of influenza A known as H1N1 caused the first global influenza pandemic since 1968, with an estimated 59 million illnesses and 12,000 deaths in the United States alone. Although early in the year it seemed as though "bird flu" or H5N1 influenza would be the greatest concern to public health, it was a different strain of swine origin that resulted in a global pandemic. In April 2013, a different strain of bird flu known as H7N9 emerged in China with a disturbing 28% case fatality rate. Like the related H5N1 strain, however, human-to-human transmission was not observed, and outbreaks have been limited to clusters of individuals with very high levels of exposure to poultry.

Influenza viruses have a segmented genome and thus are able to adapt and evolve quite rapidly to evade slower adaptive immune responses. Through antigenic drift, small changes occur in cell surface genes through time, resulting in subtle structural changes to the cell surface proteins neuraminidase and hemagglutinin and decreased recognition by the immune system. In antigenic shift, genome segments from diverse strains recombine in a single new virus particle, resulting in abrupt and substantial changes in antigenic variation. Typically, shifts are more likely to cause pandemics because of the increased number of nonimmune hosts in the population.

Although the clinical manifestations of H1N1 influenza seemed to be similar to those of prior influenza outbreaks, this strain resulted in more severe cases and higher mortality in previously healthy young people than in typical influenza epidemics. Testing for H1N1 most commonly involves antigen-based PCR methods with variable sensitivities and specificities. Management of severe cases consists either of oral oseltamivir phosphate or inhaled zanamivir. Although oseltamivir phosphate resistance outside the United States has been reported, it remains the drug of choice.

The more recently recognized H7N9 strain seems to be more virulent than H1N1, with a high proportion of patients presenting with severe pulmonary manifestations. In the preliminary reports of the first 111 patients in China, 77% were admitted to an intensive care unit and 28% died. Because of the ability of influenza virus to change rapidly with genetic drift and shift, health officials are on alert for any increase in H7N9 activity in the fall influenza season. The 2018 to 2019 influenza season was moderately severe, and the 21-week season was longer than seasons from the prior 10 years. The 2 major strains were H1N1 and H3N2.

Chikungunya

A vector-borne disease transmitted primary by *Aedes* species mosquitoes, chikungunya was first described in Tanzania in 1953. It

often occurs in epidemic outbreaks rather than steady endemic patterns and is most commonly seen in tropical Africa and Asia. More recently, outbreak ranges have expanded slightly, occurring in Italy and Madagascar. Chikungunya virus disease became a nationally notifiable condition in 2015. A total of 156 chikungunya virus disease cases with illness onset in 2017 have been reported from 28 US states. All reported cases occurred in travelers returning from affected areas. No locally transmitted cases have been reported in the United States. The clinical hallmark of chikungunya fever is the presence of intense arthralgias and occasionally frank arthritis after a febrile illness with rash and conjunctivitis. Whereas the clinical illness of malaise and fever may last days to weeks, the joint symptoms may last months to years. Other than the possibility of persistent and nagging arthralgias, severity is typically mild, and fatality is rare. Management of chikungunya is generally supportive, because no specific antiviral agents are available.

Coronaviruses: Severe Acute Respiratory Syndrome and Middle East Respiratory Syndrome

From 2002 to 2004, an epidemic of severe pneumonia resulting from a previously unrecognized coronavirus (ie, SARS-CoV) caused considerable international concern because of its highly infectious nature and high mortality rate. Epidemiologic studies resulted in identification of palm civets as the main reservoir of transmission to humans from contact in the marketplace. Further studies suggested that horseshoe bats were the likely natural reservoir. The epidemic, which originated in China, eventually spread to 29 countries with an overall mortality rate of 9.6%, which included numerous health workers. Clinical features included a mean incubation period of 4.6 days, with a presentation of severe pneumonia with a high rate of respiratory failure. Additional clinical manifestations included watery diarrhea and hepatitis. Common laboratory features included lymphopenia, neutropenia, and disseminated intravascular coagulation. The cornerstone of management was supportive care. Although many individuals received ribavirin, no proven role for it or any antiviral agent existed during the outbreak. Despite the impressive nature of this epidemic, it subsided rapidly and no evidence exists of ongoing SARS-CoV transmission. This epidemic highlighted an agent with high transmissibility, morbidity, and mortality but with only a transient global impact.

In 2012, a second emerging coronavirus was identified as the cause of a severe acute respiratory infection in a patient in Saudi Arabia. From 2012 to 2013, 130 cases were reported, all of which involved direct or indirect travel or residence in 4 countries: Saudi Arabia, Qatar, Jordan, and the United Arab Emirates. The reservoir has not been conclusively established yet, although a zoonotic origin has been suggested resulting from the identification of related coronaviruses in bats and camels. As of 2017, approximately 2,000 cases have been confirmed in countries in the Arabian peninsula. The clinical features include an incubation period of 5.2 days with symptoms that range from none or mild to severe disease, including death in 45% of reported cases. A large proportion of patients (96%) have underlying comorbidities, and 80% required ventilatory support.

Bacteria: Drug-Resistant

Community-Acquired Methicillin-Resistant Staphylococcus Aureus

Methicillin-resistant *S aureus* (MRSA) strains were recognized shortly after the introduction of methicillin in the 1960s and have been a substantive problem in health care settings for several decades. Health care-associated MRSA (HA-MRSA) has well-established risk factors, including exposure in the health care setting (eg, hospital, nursing facility) and the presence of comorbid medical conditions (eg, malignancy, chronic liver or lung disease, indwelling catheters). In the 1990s, a new strain of community-acquired MRSA (CA-MRSA) appeared that was not associated with these traditional risk factors, because often it was found in otherwise healthy individuals with no health care–related exposure. Furthermore, CA-MRSA carries the *mecA* resistance gene on a type IV or V cassette chromosomes in contrast to HA-MRSA, which carries type I through III cassette chromosomes. Community-acquired MRSA is also more likely to contain the Panton-Valentine leukocidin genes, which may encode virulence factors that influence clinical symptoms. These genotypic differences have facilitated epidemiologic studies that suggest that CA-MRSA is a distinct MRSA strain that has increased in frequency throughout the United States and is a bona fide emerging pathogen. In addition to genotypic differences, CA-MRSA is less likely than HA-MRSA to have a multidrug–resistant susceptibility pattern. Treatment of CA-MRSA follows similar principles to HA-MRSA with the exception that more antibiotic choices are generally available. For an uncomplicated cutaneous abscess, incision and drainage without antibiotics is often sufficient. For deeper or more severe infections, empiric treatment with trimethoprim-sulfamethoxazole, clindamycin, a tetracycline (doxycycline or minocycline), or linezolid are empiric options while awaiting antibiotic susceptibilities. Although linezolid is an effective drug, it is far more expensive than the other choices. Tetracyclines should not be used in children younger than 8 years. For impetigo and other minor infections, topical mupirocin can be used.

Resistant Gram-Negative Bacteria and Streptococcus Pneumoniae

Similar to CA-MRSA, other resistant bacteria have established significant niches. For example, *S pneumoniae* was historically uniformly sensitive to penicillin. Currently, penicillin- and ceftriaxone-resistant strains of *S pneumoniae* are now common and circulating in the community. Similarly, several gram-negative bacteria, such as *Escherichia coli* and *Klebsiella pneumoniae,* are highly resistant because of a variety of plasmid and chromosomally encoded mechanisms, such as β-lactamases, cephalosporinases, carbapenemases, porins, and efflux pumps. These strains are most common in the nosocomial setting, although community circulation of these strains has also occurred. Although the emergence of these strains is not as extensive or as clearly delineated as CA-MRSA, each of these strains has similarly "emerged" to a prevalence level in the population that substantially affects human health.

Ehrlichiosis and Anaplasmosis

Ehrlichia chaffeensis, the etiologic agent of human monocytic ehrlichiosis (HME), and *Anaplasma phagocytophilum*, the etiologic agent of human granulocytic anaplasmosis (HGA [formerly human granulocytic ehrlichiosis]), are examples of infections that were identified after the development of new diagnostic tests. Both infections were initially recognized as infections of the veterinary world until the application of molecular methods to humans with undiagnosed febrile illnesses. These infections likely have caused human disease for a long time, although the incidence may have increased with the recent resurgence of populations of some animal reservoirs, such as the white-tailed deer. In the early 1990s, *E chaffeensis* and *A phagocytophilum* were identified as human pathogens that are transmitted by ticks. *Ehrlichia chaffeensis* is transmitted by several ticks (ie, *Amblyomma americanum*, *Dermacentor variabilis*, *Ixodes pacificus*) and is found in the Southeastern and South Central United States as well as California. *Anaplasma phagocytophilum* is transmitted by *Ixodes scapularis* and is found in the northern United States. Both agents cause a febrile illness with headache, myalgia, and malaise that is often accompanied by thrombocytopenia, leukopenia, and transaminitis. Rash, which occurs in 90% of subjects with Rocky Mountain spotted fever (caused by *Rickettsia rickettsii*), is less often found with HME (31%) and rarely with HGA. Diagnosis of these infections can be made by PCR testing and less commonly with direct microscopy because the latter methods are insensitive (<10% for HME and 25%–75% for HGA). Because of the potential severity of the illness, however, if clinical suspicion is high empiric treatment should be initiated while awaiting the diagnostic workup. Doxycycline is the drug of choice for management of HGA and HME. Because of a lack of reliable alternative drugs, doxycycline is recommended for children younger than 8 years as well.

Fungi: *Cryptococcus Gattii*

Cryptococcus gattii (formerly *Cryptococcus neoformans* var *gattii*) and *C neoformans* are yeast that cause pneumonia and CNS infections in immunocompetent and immunocompromised hosts. Although *C neoformans* is present in most regions of the world, *C gattii* has a restricted geographic distribution and previously had been identified in tropical and subtropical countries such as Australia, New Zealand, and Papua New Guinea. In the early 2000s, *C gattii* was identified as a cause of meningoencephalitis for the first time on Vancouver Island in British Columbia. From 1999 to 2007, 218 cases were reported, with a case fatality rate of 8.7%. Subsequent studies identified its presence in the Pacific Northwest, including the states of Washington and Oregon. Similar to many emerging pathogens, the increased number of cases may be the result of improved diagnostics and surveillance as opposed to the actual emergence of a new infection to a region. Some molecular evidence suggests that the strain on Vancouver Island is novel, however. Clonal analysis suggests that it arose from an unusual type of sexual mating that generated a hypervirulent strain. This mechanism of emergence suggests that a species endemic to an original location (eg, tropics) can emerge in a new geographic region (eg, Vancouver Island) in a clonal manner. The clinical presentation of *C gattii* is similar to *C neoformans*, although *C gattii* may be associated with an increased frequency of cryptococcoma in the lungs and CNS. Treatment principles are the same for both species and include initial management with amphotericin B and 5-fluorocytosine for meningitis followed by consolidation therapy with fluconazole. For uncomplicated pulmonary disease, fluconazole is the cornerstone of treatment. *Cryptococcus* species, including *gattii*, infect children as well, and treatment principles are similar to those for adults.

Summary

Contrary to myopic claims that public health would conquer infectious diseases in the 20th century, new pathogens have continued to emerge and old ones have reemerged time and time again, making for a challenging future of disease identification and control. Transcontinental air travel has made even the most remote areas of the world reachable within 24 hours, bringing the distant populations much closer and exponentially increasing the potential for disease transmission and outbreak propagation. The tools used by public health include surveillance and response; however, most of the major epidemics identified in the past 20 years began with astute clinical observation at the primary care level. Thus, it is essential for primary care physicians and others caring for children to remain vigilant to the constant and unpredictable nature of emerging infectious diseases. With astute primary care physicians, attentive scrutiny of new outbreaks, and collaboration with regional and national public health laboratories and officials, it is hoped that the medical field will keep pace with emerging and reemerging pathogens.

CASE RESOLUTION

The patient was hospitalized and underwent an extensive diagnostic workup for infectious causes of fever and rash. A lumbar puncture revealed mild lymphocytic pleocytosis. The patient received 2 days of empiric antibiotic therapy, which was discontinued when cultures were negative for 48 hours. The pediatrician notified the local health department, which facilitated laboratory testing performed by the state public health laboratory, and the CDC.

Serologic testing at the state health department was positive for IgM antibodies against dengue virus. This was confirmed on samples sent to the CDC; additionally, based on reverse-transcriptase PCR testing, CSF sent to the CDC was found to be positive for dengue virus serotype 1. The patient recovered uneventfully in the following 2 weeks, but a public health investigation was launched that eventually resulted in the identification of 27 total cases of dengue fever acquired in Key West. Subsequently, an adult serosurvey was conducted indicating recent exposure to dengue in 5.4% of the adults studied.

This outbreak, which occurred in 2009 to 2010, represented the first reported cases of dengue fever acquired in Florida since 1934. Although dengue is the most common virus transmitted by mosquitoes in the world, no cases had been acquired in the continental United States between 1946 and 1980 and, subsequently, only sporadic cases were known along the United States (specifically, Texas)–Mexico border. Reported dengue cases have increased 4-fold in Latin America since 1980, and incidence has risen steadily among returning travelers from the United States. Dengue represents a truly reemerging infectious disease, and primary care physicians should be aware of its rising incidence.

CHAPTER 69

Febrile Seizures

Hanalise V. Huff, MD, MPH, and Kenneth R. Huff, MD

CASE STUDY

A 12-month-old girl is brought to the emergency department by paramedics because she is having a seizure. She is unresponsive and hypertonic, with arched trunk and extended arms and legs that are jerking rhythmically. Her eyes are open, but her gaze is directed upward. She has bubbles of saliva around her lips as well as circumoral cyanosis. Her vital signs are a respiratory rate of 60 breaths/minute, heart rate of 125 beats/minute, blood pressure of 130/78 mm Hg, and temperature of 41.0°C (105.8°F). An assessment of her respiratory status shows that she is moving air in all lung fields, and no evidence exists of upper airway obstruction.

The paramedics inform you that the girl has been convulsing with varying intensity of tone and movements but has remained unresponsive for approximately 6 minutes. Glucometer testing reveals a normal serum glucose level. Blood samples for other tests are sent to the laboratory, and urine is collected. An intravenous (IV) line is started, and the girl is given lorazepam by IV push. Within 2 minutes the movements cease, and her respirations become slow and even. No signs of trauma are evident on physical examination. Her only abnormality other than her unresponsive mental status is an inflamed and bulging right tympanic membrane.

The girl's parents tell you that she has had a mildly stuffy nose for 2 days but has been afebrile and has seemed to be her usual self. While she was playing she became irritable, and her parents put her in her crib for her nap. Thirty minutes later they heard grunting noises, found her in the midst of a seizure, and called the paramedics. This is the girl's first seizure. Her father recalls that his mother once told him that he had several "fever seizures" as an infant.

Questions

1. What are the characteristics of simple febrile seizures versus complex febrile seizures?
2. What is the appropriate evaluation of the child with febrile seizure, whether it is the first or a recurrence?
3. What is the recurrence risk for febrile seizure and the risk of developing unprovoked seizures after a febrile seizure?
4. What are the management options for the child with febrile seizure?

Febrile seizures are easily recognized, dramatic, generalized convulsions. A *febrile seizure* is defined by the presence of a fever or an acute inflammatory illness (often sudden) from a source outside the nervous system; patient age of approximately 5 years or younger; absence of chronic brain pathology, including developmental delay; absence of metabolic or structural abnormalities of the brain; and absence of previous nonfebrile seizures. Frequently, familial predisposition to similar seizures or a history of similar events in other family members is present. Despite the relatively uniform presentation of the seizure, other factors, such as genetic abnormalities in channels, neurotransmitter receptors, or hippocampal damage may influence prognosis, and individual clinical variables and social factors may influence management.

Epidemiology

Febrile seizures occur in children between 6 months and approximately 5 years of age, but they are more common in children younger than 3 years. Some studies indicate that as many as 5% of all children in the United States experience at least 1 febrile seizure, and the prevalence is higher in the Asian population (eg, 6%–9% in Japan). The recurrence rate is 30% to 50% in children younger than 1 year, drops to 25% between 1 and 3 years of age, and falls to 12% after age 3 years. Seizures are associated with a higher maximum temperature and may occur with the rise in temperature and often so suddenly that the febrile illness is not recognized by the family prior to the seizure. Frequently, the febrile illness eventually is diagnosed as an upper respiratory tract or influenza infection or follows immunization. Human herpesvirus 6 infections may be associated with one-third of first-time febrile seizures and a somewhat higher rate of complex febrile seizures. Febrile seizures often occur in children with a first-degree relative who experienced the problem at the same age.

Clinical Presentation

A *simple febrile seizure* is characterized by a single episode of generalized, symmetric, tonic posturing and clonic movements of a few minutes' duration that occurs suddenly in the child whose developmental progress is generally normal. Fever or an acute inflammatory illness is present, although it may not have been recognized before the seizure, and its source is outside the nervous system. A short time after the seizure (typically after 1–2 hours of postictal sleepiness), the child returns to a normal neurologic state (Box 69.1).

Box 69.1. Diagnosis of Febrile Seizure in the Pediatric Patient

- Sudden unresponsiveness, tonic posturing, and generalized rhythmic jerking
- Fever or acute inflammatory illness source outside nervous system
- Age 6 months to approximately 5 years
- Normal neurodevelopmental history

The recently described *generalized epilepsy with febrile seizures plus* (GEFS+) is characterized by the association of generalized febrile seizures after age 6 years and afebrile generalized convulsions, a positive family history of epilepsy with variable phenotypes, and a benign prognosis in most cases. The same families may have simple febrile seizures, febrile seizures after age 6 years, febrile seizures and absences, atonic or myoclonic seizures, and myoclonic-astatic epilepsy or Dravet syndrome.

Pathophysiology

The susceptibility of young children to febrile seizures may be related to an increased incidence of sudden high fevers in this age group, a developmental genetic factor that may lower the seizure threshold, or both. Animal models indicate that the immature brain has a lower seizure threshold than the adult brain, and seizures in the immature brain are more likely to occur by a mechanism different from that in the adult. Febrile seizure has a mild association with prenatal nicotine exposure, iron insufficiency, and atopic conditions. A sudden increase in temperature to a sufficiently high level can provoke seizure regardless of age. Cultured neurons subjected to hyperthermia show epileptiform activity. Seizures occur more frequently with fever in many seizure-prone patients who have seizures of different etiologies, including genetic epilepsies. It may be that circulating pyrogens or interleukins interact with a brain cellular circuitry mechanism or susceptible ion channels, causing hypersynchronous depolarization and seizure. The commonly noted multigenerational familial history is suggestive of a dominantly expressed genetic transmission with reduced penetrance or a polygenic model. Different families have different loci linkages.

The precise definitions of the genetic markers and mechanisms of generalized seizures in all cases are not yet fully understood. Recent work suggests possible mechanisms. Mutations in γ-aminobutyric acid $(GABA)_A$ receptor genes have been found to be associated with febrile seizures and GEFS+ pedigrees. The $GABA_A$ receptors transmit inhibitory signals and are composed of combinations of 5 subunits. The γ2 subunit is critical for receptor trafficking, clustering, and synaptic maintenance, and mutations in this subunit have been associated with febrile seizure families. It has also been found that the trafficking of mutant receptors with γ2 subunit mutations was more highly temperature dependent than mutations of other subunits and impaired membrane insertion or accelerated receptor endocytosis when brief increases of 37°C to 40°C (98.6°F to 104°F) occurred. In families with these mutations, febrile seizures may be caused by a fever-induced change in the status of a dynamic membrane receptor system, producing reduced numbers of available $GABA_A$ receptors.

In other families with GEFS+, it has been found that mutations in the *SCN1A* (sodium voltage-gated channel alpha subunit 1) gene have occurred. Mutations in this same gene may occur in sequences that encode for the critical "pore" region of the subunit protein that participates in ion selectivity and results in a more severe phenotype with early prolonged resistant seizures and later, intellectual and developmental disability and Dravet syndrome. A less severe GEFS+ phenotype is associated with a less functionally critical position of the missense mutation in the *SCN1A* gene. A rat model of hyperthermic seizures has a comparable mutation and may provide additional clues related to pathophysiology.

Differential Diagnosis

When a young child presents with a fever and a seizure, the possibility that the seizure is symptomatic of meningitis, encephalitis, or brain abscess must be considered, although other clinical signs are nearly always present. Signs of meningeal irritation may not be reliable in infants younger than 12 months, however, and these and other signs of the illness may be obscured in the postictal period. If a history of lethargy or persistent vomiting exists; the seizure is focal in onset or prolonged or multiple seizures occur; or the postictal depression is prolonged, an examination of the cerebrospinal fluid (CSF) should be done. In addition, if the patient is deficient in *Haemophilus influenzae* type b or *Streptococcus pneumoniae* immunizations or the patient has been pretreated with antibiotics, which could mask meningeal signs or symptoms, a CSF examination should be considered. It is rare that a febrile seizure would cause CSF pleocytosis (>10–20 white blood cells/mm^3). The fever also could be provocative or coincidental to a seizure of different etiology, such as trauma, toxic ingestion, metabolic derangement, degenerative or neurocutaneous disorder, or stroke.

A useful concept for the physician caring for a child with a febrile seizure has been the differentiation of simple febrile seizure from complex febrile seizure (Table 69.1). A question with prognostic implications is whether a child in the appropriate age range has had a true febrile seizure or a seizure with fever, which may be an early fever-provoked episode of a nonfebrile seizure disorder. The factors that define a complex febrile seizure also predict an increased likelihood of later unprovoked nonfebrile seizures. A complex febrile seizure may last 15 minutes or longer. Most febrile seizures are shorter than 90 seconds, although a significant number present in status epilepticus. Recurrent febrile seizures are considered complex if more than 1 febrile seizure occurs during the same infectious illness or during the first 24-hour period following the initial seizure. Febrile seizures are also complex if there is a history of a focal or partial onset or the presence of postictal focal neurologic signs. An abnormal neurodevelopmental history prior to the febrile seizure or abnormal neurologic examination or brain imaging study before or after the seizure also is indicative of an increased likelihood of later unprovoked seizures.

Table 69.1. Simple Versus Complex Febrile Seizures

Feature	*Simple*	*Complex*
Onset of clonic movements	Generalized	Focal
Length	<15 minutes (usually <90 seconds)	≥15 minutes
Number of seizures per 24-hour febrile illness	1	Recurrent
Neurodevelopmental history	Normal	Abnormal
Parent or sibling history of febrile seizure	Often positive	Often negative

Evaluation

History

After the seizure has been controlled and the child has been stabilized, a more detailed history relating to the circumstances of the seizure should be obtained, including the child's state leading up to the seizure; prenatal, birth, and developmental histories; and family seizure history (Box 69.2).

Physical Examination

The child should be examined thoroughly after stabilization, noting the possibility that the fever may be coincidental and signs from an unrelated cause inciting the seizure could be present. The physician should look for bruising, fracture, retinal hemorrhage, and other signs of trauma. The presence of dysmorphic features, enlarged organs, or bony changes should be noted. The skin should be examined for abnormal, pigmented, or textured spots. Lateralized signs of tone or strength should be assessed. An appropriate examination to determine the etiology of the fever should also be performed (see Chapter 67). Meningismus, bulging fontanelle, and prolonged postictal drowsiness should prompt consideration of meningitis or encephalitis.

Laboratory Tests

If the seizure is prolonged, focal, or multiple; if a history exists of lethargy, stupor, or persistent vomiting before the seizure; or if the patient remains ill-appearing after the postictal period, cultures should be obtained and metabolic and toxicologic blood and urine studies sent. A lumbar puncture for CSF examination for meningitis or encephalitis should be done unless signs exist of increased intracranial pressure or a lateralized neurologic examination, in which case antibiotics should be given and an imaging study obtained prior to the lumbar puncture.

If the seizure is a simple febrile seizure, without history or signs of dehydration, blood tests are of low yield. Likewise, electroencephalography has limited usefulness. The record is often abnormal in a nonspecific way and not helpful in predicting future simple febrile seizures or epilepsy. If the patient does not fully recover after the postictal period, electroencephalography may be useful to help define the nature of the encephalopathy.

Genetic testing for *SCN1A* mutations may be considered for the child with GEFS+.

Imaging Studies

Computed tomography and magnetic resonance imaging have a low yield of abnormal results in children with simple febrile seizures. However, for the child with a persistently abnormal neurologic examination or signs of increased intracranial pressure, or with an abnormal neurodevelopmental history or a focal or partial onset to seizure, an imaging study should be performed to detect a structural lesion that may be acute and the source of the present seizure and that may serve as a nidus for future seizures.

Management

If the child is still convulsing on presentation and has been for at least 5 minutes, the condition should be managed as for status epilepticus (see Chapter 131). The airway must be secured, blood drawn and sent to the laboratory for testing, an intravenous line started, and lorazepam administered in the appropriate dose to stop the seizure.

If the child is not in status epilepticus, treatment decisions are made based on a more long-term outlook (Box 69.3). Whether or not to recommend anticonvulsant prophylaxis for the child who has experienced febrile seizures is controversial. Factors that must be considered include the benign, age-limited nature of the condition; the morbidity of the anticonvulsant treatment; the chance of recurrence of febrile or nonfebrile seizures; the risk

Box 69.2. What to Ask

Febrile Seizure in the Pediatric Patient

- What were the child's symptoms for the few days before the seizure?
- Where was the child, and what was the child doing immediately before the seizure?
- Were there any pregnancy-related or perinatal complications?
- Has the child's development been normal or similar to that of siblings?
- Have any other family members had seizures of any kind, including during infancy?

Box 69.3. Treatment Options for the Pediatric Patient With Febrile Seizure

- Cooling measures during febrile illness (ie, antipyretic agents or bathing in tepid water)
- Family reassurance and education
- Diazepam, 0.3 mg/kg orally or 5–10 mg rectal gel (eg, Diastat) every 8 hours (during febrile illness only)
- Phenobarbital, 3–5 mg/kg orally daily, for prophylaxis
- Valproic acid (divalproex sodium), 30 mg/kg orally divided twice daily, for prophylaxis

of overmedication during an acute recurrence; and the family's reaction and social disruption caused by the seizures. Given the combination of these factors, particularly the weight of the first 2, most physicians do not recommend antiepileptic drug prophylaxis for febrile seizures.

Daily dosing of phenobarbital or valproic acid is an effective form of anticonvulsant prophylaxis. The most commonly used regimen is daily phenobarbital; however, the potential side effects of this agent include attention-deficit/hyperactivity disorder and depressed cognition and learning. Valproic acid can produce thrombocytopenia and may have the potential of provoking acute liver dysfunction in a patient younger than 2 years who is taking other medications. Fever control measures should be instituted to make the patient more comfortable, but these have not been found to be effective as prevention for seizures. Intermittent anticonvulsant therapy with diazepam or clobazam has the advantage of reducing (but not always eliminating) the side effects of hyperactivity, lethargy, ataxia, and sedation; however, this regimen is reliant on recognizing the fever before the seizure and mandates greater vigilance for compliance during each fever. Additionally, the evidence of this approach for reducing recurrence risk has been shown to be inconsistent at different ages. Because prolonged febrile seizures tend to recur as repeated prolonged seizures, such patients may benefit from the availability of rectal diazepam or intranasal midazolam to administer at home as an abortive drug to stop the seizure earlier in its course while paramedics are being called.

Recommendations for prophylactic anticonvulsant treatment are often individualized. Anticonvulsants usually are not recommended unless the child has presented in status epilepticus, has experienced marked respiratory compromise (perhaps needing ventilatory support) during the seizure, or has had complex febrile seizures. No definitive evidence exists that anticonvulsant prophylaxis for simple febrile seizures prevents the development of unprovoked seizures. The child who has had frequently recurring seizures that are extremely disruptive for the family and deleterious to parent-child interactions despite educational efforts by medical caregivers may also be a candidate for prophylactic anticonvulsant treatment, including the use of oral or rectal diazepam (eg, Diastat) every 8 hours during the febrile illness.

Prognosis

Febrile seizures are a common age-limited problem. The prognosis for children with simple febrile seizures is generally good and not associated with permanent neurologic deficits; the incidence of seizure episodes later in life is 3 to 6 times higher than in the general population at the same age but is still low (2% to 3%). Patients with complex febrile seizures have a higher likelihood of developing a nonfebrile seizure disorder (ie, epilepsy) compared to patients with simple febrile seizures; however, this risk is only 6% if 2 of the first 3 factors listed in Table 69.1 are present or 17% if the patients have neurodevelopmental abnormality. Overall, one-third of children with febrile seizures experience a febrile seizure recurrence. The risk of febrile seizure recurrence is most dependent on age: 50% of infants younger than 1 year at the time of their first seizure will have a recurrence, but only 20% of children older than 3 years will have a recurrence. Other factors that have a lesser influence on the recurrence risk include family history of febrile seizures but not epilepsy, temperature at the initial seizure, time since the previous seizure, and history of previous recurrences.

Animal models suggest that in the immature brain, seizures—even status epilepticus episodes—are less often associated with neuronal death; however, seizures, particularly hyperthermic seizures, can modify brain development by altering cortical motor maps and the expression of ion channels and inhibitory receptor subunits that regulate neuronal excitability. Additionally, epileptogenic mechanisms may be more robust in the immature brain than in the adult brain. However, children with febrile convulsions have shown no difference in later academic progress or behavior compared with control children.

Evidence suggests that complex febrile seizures are associated with temporal lobe epilepsy in some cases. A history of prolonged complex febrile seizures is reported in 30% of patients with mesial temporal sclerosis (MTS) who underwent surgery for intractable temporal lobe epilepsy; this is in contrast to only 6% of patients with complex febrile seizures who did not have MTS. It is possible that MTS is the consequence of prolonged febrile seizure when the hippocampus is developmentally vulnerable. Mesial temporal sclerosis is frequently unilateral and focal complex febrile seizures originate in the temporal lobe in some children; additional evidence is suggestive of causality. An alternative explanation is that some preexisting hippocampal malformation, genetic predisposition, or subsequent damage may be present in the patient with hippocampal sclerosis and prolonged febrile seizures and that the complex febrile seizure is a collateral phenomenon. Ten percent of children who present with febrile status epilepticus have evidence of hippocampal malrotation.

A small percentage of infants with febrile seizures may develop Dravet syndrome, a phenotype influencing neurocognition as well as later medication-resistant epilepsy, if they carry a particular channel subunit gene mutation. Additionally, a quite rare consequence of prolonged focal febrile seizures is hemiconvulsion-hemiplegia-epilepsy syndrome, which is characterized by unilateral swelling and later cerebral hemiatrophy of the epileptic hemisphere.

CASE RESOLUTION

The girl had a somewhat prolonged simple febrile seizure, a diagnosis that was supported by a positive family history for febrile seizures. Her family is educated about treatment options. They are comfortable with a decision to use only rectal diazepam for a subsequent febrile seizure lasting longer than 5 minutes.

CHAPTER 70

Respiratory Distress

David B. Burbulys, MD

CASE STUDY

A 6-month-old boy has been coughing and breathing fast for the past day. This morning he refused feeding and has been irritable. On examination, the infant is fussy. He has an oxygen saturation of 92%, a respiratory rate of 60 breaths per minute, a pulse of 140 beats per minute, and a normal blood pressure and temperature. Additionally, he has nasal flaring, intercostal and supraclavicular retractions, and occasional grunting.

Questions

1. What are the causes of respiratory distress in infants and children?
2. What are the signs and symptoms of respiratory distress in infants and children?
3. What are the signs and symptoms of impending respiratory failure in infants and children?
4. What are the critical interventions for infants and children in respiratory distress?

Respiratory distress and respiratory failure may cause significant morbidity and mortality in infants and children. The signs and symptoms of respiratory compromise may be subtle, particularly in small infants and early on. Decompensation may occur rapidly if ventilation or oxygenation is inadequate but may be prevented by prompt recognition and management. *Respiratory distress* is defined as increased work of breathing, and it usually precedes respiratory failure. *Respiratory failure* occurs when ventilation or oxygenation is insufficient to meet the metabolic demands of the tissues (ie, oxygenation of the blood is inadequate or carbon dioxide is not eliminated). Respiratory failure may be caused by diseases of the airway, inadequate gas exchange in the lungs, or poor respiratory effort (Box 70.1). Respiratory failure may result in cardiopulmonary arrest if not corrected promptly.

Epidemiology

Primary care physicians frequently care for children in respiratory distress in offices and emergency departments. Respiratory distress remains the most common reason for hospital admission. Such admissions usually involve young infants with acute infections, such as bronchiolitis or croup. Reactive airways disease (eg, asthma) is a common reason for respiratory distress-related admission in older children.

Clinical Presentation

Increases in respiratory rate and work of breathing are the most common signs of respiratory disease. Tachycardia is often present; the presence of bradycardia, however, may be an ominous sign of impending cardiopulmonary failure and arrest. Effortless tachypnea (ie, Kussmaul breathing) may be a sign of respiratory compensation for metabolic acidosis rather than an indication of pulmonary pathology. Similarly, hypoxia that does not improve with supplemental oxygen may be suggestive of a primary cardiac lesion. Signs of poor oxygenation include alterations in mental status, head bobbing, and change in skin color. Pallor, mottling, and cyanosis are often late signs of respiratory failure and shock. The child with severe hypoxemia may initially appear dusky or pale. If the child is anemic, cyanosis may not be evident even in the presence of low oxygen saturation (Box 70.2).

Pathophysiology

The adequacy of respiration depends on the ability to move an adequate volume of gas in and out of the airways as well as effective gas exchange of carbon dioxide and oxygen. Infants and children generally breathe with minimal effort. In very young children, the diaphragm and abdominal musculature are primarily used for ventilation, and the tidal volume is approximately 6 to 8 mL/kg. If the tidal volume is decreased because of obstruction, children compensate by increasing the respiratory rate, thus attempting to maintain adequate minute ventilation (minute ventilation = rate × tidal volume). If the minute ventilation remains insufficient for adequate gas exchange or the child can no longer sustain the increased work of breathing, respiratory failure ensues. Respiratory failure may then result in acidosis, myocardial dysfunction, and shock and may progress to complete cardiopulmonary arrest.

Infants and children are more prone than adults to respiratory distress because of the differences between their respiratory systems (Box 70.3).

Differential Diagnosis

The differential diagnosis of children with respiratory distress can include abnormalities with the pulmonary, cardiovascular,

Box 70.1. Common Causes of Respiratory Distress in Infants and Children

Upper Airway
- Aspirated foreign body
- Croup
- Epiglottitis
- Anaphylaxis
- Airway anomalies or immaturity

Lower Airway
- Reactive airways disease (eg, asthma)
- Bronchiolitis
- Pneumonia
- Pulmonary edema

Metabolic
- Acidosis
- Anemia

Cardiac
- Congenital heart disease
- Congestive heart failure
- Dysrhythmia
- Pericarditis or tamponade

Neurologic
- Central
- Peripheral
- Neuromuscular

Traumatic
- Chest wall injury
- Pneumothorax, hemothorax, or pulmonary contusion
- Submersion injury
- Smoke inhalation
- Toxin exposure or ingestion

Box 70.2. Respiratory Distress

- Increased respiratory rate
- Poor feeding
- Inability to speak in sentences
- Changes in tidal volume or minute ventilation
- Nasal flaring
- Presence of retractions: intercostal, substernal, diaphragmatic, or supraclavicular
- Changes in inspiratory-expiratory ratio
- Production of sounds with respiration (eg, grunting, gurgling, stridor, rhonchi, rales, wheezes)
- Diaphoresis
- Decreased or absent breath sounds
- Presence of pale or cyanotic skin
- Presence of central cyanosis
- Alterations in mental status

nervous, or metabolic systems. It is also important to make an initial differentiation between upper and lower airway disease based on the presence or absence of stridor, rhonchi, rales, or wheezes on examination. Many common causes are listed in Box 70.1.

Evaluation

History

A brief history should be obtained while concomitant physical examination proceeds and initial treatment is begun (Box 70.4).

Physical Examination

Before a complete assessment can proceed, critical interventions that may change a child's clinical status should be undertaken. The child should be placed in a position of comfort if possible, and oxygen should be applied. Ventilation and oxygenation should be assessed. Nasal and/or oropharyngeal suctioning should be done if necessary.

Box 70.3. Comparison of Respiratory Systems in Children and Adults

- The head in children is proportionally larger and has less muscular support.
- The tongue in children is larger in relation to the mouth, is poorly controlled, and can cause airway obstruction.
- The airway diameter is smaller in children and collapses easily. Reductions in size resulting from secretions or inflammation cause greater resistance to air flow (resistance is proportional to $1/\text{radius}^4$).
- The larynx is higher and more anterior in children and the epiglottis is floppy, which makes visualization of the vocal cords more difficult.
- The narrowest part of the airway in children is at the cricoid ring, unlike in adults, in whom the narrowest point is at the vocal cords.
- The trachea in children is short. In newborns it is 4 cm long; in 18-month-old infants, 7 cm long; and in adults, 12 cm long.
- The major muscle of respiration in children is the diaphragm. Any interference with diaphragmatic motion in young children impedes respiratory function. Intercostal muscles are immature in children and fatigue easily.
- Children have less pulmonary reserve and higher metabolic demands.
- Normal respiratory rates are higher in children and vary by age.

Box 70.4. What to Ask

Respiratory Distress
- What was the onset of this problem like, and how has it progressed?
- For how long has it been occurring, and has a similar problem ever occurred before?
- Did the problem begin while the child was eating or playing?
- Has the child had any recent infections or fever?
- Are any members of the household ill?
- Is the child taking any medications?

Respiratory and heart rates should be determined for a period of at least 30 seconds. In the infant, abdominal excursions should be counted; in the older child, chest excursions should be counted. Respiratory rates in children are higher than in adults; infants may breathe 40 times per minute, 1-year-olds 25 times per minute, and 10-year-olds 18 times per minute (Table 70.1). These rates vary with age and changes of activity, emotion, and illness. Abnormal respiratory rates are defined as being faster than normal (ie, *tachypnea*), slower than normal (ie, *bradypnea*), or absent (ie, *apnea*). The neonate may exhibit periodic breathing, with periods of regular respirations alternating with irregular breathing. This is a normal variant for age. True apnea (ie, cessation of respiration) is accompanied by change in skin color or muscle tone and may be accompanied by bradycardia or altered level of consciousness.

The depth of respiration should be noted. Whether breaths are deep, gasping, or shallow should be determined. Rapid, shallow respirations may not provide enough inspiratory time for adequate gas exchange. The heart rate may also reflect respiratory compromise. Breath sounds should first be listened to in the axillae and then at the bases and apices. The absence of breath sounds may be an ominous sign. Children's breath sounds are usually well transmitted across the thorax because of the thin chest wall. It is common to hear upper airway noises when auscultating the lungs.

Abnormal sounds are caused by turbulent air passing through a narrowed airway. Resistance to flow through a hollow tube increases to the fourth power. Thus, the smaller the airway, the greater the resistance to flow generated by even small changes in the radius (as with edema, secretions, or foreign bodies). The nature of the sounds produced depends on the location of the narrowing in the airway. Gurgling, snoring, and stridor arise from the upper airway; rales, rhonchi, and wheezing arise from the lower airway. If no abnormal sounds are evident and breath sounds are absent or decreased, the upper or lower airways may be totally obstructed. *Grunting* is caused by turbulent air contacting a partially closed glottis. The child who grunts is generating partial obstruction of the upper airway and positive end-expiratory pressure to increase oxygenation.

The physician should also observe the effort the child expends in breathing. Increased work of breathing occurs when intercostal, subcostal, or supraclavicular retractions are present, the accessory muscles of respiration are used, breathing is abnormally noisy, or nasal flaring is seen. The normal work of breathing consumes 2% to 3% of total oxygen consumption. The increased work of breathing in the child with severe respiratory distress can potentially increase total oxygen consumption to 50%. Increased work of breathing can also be manifested by feeding difficulties and diaphoresis in infants and young children.

Additionally, the physician should observe the inspiratory-expiratory ratio while assessing the work of breathing. The ratio is approximately 1:1 in most patients. Prolonged expirations are most often noted with reactive airways disease.

Oxygen saturation should be measured by pulse oximetry in every child with respiratory symptoms. Levels below 93% while awake are indicative of significant hypoxemia.

Table 70.1. Vital Signs by Age

Age	Respiration (breaths/minute)	Pulse (beats/minute)	Systolic Blood Pressure (mm Hg)
Newborn	30–60	100–160	50–70
1–6 weeks	30–60	100–160	70–95
6 months	25–40	90–120	80–100
1 year	20–40	90–120	80–100
3 years	20–30	80–120	80–110
6 years	12–25	70–110	80–110
10 years	12–20	60–90	90–120

Laboratory Tests

Although the physical examination is the most important tool for assessing children in respiratory distress, laboratory tests such as respiratory viral and bacterial respiratory panels using polymerase chain reactions and other methodologies, complete and differential blood cell counts, and blood cultures may help in the diagnosis of infection. Point-of-care respiratory syncytial virus or influenza testing may also be beneficial during the peak seasons. It is important to note that meningitis, sepsis, and metabolic derangement may present with effortless tachypnea not associated with increased work of breathing. Arterial or venous blood gases may be beneficial in this situation; however, generally these should be reserved for patients in impending respiratory failure.

Peak expiratory flow or forced expiratory volume in 1-second determinations can be helpful in assessing the compliant older child with reactive airways disease. Oxygen saturation measurements can also be helpful in these children, because reduced levels (<100%) often correlate with the severity of disease.

Imaging Studies

Chest radiography can aid in assessing the child in respiratory distress, but such imaging should not be routinely obtained in patients with known reactive airways disease unless the child has a fever or is in status asthmaticus. Anteroposterior and lateral radiographs of the neck may also be beneficial in the patient with stridor. A patient with significant respiratory distress should not be moved from a monitored setting to the radiology suite; rather, portable radiographs should be obtained, if necessary.

Management

All infants and children in respiratory distress should be managed emergently. As stated previously, in such situations assessment and intervention often occur simultaneously. All children in respiratory distress should be reassessed frequently. Initially, the highest possible oxygen concentration should be delivered. Children who are able to maintain their own airway should never be forced to use an airway adjunct, because this may cause increased anxiety and distress. The patient with clear airways can be maintained with simple

interventions, such as oxygen blown by the face or given by mask or nasal prongs. Many patients with more severe croup, reactive airways disease, bronchiolitis, or pneumonia may benefit from noninvasive respiratory support, such as with continuous positive airway pressure or a heated humidified high-flow nasal cannula. More advanced airway management, such as bag-valve-mask ventilation or endotracheal intubation, may be necessary for the child who required assisted ventilation, airway protection, or hyperventilation.

Position

The child in respiratory distress who is alert and breathing spontaneously should be allowed to choose a position of comfort. Small infants who are incapable of positioning themselves are best placed upright with care taken not to flex or extend the neck. Children and their caregivers should be kept together to reduce anxiety.

The proper position for the unconscious child is the "sniffing position," with the neck slightly flexed and the head extended to open the airway. This can be facilitated by placing a towel under the occiput of the head or shoulders. If simple positioning does not relieve an obstruction, the airway should be opened using the chin lift or jaw thrust. If spinal trauma is a possibility, only the jaw thrust should be used. If this is unsuccessful, airway adjuncts, such as nasopharyngeal or oropharyngeal airways, can be placed to help prevent the soft tissue of the oropharynx from collapsing against the posterior pharyngeal wall.

Monitoring

All infants and children in respiratory distress should be carefully monitored. Pulse oximetry is helpful in determining the degree of oxygen saturation, and cardiac and respiratory monitoring provides constant readings of respirations and heart rate. Continuous end-tidal capnography may be beneficial in monitoring the patient with impending respiratory failure or the patient who requires ventilatory support. Frequent assessments of the patient are critical to ensure a good outcome.

Oxygen Administration

Oxygen should be delivered by the best method tolerated by the child. The 2 advantages of nasal prongs are that they are noninvasive and allow maintenance of a constant gas flow even when talking and eating. The concentration of oxygen delivered is limited, however, and irritation and drying of the mucous membranes may result.

Oxygen masks deliver a higher concentration of humidified oxygen than nasal prongs. Disadvantages include obstruction of the child's visual field, the potential for carbon dioxide retention, and anxiety because the face is covered. Various types of mask are available. The simple mask can deliver 30% to 60% oxygen concentration at flow rates of 6 to 10 L/min. Room air is drawn into the mask through the exhalation ports in the side of the mask. A non-rebreathing mask has valves that allow only oxygen (85%–95%) to flow from the reservoir bag to the patient on inhalation and additional valves on the exhalation ports of the mask that prevent entrapment of room air (Figure 70.1). The face tent is a soft plastic bucket shaped to the chin that is well tolerated by children (Figure 70.2). The face tent allows up to 40% oxygen to be delivered, and it has the advantage of allowing access to the face and mouth. A pocket mask is a small device that can be readily used in the office setting (Figure 70.3). A Venturi mask is rarely used in children but has the advantage of precisely titrating the oxygen concentration to be delivered from 24% to 60%.

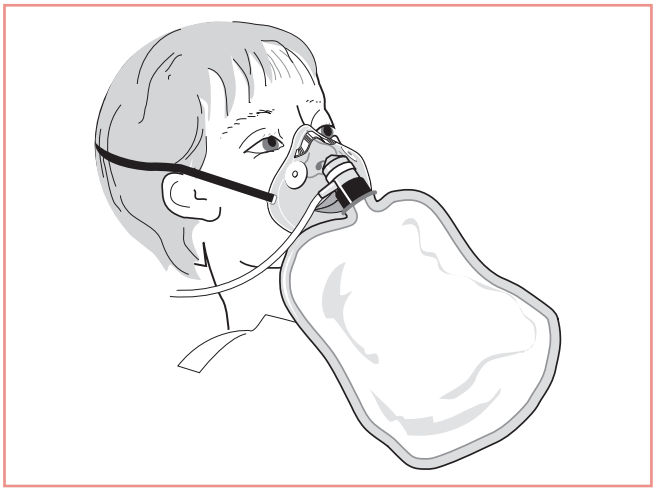

Figure 70.1. A non-rebreathing mask, which can deliver a high concentration of oxygen to a patient in respiratory distress.

Figure 70.2. Use of a face tent.

Noninvasive respiratory support, such as continuous positive airway pressure or heated humidified high-flow nasal cannula, is frequently used in patients with more significant disease or impending respiratory failure with excellent results. It decreases the work of breathing, increases oxygenation, and frequently serves as a bridge treatment while other agents are taking effect (eg, β agonists, steroids, antibiotics).

The child with respiratory failure requires assisted ventilation with a bag-valve-mask device or endotracheal intubation. A mask of the proper size should be used. The upper edge of the mask should fit snugly over the bridge of the nose without touching the eyes. The lower edge should rest directly on or just above the mandible. In the unconscious child, an oropharyngeal airway should

be inserted to prevent the tongue from obstructing the upper airway (Figure 70.4A). An appropriately sized oropharyngeal airway should reach from the patient's earlobe to the corner of the mouth. If the patient has an intact gag reflex, a nasopharyngeal airway may be inserted to achieve the same goal (Figure 70.4B). The nasopharyngeal airway is measured from the child's earlobe to the tip of the nostril. Endotracheal intubation is indicated in the child who requires control of the airway, needs airway protection, or requires hyperventilation.

Prognosis

Respiratory failure and resulting cardiopulmonary arrest are preventable in most infants and children if the condition is carefully assessed and appropriate critical interventions are implemented. Careful attention to ventilation and oxygenation usually results in a good outcome.

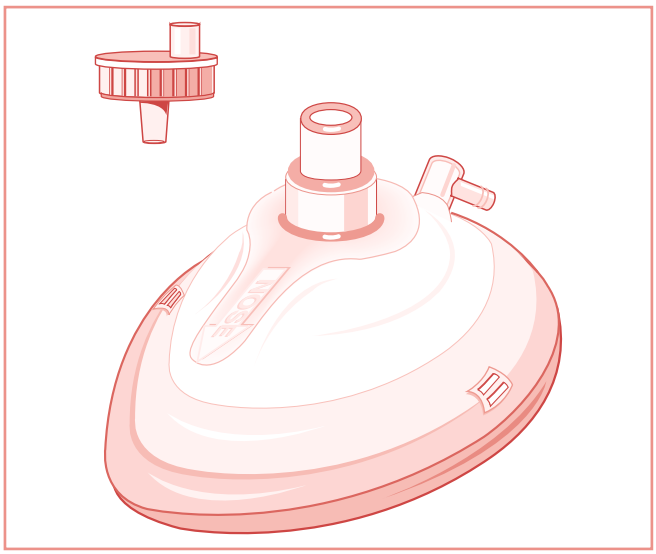

Figure 70.3. A pocket mask with a one-way valve and side oxygen port that can be used for assisted ventilation in the office setting.

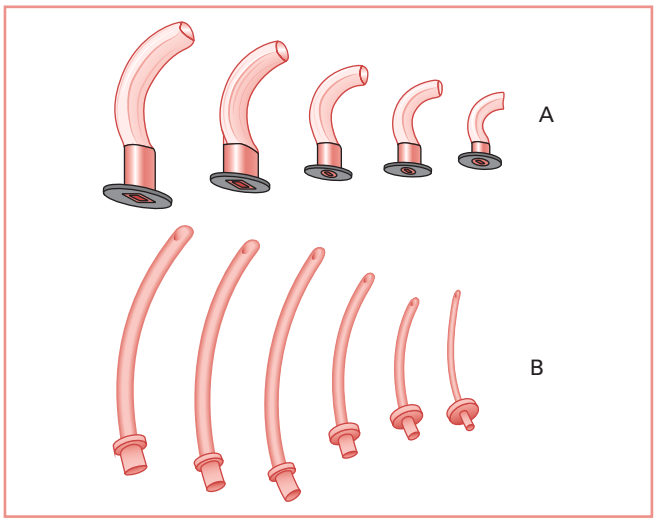

Figure 70.4. A, Oropharyngeal airways. B, Nasopharyngeal airways.

CASE RESOLUTION

The fussy infant has obvious signs of respiratory distress, including tachypnea, tachycardia, grunting, nasal flaring, and retractions. The differential diagnosis includes foreign body, infection (eg, croup, bronchiolitis), and reactive airways disease. The infant is placed in a position of comfort seated on his mother's lap and provided blow-by oxygen and a treatment with albuterol. A portable chest radiograph is obtained that shows mild hyperinflation but no infiltrate. His pulse oximetry reveals a level of 94%. A respiratory viral panel is obtained and the results reveal the presence of respiratory syncytial virus. The infant falls asleep, and his respiratory and heart rates return to normal. He is diagnosed with bronchiolitis and discharged home, and his mother is advised to return should he experience any further respiratory distress.

CHAPTER 71

Stridor and Croup

David B. Burbulys, MD

CASE STUDY

A 2-year-old boy has been breathing noisily for 1 day. For the past 3 days he has had a "cold," with a runny nose, fever (temperature up to 100.4°F [38°C]), and slight cough. The cough has gradually worsened and now has a barking quality.

On examination, the child is sitting up and has a respiratory rate of 48 breaths per minute with marked inspiratory stridor and an occasional barking cough. His other vital signs include an oxygen saturation of 95%, heart rate of 100 beats per minute, and temperature of 101.2°F (38.4°C). He has intercostal retractions, his breath sounds are slightly decreased bilaterally, and his skin is pale. The remainder of the examination is normal.

Questions

1. What is stridor?
2. What are the common causes of stridor?
3. What is the pathophysiology of viral croup?
4. How are children with croup managed?

Noisy breathing is a common symptom that often accompanies respiratory infections in children. The presence of stridor, a high-pitched crowing sound, often concerns children's caregivers. Some parents and guardians try home remedies to alleviate the symptoms, whereas many others immediately seek help in the office or emergency department setting. *Croup* is an inflammation of the larynx, trachea, and upper bronchioles (ie, laryngotracheobronchitis) that causes noisy breathing and stridor. It is among the most common causes of a seal-like barking cough and stridor in children.

Epidemiology

Croup most commonly affects children between 6 months and 3 years of age, generally in the fall or early winter. Children younger than 1 year account for 26% of cases. Infants are frequently more severely affected than older children. The condition is more common in boys than girls; two-thirds of all hospitalized children with croup are boys.

Stridor, which may be indicative of croup, may also be a sign of epiglottitis. The incidence of epiglottitis in children has dramatically decreased since 1988 following the development and widespread use of the vaccine against *Haemophilus influenzae* type b. Many young children may be incompletely immunized, and other bacteria exist that may cause epiglottitis; thus, epiglottitis should still be considered in toxic-appearing children with rapid onset of symptoms of upper airway obstruction. Before *Haemophilus influenzae* type b immunization, the ratio of cases of epiglottitis to croup was 1:100. Currently, epiglottitis in children is exceedingly rare.

Clinical Presentation

Viral Croup

Viral croup commonly begins with 2 to 3 days of viral upper respiratory symptoms (eg, rhinorrhea, sore throat, cough) and a generally low-grade fever. Higher-grade fevers may occur depending on the causative agent. At day 3 or 4, the characteristic signs of a hoarse voice, barking cough, and inspiratory stridor manifest. This frequently occurs suddenly and often at night. Symptoms worsen in the next 1 to 2 days and then resolve over the next several days.

Spasmodic Croup

Spasmodic croup typically occurs in children 2 to 5 years of age and often presents suddenly, commonly at night, without the previous complaint of upper respiratory symptoms. As in viral croup, hoarseness, barking cough, and stridor occur; however, these symptoms generally are less severe in spasmodic croup. The condition frequently resolves completely when affected children are exposed to cool or humified air. It may be recurrent. Some children may have the prodrome of a viral upper respiratory syndrome. Fever is uncommon. The etiology is unknown but is likely a reaction to a viral infection or an allergic phenomenon. A family history of recurrent stridor in children with spasmodic croup may exist.

Bacterial Tracheitis

The classic presentation of bacterial tracheitis is of a school-age child presenting with a prodrome of an upper respiratory infection. After a few days, this is followed by the abrupt progression to toxic appearance. A high fever, productive cough, inspiratory stridor, and tachypnea with moderate to severe respiratory distress commonly occur.

This generally occurs as the airway becomes secondarily infected with staphylococcal or streptococcal species. White blood cell counts are frequently significantly elevated. Abrupt decompensation may occur as pseudomembranes loosen and obstruct the airway.

Epiglottitis

Whereas acute bacterial epiglottitis was classically seen in young children, currently it is more common in adolescents and young adults. Historically, it presented with the abrupt onset of toxic appearance, high fever, sore throat, odynophagia, and muffled voice. Rapid progression followed with severe respiratory distress, drooling, stridor, tripod positioning, and frequent airway obstruction. Modern presentations are commonly less severe or progressive because of the change in pathogens. Sore throat, odynophagia, muffled voice, and significant tenderness to palpitation of the larynx frequently occur, but currently, toxic appearance and progression to airway obstruction are uncommon.

Foreign Body

Laryngotracheal foreign body aspiration may occur as a witnessed event. Choking, coughing, gasping, and stridor frequently occur, and the patient may present with these symptoms or they may have resolved by the time the patient is seen in the doctor's office. Presenting symptoms of foreign bodies in the lower larynx include dysphagia, gagging, and throat discomfort. Presenting symptoms of foreign bodies in the trachea include coughing, wheezing, and, with time, pneumonia.

Pathophysiology

Stridor

Stridor is generally caused by partial obstruction of the airway between the nose and larger bronchi. Obstruction at the level of the nose or pharynx may produce snoring or gurgling sounds. Turbulent airflow in the laryngeal area or upper trachea causes the high-pitched crowing sound characteristic of stridor. Edema and inflammation at the vocal cords and subglottic areas result in inspiratory stridor, whereas obstruction below the cricoid cartilage may cause inspiratory and expiratory stridor. Some of the more common causes of stridor are listed in Box 71.1.

The sounds produced at various levels of obstruction can give the primary care physician clues about the etiology of the problem. The most common cause of stridor that begins shortly after birth is tracheomalacia, a condition secondary to the immaturity of the cartilage of the trachea. Laryngomalacia, which is caused by floppy supraglottic structures, resolves after several months.

The upper airway of infants and children is more susceptible to obstruction as the result of anatomic differences between children and adults. The tongues of children are relatively large, and the epiglottis is floppy and shaped somewhat like the Greek letter omega (Ω). The angle between the epiglottis and glottis is more acute in children, which makes direct visualization of the airway more difficult than in adults. Cartilaginous structures are less rigid in infants. During inspiration, negative intraluminal pressure is generated below the level of obstruction, which causes narrowing of the airway and turbulence of the airflow. This occurs more often in children than adults because the tracheal rings are not well formed. Additionally, the smaller size of the airway in children makes resistance to airflow greater when obstruction is present.

Resistance increases exponentially, so the smaller the airway the greater the resistance to flow. Alterations in the diameter of the airway are most often caused by edema and inflammation. Stridor may also occur from a variety of conditions, including congenital anomalies, infection, allergic and anaphylactic reactions, cysts, tumors, and trauma. Even small localized areas of airway narrowing in infants and children can cause respiratory distress.

Box 71.1. Causes of Stridor

Congenital Anomalies
- Choanal atresia
- Laryngeal web
- Laryngocele
- Laryngomalacia
- Macroglossia (Beckwith syndrome)
- Subglottic stenosis
- Tracheal web or cyst
- Tracheomalacia
- Vascular ring

Inflammatory/Infectious Lesions
- Abscess (ie, retropharyngeal, peritonsillar, parapharyngeal)
- Angioedema
- Bronchitis
- Diphtheria
- Epiglottitis
- Infectious mononucleosis
- Severe tonsillitis
- Tracheitis
- Viral croup

Trauma
- Direct trauma to the upper airway
- Postintubation subglottic stenosis

Neurogenic
- Laryngeal paralysis
- Poor pharyngeal muscle tone

Caustic or Thermal Injury
- Hot gas or liquid
- Lye or caustic ingestion

Foreign Body
- Neoplasm

Croup

Croup is most often caused by an infection with parainfluenza virus (type 1 or 2). Several other causes include respiratory syncytial virus, influenza virus A or B, adenovirus, rhinovirus, coxsackievirus,

measles, and herpes simplex virus infections. Metapneumovirus and novel coronavirus, which more commonly cause bronchiolitis, have also been implicated. Simultaneous infections with more than 1 virus are common. Particularly severe disease may be associated with influenza A, respiratory syncytial virus, or adenovirus infection. Infection occurs via respiratory droplets spread from other infected individuals.

The virus first attacks the nasopharynx and subsequently spreads to the larynx and upper trachea. The infection causes inflammation and edema of the airway that often involves the vocal cords and subglottic areas, producing the typical barking cough, hoarseness, and inspiratory stridor. Uncommonly, in severe cases, the lower airways also may be involved, resulting in impaired alveolar ventilation and wheezing. In some children, secondary bacterial superinfection may rarely occur with bacterial tracheitis or extension of infection to the lower airway producing pneumonia. Airways of infants are small and particularly susceptible to obstruction because of the narrow subglottic region and laxity of the cartilaginous structures.

Differential Diagnosis

The differential diagnosis of stridor is presented in Table 71.1.

Evaluation

History

A complete history should be obtained (Box 71.2).

Physical Examination

It is important to assess the degree of respiratory distress and place children in a position of comfort; monitor heart rate, ventilation, and oxygenation; deliver oxygen; and suction the nasopharynx if necessary (see Chapter 70). The stridorous sounds produced are usually inspiratory but may be inspiratory and expiratory if the disease progresses to the lower airway. The presence of stridor at rest or with sleep should be assessed as well as the severity of retractions with breathing. Breath sounds may be decreased bilaterally, and severe tachypnea, with respiratory rates from 40 to 80 breaths per minute, may occur. Peripheral or central cyanosis and alterations in mental status associated with severe disease should be noted. Assessment of croup severity may be helpful to direct initial therapy in mild, moderate, or severe cases as well as monitor response to treatment and predict disposition (Table 71.2).

Laboratory Tests

Investigations, such as a complete blood cell count and cultures, are rarely helpful unless the physician is concerned about secondary bacterial infection. The white blood cell count may be normal or mildly elevated, and the differential count may show a predominance of polymorphonuclear cells. Polymerase chain reaction viral and bacterial respiratory panels may be helpful in more severely ill or admitted patients.

Imaging Studies

Radiographs of the soft tissues of the upper airway are sometimes helpful. In children with croup, the classic steeple sign of the subglottic area where the airway narrows like a church steeple or pencil tip is demonstrated on the frontal view. A lateral neck radiograph may reveal ballooning of the hypopharynx, a normal epiglottis, and a normal retropharyngeal space (Figure 71.1). Radiography is not recommended with a classic presentation of croup. Thickening of the epiglottis, which appears thumbprint-shaped, and obliteration of the vallecular space may be seen on

Table 71.1. Differential Diagnosis of Stridor

Factor	*Viral Croup (Age 3–36 Months)*	*Spasmodic Croup (Age 3–36 Months)*	*Bacterial Tracheitis (Age 1–10 Years)*	*Epiglottitis (Age 1–8 Years)*	*Foreign Body (All Ages)*
Prodrome	Upper respiratory infection symptoms; onset over 2–5 days	None; sudden onset at night	Upper respiratory infection symptoms for days, followed by rapid-onset fever and respiratory distress	Usually none; rapid onset over several hours	None; sudden onset
Fever	Low grade	None	Low grade initially, then higher	Usually temperature above 102.2°F (39°C)	None
Cough	Barking	Barking	Dry initially, then barking	None or dry	May or may not be present
Respiratory distress	Present	Present	Absent or mild initially, then severe	Present and severe	Usually present
White blood cell count	Normal or slightly elevated	Normal	Normal initially, then elevated	Elevated	Normal
Blood culture	No growth	No growth	Growth uncommon	*Haemophilus influenzae*	No growth
Radiograph	Subglottic narrowing; steeple sign	Subglottic narrowing may or may not be present	Subglottic narrowing; steeple sign and ragged trachea	Swollen epiglottis	Air trapping; may demonstrate a foreign body

Box 71.2. What to Ask

Stridor and Croup

- Did the child have an antecedent respiratory infection?
- Does the child have a fever? If so, how high is the temperature?
- Was the onset of stridor abrupt?
- Is there stridor at rest/sleep or only with agitation?
- Has the child had stridor previously?
- Does the child have any ill contacts?
- Does the child have any associated symptoms, such as vomiting, diarrhea, or rash?
- Is the child feeding normally?
- Is the child drooling?

lateral neck radiographs in patients with epiglottitis. Widening of the retropharyngeal space dorsal to the tracheal air column may be seen with retropharyngeal abscess. Children with respiratory compromise should be evaluated in the emergency department with portable X-ray equipment.

Direct visualization or imaging studies (eg, barium swallow, computed tomography of the neck or thorax) are helpful in diagnosing congenital anomalies (eg, vascular ring) in atypical or recurrent cases.

Management

Most children with croup and stridor can be managed as outpatients. Caregivers should be given careful instructions so that they understand the course of the illness, know what to expect, and realize when emergency care is needed. Children with a prolonged or recurrent history of stridor may require consultation with a head and neck specialist. If a specific cause of stridor is identified, such as a foreign body, appropriate management should be instituted.

Children with croup should be treated with gentleness and should not be upset. They should remain with their caregivers and be allowed to assume a position of comfort. Agitation and crying increase respiratory distress and oxygen demand. Procedures should be kept to a minimum. The heart rate, respiratory status, and oxygen saturation should be continuously monitored while the patient is being treated and observed. Airway adjuncts that increase agitation should not be used.

Historically, cool mist has been provided by blow-by or mask. Humidified oxygen or air, which is thought to decrease the viscosity of secretions and reduce airway edema, had long been the mainstay of therapy for croup. Several randomized, controlled trials have questioned this practice, however, demonstrating no benefit of cool humidified mist therapy. Consensus statements now reflect this finding, and most physicians have abandoned this treatment practice. Symptoms of spasmodic croup usually resolve within 6 hours of the onset without treatment; however, cool, humidified mist is still often used as the sole therapy for this disorder.

Currently, treatment of croup with corticosteroids is the mainstay of therapy, and its use is less controversial than the use of cool mist. Several studies have demonstrated that dexamethasone given as a single dose of 0.6 mg/kg is effective in shortening the course and severity of mild, moderate, and severe croup if given in the first 3 days. Several smaller randomized trials have also suggested that one-half the dose of dexamethasone may be equally effective, with fewer adverse effects in patients with mild or moderate croup. Dexamethasone should be given orally but may be given

Table 71.2. Clinical Assessment of Croup Severity

Sign or Symptom	*Normal*	*Mild*	*Moderate*	*Severe*
Air entry	Normal	Mild decrease	Moderate decrease	Marked decrease
Color	Normal	Normal	Cyanotic if agitated	Cyanotic at rest
Level of consciousness	Normal	Restless when disturbed	Restless when undisturbed	Lethargic
Retraction	None	Mild	Moderate	Severe
Stridor	None	Only with agitation	Moderate at rest	Severe at rest
Disease Categories				
Degree	*Management*			
Mild	Dexamethasone 0.3–0.6 mg/kg orally Outpatient observation			
Mild to moderate	Dexamethasone 0.3–0.6 mg/kg orally; consider racemic epinephrine If child improves after observation, is >6 months of age, and has a reliable family, outpatient observation			
Moderate	Dexamethasone 0.6 mg/kg orally or intramuscularly; racemic epinephrine and hospital admission			
Severe	Racemic epinephrine, dexamethasone 0.6 mg/kg orally or intramuscularly, oxygen, and admission to intensive care unit			

Figure 71.1. Lateral neck radiograph of viral croup. Note the ballooning of the hypopharynx and narrowing in the subglottic area.

as an intramuscular or intravenous injection for children who are unable to take oral medication or have persistent emesis. Use of the tablet preparation ground up in applesauce is often recommended, because the liquid preparation does not taste good and is not well tolerated. Recent studies using nebulized budesonide also demonstrate the same efficacy in reducing respiratory distress and decreasing croup severity but at higher cost. Continuous or long-term therapy with steroids does not seem to alter the clinical course of the disease or the period of hospitalization and is not recommended. Treatment with antibiotics is not indicated unless infection with bacteria is evident.

Use of racemic epinephrine has also become less controversial. Several older studies have shown that there was no difference in the long-term outcome between children who were treated with epinephrine and those who received a placebo. More recent and robust studies have clearly demonstrated clinical benefit of the drug when given via nebulizer. This effect lasts a few hours, and repeat doses of the drug may be needed until the anti-inflammatory properties of the administered steroids show clinical effect. Thus, if racemic epinephrine is used on patients who are going to be discharged, it is prudent to observe them for 3 to 4 hours after treatment for return or worsening of stridor. The anti-inflammatory effects of dexamethasone take several hours for onset, and racemic epinephrine may have significant bridging effects in reducing symptoms during this period.

Hospitalization is required for less than 10% of patients presenting to the emergency department. It should be considered for children with an oxygen requirement, who are in moderate to severe respiratory distress, with significant stridor at rest, who are unable to eat, or whose parents are unable to cope with the tasks required to manage the child at home. It is always indicated for children with a bacterial infection, such as epiglottitis or tracheitis.

Studies are ongoing, but early results suggest that continuous positive airway pressure and heated humidified high-flow nasal cannula noninvasive ventilation significantly improve croup symptoms, decrease the work of breathing, and reduce the rates of respiratory failure and need for invasive ventilation in many patients. Use of either therapy use should be considered in most hospitalized patients.

With early steroid administration, racemic epinephrine use, and noninvasive ventilatory support only approximately 1% of infants and children with croup require controlled ventilation with endotracheal intubation. Indications for intubation include severe respiratory distress, altered mental status, hypoxia, and hypercapnia. A major complication of endotracheal intubation in children with croup is subglottic stenosis, which occurs because the endotracheal tube may traumatize the inflamed airway, resulting in permanent damage. Patients should be extubated as soon as possible.

Direct laryngoscopy may be necessary in some children in whom the etiology of stridor is not clear. This procedure should be done by a physician who is experienced in managing the airway.

Prognosis

Stridor is a serious sign indicative of upper airway obstruction and potential respiratory compromise. Although it has many causes, the prognosis typically is determined by the rapidity of diagnosis and institution of appropriate therapeutic measures, particularly stabilizing the patient and ensuring patency of the airway. Certain conditions, such as croup, often resolve spontaneously within a few days, although some children require hospitalization and, rarely, assisted ventilation. Other conditions, such as foreign bodies or tumors, necessitate aggressive intervention to prevent death resulting from airway obstruction.

CASE RESOLUTION

The 2-year-old with the antecedent infection and stridor has the classic signs of mild to moderate croup. Initially, adequate ventilation, oxygenation, and circulation should be ensured. Following this, other diagnostic studies and specific therapy can be considered, such as nasal suctioning, dexamethasone, and racemic epinephrine. A period of posttreatment observation is warranted. If his condition improves, close outpatient management may be considered.

CHAPTER 72

Sudden Unexpected Infant Death and Brief Resolved Unexplained Events

Sarah M. Gustafson, MD, FAAP, and Lynne M. Smith, MD, FAAP

CASE STUDY

A 4-month-old boy is brought to the emergency department by paramedics after being found blue and not breathing by his mother. He had previously been well except for a mild upper respiratory infection. His mother fed him at 2:00 am and found him blue and lifeless lying next to her in bed at 6:00 am. Although the mother smoked cigarettes during pregnancy, the pregnancy and delivery were otherwise normal. The infant received the appropriate immunizations at 2 months of age.

Questions

1. What factors are associated with sudden unexpected infant death?
2. What is the relationship between sudden infant death syndrome and sudden unexpected infant death?
3. What should parents be advised to help prevent sudden unexpected infant death?
4. What is the appropriate evaluation of the infant who presents with a brief resolved unexplained event?
5. Why are sudden unexpected infant death and brief resolved unexplained events not related?
6. What services are available to families whose infant has died from sudden unexpected infant death?

Sudden unexpected infant death (SUID) refers to all sudden, unexpected death in infants younger than 1 year. *Sudden infant death syndrome* (SIDS), a subcategory of SUID, is a diagnosis of exclusion following the death of a previously healthy infant younger than 1 year in which no contributing factors are identified (including the absence of an unsafe sleep environment) after obtaining a comprehensive medical history of the infant and family and performing a thorough postmortem examination and death scene investigation. In the United States, SUID is the most common cause of death in children younger than 1 year (excluding the neonatal period); in most cases, a contributory factor is present, such as an unsafe sleep environment.

A *brief resolved unexplained event* (BRUE) is a sudden, brief, and resolved event that occurs in an infant younger than 1 year of age and that involves at least 1 of the following findings: cyanosis or pallor; decreased, absent, or irregular breathing; change in tone; or decreased responsiveness. What is now known as BRUE was formerly termed an "apparent life-threatening event" (ALTE). For historical reasons, BRUE and SUID are discussed in this chapter because ALTE and SIDS were once thought to be related. A BRUE is not a risk factor for SUID, however.

Sudden Unexpected Infant Death

Epidemiology and Risk Factors

Sudden unexpected infant death accounts for 3,000 to 4,000 infant deaths per year in the United States, with an overall incidence of 0.93 per 1,000 live births. These figures were dramatically higher before the Safe to Sleep campaign (originally the Back to Sleep campaign) promoted by the American Academy of Pediatrics (AAP) to place babies in the supine position for sleep. Before the institution of this campaign, the annual death rate from what was then termed SIDS was approximately 5,000 to 8,000, with an incidence of approximately 1.4 per 1,000 live births.

Sudden unexpected infant death more commonly affects boys than girls and occurs more often in the winter months. The peak incidence of SUID occurs at 2 to 3 months of age, with 90% of deaths occurring before age 6 months.

The frequency of SUID differs in different populations in the United States and other countries. Although the incidence of SUID is decreasing among all groups, the rates in black and American Indian/Alaska Native children is 2 to 3 times the national average. One factor contributing to the higher rate of SUID is the increased

incidence of nonsupine sleeping in black infants. In 2001, the prevalence of prone positioning was 11% for white infants and 15% to 21% for black infants.

Clinical Presentation

Patients with SUID present in cardiopulmonary arrest, with a history of previous good health or antecedent upper respiratory infection. They often present in the early morning hours, having succumbed during sleep. The physician cannot determine the cause of death of the deceased infant; that is the role of the coroner.

Pathophysiology and Risk Factors

Numerous epidemiologic, maternal, and infant factors have been associated with SUID, including preterm birth and intrauterine growth restriction (Box 72.1). Mothers of children with SUID are frequently young and unmarried, smoke cigarettes, and have had fewer than recommended doctor visits during the prenatal and postpartum periods. Parental alcohol use is also a risk factor for SUID. In 1 study SUID rates were 33% higher on New Year's Day than any other day, which suggests that parents under the influence of alcohol are less able to monitor their infants safely. Despite initial reports and significant research efforts, no data have established a causal relationship of BRUEs, apnea, immunizations, or repeated episodes of cyanosis with SUID.

Although bedsharing was once promoted to enhance breastfeeding, accidental suffocation and SUID are associated with this practice. The importance of a safe sleep environment is underscored by a study published in 2000 in which the authors investigated 119 SUID cases over a 4-year period following the initiation of the Back to Sleep campaign. In only 8.4% of these SUID cases was the infant found in a nonprone position, alone in their bed and without any potential obstructions of the external airway by bedding.

Pediatricians play a critical role in counselling parents about safe sleep practices. One study reported that 11% of new mothers reported "usually" bedsharing, yet only 36% of parents had a conversation about bedsharing with their pediatrician. If their pediatrician had a negative view of bedsharing, parents were less likely to bedshare. If the pediatrician had a neutral view, parents were more likely to bedshare. Because approximately 20% of SUID cases in the United States occur while in the care of someone other than the parent, secondary caregivers and staff at child care centers also should be educated about the critical need for babies to sleep on their backs and in a sleep space free of blankets, pillows, and other objects that may obstruct an infant's airway.

Box 72.1. Factors Associated With Sudden Unexplained Infant Death

- Sleeping in prone or side-lying position
- Soft bedding
- Overheating
- Bedsharing
- Socioeconomic disadvantage
- Maternal smoking
- Preterm birth
- Male sex
- Maternal youth
- Low birth weight
- Poor prenatal care
- Family previously reported to child protective services

In addition to exposure to the environmental factors that increase an infant's risk for SUID, most theories suggest the existence of an underlying vulnerability in those who experience SUID. The brainstems of infants who died of SUID have significantly lower concentrations of serotonin and tryptophan hydroxylase, a biosynthetic enzyme of serotonin; higher serotonergic neuron counts; decreased serotonin 1A receptor binding; and reduced serotonin transporter binding in the medulla. Furthermore, several studies have shown a significant increase in monoamine oxidase A (MAO-A) gene polymorphisms that could cause overexpression of MAO-A. These findings suggest that abnormalities in serotonin synthesis, release, and clearance impair the infant's ability to appropriately regulate arousal and respiratory drive in response to potential life-threatening challenges during sleep.

Numerous other associations with SUID have been reported, including altered polymorphisms of proinflammatory cytokines, abnormalities in other neurotransmitters, small mandibular size, disorders of fatty acid oxidation, and cardiac channelopathies, including long QT syndrome. The AAP does not currently recommend universal electrocardiography (ECG) screening at birth to identify potential SUID patients, however, although ECG has been recommended for infants with abnormal hearing screening because of the association of hearing deficits with long QT syndrome. Additionally, pulse oximetry in the newborn period may help identify infants with occult congenital heart disease.

The association between SUID and fatal child abuse has also received attention, although infanticide is estimated to be the cause in less than 5% of suspected SUID cases. The evaluation of the home environment of infants who have died from SUID, referred to as *death scene investigations*, may reveal factors that contributed to the death of some of these infants. Unsafe sleeping environments (eg, sofas) and parental drug paraphernalia may identify such factors. A complete postmortem examination may reveal prior or recent trauma. An autopsy should include an assessment for long bone fractures as well as intracranial hemorrhage, although these findings may account only for the existence of prior trauma rather than for the infant's death. In some municipalities, child fatality boards review each case of reputed SUID to assess whether an etiology can be determined. Infants who are targets of medical child abuse may present with SUID or BRUE. Such infants are suffocated by the parents until they become apneic or die. Because distinguishing between SUID and intentional suffocation is quite difficult pathologically, the AAP Committee on Child Abuse and Neglect has cited factors that should heighten the physician's suspicion for possible child abuse (Box 72.2). The use of in-hospital covert video surveillance has facilitated the recognition of apnea secondary to medical child abuse.

Box 72.2. Circumstances in Which the Physician Should Be Alert to the Possibility of Child Abuse

- Previous recurrent cyanosis, apnea, or brief resolved unexplained event while in the care of the same person
- Previous unexpected or unexplained death of 1 or more siblings
- Simultaneous or near-simultaneous deaths of twins
- Death of other infants while cared for by the same unrelated person
- Blood on the infant's nose or mouth prior to cardiopulmonary resuscitation
- Infant older than 6 months

Management

In most jurisdictions, cases of SUID must be reported to the coroner's office. The AAP recommends a prompt death scene investigation; appropriate use of available medical specialists by medical examiners and coroners, including pediatricians; and a postmortem examination within 24 hours of death, including radiologic skeletal surveys and toxicology and metabolic screening. A complete review of the medical records of the patient is essential. A timely information session with parents is recommended when the results of the investigation determine SUID or another cause of death.

Physicians must provide care to families whose infant has succumbed to SUID. Parents should be guided through issues such as planning the funeral and ending lactation when appropriate. For ongoing support, parents should be referred to groups and agencies to help them cope with the unexpected loss of their child. Information about these organizations can be obtained from First Candle (1-800-221-7437; www.firstcandle.org).

Prevention

Prevention of SUID has become a focus of public health measures, including promotion of smoking cessation and access to prenatal care. Parents must be instructed to avoid soft bedding for their infant, bedsharing, placing their infant on a sofa for sleep, and overheating, and they should be instructed to place their infant in the supine position in a crib. See Box 72.3 for additional recommendations.

Pacifier use has been associated with a decreased incidence of SUID. The AAP recommends that caregivers consider offering a pacifier at naptime and bedtime through age 12 months. The pacifier should not be reinserted after the infant falls asleep or coated in any sweet solution. The pacifier should be cleaned often and replaced regularly. For infants fed mother's milk, pacifier introduction should be delayed until breastfeeding is well established.

The AAP recommends only the supine sleep position, because side sleeping increases the risk of SUID 2-fold relative to back sleeping. A firm crib mattress covered by a fitted sheet is the recommended sleep surface for infants. Soft bedding, such as water beds and couches, or objects in the sleep environment, such as stuffed toys, pillows, quilts, and comforters, are not safe.

Box 72.3. American Academy of Pediatrics Recommendations to Reduce the Risk of Sudden Unexpected Infant Death

- Back to sleep for every sleep.
- Use a firm sleep surface.
- Breastfeeding is recommended.
- Room-sharing with the infant on a separate sleep surface is recommended.
- Keep soft objects and loose bedding away from the infant's sleep area.
- Consider offering a pacifier at naptime and bedtime.
- Avoid smoke exposure during pregnancy and after birth.
- Avoid alcohol and illicit drug use during pregnancy and after birth.
- Avoid overheating.
- Pregnant women should seek and obtain regular prenatal care.
- Infants should be immunized in accordance with American Academy of Pediatrics and Centers for Disease Control and Prevention recommendations.
- Do not use home cardiorespiratory monitors as a strategy to reduce the risk of SIDS.
- Health care providers, staff in newborn nurseries and neonatal intensive care units, and child care providers should endorse and model the SIDS risk-reduction recommendations from birth.
- Media and manufacturers should follow safe sleep guidelines in their messaging and advertising.
- Continue the "Safe to Sleep" campaign, focusing on ways to reduce the risk of all sleep-related infant deaths, including SIDS, suffocation, and other unintentional deaths. Pediatricians and other primary care providers should actively participate in this campaign.
- Avoid the use of commercial devices that are inconsistent with safe sleep recommendations.
- Supervised, awake tummy time is recommended to facilitate development and to minimize development of positional plagiocephaly.
- Continue research and surveillance on the risk factors, causes, and pathophysiologic mechanisms of SIDS and other sleep-related infant deaths, with the ultimate goal of eliminating these deaths entirely.
- There is no evidence to recommend swaddling as a strategy to reduce the risk of SIDS.

Abbreviation: SIDS, sudden infant death syndrome.

Adapted with permission from American Academy of Pediatrics Task Force on Sudden Infant Death Syndrome. SIDS and other sleep-related infant deaths: updated 2016 recommendations for a safe infant sleeping environment. *Pediatrics*. 2016;138(5):e20162938.

The AAP recommends that parents sleep in a separate but proximate sleeping environment from their infant (ie, room-sharing but not bedsharing). Dressing babies in light clothing during sleep and maintaining the room temperature at a comfortable level for adults is recommended to avoid overheating.

During the first weeks of hospitalization, preterm newborns are often placed in a nonsupine position because of respiratory complications and gastroesophageal reflux. The newborns become accustomed to this position, and the parents learn from the modeling of the hospital staff to place them in this unsafe position. The AAP

Task Force on Sudden Infant Death Syndrome encourages neonatologists and nurses to begin placing preterm newborns on their backs "significantly before the infant's anticipated discharge."

One unintended consequence of supine sleep is the increased incidence of positional plagiocephaly. To minimize the risk for head deformities and foster appropriate motor development, parents and caregivers are encouraged to vary the head position at sleep times, avoid swing and bouncy seats that increase pressure on the back of the head, and encourage adult-observed tummy time during waking hours starting from birth. The pediatrician can suggest tummy time at daytime diaper changes, even if for only 1 or 2 minutes.

Brief Resolved Unexplained Events

Epidemiology

Because BRUE is a relatively new term, studies are needed to gather epidemiologic data. The rates for ALTEs, the term previously used for many BRUEs, varied between 0.6 and 2.46 per 1,000 live births. The rates of BRUE likely are lower because unlike with an ALTE, after a cause for a BRUE is established the event is no longer classified as a BRUE; instead, it is then classified by the condition that precipitated the event.

Clinical Presentation

The infant who has experienced a BRUE at home appears well without any need for medical intervention but has a highly variable history in terms of whether resuscitation was required, length of the episode, and associated symptoms. An infant who is ill-appearing on presentation by definition does not have a resolved event and requires immediate intervention and further workup. Patients with BRUE often present between the hours of 8:00 am and 8:00 pm—a time of day different from the typical early morning hours for an SUID.

Differential Diagnosis

The major challenge for physicians is to evaluate infants who have experienced a BRUE and determine if any underlying condition caused the episode (Box 72.4). In most cases, no etiology for a BRUE is established, and the episode represents an isolated event. If an etiology is found, by definition the event is no longer unexplained, and the discharge diagnosis should reflect the etiology.

Evaluation

History

The history may provide the clue to the etiology of BRUE (Box 72.4).

Physical Examination

A complete physical examination should be conducted. If the infant is floppy, has poor color, or has required mouth-to-mouth resuscitation or vigorous stimulation, the event is not considered a BRUE because the symptoms are not resolved. The physician should check for the presence of bruising, retinal hemorrhage, dysmorphic features, growth impairment, and abnormal neurologic or developmental findings, which may suggest an alternative etiology (Box 72.5). The presence of tachypnea, retractions, wheezing, or cough is consistent with a respiratory infection, such as respiratory syncytial virus or pertussis. After an etiology for the BRUE is determined (eg, respiratory syncytial virus), the diagnosis of BRUE should be changed to reflect the etiology.

Box 72.4. What to Ask

Brief Resolved Unexplained Event

- What were the events leading up to the episode?
- Was the infant awake and eating? (Consider gastroesophageal reflux.)
- Was the infant awake, and did the eyes roll back or the body stiffen or jerk? (Consider a seizure.)
- How serious was the event? Did breathing resume spontaneously, or was it necessary to initiate cardiopulmonary resuscitation?
- Have similar events occurred in the past?
- Is the infant well? Has the infant been ill recently?
- Has the infant had respiratory symptoms, such as wheezing or cough?
- Was the infant given an over-the-counter cough and cold product?
- Do siblings have a history of sudden unexpected infant death or brief resolved unexplained event that would suggest the presence of a familial disorder or child abuse?
- Were there any problems with the pregnancy or delivery?

Box 72.5. Brief Resolved Unexplained Events: Alternative Diagnoses to Consider

- Gastroesophageal reflux or overfeeding
- Lower respiratory tract infection
- Sepsis
- Pertussis
- Respiratory syncytial virus
- Infantile botulism
- Seizure
- Incorrect medication dose or overdose
- Inborn errors of metabolism
- Child abuse
- Intracranial hemorrhage
- Airway anomaly
- Aspiration
- Breath-holding spell
- Cardiac arrhythmia/anomaly

Risk Stratification

Before publication of the current guidelines, it was common to admit all infants with BRUE for observation, workup, and monitoring. The 2016 AAP guidelines identify a low-risk subset of patients who require a much more limited evaluation without laboratory testing (Box 72.6).

Management

The management of BRUE depends on whether the BRUE is classified as low- or high-risk. Guidelines for management of BRUE are

Box 72.6. Patients at Low Risk for Brief Resolved Unexplained Event

- Age >60 days
- Born ≥32 weeks' gestational age and corrected gestational age ≥45 weeks
- No cardiopulmonary resuscitation by a trained medical provider
- Event duration <1 minute
- First event
- No concerns on history and physical examination (eg, no family history of sudden cardiac death)

detailed in this section, and a treatment algorithm is provided in Figure 72.1.

Low-Risk Brief Resolved Unexplained Event

The patient may be observed briefly (ie, for 1–4 hours) with serial examinations with or without pulse oximetry. Pertussis testing may be considered, especially in the setting of exposure or unvaccinated caregivers. If a diagnosis of pertussis is likely, the patient typically is observed and started on empiric antibiotics pending results.

Although arrhythmia is rare, an ECG may be indicated because it is a noninvasive test with high negative predictive value. Syncope is associated with future sudden cardiac death in patients with long QT syndrome. Other channelopathies, Wolff-Parkinson-White syndrome, and cardiomyopathy or myocarditis also can be detected on ECG.

In general, the low-risk infant who experienced a BRUE and does not have an identifiable precipitating condition may be discharged from the emergency department after a brief observation of 1 to 4 hours. Prior to discharge from the hospital, the parent or caregiver of the infant who experienced a BRUE should receive resources for cardiopulmonary resuscitation training, be educated about BRUE, and be counseled to arrange close follow-up care. The previous guidelines for ALTEs advised eliminating tobacco smoke exposure, which is not explicitly addressed in the BRUE guidelines. However, given the overall health risks of secondhand smoke exposure, the physician should use every opportunity to counsel caregivers on smoking cessation.

Historically, home apnea monitoring was prescribed for the newborn at risk for apnea. Based on a plethora of studies, the AAP does not recommend home apnea monitors for the prevention of SUID. Home apnea monitoring may be considered for the preterm newborn or infant at risk for repeated episodes of apnea of prematurity on discharge from the hospital. Discontinuation of such monitoring at approximately 43 weeks' gestational age should be considered.

If questions about home monitoring arise, the family of an infant who experienced BRUE should be informed that a home apnea monitor has not been shown to prevent SUID and is not indicated for that purpose. Parents and caregivers can be informed that a BRUE is not a risk factor for SUID. In a prospective study, patients who experienced what was then termed ALTE did not experience SUID. The Collaborative Home Infant Monitoring Evaluation study instituted home monitoring for more than 1,000 healthy term infants and found that 43% of term infants experienced apnea or bradycardia episodes, which indicates that these cardiorespiratory events are common in all infants and are unlikely to be precursors to SUID. Furthermore, SUID usually occurs during infant sleep, whereas an estimated 50% of BRUEs occur during wakefulness.

High-Risk Brief Resolved Unexplained Event

If the patient does not meet all the criteria for low-risk BRUE, the patient is considered high risk. For these infants, if any localizing signs or symptoms exist, the workup should be directed toward that diagnosis. The infant who was not fully resuscitated in the field should be resuscitated, stabilized, and admitted. Any identifiable conditions, such as sepsis, seizures, and gastroesophageal reflux, should be appropriately managed.

Prognosis

Further research is necessary to determine the prognosis for the child who has experienced a BRUE. Parents and caregivers can be assured that most BRUEs are isolated events and the risk of a chronic condition (eg, seizure disorder) is extremely rare.

CASE RESOLUTION

The infant succumbed to SUID. Despite resuscitative efforts by the paramedics, he could not be revived. The mother was advised of the diagnosis of suspected SUID and referred to appropriate agencies and support groups. The coroner was notified of the case. The mother was advised that a coroner investigator would visit her to learn more about the circumstances surrounding the sudden death of her infant.

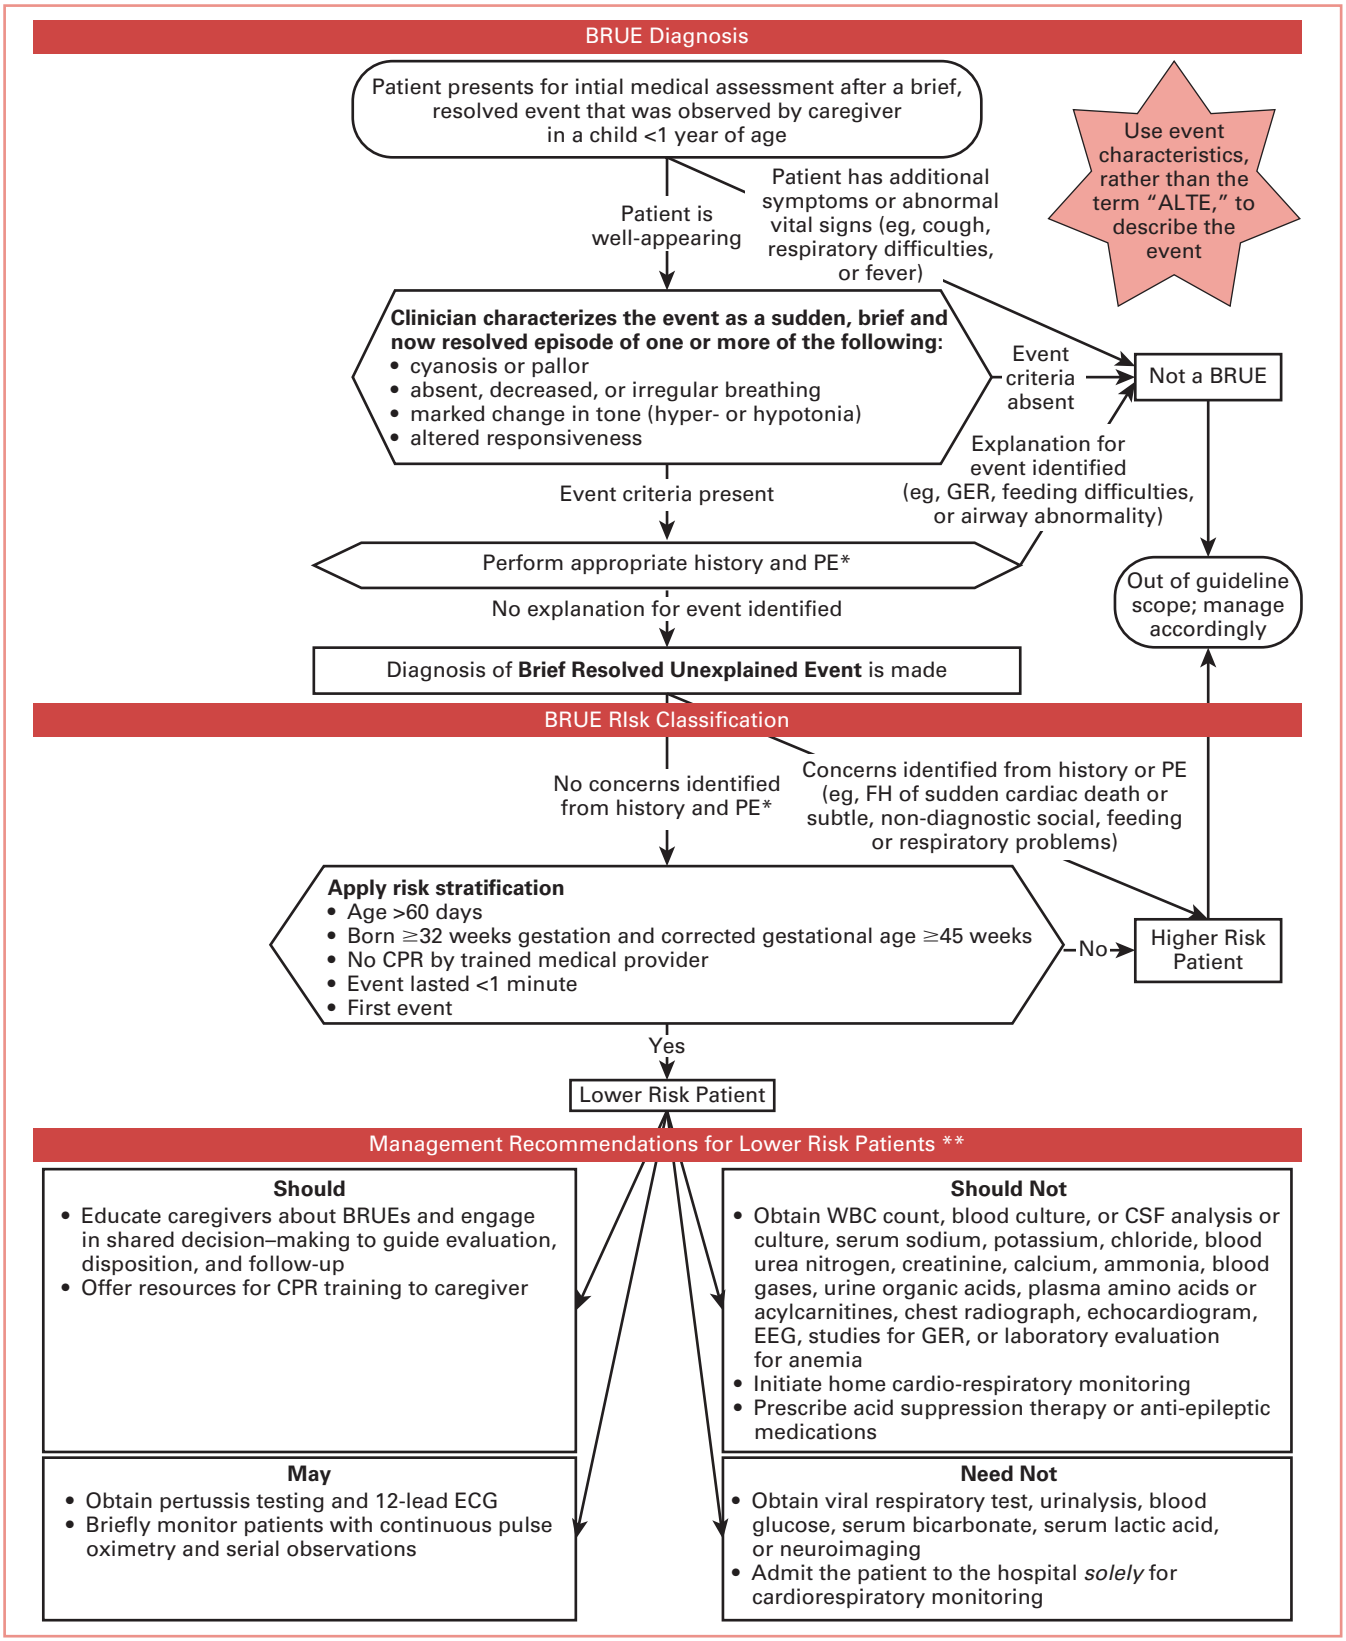

Figure 72.1. Diagnosis, risk classification, and recommended management of a BRUE.

Abbreviations: ALTE, apparent life-threatening event; BRUE, brief resolved unexplained event; CPR, cardiopulmonary resuscitation; CSF, cerebrospinal fluid; ECG, electrocardiography; EEG, electroencephalogram; FH, family history; GER, gastroesophageal reflux; PE, physical examination; WBC, white blood cell.

CHAPTER 73

Syncope

David Atkinson, MD, and Michael Nguyen, DO

CASE STUDY

A 16-year-old girl presents to your office with the chief report of fainting at marching band practice on the day prior. She has been in marching band for the past 2 years and states that nothing like this has occurred before. She is concerned about fainting again. She tells you that she "wasn't able to eat or drink" on the day she fainted because she was too busy studying for finals.

She reports that practice was fairly routine up until her fainting episode. Prior to the episode, she was standing in the field, listening to her teacher give instructions for a new routine. The last thing she remembers after standing awhile was feeling lightheaded and sweaty. The next thing she can recall is lying on the ground with her classmates and teacher around her. She denies any chest pain, shortness of breath, or palpitations prior to the episode. Her teacher told her she was unconscious for approximately 10 to 15 seconds without any shaking of extremities. She was immediately back to baseline after she woke up. She denies incontinence. She says that when she stands up too quickly she sometimes feels lightheaded for a few seconds, but she had never fainted before yesterday.

When asked, she denies any past significant medical history. Her mother states that she is very healthy. She has only gone to the emergency department 1 time previously, when she was 2 years old. At that time, she passed out for 30 seconds after crying. She was diagnosed with a breath-holding spell and has not had any other issues since. There is no family history of sudden death and seizures. When questioned alone, she denies use of any illicit drugs or any sexual activity. Her mother asks if it is okay for her to continue to participate in physical activities. She has recently read about sudden death in high school athletes.

The girl's physical examination is unremarkable, and all vital signs are within normal limits for age. Electrocardiography shows normal sinus rhythm with normal voltages and intervals for her age.

Questions

1. What are the causes of syncope?
2. What workup is recommended to evaluate for syncope?
3. When should patients who experience syncope be referred to a subspecialist?
4. Which pediatric subspecialists assist in the evaluation of a patient with syncope?
5. Which patients presenting with syncope are at greatest risk for sudden death?

Syncope, or fainting, is a transient loss of consciousness and tone; it is a common clinical problem in pediatric patients, particularly during puberty and adolescence. The most common causes of syncope in pediatric patients are benign neurocardiogenic events; however, in rare instances syncope is a harbinger of sudden death from arrhythmia, obstruction of aortic outflow, or other serious cardiovascular events.

The 3 general categories of syncope are neurocardiogenic (also called vasovagal syncope), cardiac syncope, and noncardiac syncope (Box 73.1). The workup for syncope can easily become expensive and time-consuming, and it may provide little information beyond that gleaned by the initial history and physical examination. It is the role of the pediatrician to appropriately direct the evaluation for syncope so that a cost-effective evaluation may occur without missing the patient who may be at risk for a sudden death event.

Epidemiology

Syncope is a temporary, transient loss of consciousness and muscle tone that usually is associated with rapid recovery. It is the result of decreased cerebral blood flow that can occur through many different mechanisms. Syncopal events are very common in the pediatric population; up to 50% of college undergraduates have reported experiencing syncope or near syncope, and it accounts for approximately 1% of all pediatric emergency department visits. Females are more commonly affected than males, and the mean age at presentation is 10 to 12 years. Syncope is uncommon in children younger than 5 years. Many cases of syncope quickly resolve and medical attention is not sought; thus, the true incidence of syncope is almost certainly underestimated.

Clinical Presentation

The clinical presentation of syncope varies with the etiology. Vasovagal syncope often is associated with a prodrome of symptoms, including lightheadedness, visual disturbances, nausea, and diaphoresis. The patient has usually been standing for a long period or has suddenly moved from the supine or sitting position to standing. Other forms of neurally mediated syncope include hair-grooming syncope, which occurs mostly in girls while combing, brushing, or blow-drying their hair. Micturition syncope, although

Box 73.1. Causes of Syncope

Neurocardiogenic (ie, Vasovagal Syncope)

Cardiac

- Tachyarrhythmias
  - Supraventricular tachycardia
  - Ventricular tachycardia
- Bradyarrhythmias
  - Second- or third-degree heart block
  - Sinus node dysfunction
- Left or right ventricular outflow tract obstruction
  - Hypertrophic cardiomyopathy
  - Aortic stenosis
- Idiopathic pulmonary hypertension
- Coronary artery disease
  - Acquired coronary artery disease
    - Kawasaki disease
  - Congenital coronary anomaly
    - Intramural coronary artery
    - Anomalous origin of a coronary artery
- Primary cardiac dysfunction
  - Dilated cardiomyopathy
  - Noncompaction cardiomyopathy
- Secondary cardiac dysfunction
  - Viral or idiopathic myocarditis
  - Restrictive cardiomyopathy

Noncardiac

- Orthostatic hypotension
- Neurologic (eg, seizures, atypical migraine, dysautonomia)
- Breath-holding spells
- Psychogenic (eg, hysteria, hyperventilation)
- Self-induced (eg, hyperventilation, "the choking game")
- Metabolic abnormality (eg, hypoglycemia, anemia)

most common in the elderly, may occur in individuals of any age. Younger patients with this type syncope tend to be male; predisposing factors may include reduced food intake, fatigue, alcohol ingestion, and recent respiratory infection. Micturition syncope often occurs at night when voiding after awakening from sleep (ie, while standing immediately after being recumbent). Recurrences of micturition syncope are rare in young patients. Breath-holding spells in toddlers brought on by anger, pain, fear, or frustration may be associated with syncope; this is an infantile form of cardioinhibitory neurally mediated syncope. Infants who experience syncopal breath-holding spells are more likely to grow up and have neurally mediated syncope (see Chapter 52).

Syncope of cardiac etiology often lacks the prodrome of vasovagal syncope. The main cardiac causes of syncope are arrhythmia and left ventricular outflow obstruction. Patients may report palpitations, chest pain, or chest tightness. Cardiac syncope commonly occurs during physical activity and may be accompanied by complete loss of body tone.

Syncope related to seizures generally has a longer recovery time associated with the postictal phase; witnesses may describe the patient as being dazed or "having a blank look on their face" before fainting. These episodes may occur whether the patient is recumbent or upright.

Pathophysiology

Autonomic

Autonomic causes of syncope are the most common etiology, accounting for up to 80% of cases of syncope that come to medical attention. They are also referred to as neurally mediated reflexive syncope, vasovagal syncope, neurocardiogenic syncope, and, in toddlers, pallid breath-holding spells. They have in common disturbances in autonomic control of heart rate and blood pressure in response to postural changes, bodily functions, pain, fear, or other strong emotional events. Vasovagal syncopal events usually occur when the patient is upright, resulting in decreased venous return, decreased arterial blood pressure, and decreased left ventricular volume. The resultant reflex stimulation of vagal fibers results in bradycardia, vasodilation, and worsening hypotension (ie, Bezold-Jarisch reflex). The 3 clinical types of neurally mediated syncope are vasodepressor, which starts and is primarily marked by profound hypotension; cardioinhibitory, which is marked by severe bradycardia or even brief asystole; and mixed response, which is a mixture of both vasodepressor and cardioinhibitory types.

Cardiac

Cardiac causes of syncope are more likely than noncardiac causes to be associated with sudden death than non-cardiac causes, so it is important to identify and treat these abnormalities. Cardiac mechanisms of syncope are mainly related to obstructive lesions or arrhythmias. Obstructive lesions cause decreased ventricular outflow, resulting in decreased cerebral perfusion; arrhythmia may result in decreased ejection volume, also causing cerebral hypoperfusion and syncope.

Left-sided obstructive lesions, including aortic stenosis and hypertrophic cardiomyopathy, are the most likely cause of obstructive syncope. Rarely, syncope is caused by pulmonary stenosis or severe primary pulmonary hypertension, mitral stenosis, atrial myxoma, or cardiac tamponade. Cardiac syncope, unlike routine vasovagal syncope, often occurs during exertion, because of the inability of the heart to increase cardiac output to meet the demands placed on it by increased physical activity. Increased diastolic pressure caused by an obstructive lesion may also decrease myocardial perfusion, resulting in cardiac ischemia, dyskinesis, or ventricular arrhythmias, thereby further decreasing ventricular output.

Anomalous origin of the coronary arteries is not an obstructive lesion; however, it too may cause syncope with exercise. The left coronary artery may arise from the pulmonary artery, delivering deoxygenated blood to the left coronary system; alternatively, the left coronary artery may arise from the right coronary cusp and course between the aorta and pulmonary arteries. When the patient is in a high cardiac output state, such as during exercise, the left coronary artery may be compressed between the great arteries, resulting in ischemia or arrhythmia.

Primary arrhythmias causing syncope are a rare but important cause of syncope. Typically, chest radiography, echocardiography, and other imaging modalities are normal, with no evidence of structural heart disease or pulmonary edema. Supraventricular tachycardia may cause syncope or near syncope. In most pediatric patients, the tachycardia is propagated through a concealed pathway, and the resting electrocardiogram (ECG) is normal if the tachycardia is not occurring while the ECG is being obtained. Supraventricular tachycardia may also be associated with Wolff-Parkinson-White syndrome, which itself is characterized by a short P-R interval followed by an abnormally wide QRS complex with an initial delta wave.

Ventricular tachycardia is rare in children with no underlying structural heart disease, but it may be brought on by infection (especially myocarditis or pericarditis), cardiomyopathies, drugs (eg, cocaine, amphetamines), drug interactions (eg, non-sedating antihistamines taken with erythromycin or ketoconazole), and long QT syndrome.

Patients with long QT syndrome have prolonged cardiac repolarization, which usually manifests on the resting ECG as a prolongation of the corrected QT interval. The prolongation of the repolarization period of the heart puts patients with long QT syndrome at risk for torsades de pointes, a malignant form of ventricular tachycardia. The genetic forms of long QT syndrome result from mutations in genes that code for ion transport channels or related proteins. Jervell and Lange-Nielsen syndrome is an autosomal-recessive form of long QT syndrome that is associated with congenital deafness. Autosomal-dominant long QT syndrome that is not associated with congenital deafness has been referred to as Romano-Ward syndrome. Although the clinical diagnosis of long QT syndrome is based on a QTc that is prolonged for the patient's age, an estimated 20% of patients with a gene mutation associated with long QT syndrome have a normal resting ECG; thus, a critical part of the evaluation of the syncopal patient is obtaining a family history of long QT syndrome, sudden death or near sudden death, seizures, or a history of torsade de pointes. Long QT syndrome also may be brought on by electrolyte imbalance, increased intracranial pressure, or medications (Table 73.1).

Table 73.1. Drugs Known to Increase the Risk for Ventricular Arrhythmia in Patients With Long QT Syndrome[a]

Drug	*Class*	*Clinical Use*
Amiodarone hydrochloride	Antiarrhythmic	Abnormal heart rhythm
Arsenic trioxide	Anticancer	Leukemia
Bepridil hydrochloride	Antianginal	Heart pain
Chloroquine	Antimalarial	Malaria infection
Chlorpromazine	Antipsychotic/antiemetic	Schizophrenia/nausea
Cisapride	GI stimulant	Heartburn
Clarithromycin	Antibiotic	Bacterial infection
Disopyramide	Antiarrhythmic	Abnormal heart rhythm
Dofetilide	Antiarrhythmic	Abnormal heart rhythm
Droperidol	Sedative/antiemetic	Anesthesia adjunct/nausea
Erythromycin	Antibiotic/GI stimulant	Bacterial infection/Increase GI motility
Halofantrine hydrochloride	Antimalarial	Malaria infection
Haloperidol	Antipsychotic	Schizophrenia, agitation
Ibutilide fumarate	Antiarrhythmic	Abnormal heart rhythm
Levomethadyl acetate	Opiate agonist	Pain control, narcotic dependence
Mesoridazine	Antipsychotic	Schizophrenia
Methadone hydrochloride	Opiate agonist	Pain control, narcotic dependence
Pentamidine isethionate	Anti-infective	Pneumocystis pneumonia
Pimozide	Antipsychotic	Tourette syndrome tics
Procainamide hydrochloride	Antiarrhythmic	Abnormal heart rhythm
Quinidine	Antiarrhythmic	Abnormal heart rhythm
Sotalol hydrochloride	Antiarrhythmic	Abnormal heart rhythm
Sparfloxacin	Antibiotic	Bacterial infection
Thioridazine	Antipsychotic	Schizophrenia

Abbreviation: GI, gastrointestinal.

Noncardiac

Noncardiac causes of syncope include neurologic etiologies (eg, seizures, migraines), metabolic disturbances (eg, hypoglycemia), hyperventilation (panic attacks or self-induced), and hysteria. Low iron stores have been associated with neurally mediated syncope in both children and adolescents and may provide a partial explanation for the higher incidence of neurocardiogenic syncopal events in adolescent girls than boys. Seizures may be difficult to distinguish from vasovagal events, because both can have tonic-clonic movements. Unlike vasovagal or cardiac syncope, seizures result in unconsciousness secondary to neurologic dysfunction. Syncope associated with hypoglycemia is caused by the insufficient delivery of substrate (glucose) to the brain. Cerebral vasoconstriction secondary to arterial hypocapnia produces syncope with hyperventilation that may be secondary to panic attacks or may be self-induced. The "choking game" or "fainting game" refers to intentional cutting off of oxygen to the brain, with the goal of inducing a "high" or euphoric feeling, usually resulting in syncope and occasionally in serious injury or death. Hysterical syncope lacks a true prodrome, and patients usually suffer no injury when they fall. This form of syncope is thought to be related to Munchausen syndrome.

Differential Diagnosis

The differential diagnosis of syncope is presented in Box 73.1. Events that precede and follow the syncopal event are key in determining the etiology of syncope.

Evaluation

History

A thorough history should be obtained from the family and patient, focusing on the patient's symptoms, the situation surrounding the event, and the family history (Box 73.2). A primary goal of the history is to identify any underlying cardiac problems, because these patients are at the greatest risk for sudden death.

Physical Examination

The patient with syncope must undergo a thorough physical examination. Physicians should assess the blood pressure to screen for hypotension and hypovolemia. The cardiac examination should include palpation of the chest for the point of maximal intensity, thrills and lifts, and auscultation to assess the intensity of the heart sounds and detect the presence of murmurs or other adventitial sounds. Upper- and lower-extremity pulses should be palpated for their presence and quality. The remainder of the examination should focus on identifying any abnormal neurologic findings.

Laboratory Tests

The history and physical examination should guide which laboratory tests are necessary. Generally, few tests are needed. Serum glucose level shortly after the syncopal event may be abnormally low and reveal hypoglycemia. Fasting glucose or glucose tolerance tests are usually normal, and such testing is not indicated. In pubertal females, a pregnancy test should be obtained as well as a hemoglobin level. Iron levels may be low in patients with neurally mediated syncope.

Box 73.2. What to Ask

Syncope

- What was the patient doing when the episode occurred?
- What was the position of the patient?
- Did the patient have any symptoms before the syncopal event?
- Did the patient have any chest pain or palpitations during the event?
- How long did it take for the patient to recover from the syncopal event?
- Were any residual symptoms present after the syncopal event?
- Has the patient recently been ill, dehydrated, or fatigued?
- Does the patient have a history of underlying cardiac disease?
- Is the patient taking any type of medication (prescribed, over-the-counter, or illicit)?
- Does the patient have a history of breath-holding or pallid spells?
- Is there a family history of sudden death, seizures, deafness, or cardiac abnormalities?

Imaging Studies

Every patient who is being evaluated for syncope requires an ECG. The ECG may reveal Wolff-Parkinson-White syndrome or a prolonged QT interval, neither of which can be diagnosed on history and physical examination alone. These studies also can be useful in identifying underlying structural abnormalities, such as right ventricular hypertrophy secondary to pulmonary hypertension, left ventricular hypertrophy secondary to hypertrophied cardiomyopathy, or Q waves associated with anomalous origin of the coronary arteries. Patients with findings suggestive of cardiac disease, that is, with a positive history, physical findings, or an abnormal ECG, require referral to a pediatric cardiologist for further evaluation. The cardiac workup of syncope may include a Holter monitor or an event recorder. The Holter monitor is worn for 24 hours and continuously records the heart rhythm. Because this is a limited window of observation, the Holter monitor captures arrhythmia less than 20% of the time, even in patients with known arrhythmias. Event recorders are worn for longer periods, often up to several weeks. They can record and retain the cardiac rhythm before, during, and after an event. When the patient activates the monitor, the recording is saved for download to the cardiologist. If the monitor is not activated, the event recorder will not save the information but will record over it. Although the event recorder has a higher probability than a Holter monitor of capturing an arrhythmia, the tracings are generally lower quality. Small, digital ambulatory cardiac monitors are a relatively new innovation. They are waterproof, may be worn for up to 14 days, and may provide benefits of both the Holter monitor and the traditional event recorder. Exercise stress testing is often used to evaluate the patient's response to exertion and potentially replicate symptoms in a monitored setting. Electrophysiology studies may be ordered if an arrhythmia is uncovered during the evaluation.

The workup for patients without evidence of cardiac disease, that is, with a negative family history for cardiac disease or sudden death and no exertional symptoms such as chest pain, should focus on the noncardiac or autonomic causes of syncope. Patients with prolonged recovery time or persistent neurologic symptoms following an event should be referred to a neurologist and may require electroencephalography to rule out seizure disorders.

A tilt test may be used to aid in the diagnosis of vasovagal syncope, although in most cases the history is sufficient. For this test, the patient is placed on a table that is then tilted to simulate standing in an upright position, a condition that is commonly associated with vasovagal syncope. Great variability exists in the tilt test, however, with a false-positive rate of up to 20%. Factors that influence the test results include the time of day, whether the patient has fasted, hydration status, and whether the test was augmented with isoproterenol. Few false-negative tilt test results have been reported; however, because of the high number of false-positive results the tilt test should be reserved for refractory, recurrent, or unexplained syncope only.

Management

Management of syncope depends on its cause. Recurrent vasovagal syncope may be treated simply with increased fluid intake, including carrying a water bottle in school, and increased salt intake. For patients who are not responding to conservative measures and who are experiencing recurrent vasovagal syncope, it is reasonable to prescribe midodrine hydrochloride. Fludrocortisone acetate, a mineralocorticoid, is a common medical intervention for vasovagal syncope, although the efficacy is not well established. Other treatments include vagolytic drugs (eg, disopyramide), or centrally acting drugs (eg, imipramine, fluoxetine). These medications have varied benefits, and results between small controlled trials are not consistent. The use of beta blockers is not beneficial and may result in a higher recurrence rate.

Patients with neurologic syncope secondary to seizures should be treated with anticonvulsants. Patients with hyperventilation, hysteria, or hypoglycemia are most amenable to behavioral interventions. Patients with syncope secondary to a cardiac etiology should be referred to a cardiologist for further evaluation and correction of the underlying problem. Syncopal episodes of a cardiac etiology may require more aggressive management, such as surgery or cardiac pacing, because they are more likely to result in sudden death.

Prognosis

The prognosis for autonomic and noncardiac syncope is good. Often, patients with vasovagal syncope experience only a single event, and those with recurrent events can be treated with increased fluid intake or with medication. One subgroup to be aware of is children with pallid breath-holding spells; although these spells resolve by 5 years of age in most children, up to 17% of patients may continue to have syncope in adulthood. Patients who have syncope with an underlying cardiac etiology are at the greatest risk for sudden death, and it is only through identification and treatment of these structural or rhythm abnormalities that sudden death may be prevented.

CASE RESOLUTION

The adolescent girl describes symptoms consistent with vasovagal syncope. Her family history, physical examination, and ECG are not suggestive of underlying cardiac disease. The patient and her family should be informed that certain factors, such as dehydration, fatigue, and hunger, can precipitate syncope. Behavioral changes, such as eating breakfast and drinking plenty of water, should be implemented to prevent or limit recurrence of syncope. The patient should be encouraged to carry a water bottle in school, and if necessary a physician note should be sent to the school to allow her to do so. Management with medications is not indicated at this time.

CHAPTER 74

Shock

Kelly D. Young, MD, MS, FAAP

CASE STUDY

A 7-month-old boy is brought in by his parents with a history of vomiting and diarrhea for 2 days. He also has had a low-grade fever and, according to his parents, has become progressively more listless. Vital signs show a heart rate of 200 beats per minute, respiratory rate of 30 breaths per minute, and blood pressure of 72/35 mm Hg. The infant is lethargic, and his skin is mottled. Capillary refill time is 3 seconds. His anterior fontanelle is sunken, and his mucous membranes are dry. The abdomen is flat and nontender, and hyperactive bowel sounds are heard.

Questions

1. What is shock, and what clinical signs can help in the recognition and assessment of shock?
2. What are the stages of shock?
3. What are the different types of shock, and what are the possible causes of each type?
4. What are the management priorities in treating shock?

Shock is defined as a state of circulatory dysfunction resulting in insufficient delivery of oxygen and other metabolic substrates to the tissues. Shock is not a disease but rather an abnormal physiologic state that may result from many disease processes. Early recognition and prompt management of shock are critical to avoid permanent end-organ damage or death.

Epidemiology

The most common type of shock in children worldwide is hypovolemic shock, and the most common causes are dehydration resulting from gastrointestinal infections that cause vomiting and diarrhea, and hemorrhage resulting from traumatic injury. Epidemiology may differ in tertiary care health care systems in developed countries, however. In a case series of 147 pediatric patients with shock (excluding trauma patients) from Children's Hospital of Nevada at UMC, septic shock was the most common etiology, with 57% of patients presenting with that type. Of the remaining patients, 24% had hypovolemic shock, 14% had distributive shock, and 5% had cardiogenic shock. Shock may occur in any age group, but it is more difficult to recognize the early stages in young children because early clinical signs of shock in children are subjective and may be attributed to other causes. By the time young children have developed more typical signs, such as a thready pulse and hypotension, they are in the late stages of shock.

Clinical Presentation

Early signs of shock include tachycardia; cool, clammy, pale, or mottled skin; and delayed capillary refill time. The patient may have a history of decreased urine output. In this early compensated stage, perfusion to vital organs, such as the brain and heart, is maintained by compensatory physiologic processes. As the shock state progresses it becomes uncompensated, resulting in impairment of vital organ perfusion. Signs of uncompensated shock include hypotension; altered mental status (eg, irritability, lethargy, decreased interactivity); weak, thready, or absent pulses (although pulses may be bounding in "warm" septic shock); and severely mottled or cyanotic skin (Box 74.1). In the Nevada epidemiologic study, young children commonly presented with poor extremity

Box 74.1. Diagnosis of the Stages of Shock

Compensated

- Tachycardia
- Normal blood pressure
- Normal or bounding pulses
- Normal or cool, clammy skin
- Pale or mottled skin color
- Alert, anxious mental state
- Mildly delayed capillary refill time
- Decreased urine output

Uncompensated

- Tachycardia or bradycardia
- Hypotension
- Weak, thready, or absent pulses
- Cool, clammy skin
- Severely mottled or cyanotic skin color
- Altered mental state, lethargic
- Delayed capillary refill time
- Decreased or absent urine output

Irreversible

- Multiple organ failure and death

perfusion and poor pulses, whereas adolescents presented with hypotension. Irreversible shock occurs when multiple organs fail and death occurs.

Pathophysiology

Shock occurs when oxygen delivery to tissues is impaired. Adequate oxygen delivery depends on sufficient blood oxygen content and adequate circulatory blood flow (Figure 74.1). The oxygen content in blood depends primarily on the concentration of hemoglobin and the amount of oxygen bound to hemoglobin. In children, oxygen consumption by end organs depends most on oxygen delivery, whereas in adults it depends on oxygen extraction by the tissues.

Blood flow, or cardiac output, is determined by heart rate and stroke volume. Stroke volume depends on preload, contractility, and afterload. *Preload* refers to the amount of blood entering the heart from the systemic vasculature. Increasing preload, for example, via administration of intravenous (IV) fluid boluses, will increase cardiac output until a point of optimal heart muscle fiber length is reached. The Starling curve demonstrates that increased stretching of a muscle fiber results in improved performance of that muscle fiber (ie, improved stroke volume and cardiac output); however, after the point of optimal stretching is reached, performance declines (Figure 74.2).

Contractility, or *inotropy*, is the intrinsic ability of the heart to contract and pump blood to the body. *Afterload* refers to the systemic vascular resistance impeding ejection of blood from the ventricles. Optimal cardiac output depends on sufficient preload, unimpaired cardiac contractility, and the ability of the heart to overcome any afterload. During states of decreased cardiac output resulting in decreased tissue perfusion, adults compensate primarily by decreasing systemic vascular resistance, increasing cardiac contractility, and increasing heart rate, whereas children compensate primarily by increasing their heart rate and by vasoconstriction (to preferentially redistribute blood to essential organs, such as the heart and brain). The vasoconstriction in children may make hypotension a late sign of shock. Irreversible septic shock in adults is often caused by vasomotor collapse, whereas in children cardiac failure plays a larger role in this type of shock.

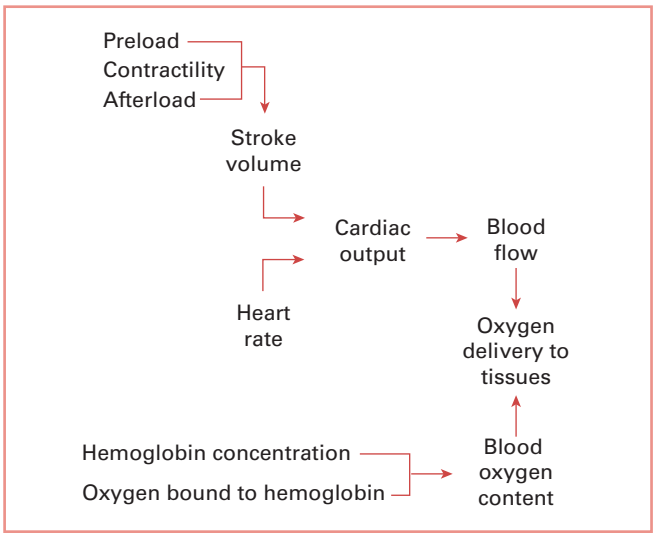

Figure 74.1. Pathophysiology of shock. Factors affecting oxygen delivery to tissue.

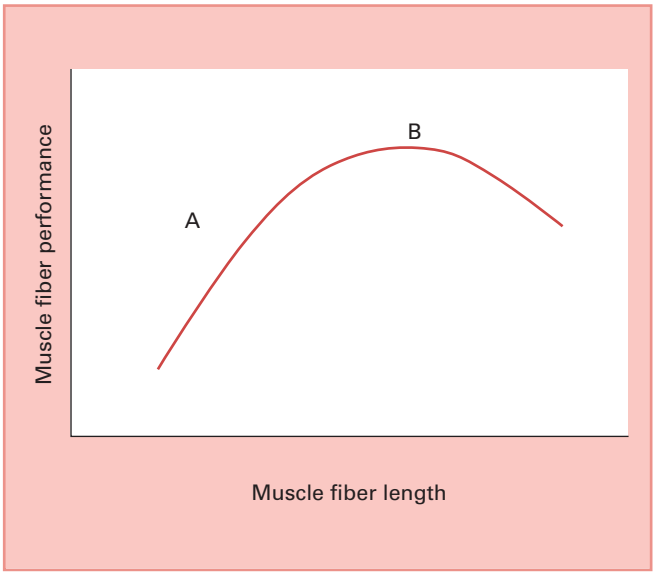

Figure 74.2. Starling curve of cardiac output. As muscle fiber length increases (A), performance increases. After muscle fiber reaches its optimal length (B), performance declines.

Differential Diagnosis

The several types of shock differ based on the underlying pathophysiology (Table 74.1). Hypovolemic shock is the most common type occurring in children and usually results from dehydration or traumatic hemorrhage. Hypovolemia results in inadequate preload, which leads to impaired cardiac output and impaired perfusion. Other causes of hypovolemic shock include dehydration caused by osmotic diuresis in diabetic ketoacidosis and third spacing of fluids (ie, shifting from intravascular to extravascular sites) from peritonitis and burns. Nontraumatic hemorrhage may occur from entities such as epistaxis, gastrointestinal bleeding, and vessel fistula formation.

Distributive shock is a relative hypovolemia; vasodilation results in inadequate circulating blood volume relative to the vasodilation (ie, the "tank" has been made larger by vasodilation, resulting in insufficient fluid to fill the tank). Causes include anaphylaxis and sepsis, which result in the release of vasoactive mediators that cause vasodilation. Spinal cord injury, which can result in neurogenic shock, may result in loss of sympathetic nerve-mediated vascular tone and subsequent vasodilation. Certain ingestions, such as iron, barbiturates, and tricyclic antidepressants, can cause vasodilation and distributive shock.

Cardiogenic shock is an uncommon but important cause of shock in children. Congestive heart failure caused by a congenital heart lesion, myocarditis, or cardiomyopathy results in impaired cardiac contractility and decreased cardiac output. Tachydysrhythmias, such

Table 74.1. Types of Shock

Type of Shock	*Physiologic Mechanism*	*Common Causes*
Hypovolemic	Inadequate preload	Dehydration Traumatic hemorrhage Nontraumatic hemorrhage Diabetic ketoacidosis Peritonitis Burns
Distributive	Relative hypovolemia resulting from vasodilation	Sepsis Anaphylaxis Neurogenic Toxin-mediated
Cardiogenic	Decreased contractility	Congestive heart failure from congenital lesions Myocarditis Tachydysrhythmias
Obstructive	Impaired cardiac output to systemic circulation	Pulmonary embolus Pericardial tamponade Tension pneumothorax Ductal-dependent cardiac lesions
Dissociative	Abnormal hemoglobin—inadequate oxygen bound	Carbon monoxide poisoning Methemoglobinemia

as supraventricular tachycardia, may also result in cardiogenic shock because they do not allow sufficient time for the ventricles to fill with blood, resulting in decreased stroke volume.

Rare causes of shock in pediatric patients include obstructive and dissociative types. In *obstructive shock*, cardiac output to the systemic circulation is obstructed as the result of pulmonary embolus, cardiac tamponade, or tension pneumothorax. Closure of the ductus arteriosus in a neonate with a ductal-dependent congenital heart lesion is another cause of insufficient cardiac output and obstructive shock. In *dissociative shock*, abnormal hemoglobin (eg, methemoglobin), or carboxyhemoglobin caused by carbon monoxide poisoning results in decreased oxygen bound to hemoglobin and decreased oxygen delivered to tissues.

Septic shock combines elements of distributive, hypovolemic, and cardiogenic shock. Vasoactive mediators cause decreased systemic vascular resistance and relative hypovolemia. Third spacing of fluid results in a true intravascular hypovolemia as well. Additionally, mediators of sepsis cause impaired cardiac function.

Because shock is a physiologic state resulting from a variety of etiologies and because it is recognized through clinical findings, it is important to interpret individual findings in the context of the patient as a whole. Heart rate may be elevated for many reasons, including fear, anxiety, and fever. Capillary refill may appear delayed in the extremities of a child who is cold. Blood pressure may appear artificially low when too large a cuff is used to measure it. The health professional must consider whether the child's history is consistent with risk for shock and whether the physical examination as a whole supports the diagnosis.

Evaluation

Early recognition and prompt treatment of shock is the goal. A rapid, focused history and physical examination should be performed to identify patients in shock, and early therapy should be instituted before taking the time to perform a more complete evaluation. Recognition of shock depends on history and physical examination alone; therapy should never be withheld while awaiting results of diagnostic tests.

History

A history of vomiting with or without diarrhea, decreased oral intake, and decreased urine output, especially in infants, should alert the physician to possible hypovolemic shock. Children presenting with major trauma should be evaluated for hemorrhagic shock. A history of fever, lethargy, or irritability, and sometimes a rash, may point toward septic shock. Patients with asplenia, sickle cell disease, or indwelling catheters and those who are immunocompromised (eg, young infants or children on chemotherapy) are at increased risk for sepsis. Children in cardiogenic shock may have a history of a murmur, poor feeding, sweating with feeds, cyanosis, tachypnea, or dyspnea, and the older child may have a history of palpitations.

Physical Examination

A brief physical examination to identify shock focuses on mental status, vital signs, pulses, and skin signs. Impaired level of consciousness, such as lethargy or lack of recognition of parents, occurs later in shock. Earlier in the process, children are anxious, fussy, or irritable. Tachycardia occurs early in shock but must be interpreted in the context of other signs of shock, because tachycardia also may result from fever, pain, or fear of the examination process. Bradycardia is a late, ominous sign in shock and often results from hypoxemia. Hypotension is also a late sign in pediatric shock. It is important to remember that normal values for heart rate and blood pressure vary by age. The lower limit of acceptable systolic blood pressure in a neonate from birth to 1 month is 60 mm Hg and in an infant from 1 month to 1 year is 70 mm Hg. For a child 1 year or older, the lower limit can be estimated using the formula 70 + (2 × age in years) mm Hg; the lower limit is 90 mm Hg for children 10 years or older. Systolic blood pressures lower than these guidelines represent hypotension and late uncompensated shock. Heart rate and blood pressure values requiring immediate attention are shown in Table 74.2.

Presence and quality of pulses should be checked. Weak, thready, or absent peripheral pulses are indicative of shock. However, in warm septic shock, pulses may be bounding. Skin color, moisture, and temperature give valuable clues to diagnosis. Children in shock may have pale, cyanotic, or mottled skin. Early in shock, however, skin color may be normal. Some infants may also have mottled skin

Table 74.2. Critically Abnormal Heart Rate and Blood Pressure

Age	Bradycardia	Tachycardia	Hypotension
Neonate 0–28 days	<100 bpm	>180 bpm	<60 mm Hg
Infant 1–12 months	<90 bpm	>160 bpm	<70 mm Hg
Child 1–10 years	<60 bpm	>140 bpm	<70 + (2 × age) mm Hg
Child >10 years	<60 bpm	>120 bpm	<90 mm Hg

Abbreviation: bpm, beats per minute.

normally. As with tachycardia, isolated signs must be correlated with the bigger clinical picture to diagnose shock. Decreased perfusion in shock results in cool and clammy skin. This is often best initially appreciated in the hands and feet.

Capillary refill is tested by compressing the capillary bed of a fingertip, palm, or dorsal foot with gentle pressure until it blanches. On release, color should return in 2 seconds or less; a capillary refill time of 3 seconds or more is abnormal and indicative of shock. Children in warm septic shock may display "flash" (ie, shortened) capillary refill time. Capillary refill should be tested with the extremity elevated above the heart so that arterial, not venous, perfusion is tested. Additionally, cool ambient temperatures can falsely delay capillary refill times.

In hypovolemic shock caused by dehydration, the patient should be assessed for signs of dehydration, such as dry mucous membranes, lack of tears, sunken eyes, sunken anterior fontanelle in infants, and poor skin turgor. Often, the degree of dehydration can be estimated clinically (see Chapter 80). Patients with hemorrhage, whether traumatic or nontraumatic, must be examined thoroughly to locate the source of hemorrhage.

Children with congestive heart failure and cardiogenic shock may demonstrate dyspnea on exertion, tachypnea, orthopnea, rales, hepatomegaly, gallop rhythm, and a heart murmur; these physical examination signs may be difficult to appreciate in a tachycardic, fussy, ill child. Jugular venous distention and peripheral edema are appreciated less often in children compared with adults. Other signs may include hepatomegaly and/or cardiomegaly on chest radiography as well as a differential in pulses, blood pressure, or pulse oximetry between upper and lower extremities.

Ductal-dependent cardiogenic shock should be suspected in the newborn who presents with shock and/or severe cyanosis unresponsive to oxygen therapy in the first few weeks after birth. Cardiac tamponade is suspected in the patient with muffled or decreased heart tones, paradoxical pulse (ie, decrease in systolic blood pressure >10 mm Hg during inspiration), and distended neck veins. Tension pneumothorax is suspected in patients with deviated trachea (ie, away from the affected side), decreased breath sounds and hyperresonance to percussion on the affected side, and distended neck veins. Pulmonary embolism is rare in pediatric patients, and the signs are subtle. It is mainly suspected in the presence of predisposing factors.

Approximately 20% of children with septic shock present with the classic adult form of warm shock, including increased cardiac output, hypotension, decreased systemic vascular resistance, warm non-mottled skin, bounding pulses, and flash capillary refill. Because children compensate for shock with vasoconstriction, they are more likely than adults to present with cold septic shock, including decreased cardiac output; increased systemic vascular resistance; normal blood pressure to hypotension; cool, clammy, or mottled skin; thready pulses; and delayed capillary refill. The remaining 20% of children with septic shock present with both decreased cardiac output and decreased systemic vascular resistance. Petechiae or purpura are suggestive of meningococcemia as the etiology of septic shock. A sunburn-like rash may occur in patients with toxic shock syndrome caused by streptococcus or staphylococcus.

Laboratory Tests

The suspected cause of shock dictates which laboratory tests are performed. In hypovolemic shock secondary to dehydration, a chemistry panel should be obtained for electrolyte abnormalities and acidosis. Serial hematocrit determinations and a type and crossmatch are important studies in traumatic and nontraumatic hemorrhage, whether known or suspected. In septic shock, a complete blood cell count and blood cultures should be obtained, as well as cultures of other potential sources of infection (eg, urine, cerebrospinal fluid, wound, indwelling venous access line). Results of coagulation studies, including panels to evaluate for disseminated intravascular coagulopathy, and results of electrolyte studies, including calcium and magnesium levels, are frequently abnormal in sepsis. Hypoglycemia is a common finding in any type of shock, and a rapid bedside glucose determination should be performed for all critically ill pediatric patients. Arterial blood gases can demonstrate adequacy of oxygenation and degree of acidosis and are necessary to diagnose elevated carboxyhemoglobin and methemoglobin levels. Initial lactate levels, particularly in patients with septic shock and in trauma patients, may be correlated with overall prognosis and can be followed serially to chart progress. Procalcitonin is another increasingly popular biomarker followed in suspected sepsis. Troponins may be useful in determining severity of disease and following patients with cardiogenic shock. D-dimer assay is useful in patients with suspected pulmonary embolism.

Other Studies

Chest radiography, electrocardiography, and echocardiography may be obtained for patients with cardiogenic or ductal-dependent obstructive shock to further elucidate the specific etiology. Workup of stabilized trauma patients may include bedside ultrasonography, radiography, or computed tomography. Imaging studies contribute to the diagnoses of cardiac tamponade, tension pneumothorax, and pulmonary embolism. Invasive monitoring with arterial lines for systemic arterial blood pressure and central venous lines for central venous pressure or pulmonary artery wedge pressure may be helpful in the ongoing management of shock, particularly fluid-resistant shock.

Management

The first management priority in the treatment of any critically ill child is attention to airway patency and ventilation. For the patient with significant respiratory compromise, bag-and-mask ventilation followed by endotracheal intubation is performed. Usually, however, patients in compensated shock do not require initial advanced airway management. Instead, the immediate priorities are administration of oxygen and initiation of cardiorespiratory monitoring. Oxygen by mask or nasal cannula, preferably heated and humidified, should be administered immediately. Elective rather than emergent endotracheal intubation should be considered to reduce metabolic demands caused by increased work of breathing. When intubating and sedating patients in shock, sedative agents with fewer hemodynamic effects, such as ketamine or fentanyl, are preferred over those that may contribute to hypotension, such as other opiates, benzodiazepines, and propofol. Etomidate, however, although its effects are hemodynamically neutral, is not recommended in septic shock because of its cortisol suppressive effect. Mechanical ventilation settings should emphasize a lung-protective approach.

Almost concurrently, the next priority is achieving intravascular access and, in most cases, administering fluids. Peripheral IV access should be attempted. If this is unsuccessful after 3 attempts or 90 seconds, an intraosseous line may be placed or IV access may be obtained by placement of a central venous catheter or by cutdown technique. Ultrasound-guided vascular access is another option. Intraosseous lines have been demonstrated to provide much more rapid vascular access compared with central line placement. Umbilical venous lines can sometimes be placed in neonates within the first 1 to 2 weeks after birth. More than 1 intravascular line is usually needed for managing patients in shock.

Decreased preload and hypovolemia (actual or relative) are present in the most common causes of pediatric shock. Cardiogenic shock is the only form of shock that may not benefit from increasing preload via a fluid bolus. For other forms of shock, an initial fluid bolus of 20 mL/kg isotonic crystalloid fluid (maximum 1 L), such as normal saline or lactated Ringer solution, should be rapidly infused over 5 to 10 minutes; this may require manually pushing the fluid using a large syringe or a pressure bag. Fluid boluses can be hand pushed into an intraosseous line. Colloid fluid (eg, albumin) theoretically has the advantage of remaining intravascular a longer period of time than normal saline, but this has not been proved to result in a measurable benefit. Crystalloid fluid is recommended for initial boluses because it is less expensive and more readily available than colloid fluid. If a patient with traumatic hemorrhage remains hemodynamically unstable after 2 crystalloid fluid boluses, packed red blood cells at 10 mL/kg may be required. The patient should be assessed for improvement in mentation, vital signs, peripheral pulses, and skin signs after each fluid bolus. Repeat fluid boluses of 20 mL/kg (1 L) to a total of 80 mL/kg (4 L) or more may be necessary to restore intravascular volume. Patients should be reassessed after each bolus before ordering another bolus. Development of hepatomegaly or rales may indicate fluid overload and the need to begin other therapies, such as vasoactive infusions. This is particularly true for cardiogenic and septic shock.

A well-designed and executed trial performed in Africa, the Fluid Expansion as Supportive Therapy (FEAST) trial, has called into question aggressive fluid resuscitation in patients with septic shock. Although patients randomized to rapid fluid therapy showed earlier improvement in circulatory parameters, their mortality was consistently higher. It has been suggested that the results of this trial may not be generalizable to patients in developed countries because of differences in malaria infection, nutritional status, and other factors. The authors suggest that aggressive fluid therapy is particularly associated with increased mortality in highly acidotic patients, especially in developing countries in which inotropic support and mechanical ventilation may not be available. Currently, expert guidelines still recommend early aggressive fluid therapy for septic shock in developed countries in which inotropes and mechanical ventilation are available.

The mnemonic SHOCKED (sound the alarm, help hypovolemia, optimize oxygenation, constrict and contract, keep in mind underlying causes, electrolytes and glucose normalized, decrease metabolic demand) may be used to recall overall management (Box 74.2). Further management in addition to fluids is dependent on the specific etiology. Patients in septic shock should receive empiric broad-spectrum antibiotic coverage within the first hour after presentation. Patients with toxic shock syndrome should receive antibiotics, including clindamycin. A surgeon must assist in identifying the source of hemorrhage and controlling the bleeding in patients with traumatic hemorrhage and may be required for

Box 74.2. SHOCKED Mnemonic for Management of Shock

- **Sound the alarm:** Obtain help from consultants, intensivists, and ancillary personnel. Move the patient to a monitored room and place on a cardiorespiratory monitor, automated blood pressure measurement, and pulse oximetry.
- **Help hypovolemia:** Get intravascular access and start 20 mL/kg crystalloid fluid bolus. Reassess after each bolus and continue giving boluses unless hepatomegaly or rales develop. Patients may require ≥80 mL/kg of fluids.
- **Optimize oxygenation:** Give supplemental oxygen regardless of pulse oximetry values. Consider elective intubation and artificial ventilation to reduce metabolic demands as indicated. Transfusion may be required if hemoglobin is low (<8–10 g/dL).
- **Constrict and contract:** Use inotropic and vasoconstrictive agents as necessary for fluid-refractory shock.
- **Keep in mind underlying causes:** Give or apply therapies specific to the underlying cause.
- **Electrolytes and glucose normalized:** Measure and normalize electrolytes (especially calcium) and glucose. Control hyperglycemia, with a target of ≤180 mg/dL.
- **Decrease metabolic demand:** Manage hyperthermia and pain to reduce metabolic demand on the patient. Consider elective intubation. Keep patient nil per os (ie, nothing by mouth).

management of nontraumatic hemorrhage as well depending on the specific etiology. Blood transfusions may be required. Spinal cord injury is treated with supportive care in consultation with a neurosurgeon. Anaphylactic shock is treated with IV epinephrine, IV diphenhydramine, antihistamine H_2 receptor blockers, glucocorticoids, and nebulized albuterol. Pericardial tamponade is relieved by pericardiocentesis, tension pneumothorax by needle or tube thoracostomy, and pulmonary embolus with supportive care and thrombolytic agents. Carbon monoxide poisoning is managed with 100% oxygen and, if severe, hyperbaric oxygen therapy. Patients with methemoglobinemia appear cyanotic even while receiving 100% oxygen and may be treated with methylene blue. Supraventricular tachycardia should be managed with adenosine if the patient is hemodynamically stable and with synchronized cardioversion if the patient is unstable. Ductal-dependent obstructive shock should be treated with prostaglandin E_1 (PGE_1) infusion.

Patients with cardiogenic shock require inotropic agents to increase cardiac contractility and improve tissue perfusion. Patients in the later stages of other forms of shock (eg, hypovolemic, distributive, septic) may also suffer cardiac dysfunction. In such patients, only after adequate fluid resuscitation has been performed and signs of shock or hypotension persist (ie, fluid-refractory shock) should inotropic agents be started. Central venous pressure monitoring may be necessary to determine whether fluid resuscitation is adequate. Patients with septic shock may require vasoactive agents to reduce or increase systemic vascular resistance.

Epinephrine or dopamine is often the first-line inotropic agent, with recent literature and expert opinion favoring epinephrine. Guidelines recommend beginning inotropic agents when indicated in a peripheral line until a central line is available; that is, do not delay. At low doses (2–5 mcg/kg/min), dopamine improves renal blood flow and enhances urine output. At midrange doses (5–10 mcg/kg/min), dopamine exerts primarily a β-adrenergic effect, improving contractility and increasing heart rate. At higher doses (10–20 mcg/kg/min), the α-adrenergic effects of dopamine cause peripheral vasoconstriction to improve hypotension. Recent data show increased mortality and increased dysrhythmias in patients receiving dopamine as first-line inotrope; as a result, epinephrine has become the preferred first-line therapy. Epinephrine has predominantly β-adrenergic effects at lower doses (0.05–0.1 mcg/kg/min) and α-adrenergic effects at higher doses (≤1.0 mcg/kg/min). Because epinephrine is a strong inotrope, it is recommended for cold septic shock. Norepinephrine (0.01–1.0 mcg/kg/min) has predominantly α-adrenergic vasoconstrictive effects and therefore is preferred for warm septic shock with low systemic vascular resistance and for distributive shock states (eg, anaphylaxis, neurogenic shock, certain toxin-induced shock states). Dobutamine (1–20 mcg/kg/min) may be the most useful drug for cardiogenic shock because it is selective for β-adrenergic effects, thereby increasing cardiac contractility. In the setting of hypotension, however, dobutamine-mediated peripheral vasodilation may be detrimental. Dobutamine is typically used in a range of 10 to 20 mcg/kg per minute. Combinations of inotropic agents may be beneficial to maximize improvements in cardiac contractility and cardiac output without compromising renal perfusion or worsening hypotension. Dopamine and dobutamine may be less effective in infants younger than 12 months than in older children. This is another reason that some institutions recommend epinephrine as the first-line inotropic agent.

Patients in cardiogenic shock or cold septic shock may also benefit from afterload reduction using systemic vasodilators, such as nitroprusside (0.5–5 mcg/kg/min). If these are used, blood pressure should be continuously monitored, typically in the setting of an intensive care unit. Cold septic shock refractory to epinephrine may also be treated with type 3 phosphodiesterase inhibitors (eg, inamrinone 1–20 mcg/kg/min, milrinone 0.25–1.0 mcg/kg/min), which exert inotropic and vasodilator actions (ie, inodilators). Typically, a pediatric intensive care specialist should be involved in the care of the patient, and central venous pressure monitoring should be begun before vasodilator agents are started.

Neonates with ductal-dependent lesions present with a sudden onset of shock and cyanosis, typically in the first 2 weeks after birth. Common lesions include hypoplastic left heart syndrome, aortic coarctation, and tricuspid atresia. Prostaglandin E_1 (0.1 mcg/kg/min, titrated to effect), which acts to keep the ductus arteriosus open, should be immediately infused if a ductal-dependent lesion is suspected as the cause of shock. Apnea may result from PGE_1 therapy, and attention to airway management is of critical importance.

Historically, it was common to mix vasoactive infusions using the "rule of 6 and 0.6." That is, for dopamine, dobutamine, and nitroprusside, mix 6 mcg/kg of drug with enough dextrose 5% in water to produce a final volume of 100 mL. Infusion at 1 mL per hour provides a dose of 1 mcg/kg per minute. For epinephrine, norepinephrine, and PGE_1, mix 0.6 mcg/kg of drug with enough dextrose 5% in water to produce a final volume of 100 mL. Infusion of 1 mL per hour provides a dose of 0.1 mcg/kg per minute. Calculations such as these are prone to error, however, and computerized order forms with automatic error alerts or "smart" pumps that automatically calculate doses based on the patient's input weight are better choices.

Treatment of patients in shock must include attention to conditions that increase metabolic demand. Acidosis should be assessed, and medical therapy and ventilator management should be done with the intent to improve acid-base status. Temperature should be kept neutral, with antipyretic agents and cooling measures used as needed. Electrolyte abnormalities, particularly hypocalcemia and hypoglycemia, must be assessed and corrected. If a hypothyroid state is suspected, thyroid hormone replacement therapy is important. Blood products may be required for patients with septic shock and disseminated intravascular coagulation. Packed red blood cells, 10 mL/kg at a time, should be administered to maintain hemoglobin of at least 10 g/dL for unstable, hypoxemic, or hemorrhaging patients, and 7 to 9 g/dL for stable patients. Fresh frozen plasma may be administered to correct abnormalities in prothrombin and partial thromboplastin times but should not be pushed because of its propensity to cause further hypotension. Cryoprecipitate should be reserved for documented hypofibrinogenemic states.

An expert panel from the American College of Critical Care Medicine created clinical practice parameters for the treatment of pediatric septic shock (Figure 74.3). Recommended therapy is divided between therapies for the first hour (ie, "golden hour") and therapies beyond the first hour (often with critical care specialists involved). In the first 15 minutes after recognition of septic shock, practitioners should attend to the airway and establish intravascular access, begin fluid boluses in 20 mL/kg increments, and diagnose and correct any hypoglycemia and hypocalcemia. The goal of therapy is normalization of heart rate, blood pressure, and capillary refill (≤2 seconds), no difference between peripheral and central pulses and warm extremities, urine output greater than 1 mL/kg per hour, normal mental status, cardiac index between 3.3 and 6.0 L/min/m^2, and superior vena cava (SVC) oxygen saturation (O_2 sat) 70% or higher. Patients who are responsive to fluid may be observed in the pediatric intensive care unit. Epinephrine infusion should be started for those who remain hypotensive after fluid resuscitation. Norepinephrine infusion is recommended for the less common warm septic shock state. The guidelines emphasize that inotropic therapy should not be withheld because there is no central line; it can be administered peripherally if no other options exist. Two studies of patients transferred into a tertiary pediatric medical center showed significantly reduced mortality and morbidity for patients cared for by community practitioners who followed these guidelines for the first hour of care.

Corticosteroids are controversial in the management of sepsis. Guidelines suggest administering "stress doses" of hydrocortisone 2 mg/kg or 50 mg/m^2 body surface area beyond the first hour of therapy for catecholamine-resistant septic shock in cases of suspected adrenal insufficiency. Adrenal insufficiency may be suspected in patients with a history of a central nervous system abnormality or pituitary abnormality, a known adrenal gland disorder, recent surgery, history of chronic steroid therapy (eg, for asthma, inflammatory bowel disease, a rheumatologic condition), and in purpura fulminans. "Shock doses" of hydrocortisone (50 mg/kg) may be administered in the setting of catecholamine-resistant fulminant septic shock and dopamine-resistant purpura fulminans. It is suggested that a baseline cortisol level be drawn before administering corticosteroids.

After the first hour of therapy, a vasodilator (eg, nitroprusside) or type 3 phosphodiesterase inhibitor (ie, inamrinone, milrinone) along with further volume loading may be helpful in catecholamine-resistant cold septic shock with normal blood pressure and SVC O_2 sat less than 70%. In cases of cold septic shock with low blood pressure and SVC O_2 sat less than 70%, continued titration of epinephrine and volume, addition of norepinephrine, and consideration of other vasoactive drugs is recommended. For warm septic shock, continued titration of norepinephrine and volume is recommended, with the possible addition of vasopressin (0.0003–0.0008 U/kg/min), terlipressin, or angiotensin, and consideration of other vasoactive drugs. Vasopressin and terlipressin have not been well studied in children but show promise in adults. For persistent catecholamine-resistant shock (particularly septic or cardiogenic), consideration may be given to ventricular assist devices or extracorporeal membrane oxygenation. Recombinant activated protein C (ie, drotrecogin alfa) was recommended for some septic adult patients but not for pediatric patients, and the commercial product Xigris is no longer available.

Prevention

Improving outcomes is focused primarily on early recognition and early appropriate therapy of shock. One study showed significantly reduced morbidity and mortality in shock patients transferred to a tertiary pediatric medical center if community hospital physicians recognized shock and used pediatric advanced life support (PALS)–recommended interventions early. Appropriate PALS-recommended therapy was defined as more than 20 mL/kg of fluids (except in those with cardiac conditions) and use of inotropes in patients in fluid-refractory shock. Unfortunately, although 37% of the patients transferred during the study period were in shock, as defined by prolonged capillary refill time or hypotension, only 7% were identified as in shock during the referral process. Early recognition of compensated shock is a key preventive measure to reduce mortality. In the same study, only 36% of those in shock received appropriate PALS-recommended therapy before transfer. Community health professionals must concentrate on obtaining vascular access (with an intraosseous needle, if necessary), giving fluid boluses early, and starting inotropes (through a peripheral IV line, if necessary) for the management of fluid-refractory shock within the first hour. Sepsis recognition bundles including a trigger tool based on vital signs, triage physical examination, and patient risk factors (the trigger tool is often incorporated into electronic medical record systems) with rapid clinician assessment within 15 minutes for those that are trigger positive, are recommended to improve recognition. Early therapy, which often occurs before the patient reaches a tertiary care center, is another important preventive measure. Rapid response teams are increasingly being used in hospitals to institute appropriate medical therapy for inpatients with concerning symptoms or vital signs. At a minimum, community pediatricians should have the ability to administer oxygen and obtain intravascular or intraosseous access and administer rapid fluid boluses in their offices. Early broad-spectrum antibiotic therapy within 60 minutes of recognition of possible sepsis (along with blood culture, but only if it does not delay antibiotic administration) is another important element of recommended resuscitation bundles.

Prognosis

Children in shock are critically ill and at risk for progression to multiorgan failure and death. Prognosis depends on how early shock is recognized and treated and on the underlying etiology. Pediatric septic shock carries a 2% mortality rate in previously healthy children but an 8% mortality rate in children with chronic illness. These rates are significantly improved from 60% in the 1980s and 97% in the 1960s and are also lower than the adult septic shock mortality rate. Mortality rates are even lower with prompt recognition and adequate treatment.

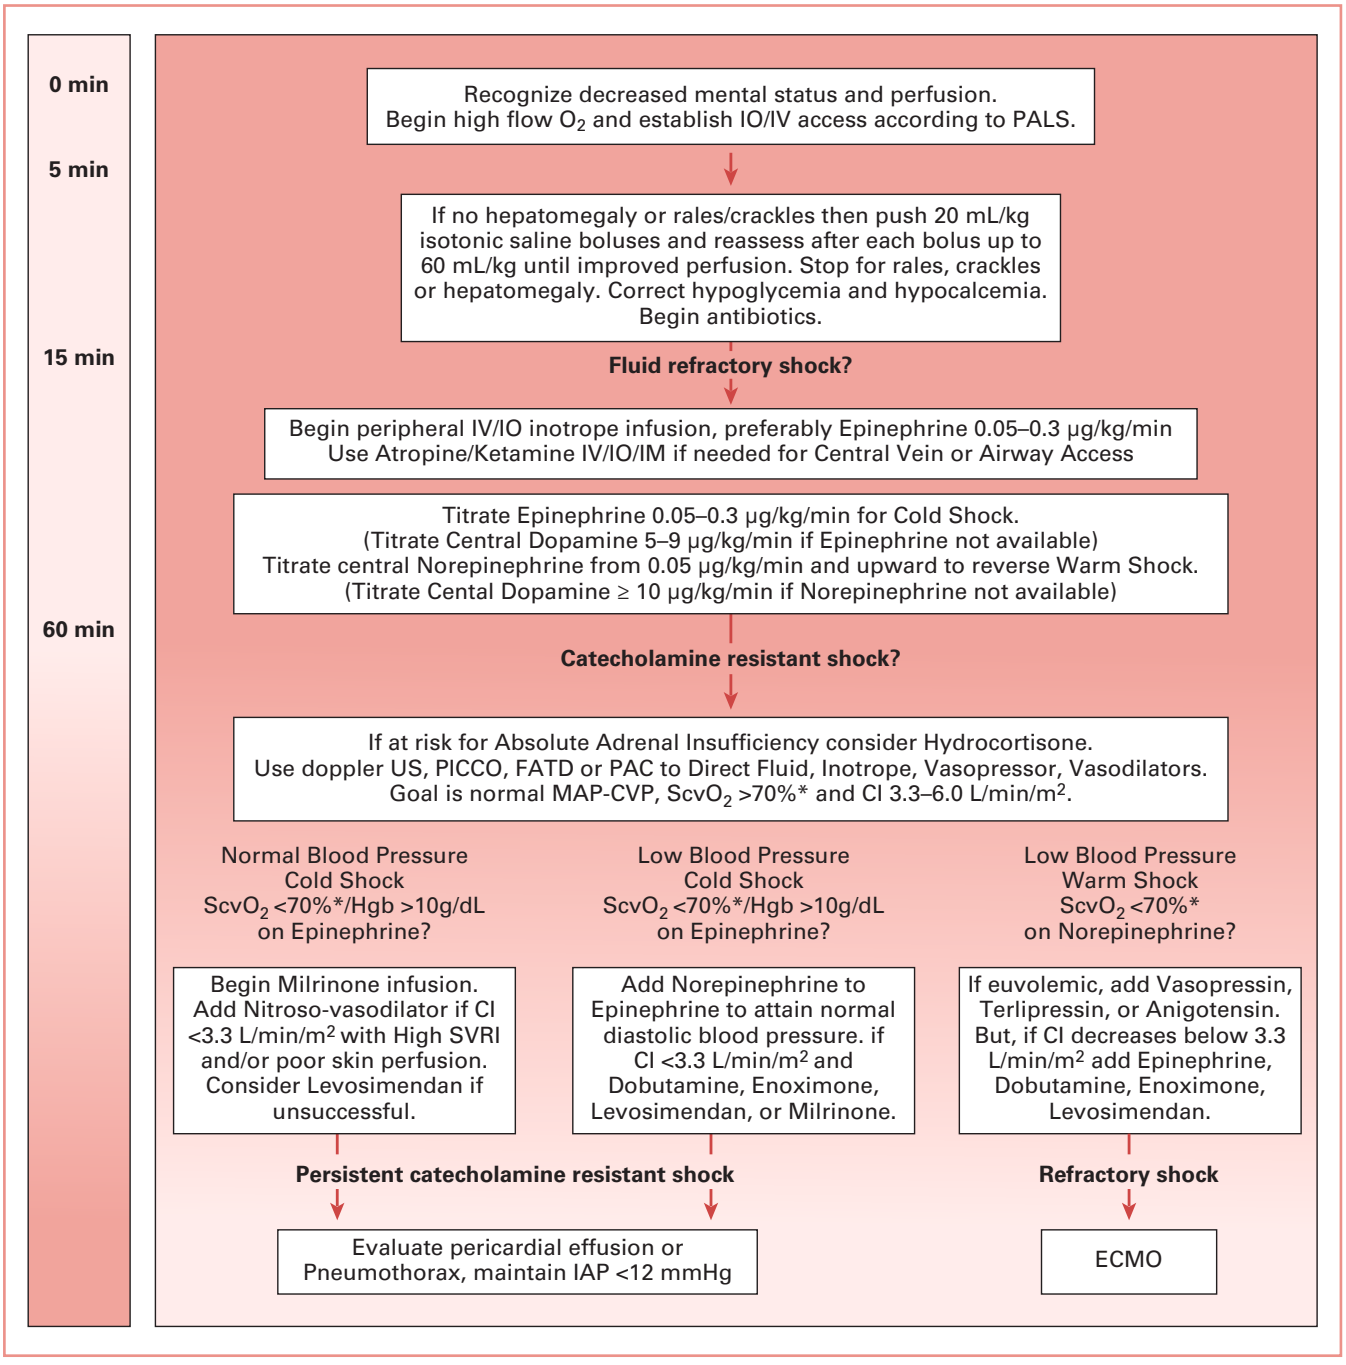

Figure 74.3. American College of Critical Care Medicine algorithm for time-sensitive, goal-directed stepwise management of hemodynamic support in infants and children. Proceed to next step if shock persists. 1) First hour goals: Restore and maintain heart rate thresholds, capillary refill within 2 seconds, and normal blood pressure in the first hour/emergency department. 2) Subsequent intensive care unit goals: If shock is not reversed, proceed to restore and maintain normal perfusion pressure (MAP – CVP) for age, $ScvO_2$ > 70% (* except congenital heart patients with mixing lesions), and cardiac index of 3.3 to 6.0 L/min/m^2 in the pediatric intensive care unit.

Abbreviations: CI, cardiac index; CVP, central venous pressure; ECMO, extracorporeal membrane oxygenation; FATD, femoral arterial thermodilution method; Hgb, hemoglobin; IAP, intra-abdominal pressure; ICU, intensive care unit; IM, intramuscular; IO, intraosseous; IV, intravenous; MAP, mean arterial pressure; PAC, premature atrial contractions; PALS, pediatric advanced life support; PICCO, Pulse index Continuous Cardiac Output; $ScvO_2$, central venous oxygen saturation; SVC, superior vena cava; SVRI, systemic vascular resistance index; US, ultrasonography.

CASE RESOLUTION

The boy is in barely compensated (ie, not hypotensive) hypovolemic shock resulting from diarrhea, vomiting, and dehydration. He should receive oxygen and cardiorespiratory monitoring, and IV access should be rapidly established. Isotonic fluid boluses of 20 mL/kg should be given, with reassessment performed between each bolus. As much as 80 mL/kg may be needed before improvements in mentation, vital signs, pulses, and skin signs are evident.

CHAPTER 75

Approach to the Traumatized Child

David B. Burbulys, MD

CASE STUDY

A 6-year-old boy is brought to the emergency department after being struck by an automobile while crossing the street. He was found unconscious at the scene. Initial evaluation shows that he has an altered level of consciousness, shallow respirations, ecchymosis across the upper abdomen, and a deformed, swollen left thigh. The pediatric emergency physician is called in to discuss an initial assessment and management plan for the injured child with the trauma surgeon.

Questions

1. What are the most common mechanisms of injury responsible for trauma in children?
2. What are some of the physiologic differences between adults and children that make children more susceptible to certain types of injury?
3. Which areas of the body are most likely to be injured in a typical automobile versus pedestrian collision?
4. What are the components of a primary survey in pediatric trauma patients?
5. What radiologic and laboratory studies should be performed in children with multiple injuries?

Trauma is often referred to as the neglected disease of modern society. Childhood trauma, in particular, is poorly understood and studied. Death from trauma is higher in pediatric patients than in adult patients. Mechanisms of injury may be similar in adults and children, but children have particular anatomic differences and physiologic responses to injury. Health professionals should realize that children have unique anatomic and physiologic features compared with adults (Box 75.1). Evaluation and management of traumatized children requires specialized knowledge, training, and equipment. Recognition of such facts, coupled with expertise in the performance of emergency procedures, has improved the outcomes of children who sustain major injuries.

Epidemiology

Traumatic injuries are the most common cause of death in children aged 1 to 21 years (and in adults aged 21–44 years) in the United States. In many of these age groups, murder and suicide are the second and third leading cause of death, respectively. Approximately 7 to 8 million pediatric injuries result in 250,000 to 500,000 hospitalizations and 15,000 to 25,000 deaths each year. Medical costs associated with these injuries exceed $50 billion annually. Infants are most likely to die from suffocation, young children from drowning, school-age children from motor vehicle collisions or after being struck by an automobile, and adolescents from motor vehicle crashes. Boys are twice as likely as girls to be injured and die. The magnitude of pediatric trauma becomes even more evident when

Box 75.1. Characteristics of Children That Result in Increased Susceptibility to Injury

Anatomic

- Smaller body size allows for the greater distribution of force with trauma, so multisystem injury is common.
- A prominent occiput, exaggerated head-to-body ratio, weak neck muscles, and higher center of gravity predispose younger children to head injury.
- Cranial bones are thinner, and the brain is less myelinated, resulting in more serious head injury.
- Skeletal and ligamentous structures have increased flexibility, which results in greater transmission of force to internal organs.
- Less protective muscle and subcutaneous tissue over internal organs expose them to injury.
- Growth plates are not yet fused, which results in Salter-Harris-type fractures and possible bone growth abnormalities with healing.

Physiologic

- High body surface area-to-weight ratio predisposes children to hypothermia, which may complicate shock and worsen acidosis and coagulopathy if it is not corrected.
- Hypoxia and respiratory failure are more likely in children.
- Hemorrhagic shock is initially well tolerated by increasing heart rate and peripheral vascular resistance without significant changes in systolic blood pressure.

morbidity is considered. Between 50,000 and 100,000 children per year become permanently disabled as a result of their injuries. Such disabilities have an enormous effect on society; they result in financial and emotional losses for families and years of lost productivity for the injured individuals themselves.

Blunt trauma, which is more common than penetrating injury in children, represents approximately 87% of all childhood injuries. Head injuries, followed by thoracoabdominal injuries, are the leading causes of death in this group. In adolescents and young adults, however, penetrating injury (ie, homicide, suicide) accounts for a higher percentage of total trauma, especially among minority populations in urban areas. Causes of nonpenetrating trauma are motor vehicle crashes (>40%), falls (25%–30%), drowning (10%–15%), and burns (5%–10%). Included in the remainder are bicycle-related and automobile versus pedestrian injuries. These numbers vary significantly by locale and age. In some centers, a high percentage of trauma deaths are related to child abuse.

Clinical Presentation

Children who sustain severe trauma present with multiorgan system injury manifested by shock, respiratory failure, or altered mental status, either alone or in combination. Those with mild to moderate injury may present in this way or may simply present with localized signs and symptoms in the injured area.

Pathophysiology

It is important to identify patterns of injury to develop strategies for injury prevention as well as anticipate injuries during treatment. One common pattern is the *Waddell triad*, that is, the triad of injuries that results from an automobile versus pedestrian collision (Figure 75.1).

Multisystem injury is the rule rather than the exception in children. Internal injury must always be suspected when the mechanism of injury warrants such injury, even in the absence of apparent evidence suggestive of external trauma. Because children are anatomically and physiologically different from adults, they are more susceptible to diverse types of injury (see Box 75.1). The most striking physiologic differences between adults and children concern responses to acute blood loss. Children have a tremendous capacity to maintain systolic blood pressure despite 25% to 30% acute blood loss.

Hypovolemic shock secondary to acute blood loss is the most common cause of shock in pediatric trauma patients. *Hemorrhagic shock* is a clinical state in which cardiac output is unable to meet the metabolic demands of tissues for oxygen and nutrients; it is not defined by any absolute blood pressure value.

Acute blood loss stimulates peripheral and central receptors and results in increased production of catecholamines and corticosteroids. The body responds by increasing peripheral vascular resistance, stroke volume, and heart rate. Children have the capacity to dramatically increase heart rate and peripheral vascular resistance, and they often may exhibit normal blood pressure in the presence of hypovolemic shock. By the time their blood pressure falls, they commonly have lost 20% to 25% of their circulating blood volume. In adults, blood pressure tends to decline after a less significant blood loss, resulting in earlier recognition of the extent of blood loss (Figure 75.2). Subtle changes in heart rate, blood pressure, pulse pressure, and capillary refill may indicate impending cardiovascular collapse in children who have sustained traumatic injury and should not be overlooked. Indicators of end-organ perfusion, such as lactic acid levels or calculated base deficit, may also be helpful and predictive.

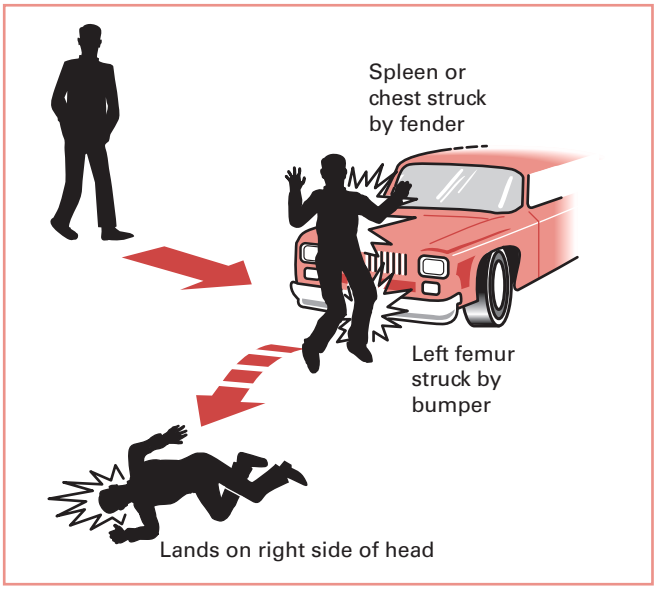

Figure 75.1. The Waddell triad, that is, femur, abdominal, and contralateral head injuries, should be expected to result from automobile versus pedestrian collisions in the United States. For example, a child crossing the street is struck on the left side of the body by an automobile traveling on the right side of the road. The left femur is likely to be injured by the bumper, and the abdomen or chest strikes the grille as the child is lifted into the air and lands on the opposite side of the head, sustaining blunt head trauma. The Waddell triad illustrates the necessity of having a high degree of suspicion for predictable injuries based on a well-known mechanism.

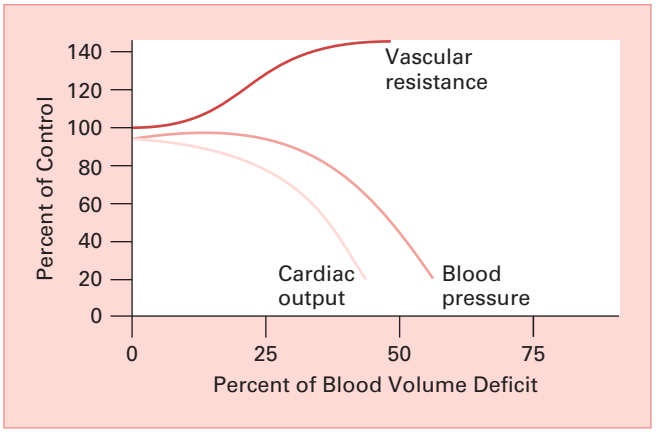

Figure 75.2. Cardiovascular response to hypovolemia in children. Blood pressure does not begin to decline until the volume deficit is more than 25% because of the compensatory increase in vascular resistance. Cardiac output drops earlier and is manifested clinically as delayed capillary refill; cool, clammy skin; and tachycardia.

Another obstacle to the recognition of shock in children is the lack of knowledge on the part of many health professionals of age-appropriate vital signs, particularly blood pressure. Table 75.1 gives the normal blood pressure ranges for children of different ages.

Three stages of shock correspond to the progression of volume loss. In the first stage, compensated shock, mechanisms for preserving blood pressure remain effective. Decreased capillary refill, diminished pulses, cool extremities, and tachypnea may be apparent, but blood pressure is normal (although accompanied by tachycardia). Unrecognized, untreated compensated shock rapidly progresses to uncompensated shock. Examination reveals decreased level of consciousness, pallor, reduced urine output, and lower blood pressure with weak, thready pulses and marked tachycardia. With inadequate therapy, uncompensated shock becomes irreversible shock, resulting in irreparable organ damage and often unpreventable death. (See Chapter 74 for a more extensive discussion.)

Shock has several causes, and it is important to emphasize that in trauma patients, it should always be initially attributed to hemorrhage. Shock resulting from obstructive cardiac output causes, such as tension pneumothorax or cardiac tamponade, is much less common. Shock resulting from spinal cord injury is exceedingly rare. Shock should never be attributed solely to head trauma. The pathways resulting in decreased blood pressure in patients with head trauma are present only at the terminal stages. Therefore, the possibility of blood loss from internal organs should be pursued promptly and aggressively. The most common site of hemorrhage resulting in preventable mortality is intra-abdominal. Other sources of hemorrhage are external, thoracic, pelvic, and retroperitoneal.

Evaluation and Management

Because of the high potential for serious morbidity and mortality in trauma patients, evaluation and management are performed simultaneously. This care is best managed using an organized, multidisciplinary team approach, with preestablished criteria for activation of the trauma team. History of the event provides important information when implementing these criteria. For example, the entire team responds for all pedestrians struck by an automobile. The types of subspecialists that make up a trauma team are decided by individual institutions and commonly include pediatric emergency and critical care specialists, anesthesiologists, trauma surgeons, surgical subspecialists, emergency nurses, respiratory therapists, social workers, and radiology technicians.

Several approaches to the assessment of trauma patients have been developed by professional organizations. The Advanced Trauma Life Support (ATLS) course of the American College of Surgeons and the International Trauma Life Support (ITLS) course (formerly Basic Trauma Life Support, which was initially funded by the American College of Emergency Physicians) are 2 such approaches. The ATLS and ITLS methods stress the importance of a primary evaluation, or primary survey, to identify and manage immediate life-threatening injuries followed by a more detailed regional examination, or secondary survey, after stabilization, to identify and manage all other injuries. Additionally, both protocols adhere to the principles of serial examination and reassessment after each intervention. The primary survey and initial resuscitation efforts must occur simultaneously and within the first several minutes of the evaluation. The secondary survey is meant to enhance the primary survey. Vital signs should be reassessed frequently during the primary and secondary survey until the trauma team feels the patient has been adequately stabilized. The physician should understand the rationale for the trauma examination and its parts. This topic is beyond the scope of this chapter, but articles that explain the rationale for trauma examination and provide detailed descriptions of evaluation and management techniques are listed in the Selected References section.

Physical Examination

The primary survey begins with an assessment of level of consciousness, patency of the airway (Box 75.2), and quality of breathing (Box 75.3). When evaluating injured patients, physicians should always assume that the cervical spine has been injured and should use in-line immobilization to secure it. Basic airway maneuvers for positioning should be performed, the safest of which is the jaw thrust to avoid moving the cervical spine (Figure 75.3). The oral cavity should be examined for foreign bodies, blood, or secretions. The most common form of airway obstruction in children is a posteriorly displaced tongue, which is relieved by good airway positioning. Advanced airway maneuvers (ie, bag-valve-mask ventilation, endotracheal tube intubation) are performed during the primary survey if the child has apnea, significant respiratory distress, severe head trauma, or an airway that cannot be maintained with basic

Table 75.1. Normal Vital Signs for Children by Age

Age	*Respiration (breaths/min)*	*Pulse (beats/min)*	*Blood Pressure (Systolic)*
Newborn	30–60	100–160	50–70
1–6 weeks	30–60	100–160	70–95
6 months	25–40	90–120	80–100
1 year	20–40	90–120	80–100
3 years	20–30	80–120	80–110
6 years	12–25	70–110	80–110
10 years	12–20	60–90	90–120

Box 75.2. Airway Assessment and Treatment

Assessment

- Airway patency and ability to protect it.
- Level of consciousness.
- Stridor.

Treatment

- Spinal immobilization.
- Jaw thrust and suctioning.
- 100% oxygen by non-rebreathing mask.
- Intubate for Glasgow Coma Scale score <9, or absence of an intact gag reflex.

Box 75.3. Breathing Assessment and Treatment

Assessment

- Respiratory rate and depth.
- Chest wall compliance, symmetry, and movement.
- Tracheal deviation.

Treatment

- 100% oxygen by non-rebreathing mask.
- Intubate for respiratory failure or severe flail chest.
- Compress obvious bleeding sites.
- Seal open pneumothorax with occlusive dressing.
- Needle decompression for tension pneumothorax.
- Place chest tube for pneumothorax or hemothorax.

Box 75.4. Circulation Assessment and Treatment

Assessment

- Identify obvious bleeding sites.
- Peripheral pulses and capillary refill.
- Heart rate.
- Level of consciousness.

Treatment

- Compress obvious bleeding sites.
- 100% oxygen by non-rebreathing mask.
- 2 large-bore intravenous lines.
- Fluid resuscitation with 20 mL/kg normal saline.
- Administer packed red blood cells at 10 mL/kg if after 60 mL/kg normal saline and patient still in shock.

techniques. All trauma patients are initially given supplemental oxygen by non-rebreathing mask at a concentration of 100%. The adequacy of ventilation is assessed by a general evaluation of the respiratory rate, depth, chest movement and symmetry, and tracheal deviation.

After a patent airway and adequate ventilation have been established, circulatory status is assessed. All pediatric trauma patients require placement of the largest bore intravenous catheter obtainable for that patient; these should be placed, if possible, in each antecubital fossa. Peripheral vascular access is attempted 3 times or for 90 seconds, whichever comes first. If peripheral attempts are unsuccessful, intraosseous infusion or central venous access should be used. A bolus of 20 mL/kg of an isotonic fluid (ie, normal saline or lactated Ringer solution) should be given. This may be repeated, if necessary, to manage hypovolemic shock. After 60 mL/kg, administration of 10 mL/kg of packed red blood cells should be considered if the patient is still in shock. The likelihood of surgical exploration is high. Acutely exsanguinating wounds are managed using direct pressure or tourniquet (Box 75.4).

Figure 75.3. Correct method for positioning the head with chin lift or jaw thrust.

A brief neurologic assessment to assess patient disability is also performed during the primary survey. One rapid assessment technique is the AVPU system (alert; responds to verbal stimuli; responds to painful stimuli; unresponsive). Subsequently, a *Pediatric Glasgow Coma Scale* or *Children's Coma Scale* score should be calculated (Table 75.2).

After life-threatening conditions are stabilized, more information can be collected. The secondary survey involves a thorough head-to-toe examination of the child, fully exposed, to identify additional injuries, while taking great care to maintain normothermia. It also includes a SAMPLE (symptoms, allergies, medications, past history/hospitalizations/surgeries, last meal, events preceding trauma) history. A detailed history of events preceding trauma should ensure that injuries are consistent with the causal mechanism. Health professionals should be prepared to consider abuse when specific diagnoses do not correlate with the history given by the caregiver or the developmental ability of the child. Measurement of vital signs should occur as previously described and use of other devices, such as Foley catheters and nasogastric tubes, should be considered at this time. Each time an intervention is performed, repeat reassessments that incorporate the elements of the primary survey are made.

Laboratory Tests

Most institutions have a standardized trauma panel that is initiated for all patients, consisting of complete blood cell count with differential; assessment of electrolyte blood urea nitrogen, creatinine, glucose, and lactate levels; blood gas analysis with pH and base deficit; blood tests for amylase and lipase; liver function tests; assessment of prothrombin time and partial thromboplastin time; urinalysis; and blood typing and cross matching. Additionally, drug and alcohol screening may provide important information, particularly in the child with altered mental status. Female pediatric patients of potential childbearing age should undergo a point-of-care pregnancy test as well.

Imaging Studies

Sophisticated imaging techniques, such as ultrasonography and computed tomography, are a usual part of the evaluation of the seriously injured pediatric trauma patient. The choice of test depends

on the experience of the trauma team and individual characteristics of the patient.

Point-of-care ultrasonography has become a routine part of the secondary survey in adult trauma patients. The extended focused assessment with sonography in trauma (e-FAST) examination seeks to detect intraperitoneal fluid (ie, hemoperitoneum), pericardial fluid (ie, hemopericardium), intrathoracic fluid (ie, hemothorax), and pneumothorax. The results are near instantaneous, and the examination may be done without moving the patient from the trauma bay. In critically unstable patients the e-FAST has great utility in directing the initial resuscitative efforts. The utility of e-FAST is less clear in the pediatric patient, but its use is supported, especially in the hemodynamically unstable patient.

When major trauma is suspected, computed tomography of the brain, cervical spine, chest, abdomen, and pelvis should be strongly considered after initial stabilization procedures are completed. This prevents missing injuries in children who may be unconscious or who need lifesaving procedures during resuscitation, which obscure an area of injury from examination. Additional radiographs of the extremities, for example, may be indicated when other areas of injury are detected on secondary survey. Children are often initially distracted from 1 injury because of the presence of a more painful injury.

Prevention

Mortality rates have changed little in the past several years even as trauma systems have matured and become widespread. Prevention strategies have become more important in reducing traumatic injury, but resources remain limited. Current pediatric prevention interventions are centered around reducing or preventing burns, drowning, falls, gunshot injuries, and poisoning as well as improving playground, road traffic, and sports safety.

Prognosis

Survival rates are highest for seriously injured children who are brought to the operating room for treatment within 1 hour of injury. Definitive care for trauma takes place in the operating room, and initial stabilization takes place in the emergency department. Absolute indications for surgery include hemodynamic instability despite aggressive resuscitation, transfusion of more than 50% of the total blood volume, pneumoperitoneum, intraperitoneal bladder rupture, severe renovascular injury, gunshot wounds to the abdomen, evisceration, and peritonitis. Other injuries, such as solid organ injuries, often in contradistinction to similar injuries in adult patients, are frequently treated more conservatively in the intensive care unit after complete consultation with all involved practitioners.

An organized, preestablished, multidisciplinary approach to care is essential. Studies have shown that the single most important element for any hospital treating injured children is the commitment on the part of the institution and its surgeons. Regional pediatric trauma centers have increased resources for managing severely injured patients that include long-term care and rehabilitation. Other nondesignated hospitals may do an excellent job in the initial stabilization phase of care. Indications for transfer to a specialty center include inability to provide definitive surgical intervention, inability to provide an appropriate intensive care environment, presence of multisystem injuries or injuries requiring extensive orthopedic

or plastic surgery procedures, and major burns. Health professionals who treat children should not only become adept in the recognition and initial stabilization of injuries but should also serve as advocates for injury prevention and coordinated prehospital care services in the community.

CASE RESOLUTION

The 6-year-old boy sustained multiple trauma from an automobile versus pedestrian collision. He presents with altered level of consciousness; respiratory failure (ie, shallow respirations); possible internal organ injury, which has the potential to result in shock; and probable fracture of the left femur, which may also contribute to the development of shock secondary to hemorrhage. These injuries are identified based on a primary and secondary survey. Proper management includes stabilization of the cervical spine, airway management, aggressive early shock treatment with fluid replacement, and a vigilant search for additional injuries. Continued reassessment is also an integral part of emergency department stabilization. Because of the presence of multisystem injuries, after initial stabilization the patient is transferred to a regional pediatric trauma center for extended care.

CHAPTER 76

Abdominal Trauma

David B. Burbulys, MD

CASE STUDY

An 8-year-old boy who was riding downhill on a bicycle crashed into a tree and was transported to the local trauma center by emergency medical services. On arrival he was brought to the pediatric emergency department, where the paramedics report that the bike handlebars struck the child's abdomen. The boy reports dizziness and vomits several times. Initial vital signs show a heart rate of 135 beats per minute, blood pressure of 105/60 mm Hg, oxygen saturation of 98% on room air, and a respiratory rate of 24 breaths per minute. The abdomen is flat but tender to palpation in the mid-epigastric region and left upper quadrant.

Questions

1. What are the most common mechanisms of intra-abdominal injury in children?
2. What are the diagnostic studies used to evaluate abdominal trauma?
3. What is a simple rule for establishing the lower limit of normal blood pressure in children when assessing a child for shock?
4. What are the basic components of the treatment of shock that occur after abdominal trauma?

Abdominal trauma is the leading preventable cause of fatal injury in trauma patients. Death results when the extent and nature of abdominal injuries are neither appreciated nor appropriately managed, fluid replacement is inadequate, and airway maintenance and surgical intervention are not implemented soon enough. Primary abdominal trauma is the third leading cause of traumatic death, after head and thoracic injury. Clinicians should be knowledgeable about mechanisms of injury that result in abdominal trauma, early manifestations of shock, and methods of aggressive treatment of hemorrhagic shock.

Epidemiology

Twenty-five percent of children who sustain multisystem trauma have significant abdominal injury, and 9% die from abdominal-associated trauma. The risk of death is higher with simultaneous head and abdominal injury than with the occurrence of either injury alone. Blunt-force mechanisms are responsible for nearly 85% of abdominal injuries, with the remainder resulting from penetrating injuries. Examples of blunt-force mechanisms, presented in order of frequency from most to least frequent, include motor vehicle crashes, which also are the most lethal; pedestrian versus automobile collisions; falls; bicycle injuries; sports injuries; and direct blows from abuse and assault. Injuries to the spleen and liver predominate, followed by injuries to the kidney, bowel, and pancreas. In patients with multiple injuries, the incidence of trauma involving pelvic bones and organs (eg, bladder, ureter, iliac vessels) is also high. A straddle injury (eg, a fall that occurs when climbing over a fence) can also result in abdominal and pelvic trauma.

Clinical Presentation

Pain, tenderness, ecchymoses, and peritoneal signs (ie, voluntary or involuntary guarding, rebound tenderness) are among the more reliable signs of pathology, whereas abdominal distention and absence of bowel sounds are less consistent markers of injury. (See Box 76.1 for signs and symptoms suggestive of abdominal trauma.) It is particularly important to note that no sign is completely reliable and that acute hemorrhage into the abdomen does not result in peritoneal irritation initially. A high index of suspicion must be maintained in situations in which it is warranted based on the severity of the mechanism of injury, despite minimal initial physical findings. Unexplained hypotension or shock mandates further investigation with ultrasonography or computed tomography (CT) to assess for intra-abdominal hemorrhage.

Box 76.1. Signs and Symptoms Suggestive of Abdominal Trauma

- Pain
- Tenderness
- Distention
- Peritoneal signs (eg, absent or diminished bowel sounds, rebound tenderness, guarding)
- Ecchymoses
- Tire tracks
- Seat belt marks
- Urine, stool, or nasogastric aspirate positive for blood
- Unexplained hypotension or other signs of hypovolemic shock

Pathophysiology

Blunt trauma largely involves injury to solid, not hollow, intra-abdominal organs (ie, spleen and liver rather than small bowel) for a variety of reasons. First, the rib cage is flexible in children. As a result, rib fractures are less likely to occur, thereby reducing the potential for penetration of hollow abdominal organs by broken ribs. Second, children have less well-developed abdominal musculature and less adipose tissue than adults and larger organs relative to overall body size. Thus, in children blunt force is more easily and more diffusely transmitted to the solid organs. Third, because the diaphragm is oriented more horizontally in children than in adults, the liver and spleen lie more anteriorly and caudally within the abdomen.

It is important to emphasize that abdominal injury may result in excessive blood loss. The pathophysiology of hemorrhagic shock is discussed in detail in Chapters 74 and 75. The liver and spleen are highly vascularized organs that bleed profusely when lacerated. Even the accumulation of a subcapsular hematoma without rupture may cause a profound drop in hematocrit. Because intra-abdominal organs are not directly visible when a patient is examined, signs and symptoms of injury are not always obvious. Therefore, hemorrhagic shock should always be suspected in patients with abdominal trauma. Likewise, large volumes of blood can accumulate in the pelvis and retroperitoneum, and because of their proximity to the abdomen, they should always be considered as a reservoir for hemorrhage in abdominal as well as pelvic trauma.

Differential Diagnosis

Physicians should be familiar with the most common patterns of abdominal injury and should consider the possibility of specific injuries. Any solid abdominal organ can be injured by any mechanism, whether blunt or penetrating. The spleen is the most common intra-abdominal organ injured by a blunt force. Hepatic injuries are the most common fatal abdominal injuries, although they are less frequent than splenic injuries. The right lobe of the liver is injured more frequently than the left lobe.

Injuries to hollow viscera, such as the stomach and intestines, which represent only approximately 5% to 15% of injuries from blunt forces, are difficult to diagnose and often present late only after peritonitis manifests. Three mechanisms result in injury of hollow structures: "crush" between the anterior wall of the abdomen and the vertebral column; deceleration, which causes shearing of the bowel from its mesenteric attachments; and "burst," which occurs when an air- or fluid-filled loop of bowel is closed at both ends at the time of impact. Peritonitis may manifest within 6 to 48 hours secondary to fecal spillage or devascularization as the result of any of these mechanisms. Occasionally, a diagnosis of hollow viscera injury is made incidentally or may be delayed more than 48 hours, which reinforces the necessity of observation and serial examinations. Duodenal and pancreatic injuries are examples of potentially delayed diagnoses that can have grave consequences. Leakage of bile and enzymes may activate autolysis of the pancreas and result in sepsis syndrome.

Evaluation

Determining which organ or organs may be injured as the result of abdominal trauma is difficult. Up to 50% of significant injuries are missed on initial physical examination. Children are often uncooperative or unable to assist with the evaluation. Physicians tend to focus on injuries to the extremities, pelvis, face, or chest that are painful and distracting to children and more clinically obvious to the examiner. Initial clinical impressions may be incorrect, causing delayed diagnosis or unnecessary surgical exploration.

History

The history should focus on the mechanism of injury and the physiologic response of the child, especially in the pre-hospital setting (eg, initial hypotension, tachycardia, cyanosis; Box 76.2). A poor history concerning the circumstances of the injury may contribute to a delayed diagnosis.

Physical Examination

As stated previously, an abnormal physical examination may not always be indicative of pathology. Clinicians should avoid relying on physical examination alone as a predictor of abdominal injury. Studies have demonstrated that patients with and without proven injuries often showed no significant differences with respect to physical findings. In particular, children with abusive abdominal trauma often have no cutaneous evidence of bruising, especially immediately after the injury is inflicted (see Chapter 142). Thus, definitive evaluation of the abdomen is mandated for patients with significant mechanism of injury. Such evaluation often includes point of care ultrasonography, rapid CT, formal ultrasonography, diagnostic peritoneal lavage, laparoscopy, or laparotomy.

Vital signs should be monitored and trends followed. In children, the range for normal heart rate, respiratory rate, and blood pressure is age dependent. A simple rule for calculating the lower limit of normal systolic blood pressure is 70 + (2 × age in years). Physicians should always remember that a drop in blood pressure is a very late sign in the development of shock in children (see Chapters 74 and 75).

Serial abdominal examinations increase the likelihood of detecting a previously missed condition. Inspection of the abdomen to evaluate for ecchymoses, distention, tire tracks, penetrations, or paradoxical motion should occur first. Auscultation for bowel sounds follows this inspection, and palpation should be done last. Palpation should be done in all 4 quadrants to elicit tenderness, rebound, and

Box 76.2. What to Ask

Abdominal Trauma

- How was the child injured?
- How long ago did the injury occur?
- What parts of the body were injured?
- Did the child receive any treatment before coming to the hospital, and what was the response?

guarding. If a hepatic or splenic injury is initially suspected, palpation should be minimized to avoid further hemorrhaging.

Laboratory Tests

Laboratory evaluation should be guided by the history and physical examination. A urinalysis is helpful to evaluate for hematuria and associated genitourinary injuries. Elevated serum transaminases, amylase, lipase, and alkaline phosphatase may be indicative of injury; however, normal values do not exclude pathology. A comprehensive trauma panel, which usually includes a complete blood cell count and differential, serum electrolytes, blood urea nitrogen, creatinine, glucose, prothrombin time, partial thromboplastin time, blood gas analysis with pH and base deficit, lactic acid, and blood type and crossmatch as well, should be performed for all patients with serious or multiple injuries (see Chapter 75). Additionally, drug and alcohol screens may provide important information, particularly in children with altered mental status. Female patients of childbearing age also should undergo a point-of-care pregnancy test.

Imaging Studies

Multiple imaging modalities are available to assess the pediatric trauma patient with suspected abdominal injuries. The time to perform an imaging study is after the patient is responding appropriately to resuscitation (ie, fluid therapy). Unstable patients require surgical exploration for definitive treatment of abdominal or pelvic injury.

Computed tomography remains the standard of care for imaging the injured abdomen of a pediatric trauma patient. Computed tomography has greater than 97% accuracy in identifying abdominal or retroperitoneal injury, is noninvasive, and, most notably, provides detailed specific information about injuries. The images are also routinely extended to include the pelvis, as necessary. Disadvantages of CT may include the distance from the trauma suite, which may not be ideal for unstable patients; the length of time required to perform the procedure; the need for an intravenous contrast, which has inherent risks, such as allergic reactions and renal toxicity; and radiation exposure (see Chapter 17).

The use of point-of-care and formal ultrasonography has become quite popular, with encouraging results for the identification of abdominal injury, although its use in pediatric trauma patients remains somewhat controversial. Ultrasonography can be used to rapidly and noninvasively document the presence of intraperitoneal and pelvic fluid (ie, blood). Although ultrasonography is nearly as effective as CT for documenting the presence of injury, it does not provide as much specific information about the nature of the injury and does not image the retroperitoneal space. Ultrasonography has a few additional advantages. It is relatively inexpensive; does not require contrast or radiation exposure; can be performed in minutes in the trauma room, thus minimizing the risk to an unstable patient; and can be used many times for serial assessments.

Although for several decades diagnostic peritoneal lavage was a dependable method of detecting intra-abdominal hemorrhage, its use has been largely replaced by ultrasonography, and it has limited use in the pediatric population because currently, many children with blunt trauma to the abdomen are often treated nonsurgically.

Management

Management of abdominal trauma in children occurs simultaneously with evaluation. The stabilization of children with abdominal trauma, especially in the context of multiple trauma, requires a multidisciplinary team approach that includes surgeons, pediatricians, and emergency physicians. A discussion on approach to trauma management can be found in Chapter 75.

Hypovolemic shock, if present, is the primary complication of abdominal trauma on which to focus, because the leading unrecognized cause of death in affected children is profound blood loss. Airway problems and breathing difficulties should be addressed initially, followed by vascular access and fluid replacement. No more than 3 attempts at peripheral vascular access should be made within 90 seconds before proceeding to more invasive procedures.

The intraosseous route should be used for the next vascular access attempt. The flat, medial portion of the proximal tibia is most commonly used for the procedure, which is performed with an intraosseous, bone marrow, or spinal needle (Figure 76.1). Fluids and medications delivered into the marrow cavity flow into the venous circulation. Intraosseous cannulation is rapid and simple and may be lifesaving. It is limited by low flow rates (approximately 30 mL/min), which can be augmented by using pressure on the intravenous bag or by pushing fluid by hand through a syringe. Complications associated with intraosseous line placement are rare. All physicians who care for pediatric trauma patients should be familiar with this technique.

A variety of central venous access sites, such as femoral, subclavian, and internal jugular, may be used in older children. The Seldinger technique, with insertion of a large-bore catheter over a guidewire, is often used. Intravenous access above the diaphragm is preferred in patients with blunt or penetrating abdominal trauma who have the potential for disruption of the vena cava or other large veins.

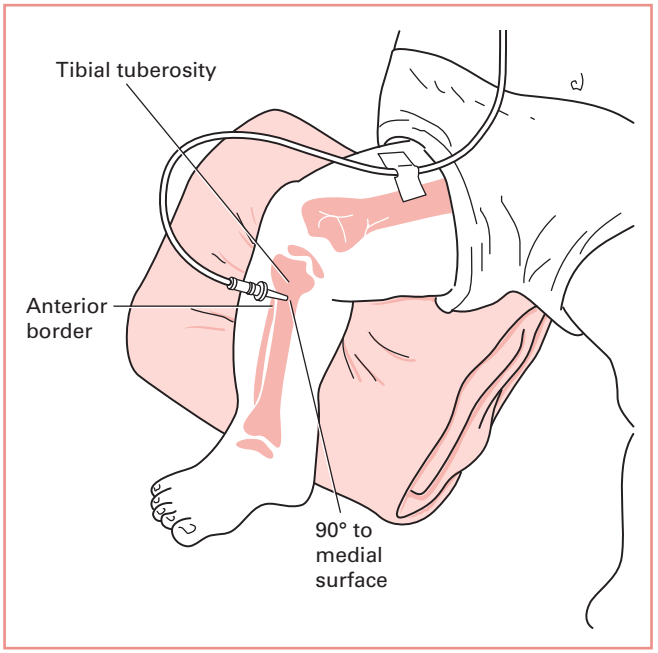

Figure 76.1. Intraosseous cannulation technique.

Fluid replacement begins with a 20 to 40 mL/kg bolus of crystalloid solution (warmed normal saline or lactated Ringer solution). If no improvement in circulation occurs, additional 10 to 20 mL/kg boluses may be given, and type-specific packed red blood cells should be considered. In most scenarios, type-specific blood is given after 60 mL/kg of crystalloid has failed to improve circulatory parameters. Frequent hematocrits or hemoglobins should be determined to monitor ongoing blood loss. Vital signs should be repeated frequently. Serial examinations, which detect the signs and symptoms of shock (Box 76.3), are the most important gauge of hemodynamic recovery and stability. All children require close hospital observation, preferably in a pediatric trauma center and pediatric intensive care unit.

Orthostatic fall in blood pressure and supine hypotension (late sign) must be aggressively managed. If hemodynamic stabilization is not achieved after appropriate vascular access and fluid resuscitation, the trauma surgeon will most likely perform an exploratory laparotomy. If the child has been stabilized with initial airway and circulatory support, diagnostic procedures (eg, CT) can be performed as part of the emergency department evaluation. Once identified, specific organ injury can be managed.

Other specific management concerns for pediatric patients with abdominal injury are early decompression of the stomach with a nasogastric or orogastric tube to prevent respiratory compromise and urinary catheter insertion to decompress the bladder. Before inserting a urinary catheter, the trauma team should evaluate for possible urethral trauma and check for the presence of blood in the urine, which may indicate other genitourinary trauma.

Nonsurgical management of minor to moderate liver or spleen injuries is common in children. A watchful waiting approach is often used after hemodynamic stability has been achieved. More severe injuries, including bowel rupture, require surgical intervention.

For injuries not requiring truly emergent surgical intervention, interventional radiology-guided arterial embolization has become a useful tool for significant liver, spleen, and kidney injuries, as well as pelvic fractures.

Prognosis

Morbidity and mortality related to abdominal trauma depend on the specific organ injury and style of management. Up to 40% of patients with major liver injuries die. However, several less severe liver injuries can be managed without surgery. Currently, an increasing number of injuries to the spleen and liver are managed with observation in the pediatric intensive care unit. Surgical exploration and repair are performed only if patients become hemodynamically unstable. Reduction in anesthesia-related mortality, postsplenectomy sepsis, and other postoperative complications have resulted from this shift in practice style. Without surgical intervention, however, a severe injury such as complete splenic rupture has a 90% to 100% mortality rate.

Box 76.3. Signs and Symptoms of Hemorrhagic Shock in Children

- Anxiety, irritability, decreased responsiveness
- Cool and mottled skin, pallor
- Delayed capillary refill (>2 seconds)
- Respiratory distress
- Tachycardia
- Thirst

CASE RESOLUTION

The boy sustained isolated abdominal trauma. Initial presenting signs and symptoms are concerning for internal organ injury, specifically splenic hematoma, pancreatic injury, internal hemorrhage, and compensated shock (eg, tachycardia, tachypnea). The child is managed with standard initial resuscitation, including fluid repletion. Because serial hemodynamic measurement and hematocrits are stable, he undergoes an abdominal CT scan, which demonstrates a splenic hematoma. A pediatric surgeon is consulted and recommends observation with continued monitoring in the pediatric intensive care unit.

CHAPTER 77

Acute Abdomen (Appendicitis)

Roxanne L. Massoumi, MD, and Steven L. Lee, MD, MBA, FACS, FAAP

CASE STUDY

A 10-year-old girl presents with abdominal pain of 24 hours' duration. The pain began in the periumbilical area and now is located in the right lower quadrant. She had 1 bout of emesis but no diarrhea. She has no fever or chills. She also has some pain with voiding. On physical examination, she has a low-grade fever and tachycardia. She is lying still in bed. Her abdomen is nondistended, but she has tenderness to palpation in the right lower quadrant. She also has rebound tenderness and guarding in this area.

Questions

1. What is the differential diagnosis for patients with acute abdominal pain?
2. What is the appropriate workup for children with suspected appendicitis?
3. What is the current management for children with appendicitis?
4. What is the expected postoperative course and possible complications following appendectomy?

Appendicitis is among the most common surgical emergencies in children. Pediatricians play a key role in the diagnosis and management of patients with abdominal pain and must be able to distinguish appendicitis from other causes of abdominal pain. When a patient presents with the classic signs and symptoms of appendicitis, the diagnosis is simple. Unfortunately, approximately 50% of patients present with atypical signs and symptoms of appendicitis, making the diagnosis difficult. Until recently, nearly every aspect of the diagnosis and management of children with appendicitis has been controversial. Thus, it is important for primary care physicians, emergency department physicians, and surgeons to communicate effectively to provide the highest level of care and cost efficiency.

Epidemiology

More than 70,000 children are affected by appendicitis each year in the United States. The lifetime risk of appendicitis is 9% in boys and 7% in girls.

Pathophysiology

The 2 main causes of abdominal pain are distention of the viscera, causing visceral pain, and irritation of the peritoneum, causing somatic pain. Distention of any hollow organ in the abdomen causes crampy and intermittent abdominal pain. Examples include distention of the biliary tree, small or large intestine, urinary structures (ie, bladder, ureters), or gynecologic structures (ie, uterus, fallopian tubes). This visceral pain is poorly localized and tends to be reported in the midline. Distention of any foregut structure localizes to the epigastric region. Foregut structures derive their blood supply from the celiac trunk and include the stomach, duodenum, and biliary tree. Distention of midgut structures localizes to the periumbilical region, and distention of hindgut structures localizes to the suprapubic region. Midgut structures are supplied by the superior mesenteric artery (ie, duodenum to transverse colon) and hindgut structures by the inferior mesenteric artery (ie, transverse colon to rectum). Unlike visceral pain, somatic pain is well localized. Irritation of the parietal peritoneum results in sharp pain and localized tenderness on examination. Anything that causes the irritated peritoneum to move or stretch worsens the pain and tenderness.

The classic example of these 2 types of pain occurs with appendicitis. The basic pathophysiology of appendicitis is obstruction of the lumen of the appendix followed by infection. Obstruction may be caused by fecal material (ie, appendicolith, fecalith), lymphoid hyperplasia, foreign body, tumor, or parasites. Following obstruction, the appendix becomes distended from accumulation of mucus and proliferation of bacteria. This distention results in a vague periumbilical pain. As intraluminal pressure increases, lymphatic and venous drainage are impaired, resulting in edema of the appendicular wall. As the overlying parietal peritoneum becomes progressively more irritated, the pain localizes to the right lower quadrant (RLQ). This stage is known as *acute appendicitis*. Further increase in pressure limits arterial inflow and ultimately results in tissue necrosis and perforation. Although the natural history of untreated appendicitis is usually perforation and abscess, not all patients progress to perforation.

Clinical Presentation

Abdominal pain is the most common symptom of and is present in nearly every patient with appendicitis. The classic presentation of a child with appendicitis includes a history of initial periumbilical

pain migrating to the RLQ. The pain is gradual in onset and progressively worsens. Anorexia, nausea, and vomiting typically are associated with appendicitis. In most cases, these associated symptoms manifest after the onset of abdominal pain. Intermittent, crampy pain that manifests after the onset of vomiting or diarrhea is less commonly associated with appendicitis. The inflamed appendix irritates the overlying peritoneum by direct contact, which results in focal peritonitis and localized RLQ pain. The symptoms vary based on the location of the appendix, however. When the appendix is retrocecal, a dull ache is often described. When the tip of the appendix is located in the pelvis, atypical pain is described. A child may report dysuria and urinary frequency resulting from the inflamed appendix irritating the bladder. Diarrhea or tenesmus may occur if the appendix is adjacent to the rectum. Fever, tachycardia, and leukocytosis occur as a consequence of systemic inflammatory mediators released by ischemic tissues, white blood cells, and bacteria. Higher fevers are associated with perforated appendicitis.

Box 77.1. What to Ask

Abdominal Pain

- When did the pain start?
- Can you describe the nature of your pain?
- Is your pain constant or intermittent?
- Where is your pain?
- What makes your pain worse? Better?
- Do you have any fever or chills?
- Do you have any nausea, vomiting, or diarrhea?
- When was your last bowel movement?
- Do you have any pain with urinating?
- Are you hungry?
- When was the last time you ate? Drank?
- Have you had any ill contacts?
- Have you had any upper respiratory symptoms?

Differential Diagnosis

Acute appendicitis can mimic nearly any intra-abdominal process and should be high on the differential in all children who report abdominal pain. Other causes of RLQ pain that are often indistinguishable from acute appendicitis include mesenteric adenitis, viral gastroenteritis, regional bacterial enteritis, tuboovarian pathologic processes, inflammatory bowel disease, Meckel diverticulum, cecal diverticulitis, and constipation. Other causes of lower abdominal pain include urinary tract infection, kidney stone, uterine pathologic process, bowel obstruction, and malignancy (eg, lymphoma). Vague abdominal pain can be caused by right lower lobe pneumonia, sigmoid diverticulitis, pancreatitis, hepatitis, and cholecystitis.

Evaluation

History

A careful history is required to distinguish acute appendicitis from other causes of abdominal pain (Box 77.1). In most patients with acute appendicitis, pain is often the first symptom. Associated symptoms, such as nausea, vomiting, and diarrhea, present after the onset of pain. It is important to distinguish intermittent crampy pain from constant and progressively worsening pain. If the patient has nausea, vomiting, or diarrhea followed by intermittent crampy pain, the diagnosis of gastroenteritis is more likely than appendicitis. A patient may develop a low-grade fever within 24 hours of the pain. Higher fevers manifest later and occur more frequently with perforated appendicitis. For the patient in whom fever is the first sign or symptom, appendicitis is less likely.

Physical Examination

A thorough physical examination is necessary to rule out other causes of abdominal pain. Upper respiratory infections may result in mesenteric adenitis, causing abdominal pain. The patient with acute appendicitis usually lies still, because movement worsens the pain. The most common finding is focal tenderness in the RLQ. Applying pressure to a stethoscope while listening to the abdomen is a subtle means of palpating the abdomen in the frightened child in whom it is difficult to obtain an accurate examination. Because of the level of discomfort, it may be difficult to elicit rebound tenderness and palpate for a mass. Asking the child to walk or jump is an easier and more accurate method of determining the degree of peritoneal irritation. Narcotic analgesics improve patient comfort but do not alter the inflammatory process; thus, tenderness persists. Localized tenderness is dependent on peritoneal irritation; thus, obesity, a retrocecal appendix, or walling off of the appendix by the omentum, mesentery, or small bowel may make the diagnosis of appendicitis more challenging.

Laboratory Tests

Laboratory studies often show a mild leukocytosis. A markedly elevated leukocyte count is suggestive of perforation or another diagnosis. A "shift to the left" in the complete blood count and differential may be a better diagnostic indicator for appendicitis. Other inflammatory markers, including C-reactive protein, procalcitonin, and lactic acid, have also been investigated but have not been routinely used in the workup of patients with suspected appendicitis. A urinalysis should also be obtained and usually is free of bacteria; however, a few or moderate number of red or white blood cells may be found because the inflammatory process of the appendix may cause localized irritation of the bladder or ureter.

Imaging Studies

Appropriate use of diagnostic imaging can minimize negative appendectomy and perforation rates.

Plain Radiography

In general, plain radiographs of the abdomen and chest may be more useful to evaluate for other disease processes when the suspicion

for appendicitis is low. Specific to appendicitis, plain radiography can show fecaliths in 10% to 20% of patients. Other helpful findings include lumbar scoliosis and obliteration of the psoas shadow.

Ultrasonography

Ultrasonography is an efficient bedside study that is noninvasive, requires no contrast, and emits no radiation. It should be the first study used in the workup of the patient with suspected appendicitis. Common ultrasonography findings consistent with appendicitis include a fluid-filled, noncompressible tubular structure; a diameter greater than 6 mm; appendicolith; and periappendicular or pericecal fluid (Figure 77.1). With an experienced technician and in the ideal situation, ultrasonography has sensitivity greater than 85% and specificity greater than 90%. Results are also influenced by patient factors, such as bowel gas pattern, obesity, and guarding or movement. When a normal appendix is identified, ultrasonography is a reliable study to rule out appendicitis. Only 10% to 50% of children with a normal appendix can be identified, however. Furthermore, when the appendix is not identified a risk for appendicitis remains despite otherwise normal ultrasonography findings.

Computed Tomography

When appendicitis cannot be excluded or confirmed on ultrasonography, additional imaging with computed tomography (CT) or observation is warranted. Findings consistent with appendicitis on CT include an enlarged appendix (>6 mm), appendicular wall thickening (>1 mm), periappendicular fat stranding, and appendicular wall enhancement (Figure 77.2). Computed tomography has a sensitivity and specificity of approximately 95%. Several concerns exist with CT, however. Significant delay in obtaining the study may occur if oral contrast is administered; the younger child may require sedation to complete the study; and growing concern exists for the increased radiation exposure from CT (see Chapter 17). Developing tissues have increased sensitivity to the effects of radiation, as evidenced by an increased risk of radiation-induced malignancy in patients exposed at a younger age.

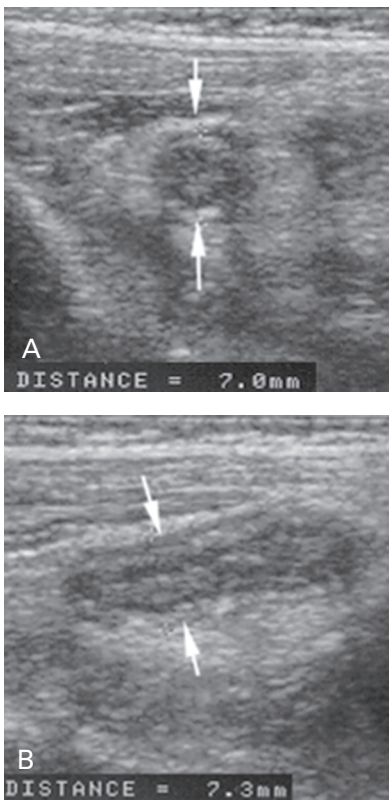

Figure 77.1. Sonograms consistent with acute appendicitis. A, Transverse view. B, Longitudinal view. In both images, the arrows are used to measure the diameter of the appendix.

Magnetic Resonance Imaging

Magnetic resonance (MR) imaging has a high diagnostic accuracy similar to CT and can be used to diagnose acute appendicitis in lieu of CT. Findings on MR imaging that are consistent with acute appendicitis include an enlarged (>6 mm), curved, and thickened blind-ended and fluid-filled tubular structure that is markedly enhanced on contrast-enhanced T1-weighted imaging (Figure 77.3). Magnetic resonance imaging has several advantages compared with CT, such as lower radiation exposure, which is particularly beneficial in the pediatric population. Additionally, MR imaging affords better visualization of an acutely inflamed and/or abnormally located appendix than ultrasonography. However, MR imaging is much costlier than ultrasonography and CT, patients must remain still for longer periods of time, it is not well suited for patients with claustrophobia, and it is not readily available at many institutions.

Observation

When appendicitis cannot be excluded or confirmed based on the history, physical examination, laboratory studies, and ultrasonography, additional imaging (ie, CT or MR imaging) or observation is indicated. Given the radiation risks associated with CT and the limited availability of MR imaging, admission to the hospital for intravenous (IV) fluids and serial examinations is a safe alternative. Food and liquids should be withheld, and a repeat complete blood cell count with manual differential should be obtained the next morning. In most instances, patients who do not have appendicitis improve and can safely be allowed to eat and discharged home. In children with appendicitis the pain will increase, and IV antibiotics should be administered while arrangements for appendectomy are made.

Management

The management of appendicitis begins with IV fluids and broad-spectrum IV antibiotics. Single- or double-agent therapy has been shown to be as effective as and more cost-efficient than triple-agent antibiotics. Management after initiating antimicrobial therapy is based on whether the patient is likely to have nonperforated or perforated appendicitis. This distinction is not always clear, even if preoperative imaging studies have been obtained. For the patient presenting with symptoms that have been present for less than 24 hours, the risk of perforated appendicitis is low. These patients

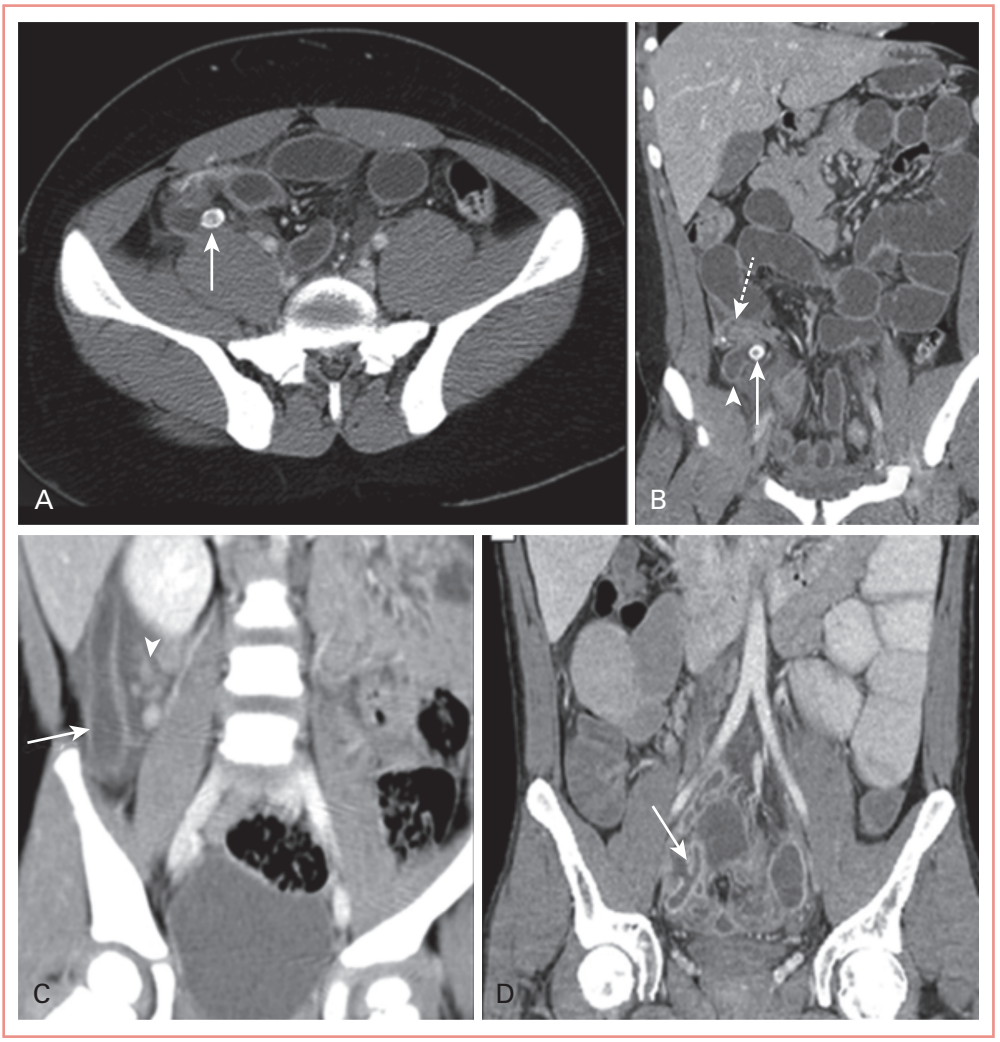

Figure 77.2. **Computed tomography images consistent with appendicitis. A, an axial view showing an appendicolith (arrow). B, a coronal view showing an appendicolith (arrow), periappendiceal inflammatory changes (dashed arrow), and an inflamed appendix (arrowhead). Figure 77.3. **Axial magnetic resonance image used to diagnose acute appendicitis (arrow).**

should be adequately resuscitated with IV fluids and antibiotics and scheduled for appendectomy at a later time. Antibiotic therapy typically halts or even reverses disease progression. Thus, the likelihood of nonperforated appendicitis progressing to perforated appendicitis is highly unlikely after appropriate antibiotics have been started. For this reason, appendectomy may be considered a semielective procedure rather than an urgent or emergent procedure as it has historically been considered. Duration of symptoms longer than 24 hours is associated with increased risk for perforation. In most instances, the patient with symptoms lasting fewer than 5 to 7 days is treated as described previously.

The patient with symptoms lasting more than 7 days likely has perforated appendicitis with or without an abscess. In the patient with prolonged duration of symptoms, appendectomy can be more technically challenging and associated with an increased rate of postoperative complications.

Nonsurgical management has been done in an attempt to reduce these risks. Nonsurgical management includes administration of IV antibiotics and drainage of intra-abdominal abscess (if present) using interventional radiologic techniques. Initial nonsurgical management is successful in approximately 85% of patients. Historically, after a patient was clinically stable the individual was discharged and elective interval appendectomy was typically performed 6 to 8 weeks later. Recent studies, however, indicate that an interval appendectomy may not be indicated for most patients unless symptoms recur. If nonsurgical management is unsuccessful, appendectomy is performed.

Charles McBurney, MD, first described open appendectomy through a traditional RLQ incision and muscle-splitting technique in 1893. Laparoscopic appendectomy was introduced more than 30 years ago and has largely replaced open appendectomy. Compared with the open technique, laparoscopic appendectomy is associated with lower wound infection rates, shorter hospital stay, fewer postoperative outpatient visits, and earlier return to routine activity. Although earlier studies associated laparoscopic appendectomy with higher postoperative abscess rates and longer duration of operation compared with the open technique, more recent studies show no difference in these areas. In fact, some studies have shown shorter surgical time and lower abscess rates with laparoscopic appendectomy.

Primary nonsurgical management of acute appendicitis, without the intention of eventual appendectomy, recently has been gaining in popularity and appears to be a clinically effective, cost efficient, and safe approach. Currently, primary nonsurgical management is reserved for uncomplicated appendicitis. After diagnosis, several doses of IV antibiotics are administered, followed by a 7- to 10-day course of oral antibiotics. To date, no standardized consensus antibiotic regimen exists. The presence of an appendicolith is associated with a high initial failure rate of nonsurgical management, and appendectomy is recommended in these cases. Currently, the initial success rate of nonsurgical management is 90% to 95%, with a recurrence rate of approximately 20% at 1-year follow-up. Thus, the overall success rate at 1 year is 75%. Patients who return with a recurrence of their symptoms do not typically experience a perforation, but appendectomy is recommended.

For the patient with nonperforated appendicitis undergoing appendectomy, antibiotics are administered for a maximum of 24 hours and typically are not necessary postoperatively. A single preoperative dose of antibiotics has been shown to decrease the risk of wound infection and abscess. For the patient with perforated appendicitis, IV antibiotics should be administered until resolution of clinical symptoms, including resolution of fever, normalization of physical examination, and full return of gastrointestinal function. If this duration of IV antibiotic therapy is for fewer than 5 days, the patient can be safely discharged on oral antibiotics to complete a 7-day course.

Prognosis

Overall complication rates are less than 3% for nonperforated appendicitis and 16% to 18% for perforated appendicitis. The common complications after appendectomy are infection related. Wound infection occurs in less than 1% of patients with nonperforated appendicitis and up to 16% of patients with perforated appendicitis. Rates of postoperative abscess are less than 1% for nonperforated appendicitis and less than 15% for perforated appendicitis. Mortality related to appendicitis is rare.

CASE RESOLUTION

The patient was found to have an elevated white blood cell count with a shift to the left and a small number of white blood cells in the urinalysis. Ultrasonography findings were consistent with acute appendicitis. She was administered IV fluids and antibiotics and underwent laparoscopic appendectomy. The postoperative course was unremarkable, and the patient was discharged the next day. She did well in follow-up and was cleared for full activity 2 weeks postoperatively.

CHAPTER 78

Head Trauma

Joseph Ravera, MD

CASE STUDY

A 2-year-old girl is playing on a window ledge unsupervised. She pushes the screen out and falls onto the concrete sidewalk below, striking her head. A neighbor reports that she is unconscious for 10 minutes. When paramedics arrive, the girl is awake but lethargic. She is transported to the emergency department. Her vital signs are normal. A scalp hematoma is present, and a depressed area of cranial bone is palpated.

Questions

1. What are the priorities in the initial stabilization and management of pediatric head trauma?
2. What is the difference between primary and secondary brain injury?
3. What are the common signs and symptoms manifested by children with head trauma?
4. What are the various modalities available for management of increased intracranial pressure?
5. What are the scoring systems used in the evaluation of mental status in children with head trauma?

Although most childhood head injuries are minor and can be managed on an outpatient basis, it is important for physicians to become adept at recognizing and managing concussions and more severe forms of head injury. Health professionals can also help reduce mortality from head trauma by actively promoting injury prevention to patients and communities.

Epidemiology

Head trauma is among the most common pediatric injuries and the leading cause of morbidity and mortality among pediatric trauma patients. Pediatric head trauma accounts for more than 500,000 emergency department (ED) visits, 95,000 hospital admissions, 7,000 deaths, and 29,000 permanent disabilities per year in the United States. Hospital care costs exceed $1 billion annually. In pediatric patients with multiple injuries, 70% of deaths that occur within 48 hours of hospitalization are the result of trauma to the head. Rates of intracranial injuries in children with only minor head trauma are low, however, with the largest numbers occurring in young children and infants, with a prevalence of 3% to 6%. Only 0.4% to 1% of children require surgical intervention after minor closed head injury.

Falls account for most cases of pediatric head trauma. Other major causes include motor vehicle crashes, vehicle versus pedestrian collisions, bicycle crashes, sports-related injuries, and recreational activities. Nonaccidental trauma (ie, child abuse) must be recognized as another important cause of head injury in children, particularly among those younger than 2 years.

Clinical Presentation

The child who has sustained head trauma may present with a history of an antecedent event (eg, fall, collision with another child) or signs and symptoms related to the injury. These include external bruising or lacerations, alterations in the level of consciousness, and neurologic findings, including seizure. Vital signs may be altered; in particular, deep or irregular respirations, hypertension, or bradycardia may be apparent (Box 78.1). These changes are indicative of elevated intracranial pressure (ICP).

Pathophysiology

Children have significant anatomic differences from adults that predispose them to head trauma and certain types of intracranial

[a] All symptoms need not be present for a diagnosis of head trauma.

injury (Figure 78.1). They have a higher center of gravity, an increased head to body ratio, and weaker neck muscles compared with adults. Additionally, children have thinner cranial bones and less myelinated brain tissue, which predisposes them to intraparenchymal injuries. Whereas adults are more likely to have focal intracranial hematomas, children are more likely to develop diffuse cerebral edema. Cerebral edema can disrupt cerebral blood flow, resulting in ischemic injury.

Normally, blood flow to the brain is maintained at a constant rate by the process of *autoregulation*. With severe brain injury, autoregulation is disrupted and blood flow to the brain is determined by cerebral perfusion pressure (CPP), which is a measure of the mean arterial pressure (MAP) less ICP (CPP = MAP – ICP). Cerebral blood flow is therefore compromised when the MAP is too low (ie, hypotension) or the ICP is too high (ie, cerebral edema). Several of the management strategies in children with severe brain injuries focus on maintaining MAP and reducing ICP; however, control of CPP after head injury can be quite difficult. Children have a greater capacity for recovery than adults; this is especially true for infants and very young children, whose open sutures and fontanels permit expansion of the skull in response to edema and blood.

In head trauma, primary and secondary brain injury can occur. Primary injury is the structural damage that occurs to the cranium and its contents at the time of injury. Secondary injury is damage to the brain tissue after the initial event. Such damage may result from hypoxia, hypoperfusion, hypercapnia, hyperthermia, and altered glucose or sodium metabolism. The main treatment strategies for patients who have sustained head trauma focus on the prevention of secondary brain injury. Primary brain injury can be prevented only through education and safety, such as advocating for wearing helmets in appropriate situations.

Types of Head Injury

Even minor head trauma in a child can result in skull fracture or intracranial injuries. Most skull fractures are simple and linear. Other fracture types are comminuted, diastatic, basilar, and depressed. A *comminuted fracture* is one involving multiple skull fragments. A *diastatic fracture* is one with a wide separation at the fracture site. *Basilar fractures* occur at the base of the skull and often have characteristic findings on physical examination (ie, bilateral periorbital ecchymosis [ie, raccoon eyes], hemotympanum, postauricular ecchymosis [ie, Battle sign]). In a *depressed fracture*, fragments of the skull are displaced inward, potentially damaging intracranial structures.

Head trauma may result in concussion, mild traumatic brain injury, or intracranial hemorrhage. A *concussion* is defined as a trauma-induced impairment of neurologic function. This may occur with or without a loss of consciousness (LOC). Neurologic examination is usually normal, but the patient may experience somatic symptoms (eg, headache), physical signs (eg, LOC, amnesia), behavioral changes, cognitive impairment, or sleep disturbances. Some of these minor and subtle neurologic sequelae can last for months after the injury (ie, postconcussion syndrome). Most resolve within a relatively short period, typically 7 to 10 days; however, with more severe trauma the symptoms can last longer.

A *cerebral contusion* is a bruise of the brain tissue and typically occurs with a more severe injury, such as a high-speed motor vehicle crash. A *contrecoup contusion* may be sustained when the brain strikes the skull on direct impact, bruising 1 portion of the brain, with resulting injury to the opposite side of the brain on rapid deceleration. Clinical manifestations depend on the location of the contusion but often include altered mental status, excessive sleepiness, confusion, and agitation. Small intraparenchymal hemorrhages and swelling of the surrounding tissues are often seen on computed tomography (CT).

An *epidural hematoma* is a collection of blood that accumulates between the skull bone and the tough outer covering of the brain (ie, dura mater). These are often the result of tears in the middle meningeal artery caused by skull fractures. Classically, patients have initial LOC followed by a lucid interval and then rapid deterioration secondary to brain compression. On CT, an epidural hematoma appears as a large collection of blood with convex borders next to the skull (Figure 78.2A). Surgical evacuation is required in most cases.

The *subdural hematoma* accumulates between the dura and the underlying brain tissue. These are associated with skull fractures and contusions. On CT, they appear to have a crescent-shaped border (Figure 78.2B). Large subdural hematomas usually require surgical evacuation. In infants and young children, subdural hematomas are often the result of nonaccidental trauma.

Diffuse axonal injury (DAI) involves extensive damage to the axonal white matter of the brain that results from shearing forces that typically occur with rapid acceleration or deceleration of the brain (Figure 78.2C). The child with DAI may have normal or nonspecific findings on CT.

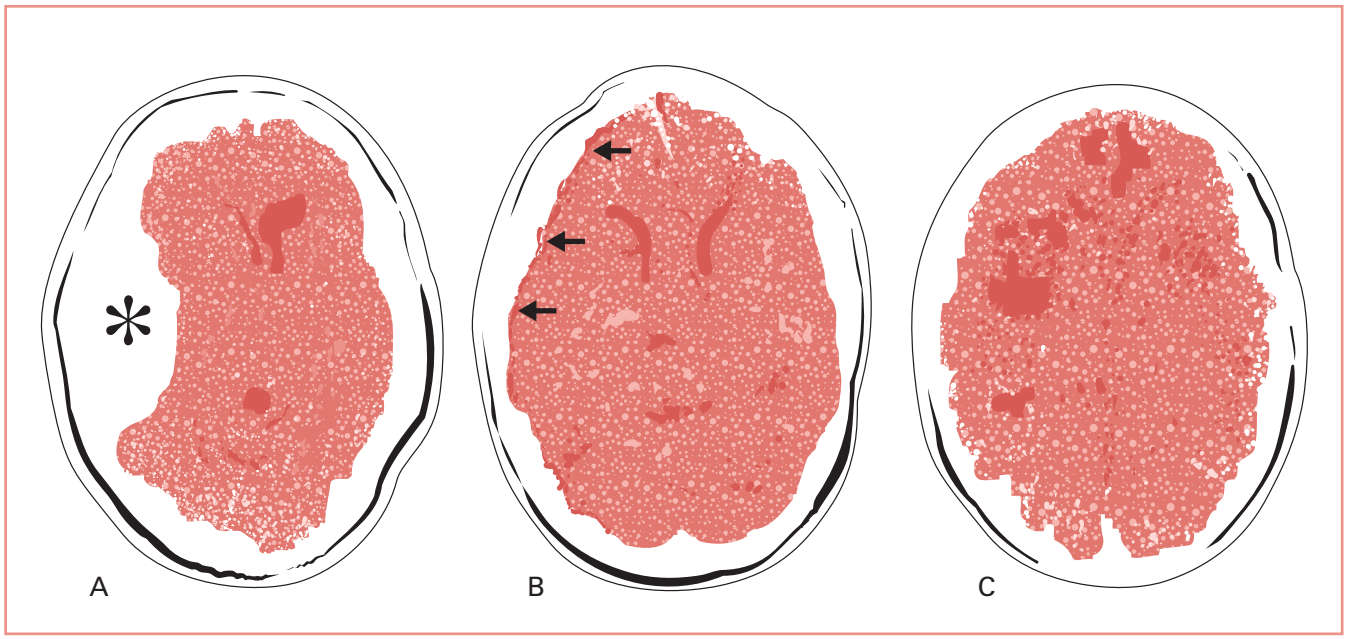

Figure 78.2. A, Epidural hematoma (asterisk). Note convex borders and midline shift. B, Subdural hematoma (arrows). Note the crescent shape. C, Diffuse axonal injury. Note the ground-glass appearance and tightly compressed ventricles.

Evaluation

History

History is obtained during the secondary survey or reassessment phase of evaluation. Prehospital health professionals or witnesses to the injury should be asked about details of the event and the child's status following the event (Box 78.2).

Physical Examination

Careful attention to the vital signs of the child with head injury is important. The presence of hypertension, bradycardia, and an irregular breathing pattern (ie, *Cushing triad*) is suggestive of a significant intracranial injury with associated increased ICP.

Box 78.2. What to Ask

Head Trauma

- What was the mechanism of injury (eg, motor vehicle crash, ejection from motor vehicle, fall, assault)?
- If a fall, what was the height of the fall?
- What was the type of impact surface?
- What was the shape of the object(s) striking the head?
- What was the child's immediate status after injury?
- What changes in status occurred before arrival at the hospital?
- Did the child lose consciousness? If so, for how long?
- Did the child vomit?
- Did the child have a seizure? If so, when did it occur in relation to the injury, and does the child have an underlying seizure disorder?

Secondary survey actions include palpation and inspection of the scalp for soft tissue swelling, step offs (ie, indentation of the skull), lacerations, and fullness of the fontanel. Facial bones should be tested for stability and deformities. Other clues to possible head trauma include the presence of a septal hematoma, draining blood or fluid from the nose or ears, dental injury, and malocclusion of the mandible. The tympanic membranes should be visualized for the presence of hemotympanum or cerebrospinal fluid otorrhea, which, along with postauricular ecchymosis (ie, Battle sign), periorbital ecchymosis (ie, raccoon eyes), or cranial nerve palsies, is suggestive of a basilar skull fracture. If possible, funduscopic examination should be performed to look for the presence of papilledema associated with increased ICP or retinal hemorrhages, which are indicative of nonaccidental trauma.

A comprehensive neurologic examination is the most important aspect of the secondary survey. This examination should include a mental status assessment, cranial nerve evaluation, and assessment of the presence and quality of deep tendon reflexes, muscle tone, muscle strength, sensation, and cerebellar function.

When describing mental status, imprecise terms such as "altered," "lethargic," and "obtunded" should be avoided. Several scoring systems are available for assessing the mental status of children who have sustained head trauma. Many are useful predictors of intracranial injury and are also useful in assessing level of consciousness in pediatric patients. The most universally accepted and widely used of these scales is the *Glasgow Coma Scale* (GCS). It is used routinely in children older than 5 years but can be modified for younger children. Like many other systems, the GCS measures responses to a variety of stimuli in 3 areas—eye opening, verbal, and motor. Scores should be tabulated when the child first presents to establish a baseline, after

which the scores can be used for reassessment on a regular basis until the patient has stabilized or returned to normal mental status. Use of these scores helps promote consistent and accurate communication among health professionals. Table 78.1 shows how to calculate the GCS and modified GCS. In some circumstances the calculation of a precise GCS can be cumbersome, especially in time-critical situations. Several rapid scoring systems have been developed and are currently under active study. One system, the AVPU, describes the type of stimulus required to provoke response in a patient as either alert, verbal, painful, or unresponsive. Recent literature has shown that either an alert or a verbal response strongly correlates with a GCS above 8.

Laboratory Tests

A complete blood cell count and serum electrolyte panel should be performed for all pediatric patients with significant head trauma. Bedside glucose monitoring should be performed in any child with a head injury with an altered level of consciousness. Toxicology evaluation may be indicated in the adolescent who appears to be intoxicated or has an altered level of consciousness. The infant or child with an intracranial hemorrhage should undergo screening coagulation studies (ie, prothrombin time, activated partial thromboplastin time) as well as a type and screen test or crossmatch, in case surgery is required.

Imaging Studies

In cases of acute pediatric blunt or penetrating trauma, a noncontrast CT of the head is currently the diagnostic study of choice. It is quite sensitive for the detection of acute hemorrhage and skull fracture. It can also provide additional information on the severity of injury, indicating increased ICP, cerebral edema, or pending herniation. Among the findings on CT that indicate severe brain injury are the shift of midline structures, effacement of the sulci, ventricular enlargement or compression, and loss of normal gray/white matter differentiation.

An emergent head CT is warranted for any child with altered mental status, a GCS below 14, penetrating trauma, or focal neurologic deficit. The question of which children with minor head trauma should undergo CT was evaluated in a study of 17,000 children from the Pediatric Emergency Care Applied Research Network (PECARN) database. In this study, a decision rule was retrospectively derived and then prospectively validated as a method to identify children at very low risk for intracranial injury. These criteria can be found in Box 78.3. If a child is otherwise healthy and meets these criteria, the risk of intracranial injury is extremely low and the child can be safely discharged from the ED or clinic with anticipatory guidance and return precautions. Neither CT nor a period of observation is required. It should be noted that this decision rule was validated as "rule out" only and meant to identify the child at very low risk. If a child does not meet all the criteria, it does not mean a CT scan is required.

With the speed and widespread availability of CT machines, radiographs of the skull have relatively little role in the acute evaluation of pediatric patients with head trauma. Currently, CT can be performed very quickly, often with little or no need for sedation. Although plain radiographs are sensitive for the detection of

Table 78.1. Pediatric Glasgow Coma Scale

	>1 Year		*< 1 Year*	*Score*
Eye Opening	Spontaneously		Spontaneously	4
	To verbal command		To shout	3
	To pain		To pain	2

Box 78.3. Low-risk Criteria for Pediatric Intracranial Injury

Age <2 Years

- Normal mental status
- No scalp hematoma except frontal
- No loss of consciousness, or loss of consciousness for <5 seconds
- Non-severe injury mechanism
- No palpable skull fracture
- Acting normally according to parents

Age ≥2 Years

- Normal mental status
- No loss of consciousness
- No vomiting
- Non-severe injury mechanism
- No signs of basilar skull fracture
- No severe headache

skull fractures, they do not provide any information about associated intracranial injuries. Additionally, several studies have demonstrated that intracranial injuries occur in the absence of a skull fracture, particularly among young pediatric patients. Plain radiography is obtained only as part of the skeletal survey in cases of suspected nonaccidental trauma.

Magnetic resonance imaging has little role in the treatment of the patient with acute injury resulting from head trauma. Computed tomography is often more sensitive in detecting acute intracranial hemorrhages and is sufficient to guide most immediate patient care issues. Magnetic resonance imaging may be superior to CT for identifying DAI and subtle brain injuries. Generally, magnetic resonance imaging takes longer to complete and often requires sedation, and the scanners frequently are located away from the ED in an area in which the child cannot be monitored appropriately.

One important consideration with any trauma victim is the possibility of a cervical spine injury. Although cervical spine injuries are rare in children, the physician must maintain a high index of suspicion when presented with a child who has suffered significant head trauma, particularly from a high-energy mechanism such as an unrestrained motor vehicle crash. Careful evaluation and imaging of the cervical spine is required for all children with an altered level of consciousness; significant, painful, distracting injuries; an inability to communicate; focal neurologic deficits; or localized pain, swelling, or ecchymosis of the cervical spine. Younger children (<8 years) have a larger occiput-body ratio than older children and adults and consequently a higher fulcrum; thus, most cervical spine injuries in this age group tend to be at higher levels (ie, C1, C2, C3). Furthermore, as the result of increased flexibility and lack of ossification, children are at risk for ligamentous or direct cord injury in the absence of a bony injury. The physician should maintain a high index of suspicion with severely injured children, even if no bony injury is evident on radiographs or CT.

Management

Assessment and management occur simultaneously in the child with acute injury. A primary survey is initially performed with attention to circulation, airway, and breathing as well as cervical spine immobilization. Prompt neurosurgical consultation should be obtained for all children with significant head trauma to assess the need for surgical management and ICP monitoring. The primary management goal of significant acute head trauma is the prevention of secondary brain injury by maximizing oxygenation and ventilation, supporting circulation to maximize cerebral perfusion, decreasing elevated ICP, and decreasing cerebral metabolic demands.

Individuals with significant intracranial injuries often require intubation for airway protection. Those individuals with a GCS score of 8 or lower should undergo rapid sequence intubation to control the airway. These individuals should be premedicated with a sedative. Historically, etomidate was the sedative of choice because it is cardiovascular neutral with minimal effect on blood pressure and because most other sedatives can cause hypotension, thereby decreasing MAP and reducing CPP. One area of controversy involves the use of ketamine for sedation prior to intubation. Ketamine is well known to raise the MAP, which has a positive effect on CPP; however, it was historically thought to increase ICP, thus making it less ideal. Recent literature, mostly in adults, has called into question the effect of ketamine on ICP. Currently, no clinical data exist to recommend or not recommend ketamine as an indication agent for intubation in a severely injured pediatric patient with head trauma. Historically, lidocaine was thought to potentially blunt the transient increase in ICP often associated with direct laryngoscopy and orotracheal intubation. Given no difference in outcomes and questionable benefit recent recommendations based on adult literature no longer recommend routine administration of lidocaine before rapid sequence intubation in patients with head trauma. Although there are no published trials involving children, short-acting opioids such as fentanyl (1 mcg/kg) may be considered prior to induction to blunt response to direct laryngoscopy and rapid sequence intubation. When intubation is indicated, steps should be taken to minimize desaturations, because several studies have demonstrated worse outcomes with hypoxia in children with severe traumatic brain injury.

Historically, moderate hyperventilation was advocated to reduce ICP. Hyperventilation reduces partial pressure of carbon dioxide, arterial, resulting in cerebral vasoconstriction and decreased cerebral blood flow, thereby reducing ICP. This has been shown to have the unwanted effect of disrupting cerebral metabolism and possibly exacerbating ischemic injury. Currently, normal ventilation is recommended, with the goal of maintaining partial pressure of carbon dioxide, arterial, no lower than 34 mm Hg. Moderate hyperventilation may have a role in the transient management of serious or acute life-threatening elevations in ICP (ie, acute herniation) as a temporizing measure until more definitive care (eg, neurosurgical decompression) can be performed.

Circulation and MAP should be aggressively supported with fluids to prevent hypoperfusion to the brain. Hypovolemia or

hypotension should never be assumed to result from head trauma alone. The child should be examined carefully for evidence of additional injury. Central venous pressure monitoring may be useful in addressing volume status; however, recent literature has suggested that point-of-care bedside ultrasonography of the size of the inferior vena cava and its respiratory variation may provide a reliable estimate of the patient's intravascular volume status. Vasoactive medications may be necessary to maintain MAP in patients with euvolemia. Morbidity has been shown to significantly increase with subsequent episodes of hypotension.

Elevations in ICP may impede cerebral blood flow and exacerbate ischemic injury. Administration of hypertonic solutions is indicated in the management of increased ICP, particularly with signs of herniation. In the most recent guidelines, hypertonic (3%) saline is the first-line agent (as opposed to mannitol). If hypertonic saline is not readily available or the patient does not have the appropriate access for its administration, however, mannitol can be used as a temporizing measure. It is important to note that the use of mannitol and other diuretics is contraindicated in patients with borderline blood pressures because these agents can cause hypotension, which can in turn decrease the MAP, thereby worsening cerebral perfusion. Additionally, elevation of the head of the bed to 30° to promote venous drainage is also used to reduce ICP. Paralytic agents, sedatives, and analgesics may be necessary to prevent agitation, which also results in increased ICP and increases cerebral metabolic demands. Painful procedures (eg, suctioning) should be preceded by administration of adequate premedication with sedatives and analgesics. The use of intraventricular pressure catheters is often necessary to allow for close monitoring of ICP. Additionally, these can be used to drain cerebrospinal fluid to help decrease elevated ICP.

Hyperthermia and seizure activity should be managed aggressively, because they increase cerebral metabolic demands. Hyperthermia should be managed with antipyretic agents and active cooling measures. Conflicting evidence exists on controlled hypothermia in children with severe brain injuries. The most recent meta-analysis did not show a benefit for therapeutic hypothermia in children; however, this remains an area of active study. Anticonvulsant prophylaxis should also be considered in the child with severe brain injury, especially within the first 7 days. It is important to remember that the ability to detect clinical seizure activity is lost if the child is paralyzed.

Serum electrolyte levels should be followed closely, and any alterations should be minimized. The patient with head injury should be monitored closely for the development of diabetes insipidus or syndrome of inappropriate antidiuretic hormone.

Often, the child with a large epidural and subdural hematoma requires surgical evacuation. The individual with a depressed skull fracture often requires surgery to lift the depressed fragment away from the underlying brain. The child with significant penetrating head trauma warrants antibiotic and antiepileptic prophylaxis and may need angiography to assess for vascular injury. In all cases, tetanus status should be updated if necessary.

As previously discussed, the child with no high-risk criteria as outlined by the PECARN guidelines can be safely discharged without a period of observation or neuroimaging. However, the child with minor head injury (GCS score, 14–15) who does not strictly meet the PECARN criteria warrants either a period of observation or CT evaluation. Signs of a basilar skull fracture and altered mental status are considered high-risk features, and the affected patient should undergo prompt CT of the head. Mechanism of injury, a scalp hematoma in children younger than 2 years, and severe headache and vomiting in children age 2 years and older are less specific for intracranial bleeding or skull fracture. Therefore, in these patients a period of observation, including a cautious challenge orally of food or liquid, is a reasonable strategy to avoid the radiation risk of CT. An algorithm of this approach is shown in Figure 78.3. The optimal time of observation is unknown; however, in most EDs a 6-hour observation period is considered appropriate. If during the observation period the child deteriorates clinically or does not return to baseline, CT of the head should be performed. The physician should be wary of discharging a child whose condition has not improved to baseline after minor injury or who has persistent emesis, even if CT is normal.

More moderate head injuries (initial GCS score, 9–12) necessitate a longer period of evaluation, likely in a monitored setting along with neurosurgical consultation. Severe head injuries (GCS score < 8) require aggressive stabilization in the ED with the measures described previously and admission to a pediatric intensive care unit.

The child who has sustained a concussion warrants close observation and reevaluation before resuming sports activities, because mounting evidence exists that multiple, sequential concussions can have long-term debilitating effects. The American Academy of Neurology has guidelines for evaluation and return-to-play parameters. These recommendations include an evaluation by a health professional familiar with concussion and the use of sideline assessment tools to rapidly evaluate the athlete for removal from play. Before returning to play, the athlete should have complete physical and cognitive rest until the athlete is symptom-free. Additionally, the neurologic examination and imaging (if performed) should be normal. Some programs use neuropsychiatric testing to evaluate for subtle deficits in the evaluation of return to play. Generally, the emergency physician should stress to the athlete being evaluated the serious nature of a concussion and not clear the athlete to play from the ED; rather, the patient should be referred through the appropriate protocols of the team.

Prognosis

Age is the most important prognostic factor in outcome. Younger children tend to do better than older children. It remains difficult to predict the outcome of any individual patient. Scalp lacerations, most skull fractures, and concussion are low-risk injuries. Intracranial hemorrhage, specific skull fractures, head injury secondary to nonaccidental trauma, and trauma accompanied by diffuse cerebral edema are high-risk injuries. If untreated, severe head injury may result in death from herniation.

Other complications from severe head trauma are posttraumatic seizures, requiring lifelong treatment with anticonvulsants;

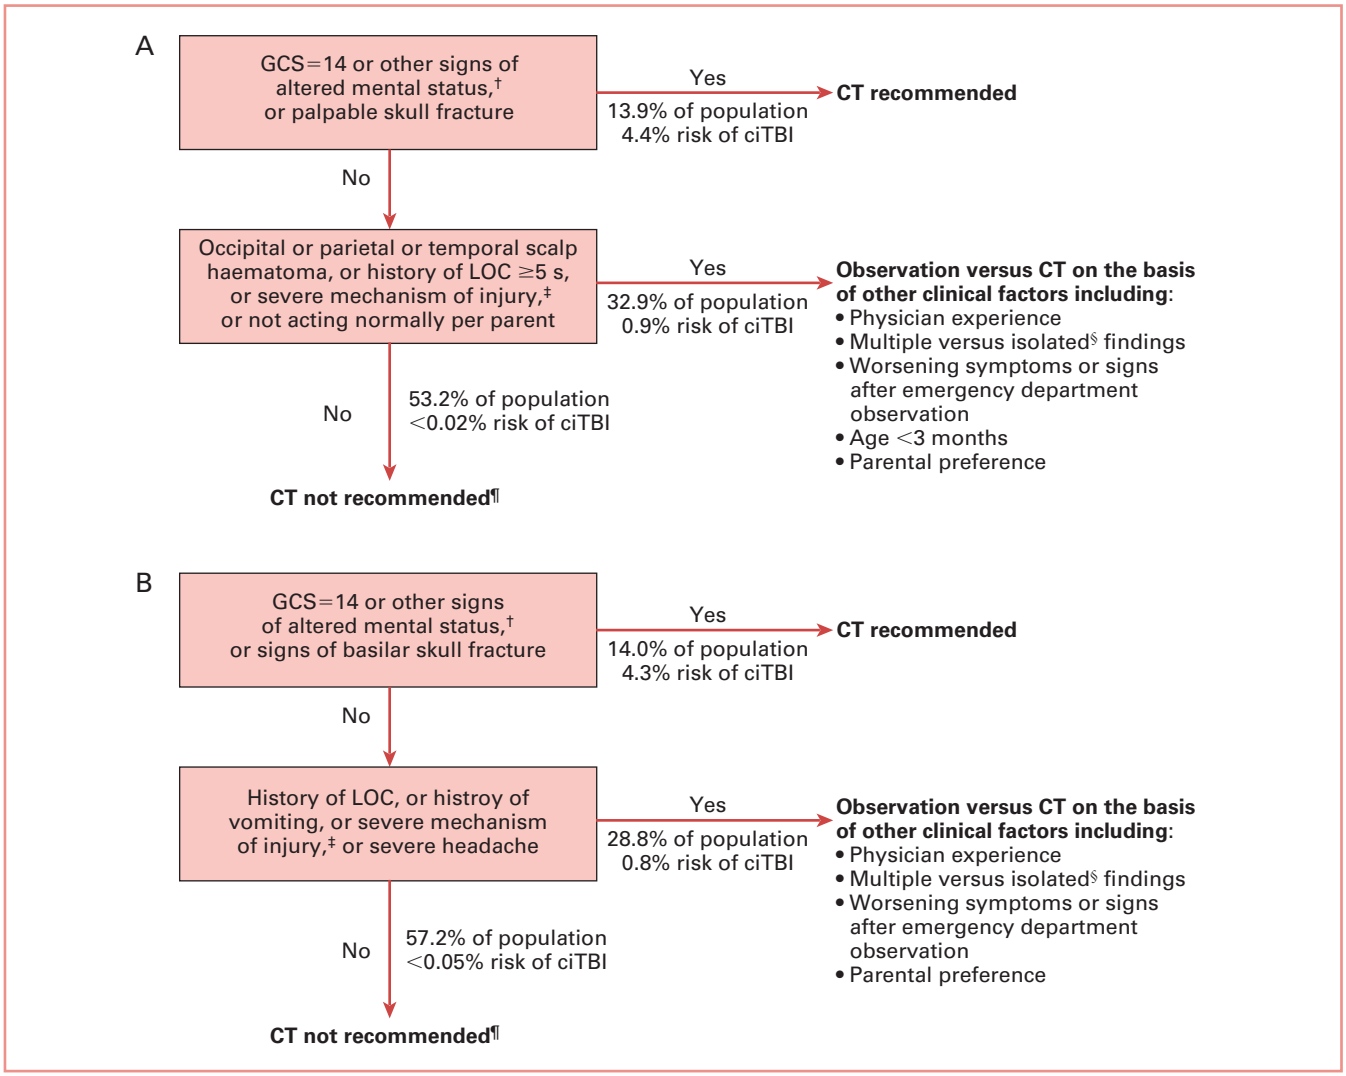

Figure 78.3. Suggested algorithm for computed tomography in children younger than 2 years (A) and for those age 2 years and older (B) with GCS scores of 14 to 15 after head trauma.*

Abbreviations: ciTBI, clinically-important traumatic brain injury; CT, computed tomography; GCS, Glasgow Coma Scale score; LOC, loss of consciousness; s, seconds.

* Data are from the combined derivation and validation populations.

† Other signs of altered mental status: agitation, somnolence, repetitive questioning, or slow response to verbal communication.

‡ Severe mechanism of injury: motor vehicle crash with patient ejection, death of another passenger, or rollover; pedestrian or bicyclist without helmet struck by a high-impact object; falls of more than 0.9 m (3 ft) (or more than 1.5 m [5 ft] for panel B); or head struck by a high-impact object.

§ Patients with certain isolated findings (ie, with no other findings suggestive of traumatic brain injury), such as isolated LOC, isolated headache, isolated vomiting, and certain types of isolated scalp hematomas in infants older than 3 months, have a risk of ciTBI substantially lower than 1%.

¶ Risk of ciTBI exceedingly low, generally lower than risk of CT-induced malignancies. Therefore, CT scans are not indicated for most patients in this group.

hydrocephalus, necessitating placement of a ventriculoperitoneal shunt catheter; and persistent vegetative or severely impaired mental state. Penetrating head injuries can result in infections (eg, meningitis, abscess) and vascular injuries (eg, aneurysm, arteriovenous malformations). Sequelae such as postconcussion syndrome may result from less severe head trauma. Some of the characteristics of this syndrome include dizziness, headache, irritability, memory deficits, impaired behavior, and impaired cognitive development. These may persist for months after the head injury and sometimes are permanent. The child with postconcussion syndrome may warrant formal neurobehavioral testing.

Prevention

Despite advancing medical knowledge and excellent critical care available to children with head trauma, little can be done to reduce the severity of primary brain injury after it has occurred. Therefore, pediatric health professionals should make every attempt to educate patients and families about prevention strategies. Some of the most

successful prevention strategies involve the required use of restraint devices (eg, seat belts) and proper safety gear (eg, bicycle helmets). Anticipatory guidance and home safety recommendations provided to parents and caregivers are also worthwhile. Finally, communities can contribute to injury prevention by providing playground resurfacing, reducing the height of playground equipment, and changing traffic laws. It is only through a combination of these prevention strategies that morbidity and mortality of pediatric head trauma will be meaningfully reduced.

CASE RESOLUTION

The young child has a significant mechanism of injury, brief LOC, and a depressed, altered mental status. Initial physical findings prompt suspicion of a depressed skull fracture and overlying soft tissue injury. Appropriate diagnostic tools after evaluation of circulation, airway, and breathing are cranial CT followed by admission for observation, monitoring, and serial neurologic examination. Surgical repair of the skull fracture may be necessary.

CHAPTER 79

Increased Intracranial Pressure

Hanalise V. Huff, MD, MPH, and Kenneth R. Huff, MD

CASE STUDY

A 7-year-old boy has a 2-week history of recurrent vomiting. No fever, abdominal pain, or diarrhea has accompanied the vomiting; the vomiting has no particular relationship to meals; and the boy's appetite has decreased only slightly. The vomiting has gradually increased in frequency and is occurring every night. The day before this visit there were 4 episodes. The boy's parents have noticed that their son is generally less active; he spends more time playing on the floor of his room and does not want to ride his bicycle or play with neighborhood friends. Some unsteadiness in the boy's gait has manifested in the past few days. His parents attribute this to weakness from the vomiting.

The child's vital signs are normal except for a blood pressure of 130/80 mm Hg. Although the boy is somewhat pale and uncomfortable, he does not appear to be in acute distress. His abdominal examination is unremarkable. His speech is grammatically correct but sparse and hesitant, and he seems inattentive. On lateral and upward gaze the boy has coarse nystagmus, and upward gaze is somewhat limited. Dysconjugate left gaze is apparent, with slight failure of left eye abduction. The left eye does not blink as much as the right eye. Fundal examination discloses elevated discs with indistinct margins. No upper extremity weakness is evident. The right foot is slightly weaker than the left, ankle tone is bilaterally increased, and 3 to 4 beats of clonus on the right and bilateral positive Babinski reflexes are present. Some tremor occurs in both arms with finger-to-nose testing. The boy walks with shuffling, small steps; his gait has a slight lurching character; and he veers to the right.

Questions

1. What clinical situations are associated with increased intracranial pressure?
2. What is the pathophysiological process leading to increased intracranial pressure?
3. What studies are used to evaluate the child with increased intracranial pressure?
4. What measures are used to treat the child with increased intracranial pressure?

The signs and symptoms of increased intracranial pressure (ICP) often signal a serious, potentially brain damaging intracranial process that may require surgical or intensive care intervention depending on the underlying cause. Recognizing signs and symptoms early often results in a determination of the underlying cause, after which management can resolve the secondarily increased ICP problem. Increased ICP can also be a critical care issue by itself even if the specific etiologic diagnosis is indeterminate. A growing number of effective medical and surgical treatments for increased ICP are available. It is critical to have an understanding about when to initiate them because they can be lifesaving.

Epidemiology

A wide variety of clinical situations, including both acute and subacute processes that occur at all ages, in both sexes, and among all ethnic groups, are commonly responsible for increased ICP. Only a few can be mentioned herein. Traumatic brain injury (TBI) is a leading cause of increased ICP. Fifty-two percent of infants with TBI may be victims of nonaccidental trauma; older children may be stricken pedestrians or bicycle riders, occupants of crashed motor vehicles, or victims of falls or sports injuries; and children of any age may suffer gunshot wounding. Traumatic brain injury is the leading source of trauma mortality and morbidity in children, most often as the result of brain-damaging increases in ICP.

Brain tumors are the most common solid neoplasms in children and frequently result in subacutely increased ICP by direct mass effect or blockage of cerebrospinal fluid (CSF) flow. Diagnosis may sometimes be suggested by neurocutaneous signs or other evidence of tumor suppressor gene mutation. Ischemic brain damage resulting from a difficult delivery at birth, a near drowning incident, or a major intracranial arterial or venous vessel thrombosis is also a significant etiologic contributor to increased ICP. Other causes of brain swelling, such as lead intoxication and liver failure in Reye syndrome, have become less common etiologies.

Idiopathic intracranial hypertension (IIHP, also called benign intracranial hypertension or pseudotumor cerebri), which has an overall prevalence of 1 to 2 per 100,000 but is 20 times higher in adolescent girls with obesity, may ultimately be found as the cause for the increased ICP. It often occurs spontaneously but may also follow the use of high doses of vitamin A, growth hormone, or tetracycline, or it may occur after withdrawal of steroid therapy. Similar physiology is seen with thrombosis of a venous sinus caused by a clotting diathesis or complicated otitis media or mastoiditis.

Clinical Presentation

The child with increased ICP may present with a history of recurrent vomiting, lethargy, and new headaches of increasing frequency or severity (ie, crescendo headaches) or that awaken the child from sleep. The physician must be acutely aware of the clinical situation. A prior history of trauma, ischemia, meningitis, hypertension, or vasculitis; presence of a CSF shunt; or a concomitant history of intoxication or metabolic aberration (ie, carbon monoxide, hyperammonemia, or diabetic ketoacidosis) may also be suspicious for increased ICP in the child with compatible examination findings. Neonates with intraventricular hemorrhage or myelomeningocele or other major central nervous system malformations are prone to hydrocephalus. Children with cyanotic congenital heart disease are prone to cerebral abscesses, and children with sickle cell disease can present with stroke or hemorrhage, resulting in increased ICP. In endemic areas of the world, cerebral malaria and intraventricular cysticercosis are frequent causes of increased ICP. The pertinent physical findings may include elevated optic disc, failure of upward gaze, hypertonicity of the extremities, and either depressed alertness or inattention or severely altered mental status. More localized findings on neurologic examination may also point to a lesion indicative of a space-occupying intracranial mass, which could contribute to increased ICP (Box 79.1).

Pathophysiology

The problem of increased ICP can be understood in terms of the Monro-Kellie doctrine, which applies to the rigid cranial compartment and pressure-volume relationships of the contents. This doctrine is conceptually useful even though not always quantitatively predictive because of the variable compliance of the child's skull and dural membranes, particularly in the first 2 years after birth before most of the cranial sutures are fused. The skull and dura mater form a relatively rigid compartment; any increase in 1 of the 3 intracranial volume components—brain parenchyma, CSF, and blood—must occur at the expense of 1 or both of the other 2. Decreased volume results in increased pressure in an inverse relationship; the rise becomes much steeper, however, when initial compliance factors are overwhelmed. Irreversible damage to brain tissue occurs primarily as a result of pressure of the other components overtaking the arterial blood pressure and not allowing adequate tissue perfusion. In younger children, nonfused sutures allow more compliance if volume increases are relatively slow, but this factor is less true for acute volume increases. Additionally, pressure gradients exist across compartments or sites of CSF flow obstruction, or even around lesions within brain parenchyma, which results in focal findings in addition to those caused by global ICP or perfusion changes.

Box 79.1. Diagnosis of Increased Intracranial Pressure

- Loss of appetite, nausea, vomiting, headache, or lethargy
- Inattention, decreased ability to arouse
- Full fontanelle, increased head circumference
- Papilledema, upward gaze paresis
- Increased tone, positive Babinski reflex
- Focal signs and history compatible with an intracranial mass
- Mass lesion, cerebral edema, occluded major vessel, or enlarged ventricles on an imaging study
- Elevated cerebrospinal fluid pressure in the lumbar intrathecal or intracranial space as measured using a manometer

Changes in any of the 3 components comprising the intracranial volume may result in increased ICP in several ways. First, the brain parenchyma component may be directly increased by mass lesions, such as neoplasms, abscesses, or hemorrhages. Vasogenic edema may increase the brain parenchyma volume because of vascular leakage due to cytokines. Brain edema may also result from cytotoxic damage, cell death, and necrosis, producing increased interstitial oncotic pressure from released proteins and ions, and cellular inflammatory and repair processes. The immediate cause may be mediated by cellular insults, including hypoxemia; intermediary metabolic toxins, including neuronal excitotoxins; and depletion of energy substrates that are consequential to major vessel occlusion, contusional trauma or traumatic diffuse axonal injury, anoxia from cardiac arrest, hypertensive encephalopathy, encephalitic infection, or external metabolic poisoning. Edema with head trauma is known to be worse in children than in adults and may be a combination of vasogenic and cytotoxic edema and may be related to neurogenic inflammatory release of substance P and calcitonin gene-related peptide at the molecular level close to vessels.

Second, the pressure of the CSF volume component (ventricles or subarachnoid spaces) may increase in the setting of hydrocephalus. Hydrocephalus can result in 2 ways: from a discrepancy in the rate of formation of CSF relative to absorption and from an obstruction between the point of formation in the lateral ventricles and the sites of absorption at the arachnoid granulations. An obstruction can occur with a congenital malformation; a parenchymal or intraventricular mass, such as a cyst or neoplasm; CSF inflammatory cells from meningitis, ventriculitis, or hemorrhage; subarachnoid protein or debris; displaced brain parenchyma from mass effect; or overgrowth of dural tissue. The small passageways connecting the ventricular system, the foramen of Monro, and the aqueduct of Sylvius; the exits of the ventricular system, the foramen of Magendie, and the foramen of Luschka; and the cisterns surrounding the brain stem are particularly vulnerable points of obstruction. Another type of brain edema, interstitial edema, is characterized by periventricular transudation of CSF into the adjacent white matter and generally occurs in the patient with acute or subacute hydrocephalus.

Third, ICP may rise because the intravascular volume component may increase. One process that leads to this increase is venous outflow obstruction, such as with a dural sinus thrombosis. Many patients initially diagnosed as having IIHP are subsequently found to have a diagnosis of transverse sinus stenosis or thrombosis. Other processes that raise jugular venous pressure may also increase ICP. Additionally, the intracranial arterial vascular volume is affected

by partial pressure of carbon dioxide. It not only increases with hypercapnia and inadequate ventilation but also decreases with hypocapnia, which occurs with compensatory central neurogenic hyperventilation or iatrogenic reduction of ICP by mechanical hyperventilation.

Because the physiology is dynamic, it has proven useful to quantitate ICP for management purposes. Intracranial pressure is often measured as centimeters of water (cm H_2O), whereas blood pressure is noted as millimeters of mercury (mm Hg). Normal ICP levels are somewhat lower in the neonatal and infantile period, at approximately 6 cm H_2O (5 mm Hg), but in adolescents, pressures above 25 cm H_2O (18 mm Hg) are abnormal and may produce symptoms. Although it is possible to have normal cognitive function at an ICP of 52 cm H_2O (40 mm Hg), this assumes an adequate perfusion pressure. Perfusion pressure is the mean arterial pressure (MAP) less the ICP. The ICP becomes clinically significant when the perfusion pressure is compromised, which may occur when the ICP is 78 cm H_2O (60 mm Hg) below the MAP, which might translate to an ICP as low as 20 mm Hg if the MAP is 80 mm Hg. It can become dangerous when the ICP is only 52 cm H_2O (40 mm Hg) below the MAP, which translates to an ICP of 40 mm Hg if the MAP is 80 mm Hg. Decreased perfusion produces swollen, damaged tissue, which increases the brain parenchymal compartment volume and further exacerbates the pressure-volume problem in a cascading fashion. Total loss of brain perfusion occurs when the rise in ICP overtakes and becomes equal to the MAP.

As ICP increases, brain perfusion pressure may be maintained transiently by a spontaneous increase in MAP, a response referred to as the *Cushing response* (ie, hypertension along with bradycardia and bradypnea). Although the relationship may not be universally reliable, when it is present with other suggestive clinical circumstances, the rise in systemic pressure can be a useful clinical sign of increased ICP. Normally, changes in arterial cerebrovascular resistance meet changes in perfusion pressure to maintain constant cerebral blood flow, a process called *autoregulation*. This process is frequently compromised after head trauma or asphyxia, however, and is shifted with chronic hypertension.

Acute or subacute changes in pressure within an intracranial compartment may produce a pressure gradient across compartments that may precipitate brain herniation syndrome (Figure 79.1). An ominous heralding sign of transtentorial herniation of the uncus of the temporal lobe is loss of the pupillary light reflex caused by entrapment of cranial nerve III. This herniation often results in irreversible brain stem damage as well as infarcts and additional secondary edema, which can end with brain death. Focally increased posterior fossa pressure may result in a pressure cone downward through the foramen magnum, compressing medullary centers, sequentially extinguishing cranial nerve functions, producing decerebrate posturing, and finally causing apnea and brain death. A marginally compensated system could be decompensated by an ill-advised lumbar puncture when the spinal compartment pressure is acutely decreased, thereby increasing the pressure gradient across the foramen magnum and producing herniation.

Differential Diagnosis

Complicated migraine, seizures, and metabolic derangements are common problems that sometimes have a clinical presentation similar to increased ICP because they may present with headache and altered mental status. A characteristic prodrome or the "pounding"

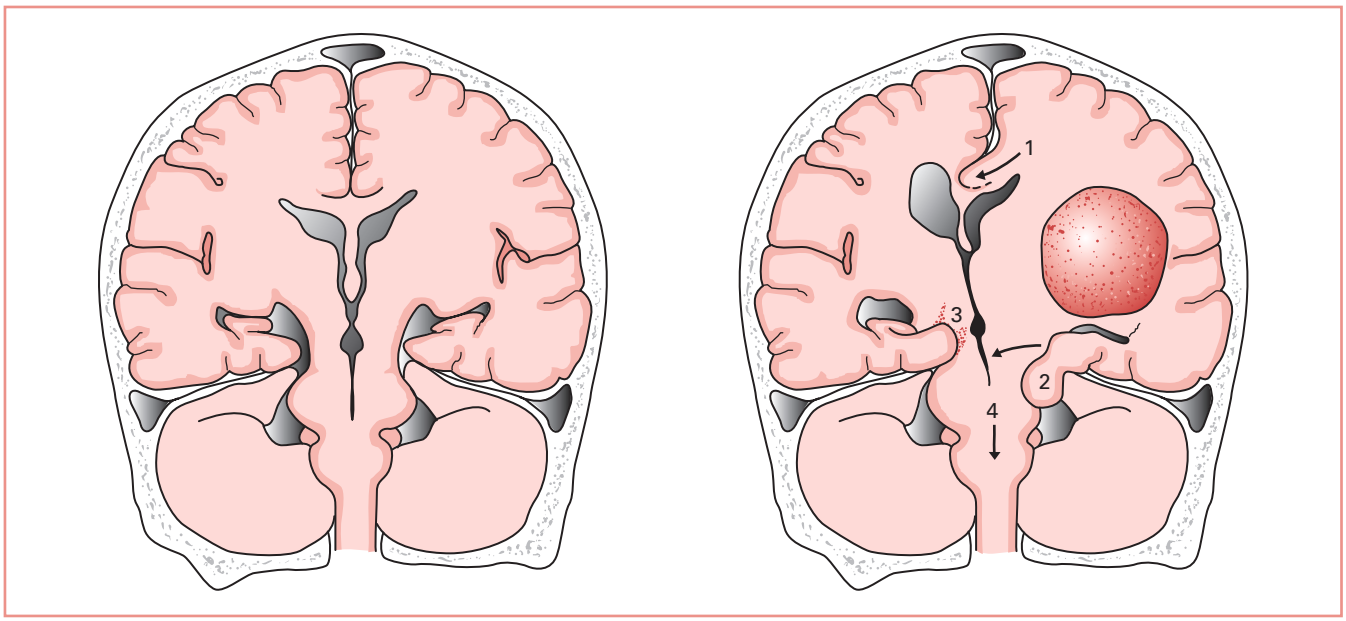

Figure 79.1. Left, Illustration of a normal brain. Right, Illustration of the anatomy of several potential herniation syndromes caused by intracranial compartment pressure gradients related to a mass in a cerebral hemisphere. 1, Transfalcine herniation. 2, Uncal herniation. 3, Contralateral tentorial-midbrain damage. 4, Central herniation and foramen magnum pressure cone. These syndromes often result in further brain ischemia and additional increases in intracranial pressure.

nature of the pain may help separate migraine from increased ICP. At the initial headache presentation or when only a short headache history is present, the complicated migraine diagnosis may be one of exclusion. If the child displays focal neurologic signs with some of the general symptoms of increased ICP, an imaging study to rule out a space-occupying lesion and confirm the safety of a lumbar puncture as well as a subsequent measurement of normal pressure by lumbar puncture manometry may be necessary to support the diagnosis of complicated migraine rather than increased ICP.

In the child who is only partially responsive, the task of distinguishing a seizing or postictal state from a condition that may be producing increased ICP is sometimes difficult. Findings suggestive of a seizure include rhythmic, clonic movements or sudden myoclonic jerks; rapid or variable changes of tone or posturing that are different from the decerebrate posturing that may accompany a process producing increased ICP; abrupt, fluctuating changes of autonomic function (eg, heart rate, blood pressure, pupillary size); saliva production without swallowing; and a history of prior seizures. Sometimes, however, only direct electroencephalography (EEG) monitoring with ICP monitoring can distinguish ongoing electrographic "subclinical" seizure activity from increased ICP as the cause of the change in level of responsiveness.

In some instances, diffuse brain dysfunction from a toxic or metabolic etiology mimics increased ICP. Such toxic or metabolic causes include medication toxicity, electrolyte or blood chemistry imbalance, and systemic infection. With toxic or metabolic disorders, inattention is often accompanied by an acute confusional state with disorientation, incoherence, and sometimes agitation. In contrast, with subacutely increased ICP, inattention frequently is accompanied by slowness of thought, perseveration, decreased mental activity, and impaired gait.

Evaluation

History

A thorough neurologic history should be obtained (Box 79.2). Headache, nausea and vomiting, drowsiness, personality change, declining school performance, and changes in visual acuity and obscurations are important historical factors. The headache history may be one of crescendoing in frequency or intensity, consistent localization, and only a few days' or weeks' duration. The headache may awaken the patient from sleep or be worsened by cough, micturition, defecation, or other Valsalva-like maneuvers. A "thunderclap" headache may be indicative of an intracranial hemorrhage. Rapid progression of symptoms generally motivates concern.

Box 79.2. What to Ask

Increased Intracranial Pressure

- How long has the child been vomiting, and when does the vomiting occur?
- Do headaches awaken the child?
- Does the child have weakness or change in gait?
- Does the child have a recent history of trauma?
- Has there been a progressive decline in activity level or loss of developmental skills?

Physical Examination

Vital signs and head circumference should be noted. Neck stiffness is an important sign of either meningeal irritation or cervical trauma. A careful neurologic examination is warranted whenever increased ICP is suspected. Particular attention should be paid to the components of the mental status and level of responsiveness and alertness of patients. The presence of papilledema and the cranial nerve functions, including visual fields, should be assessed. Papilledema may not appear for a few days after ICP is increased. Retinal hemorrhages in an infant may be suspicious for nonaccidental trauma. Cranial nerve VI is particularly susceptible to increased ICP, and an abnormality may be falsely localizing. Impaired upward gaze and lid retraction may be present. The patient may tilt the head to compensate for dysconjugate gaze. Specific muscle tone and strength as well as gait characteristics and ataxia should be evaluated in the child who cannot cooperate. In the comatose child, posturing responses to stimulation and the breathing pattern should be noted to help ascertain brain stem localization of a lesion. In a comatose child, findings should be reassessed at frequent intervals until stable to follow a potentially rapidly progressing devastating process, such as impending tentorial or brain stem herniation, which would necessitate immediate surgical intervention.

A useful quick-assessment instrument for initial, rapid evaluation and subsequent monitoring is the pediatric *Glasgow Coma Scale* (Table 79.1). These scales are a useful shorthand description for emergent triage purposes and perhaps for acute ventriculostomy decisions in trauma cases but are not sufficient for all clinical decisions related to patients with increased ICP.

The newborn or infant may display a unique collection of signs—enlarged head circumference; bulging, raised fontanelle; frontal bone bossing with prominent venous distention; irritability, *setting sun sign* (ie, inability to elevate the eyes and lid retraction resulting from midbrain tectal pressure); hypertonicity; and hyperreflexia—that may be secondary to increased ICP resulting from hydrocephalus. Papilledema is generally not present, perhaps related to greater compliance of the newborn and infant skull.

Chronic hydrocephalus as a cause of increased ICP may result in optic atrophy, depressed hypothalamic functions, spastic lower limbs, incontinence, and learning problems.

Laboratory Tests

If mental status changes are suggestive of a toxic or metabolic aberration, appropriate laboratory screening should be performed, including complete blood count, glucose level, electrolyte level, toxicology screening, liver function tests, arterial blood gasses, and kidney function tests. If signs of meningeal irritation or infection are also present without lateralized signs of altered tone or strength, evidencing an intercompartmental pressure gradient, a CSF examination

should be done. Otherwise, if the patient is at risk for herniation after lumbar puncture, a preceding brain imaging study is necessary. If the imaging study suggests that performing a lumbar tap carries a risk, CSF analysis and pressure measurements can be done based on ventriculostomy instead. For the patient with clinical signs of increased ICP and no focal clinical or imaging signs of a mass, a lumbar puncture with opening pressure measurement is also necessary for the diagnosis of IIHP.

Imaging Studies

Computed tomography (CT) should be performed whenever a child's signs and symptoms indicate the possibility of increased ICP and should be performed even in the setting of symptoms without signs in a child younger than 6 years. Patients with severe head trauma frequently have a particularly dynamic pathophysiology, and an additional early CT scan after a few hours may be indicated to assess for increasing hemorrhage, mass effect, or ventricular size along with ICP monitoring. Magnetic resonance imaging may be necessary to detect ischemia early. Intravenous (IV) contrast should be given if a source of disruption in the blood-brain barrier (eg, infection, inflammation, neoplasia) is suspected. Magnetic resonance venography can be obtained if a possibility exists of a venous sinus thrombosis. Computed tomography angiography or traditional intraluminal angiography with the option of intervention to prevent rebleeding may be the best studies in the patient with intracranial hemorrhage of unknown source.

Management

If IIHP is diagnosed, the pressure can be monitored with lumbar punctures until it is stable. Visual fields can be monitored using optical coherence tomography to assess the degree of retinal damage. Monitoring should occur at regular intervals until full recovery. Increased ICP may respond to diuretic agents, such as acetazolamide at high dose (20 mg/kg/day) or furosemide, as well as the removal of CSF during the lumbar puncture as a temporizing measure. A weight loss program is quite important if obesity is present. The primary danger in this condition is eventual blindness caused by pressure at the optic nerve head. If medical therapy is not successful, lumbar or ventricular peritoneal shunt placement or optic nerve sheath fenestration can be done surgically. The risk of severe vision loss is 6% to 14%.

The child with encephalopathy whose ICP is markedly elevated or likely to rise rapidly requires treatment in an intensive care unit. When diagnostic imaging studies reveal an etiology for the increased ICP, such as a rapidly enlarging epidural hematoma, immediate neurosurgical craniotomy may be necessary. Other focal space-occupying lesions noted on imaging studies may not require immediate craniotomy, depending on size and position of the lesion as well as the distortion of normal brain tissue and potential for imminent loss of perfusion; neoplastic lesions may require diagnostic biopsy or excisional biopsy within a few days if surgically accessible. Mineralocorticoids (eg, dexamethasone 0.25–0.5 mg/kg every 6 hours) are useful in situations in which the

pressure is produced by a component of vasogenic edema, such as that surrounding neoplasms. Measures should also be used to help prevent a stress ulcer. Hypotonic IV fluids should be avoided, and serum and urine osmolality should be monitored for the syndrome of inappropriate antidiuretic hormone secretion. Hypoglycemia and hyperglycemia should be avoided as well. If the patient is in acute danger for herniation resulting from a pressure gradient produced by CSF flow blockage, a temporary ventriculostomy may be indicated to relieve the CSF pressure. If an infectious process is suspected, including focal lesions, abscess, cerebritis, or encephalitis, antibiotics or antiviral agents are indicated. After directed specific treatment of the underlying lesion, the increased ICP may resolve spontaneously. If hydrocephalus resulting from obstruction of CSF flow persists after initial therapy is completed, ventriculoperitoneal shunting of CSF may be necessary. Endoscopic third ventriculostomy avoids the long-term complications of obstruction and infection associated with ventriculoperitoneal shunt hardware but is less often successful in relieving the pressure in younger children than older ones.

In the patient with no mass or space-occupying lesion requiring surgical removal, interventional therapies are directed toward maintaining perfusion of recovering brain tissue. In the patient with head injury, a *Glasgow Coma Scale* score of 8 or less can be used as a guideline for ICP monitoring. Intracranial pressure can be monitored on an ongoing basis with commonly used neurosurgically placed devices, including the fiberoptic microtransducer and intraventricular catheter or ventriculostomy. The fiberoptic microtransducer can measure pressure in brain parenchyma as well as in fluid-filled spaces. A distinct advantage of the intraventricular catheter is in allowing for therapeutic CSF drainage to relieve pressure, although it may be difficult to place if the ventricles are small or shifted; additionally, this device carries a slight risk of hemorrhage or infection, increasing to a plateau at day 4 of 1% to 2% per day. Intracranial hypertension frequently peaks at 1 to 4 days after severe trauma. Intracranial pressure monitoring with devices and therapy based on the aforementioned measurements, however, has not been helpful in most patients with severe ischemic damage, infection, or poisoning. This finding may be because of the widespread nature of the insult and brain involvement so that little normally responding tissue remains in which perfusion could be maintained.

The child with a decreased or fluctuating level of responsiveness may require EEG monitoring of cerebral electrical activity. Seizures may occur even in the presence of increased ICP. Anticonvulsant therapy is indicated if evidence of clinical or electrographic seizures is present. Additionally, the EEG may be used to monitor barbiturate- or benzodiazepine-induced coma, which is used in the setting of severely increased ICP.

Respiratory physiology and ventilation are important for the child with increased ICP, because hypoxia and hypercapnia can contribute to vasodilation and increased pressure. Rapid sequence intubation and avoidance of ketamine and succinylcholine help minimize elevations of ICP. Transmission of elevated intrathoracic pressure to intracranial vessels can be avoided by sedation and decreasing the inspiratory phase of the ventilator and avoiding high positive pressure and end-expiratory pressure. If acute reduction of pressure is necessary, hyperventilation to reduce the intracranial arterial blood volume is quite effective; on a chronic basis, however, partial pressure of carbon dioxide should be kept at 32 to 38 mm Hg to avoid decreasing brain cell perfusion. Indomethacin is also a cerebral vasoconstrictor and carries the same risk to adequate perfusion. Elevating the head of the bed to approximately 30° and avoiding flexion or turning of the neck to prevent jugular kinking are effective in reducing ICP. Pain, fever, shivering, and seizures must be managed aggressively. Because the goal is to ensure perfusion while reducing ICP, maintaining and even elevating systemic MAP by appropriate use of fluid therapy and pressor agents are key therapeutic measures.

Diuretic agents, such as mannitol 0.25 to 1 g/kg bolus, which is a form of osmotherapy, may also be useful through reducing brain volume by removing water, changing the rheologic characteristics of blood, and producing reflex vasoconstriction. Caution is advised, however. Mannitol used as a chronic infusion can eventually cross the blood-brain barrier and draw more fluid into the brain. It is most effective in patients in whom the blood-brain barrier is intact. Hypertonic saline (3%) 2 to 6 mL/kg bolus followed by 0.1 to 1.0 mL/kg per hour as a continuous infusion may be an effective alternative. Serum osmolarity greater than 320 mOsm/kg can result in renal failure. Generally, such effects can be avoided by giving diuretic agents at intervals as a bolus and titrating up to the ICP-reducing dose. In some instances these agents are used to counter ICP plateau waves or increased pressure associated with endotracheal suctioning or other procedures.

In the child with severe refractory increased ICP, especially if secondary to an acute focal process, a barbiturate (eg, pentobarbital) or the benzodiazepine midazolam can be given as a continuous IV infusion with appropriate monitoring of brain electrical activity, serum levels, and systemic and brain perfusion pressures (Box 79.3). These agents may serve to reduce brain metabolism without significantly impairing vascular autoregulation; however, potential risks include reducing cardiac output and inducing associated infections, particularly pneumonia. Xenon CT measures multiple areas of local blood flow and may be a useful bedside technique to help specify targeted therapies. Decompressive craniotomy or craniectomy in early severe trauma in small series of patients has been associated with good outcomes in up to 50%. Hypothermia has not been useful in the management of cardiac arrest in the pediatric patient. Numerous "neuroprotective" agents continue to be studied as means of slowing metabolism and the resulting excitotoxic glutamatergic damage and thereby reduce cytotoxic edema and spread of the volume of irreversibly damaged brain tissue into the surrounding penumbra of damaged but not dead brain.

Prognosis

The overall mortality rate for children brought to an emergency room with TBI is 4% to 5%. Most of these children die from increased ICP. Disability occurs in many of the survivors, but the extent of disability may not be known for months to years

Box 79.3. A Simplified Intensive Care Interventions Protocol for the Child With Increased Intracranial Pressure

- Attend to airway, breathing, and circulation; intubation for airway control for GCS score <8.
- Keep head of bed elevated to 30°.
- Neurosurgical consultation to consider ICP monitor for the patient with GCS score <8.
- Maintain normal or elevated systemic blood pressure, normal temperature, and normal serum glucose level.
- Continuous general and local anesthesia, sedation, muscle relaxants, and anticonvulsant agents.
- Control hyperventilation to $Paco_2$ at 32–38 mm Hg and provide supplemental oxygen and PEEP as necessary to maintain Pao_2 > 90 mm Hg.
- Dexamethasone 0.5 mg/kg (maximum of 10 mg) every 6 hours if evidence exists of vasogenic edema on a brain imaging study.
- If an ICP monitor is present, target cerebral perfusion pressure at 40–50 mm Hg (age ≥5 years) and 50–60 mm Hg (age 6–17 years).
- If ICP progressively rises, pressure waves >20 mm Hg last longerthan 5 minutes, or any pressure in the first 24 hours is >30 mm Hg, give 3% saline 5 mL/kg. Alternatively, give mannitol 250–1,000 mg/kg IV. This may be repeated to maintain serum osmolality at 300–320 mOsm.
- If 3% saline or mannitol needs repeating in <6 hours or osmolality is >320 mOsm:
  Give pentobarbital 5 mg/kg IV, then 2 mg/kg/hour IV monitoring to blood level of 25–35 mg/mL, burst-suppression pattern with 10 seconds between bursts on EEG, and cardiac index >2.7 L/minute/m^2.
  Or
  Give midazolam by titrating the dose upward starting at 0.1 mg/kg/hour IV to the same EEG criteria and limited by the same cardiac index criteria.
- Particularly in trauma cases in which the cerebral lesion is primarily unihemispheric and pressure is rapidly increasing, hemicraniectomy should be considered.

Abbreviations: EEG, electroencephalography; GCS, Glasgow Coma Scale; ICP, intracranial pressure; IV, intravenous; $Paco_2$, partial pressure of carbon dioxide; Pao_2, partial pressure of oxygen; PEEP, positive end-expiratory pressure.

afterward because recovery can be quite slow. The 10-year survival rate for all children with brain tumor is 70%. In children with encephalopathy with increased ICP with systemic hypotension, hyperglycemia, or disseminated intravascular coagulation, the prognosis for death or disability is worse regardless of cause. Some types of lesion, such as ischemia, can generate increased ICP that may advance too rapidly for therapeutic measures to take effect or are refractory to medical or surgical treatment, resulting in irreversible brain tissue damage or death. However, children can recover from increased ICP if brain perfusion pressure is adequately maintained and the underlying brain lesion generating the increased pressure can be resolved.

CASE RESOLUTION

The boy has focal signs and symptoms referable to the posterior fossa brain stem and cerebellum as well as symptoms of increased ICP. Emergent CT shows subacute hydrocephalus resulting from obstruction of CSF flow produced by a large mass in the cerebellum and brain stem on the left side. He begins taking dexamethasone and experiences some relief of increased ICP symptoms. Two days later a ventriculostomy is placed and the mass, which is found to be a medulloblastoma, is surgically removed. Because the ICP eventually subsides over the next few days and decreasing ventriculomegaly is evident on CT, a ventriculoperitoneal shunt is not required and the ventricular drain is removed. The boy's recovery is otherwise uneventful, and he begins the staging evaluation for medulloblastoma radiotherapy and chemotherapy.

CHAPTER 80

Management of Dehydration in Children: Fluid and Electrolyte Therapy

Gangadarshni Chandramohan, MD, MSc, FASN, FAAP

CASE STUDY

A 2-year-old boy presents to your office after 2 days of vomiting and diarrhea. His siblings were both ill a few days previously with similar symptoms. At a well-child visit 2 weeks previously, his weight was 12 kg (26.5 lb). Today his weight is 10.8 kg (23.8 lb). He has a pulse of 130 beats per minute, respiratory rate of 28 breaths per minute, and blood pressure of 85/55 mm Hg. He is alert and responsive but appears tired. He has dry mucous membranes, no tears with crying, and slightly sunken-appearing eyeballs. His capillary refill is 2 seconds. He urinated a small amount approximately 6 hours before this office visit. Despite his mother's best efforts in your office, the patient has vomited all the oral rehydration therapy given to him. You draw blood for analyzing electrolyte, blood urea nitrogen, and creatinine levels and initiate intravenous rehydration by administering 2 boluses each of 240 mL normal saline (0.9% sodium chloride solution).

Questions

1. How is the magnitude of dehydration in a child assessed?
2. What are the different types of dehydration?
3. How is the type and amount of fluid required by the dehydrated child determined?
4. How is renal status assessed in the dehydrated child?
5. What is the role of electrolyte and acid-base laboratory tests in the evaluation of the dehydrated child?

Dehydration resulting from gastrointestinal (GI) and other disorders, especially diarrhea, is among the most common medical problems encountered in children younger than 5 years. During the past 50 years or more, the usual therapy for children who are hospitalized with dehydration has been to administer intravenous (IV) fluids starting with 1 or 2 boluses of normal saline (NS; 0.9% sodium chloride [NaCl] solution at 20 mL/kg). This is followed by the administration of a sodium (Na^+) solution of variable concentration (usually 0.45% NaCl) mixed with 5% dextrose over the next 24 to 48 hours until the child is able to take oral fluids. The exact amount of fluid and electrolytes is calculated using complicated formulas to provide maintenance fluids and correction of remaining deficit (ie, deficit therapy). The calculation of maintenance therapy was first recommended in the 1950s, but more recently it has been suggested that dehydration management should focus on rapid restoration of extracellular fluid (ECF deficit) followed by oral rehydration therapy (ORT), and traditional calculations of fluid deficits should be abandoned. Alternatively, pediatric nephrologists and intensivists have recommended that physicians forgo sodium calculations in hospitalized children and rely solely on isotonic NS (0.9% NaCl solution) for management. Although this chapter incorporates these suggestions where appropriate, it describes the traditional approach to maintenance and deficit therapy because an understanding of the pathophysiology of dehydration helps in the treatment not only of the dehydrated child but also of children with other types of fluid and electrolyte disorders.

Epidemiology

Over the past 30 years, hospital admissions and mortality resulting from diarrhea and dehydration have decreased worldwide; nevertheless, diarrhea remains 1 of the leading medical problems in children younger than 5 years. According to the Centers for Disease Control and Prevention, more than 200,000 hospitalizations and 300 deaths of children occur each year in the United States resulting from diarrhea. Additionally, diarrhea is responsible for 2 to 3 million outpatient visits each year and contributes to 10% of all hospital admissions.

Maintenance Fluid and Electrolyte Requirements

The body has a maintenance fluid requirement to replace daily normal losses that occur through the kidney, intestines, skin, and respiratory tract. Of the various methods used to determine fluid needs, the most common is the caloric method, also called the Holliday-Segar method, which is based on the linear relationship between metabolic rate and fluid needs. For every calorie expended in metabolism, a child requires approximately 1 mL of water. Metabolic rate in children is a function of body surface area. Infants, with their higher relative surface areas per unit of body weight, have higher metabolic rates and, therefore, higher fluid requirements per unit weight compared with older children and adults. As the child grows, the relative surface area decreases, as do the metabolic rate and fluid requirement per unit weight. Using this relationship, maintenance fluid needs can be calculated for the healthy child using the method outlined in Table 80.1. These calculations of fluid needs are often used to determine the amount of IV fluids provided to a hospitalized child or to calculate the approximate amount of fluid a healthy child requires orally to maintain hydration. These calculations may not be appropriate for children who are critically ill, however, some of whom require fluid restriction and others of whom may have increased fluid needs. Moreover, the caloric method makes no allowance for extra fluid needed for weight gain, growth, activity, or pathophysiological states that increase fluid needs (eg, fever). The fluid requirement derived from this method is valid to determine the daily fluid need for an essentially healthy child. Thriving infants normally drink more fluid than indicated by this method. On average, a growing infant may take 150 to 200 mL/kg per day of milk (human milk or infant formula) as desired to support the average weight gain of 30 g (1.1 oz) per day usually observed in the first few months after birth.

Replacement of normal daily losses of electrolytes is considered when a child is not able to take adequate nutritional intake orally (as in the example in Box 80.1, in which the child receives nothing orally in preparation for surgery). Electrolyte quantities usually are expressed as milliequivalent (mEq) or millimole (mmol) amount per 100 mL of fluid required. Traditionally, the recommended sodium requirement for a healthy child is 3 mEq/100 mL fluid required (approximately 0.2% NaCl or 0.25 NS), and the potassium (K^+) requirement is 2 to 2.5 mEq/100 mL of fluid (see Box 80.1, part B, for sample calculation and IV order). Potassium should be administered only after ensuring adequate renal function. These estimations of sodium and potassium requirements are meant to replace normal daily losses and would not be adequate in the setting of increased electrolyte losses that can occur in a number of pathologic conditions (eg, diarrhea). Additionally, increased attention has recently been given to the risk of hyponatremia and related complications in hospitalized ill children.

Relatively healthy, well-nourished children receiving IV fluids for a brief period (ie, 1–2 days) during hospitalization do not routinely require supplementation with other electrolytes, such as calcium and magnesium. However, it is important to realize that standard IV fluids containing 5% dextrose, sodium chloride, and potassium chloride provide only minimal caloric needs and do not adequately support weight gain or provide other necessary nutrients. The child who requires prolonged IV therapy because of inadequate GI tract function should receive total parenteral nutrition to better meet the child's caloric and nutritional needs.

Table 80.1. Caloric (ie, Holliday-Segar) Method of Determining Maintenance Fluid Requirements in Healthy Children

Weight	*Maintenance Fluid Requirement for 24 Hours*
<10 kg	100 mL/kg/day[a] or 4 mL/kg/hour
11–20 kg	50 mL/kg/day for each kg >10 kg + 1,000 mL (fluid requirement for first 10 kg) or 40 + 2 mL/kg/hour for each kg between 11 and 20 kg
>20 kg	20 mL/kg/day for each kg >20 kg + 1,500 mL (fluid requirement for first 20 kg) or 60 + 1 mL/kg/hour for each kg >20 kg

[a] Excluding neonates and preterm infants.

Box 80.1. Example of Fluid Calculations[a]

Part A

Case: A boy weighing 22 kg is given nothing orally in preparation for an elective abdominal surgery. The following calculation is used to determine the appropriate amount of IV fluid per hour to administer as he awaits surgery.

- For first 10 kg: 100 mL/kg/day × 10 kg = 1,000 mL
- For next 10 kg (to get to 20 kg): 50 mL/kg/day × 10 kg = 500 mL
- For next 2 kg (to get to 22 kg): 20 mL/kg/day × 2 kg = 40 mL

1,000 mL + 500 mL + 40 mL = 1,540 mL/24 hour

IV rate per hour = 64.2 mL/hour (with a healthy child, round off to 65 mL/hour for ease of administration)

Part B

Question: How much Na^+ and K^+ should this patient receive in his IV fluids?

Answer:

Based on physiologic losses: 3 mEq Na^+/100 mL (1 dL) of fluid = 3 mEq × 15.4 dL = 46.2 mEq Na^+/day in 1,540 mL of water or 30 mEq NaCl/L

2.0 mEq K^+/100 mL (1 dL) of fluid = 2.0 × 15.4 = 30.8 mEq K^+/day in 1,540 mL of water or 20 mEq KCl/L

Therefore, IV order for this patient is as follows:

D5 0.2% NaCl (or 0.25 NS) with 20 mEq KCl/L to run at 65 mL/hour

Abbreviation: D5 = 5% dextrose water; IV, intravenous; K^+, potassium; KCl = potassium chloride; Na^+, sodium; NaCl, sodium chloride; NS, normal saline.

[a] Even though in this example the calculations for sodium concentration in the IV fluid is physiologic, recent American Academy of Pediatrics guidelines recommend use of NS with 5% dextrose preoperatively to prevent potential postoperative hyponatremia.

Alterations in Fluid Needs in Illness

Several conditions can influence fluid requirements. Conditions that increase a patient's metabolic rate (eg, fever) will also increase a patient's fluid requirement. A child's metabolic rate is increased 12% for every 1°C temperature elevation above normal. Most otherwise healthy children with free access to fluids will increase their own intake to account for increased needs when febrile. Other less common hypermetabolic states, such as thyrotoxicosis or salicylate poisoning, may have an even more dramatic effect, perhaps increasing metabolic rate by 25% to 50% over maintenance. In these cases and for children who are dependent on others to provide their fluids, the physician must be aware of the magnitude of increased need and provide supplemental fluids to avoid dehydration.

Other conditions may decrease a child's fluid requirement. In hypometabolic states, such as hypothyroidism, metabolic rate and fluid needs are decreased by 10% to 25%. Fluid requirements are decreased by 10% to 25% in high environmental humidity unless the ambient temperature is also high and results in visible sweating. In these situations, a healthy child with normal renal function given extra fluid beyond what is needed can, within limits, effectively excrete any excessive intake. The child with renal failure, however, poses a special challenge for the physician in the management of fluid and electrolytes. When a child cannot adequately excrete excessive fluid intake, this fluid can accumulate and result in complications such as congestive heart failure and pulmonary edema. Without functioning kidneys, only insensible fluid losses need replacing. Insensible losses occur primarily through the skin and respiratory tract; they account for approximately 40% of maintenance fluid needs. However, fluid needs for patients with renal failure usually are estimated to be 30% of the maintenance requirement, with additional fluids provided if necessary. Limiting fluids avoids the accumulation of excessive fluids that may require dialysis for removal.

Fluid requirements may also be decreased under circumstances in which arginine vasopressin (AVP; also called antidiuretic hormone) is increased. In addition to hypovolemia or hypertonicity (ie, hyperosmolality), AVP release is also stimulated by pain, nausea, surgery (ie, in the postoperative period), central nervous system (CNS) infections (eg, meningitis, encephalitis), severe pneumonia or respirator use, and certain medications, including thiazide diuretics, chemotherapeutic agents, and selective serotonin reuptake inhibitors. Arginine vasopressin release in the absence of hypovolemia or hypertonicity results in hyponatremia and is referred to as *syndrome of inappropriate antidiuretic hormone secretion*. In patients with this syndrome, fluid restriction as well as administration of fluids with a higher sodium concentration may be indicated.

The most appropriate sodium concentration of IV fluids for the hospitalized child admitted to a pediatric intensive care unit or in the postoperative patient is controversial. Over the past 25 years, most such children have been maintained on a solution containing 5% dextrose water in half NS (D5 0.5 NS) or lower sodium concentrations (D5 0.25 NS). Studies suggest that because the kidney retains free water in response to excessive AVP in these children, they are at risk for hyponatremia, hyponatremic encephalopathy, brain stem herniation, permanent brain damage, or death. Recently, some pediatric nephrologists and intensivists have recommended forgoing sodium calculations in hospitalized very sick children and instead relying solely on isotonic fluids. Others have cautioned that physicians must make certain that the new recommendations to use isotonic fluids do not result in excessive congestive heart failure or hypernatremia before abandoning previous practices. Regardless of the approach used, close attention to the type and quantity of fluids provided, quantity of body fluid output, weight change, and serial electrolyte assessments are important in the management of all sick children, and fluid and electrolytes must be individualized to each patient to prevent serious complications.

Pathophysiology

Dehydration is among the most common pathophysiological alterations in fluid balance encountered in pediatrics. Although strictly speaking, *dehydration* means deficit of water only, most children with dehydration have lost water and electrolytes. Dehydration can result from diminished intake, excessive losses through the GI tract (eg, diarrhea, vomiting), excessive losses from the kidney or skin (eg, polyuria resulting from osmotic diuresis in uncontrolled diabetes), or a combination of these factors.

Children are at increased risk for episodes of dehydration for many reasons. Infants and young children have 2 to 4 times the body surface area per unit body weight compared with adults and as a result have relatively higher fluid needs. It is therefore much easier for children to become dehydrated in the setting of decreased intake or increased losses that often accompany common childhood illnesses. For example, acute gastroenteritis, which is common in young children, often results in anorexia, recurrent vomiting, and frequent or large-volume stools, with proportionately more severe fluid loss than in older children and adults. Additionally, infants and young children are dependent beings who are unable to increase their own fluid intake in response to thirst and must rely on others to provide their fluid needs. If these fluid needs are not met or are underestimated, a child can easily become dehydrated.

Dehydration is classified as isotonic, hypotonic, or hypertonic. These terms often are used interchangeably with isonatremic, hyponatremic, and hypernatremic, respectively. The latter terms reflect the sodium content of the ECF that largely determines serum osmolality in the otherwise healthy dehydrated child. Acute isotonic or isonatremic dehydration (serum Na^+ 135–145 mEq/L), which is the most common type of dehydration, involves net loss of isotonic fluid containing sodium and potassium (Figure 80.1, top). In diarrhea-related dehydration, sodium, the primary ECF cation, is not only lost from the body but also shifts into the intracellular fluid (ICF) compartment to balance the loss of potassium, because potassium losses from cells generally are not accompanied by intracellular anionic losses in acute dehydration. The sodium that has shifted into the ICF compartment will return to the ECF compartment during rehydration as potassium is being replenished, by the action of sodium/potassium adenosinetriphosphatase (ATPase). No net loss of fluid from the ICF occurs in this

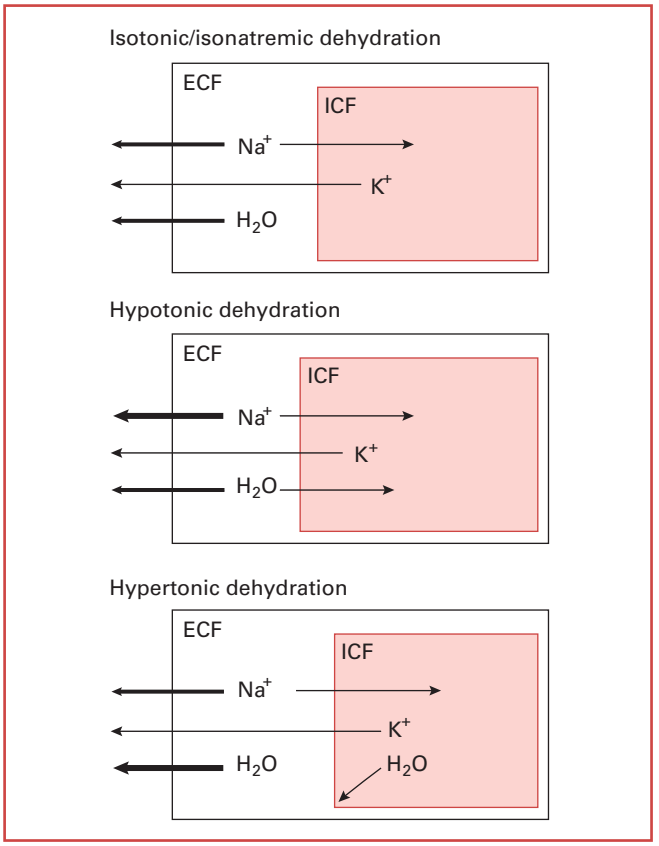

Figure 80.1. Pathophysiology of various types of dehydration. Top, Isotonic/isonatremic dehydration. Middle, Hypotonic dehydration. Bottom, Hypertonic dehydration. Abbreviations: ECF, extracellular fluid; H_2O, water; ICF, intracellular fluid; K^+, potassium; Na^+, sodium.

process; the total water deficit in dehydration comes primarily from the ECF, although some investigators have suggested, in the absence of valid data, that two-thirds of the losses come from ECF and one-third from ICF.

A variety of mechanisms exist by which hyponatremia (serum Na^+ <135 mEq/L) occurs in association with dehydration. In hypotonic or hyponatremic dehydration, the ECF volume is compromised to a greater degree than in isotonic dehydration because of osmotic shifts of ECF into the cells, resulting in more severe signs of dehydration (Figure 80.1, middle). Hypotonic dehydration typically occurs in children with gastroenteritis in the setting of excessive sodium losses in stool and oral fluids replacement with a reduced amount of sodium (ie, water, low-sodium beverages [eg, juice, tea]). Furthermore, the kidneys often retain free water (ie, excrete a concentrated urine) despite hyponatremia, because AVP is stimulated by the decreased effective circulating volume in such settings. Intravascular volume depletion seems to be a potent stimulus for AVP release, overriding the AVP suppressive effect of hypotonicity/hyponatremia. The result is that serum sodium levels are further decreased because of dilution. Hypotonic dehydration also may occur as the result of excessive loss of sodium (relative to body water) in stool (eg, cholera) or in the urine (eg, adrenogenital syndrome, cerebral salt wasting, pseudohypoaldosteronism, other salt-wasting renal disorders). This is the most dangerous form of dehydration because it can result in cerebral edema and eventually, brain herniation.

Hypertonic or hypernatremic dehydration (serum Na^+ >145 mEq/L) occurs when net loss of water exceeds that of solute loss (Figure 80.1, bottom). It usually is seen in clinical conditions in which rapid loss of hypotonic fluid in stool, vomit, or urine occurs, accompanied by failure of adequate water intake because of anorexia or vomiting. Fever or hyperventilation, if present, may intensify the disproportionate loss of water. Occasionally, hypertonic dehydration may be caused by excessive solute intake. Urinary excretion of excess solute obligates loss of large volumes of water, resulting in dehydration. The history may reveal that the child was accidentally fed a high sodium solution because of incorrect mixing of oral rehydration packets or concentrated formula. In hypertonic dehydration, shift of fluid from the ICF to the ECF occurs to attain osmotic balance. As such, the ECF volume is somewhat spared at the expense of the ICF, and signs of dehydration may be delayed. However, fluid loss from the ICF results in intracellular dehydration, the most serious effect of which can occur in the brain. If hypernatremia occurs rapidly, not only does a decrease in brain size occur, but a fall in cerebrospinal fluid pressure occurs as well resulting from diffusion of water from cerebrospinal fluid to the blood. As the brain shrinks, the bridging veins within the skull may stretch and even tear, resulting in intracranial hemorrhage or other complications. If the hypertonic state manifests more slowly, brain cell size may initially shrink minimally but will gradually return to normal size even with continued hypernatremia. Preservation of the brain cell volume despite hypernatremia is thought to be caused by the generation of idiogenic osmoles (eg, myoinositol, trimethylamines, taurine, and other amino acids) that prevent water loss and attract water back into the cell and thus maintain cell volume. Rehydration of the patient with hypernatremia must occur slowly and cautiously to avoid brain cell swelling (Figure 80.2). In the child with hypertonic dehydration, on clinical examination the skin may sometimes feel "doughy" because of intracellular dehydration. This finding, however, is inconsistent even when evaluation is done by an experienced pediatrician; thus, clinical examination of the skin should not substitute for serum sodium measurements in the diagnosis of hypernatremia.

Evaluation

History

In addition to signs and symptoms of the current illness, the history should focus on the cause of dehydration. The parent or guardian should be questioned about the type and amount of oral intake; the duration, quality, and frequency of vomiting or diarrhea; whether blood is present in the stool; the presence or absence of fever; frequency of urination; and whether a recent pre-illness weight is known for the child (Box 80.2). Changes of mental status reported by a parent or guardian is of particular concern because this can occur as the result of significant electrolyte (eg, sodium) disturbance, marked dehydration, or other serious infection or illness. The most accurate means of assessing the degree of dehydration is to compare current weight with a recent pre-illness weight. In acute

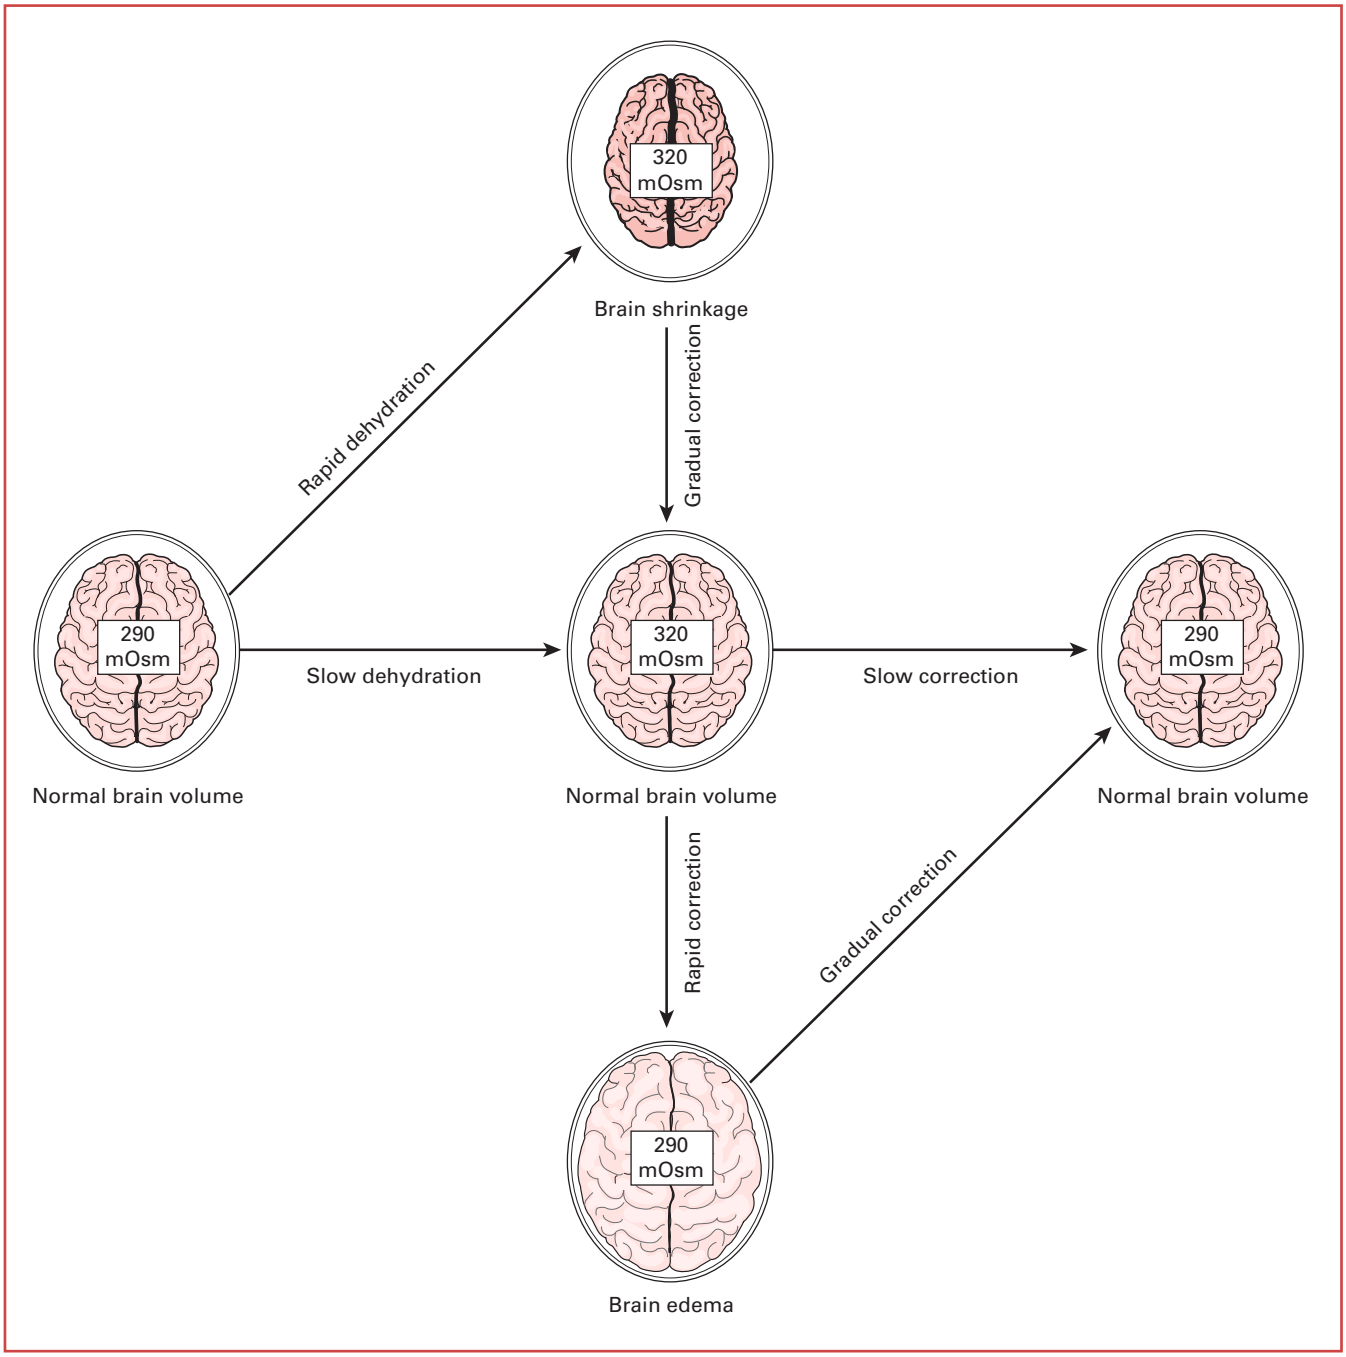

Figure 80.2. Illustration of the steps in managing hypertonic dehydration showing the effects on brain volume of rapid versus slow development of hypernatremia and the results of rapid versus slow correction of hypernatremia.

dehydration, weight loss is primarily the result of fluid loss. The difference between pre-illness and current weight can be used to determine the degree of the fluid deficit.

Physical Examination

An important goal of the physical examination of the dehydrated child is to assess the degree of dehydration. In the process, vital signs, including blood pressure and a current weight, should be obtained. Specific attention should be paid to the general appearance of the child and, in particular, whether the child is ill-appearing, listless, or less reactive. In addition to the usual components of the physical examination, it is important to assess for the following factors: whether the oral mucosal membranes appear tacky or dry, whether tears are present or absent, if tenting of the skin is present (ie, tenting remains after the skin is pinched between 2 fingers), and perfusion status of the extremities. In the process, it is important that the physician recognize whether shock is present, because this is a life-threatening condition requiring emergent treatment (see Chapter 74).

If comparison to an accurate recent pre-illness weight is not possible, the physician must rely on vital signs as well as clinical signs and symptoms to assess the degree of dehydration (Table 80.2). In infants

Box 80.2. What to Ask

Dehydration

- Has the child been vomiting and/or having diarrhea?
- How many stools has the child had, and how large was each stool?
- How many times did the child vomit, and how much vomitus occurred each time?
- Does the child have fever?
- What type fluid has the child been drinking?
- Has the child been urinating? How many wet diapers did the child have in a day?
- How much did the child weigh at the last visit to the physician?
- Has your child's behavior or level of alertness changed from normal?

and young children (ie, younger than 5 years), the estimated fluid loss for mild dehydration is less than or equal to 5% deficit of body water; moderate dehydration, 6% to 9%; and severe dehydration, 10% to 15%. The corresponding numbers for estimated fluid loss in children 5 years and older are 3%, 6%, and 9%, respectively. A variety of clinical signs have been proposed to evaluate the degree of dehydration—some more valid and reliable than others. A systematic review found that assessment of capillary refill was the most useful single sign in detecting dehydration of 5% or more. Capillary refill is assessed by placing brief pressure on the distal palmar aspect of a fingertip and assessing the amount of time for the blanched area to refill; normal is considered less than or equal to 2 seconds. Two other single signs found to be important in predicting dehydration of 3% to 5% or more were abnormal skin turgor (ie, tenting) and respiratory disturbance, in particular *hyperpnea* (ie, deep, rapid breathing without other signs of respiratory distress) suggestive of acidosis. Generally, the more signs that are present, the greater the severity of dehydration; however, a combination of prolonged capillary refill, absent tears dry mucosal membranes, and general ill appearance may be more diagnostic than tenting and hyperpnea combined in identifying the child with more than mild to moderate dehydration.

Laboratory Tests

Laboratory tests typically are not indicated in the child who presents with mild dehydration. The dehydrated child who is treated with IV fluids after a failed attempt at oral rehydration either at home or in the emergency department should undergo initial assessment of serum electrolyte, blood urea nitrogen, and creatinine levels. Initial and serial measurements of these values also should be performed during rehydration in the child with shock, severe dehydration, or decreased urine output who does not improve after initial restoration of intravascular volume; with a history and clinical findings inconsistent with straightforward isotonic dehydration; or who is found to have dysnatremia (ie, serum sodium outside the normal range of 135–145 mEq/L, whether too low or too high). Dehydration in association with dysnatremia can have serious complications, and treatment requires special considerations. Hemolytic uremic syndrome, although uncommon, should be considered in any child with gastroenteritis, particularly with a history of grossly bloody stool, who also has decreased urine output.

Very ill children may require an arterial blood gas measurement to more accurately assess their acid-base status; in others, assessing serum electrolyte levels is sufficient. The usual acid-base derangement in the moderately dehydrated child is a non-anion gap acidosis with decreased serum bicarbonate and hyperchloremia resulting

Table 80.2. Clinical Assessment of Magnitude of Dehydration

Clinical Sign	*Mild Dehydration*[a]	*Moderate Dehydration*	*Severe Dehydration*[b]
Loss of body weight			
<5 years	≤5%	6–9%	≥10%
≥5 years	3%	6%	9%
Skin turgor	Normal to slightly reduced	Decreased	Markedly decreased (ie, tenting)
Skin color and temperature	Pale or normal[a]	Ashen, cool	Mottled, cool
Dry mucous membranes	±[a]	+	++
Absent tears	±	+	++
Sunken eyeballs	±	+	++
Increased pulse	±[c]	+[c]	++ (may be thready)
Blood pressure	Normal	Normal Postural decrease ±	Reduced (ie, in late shock)
Urine output	Normal or reduced[c]	Oliguria[c]	Oliguria, anuria
Capillary refill time	Slightly prolonged[c]	Prolonged[c]	Prolonged

Abbreviations: ++, certain to occur; +, likely to occur; ±, may occur.

[a] In mild dehydration, may be only a history of fluid loss in the form of diarrhea or vomiting without any of the signs of dehydration listed in this table.

[b] Often, such patients present with hypovolemic shock, need more intense treatment, and may require additional volume expanders (eg, colloids, blood products).

[c] Usually corrects with restoration of intravascular volume.

from bicarbonate losses in the stool. Additionally, the severely dehydrated child also may exhibit anion gap acidosis resulting from lactic acid or ketone accumulation in the peripheral tissues secondary to the decreased perfusion that accompanies hypovolemia. The exception is in infants with pyloric stenosis, who typically develop a hypokalemic, hypochloremic metabolic alkalosis.

Imaging Studies

Imaging studies, such as chest radiography, abdominal ultrasonography, and computed tomography, are indicated based on the suspected etiology of the dehydration.

Management

Fluid management of the dehydrated child involves consideration of 3 components: normal maintenance, deficit replacement, and the ongoing losses of fluid and electrolytes incurred during the present illness. Most commonly, ongoing losses result from continued vomiting and diarrhea. Losses from diarrhea can be estimated at 10 mL/kg per stool and for vomiting at 5 mL/kg per episode. Other forms of ongoing losses that occasionally must be considered and replaced include those associated with burns, gastric secretion suctioned via nasogastric tube, hyperventilation, or prolonged fever. The estimation of the child's fluid and electrolyte needs and losses are almost always an approximation and require close follow-up, reassessment, and readjustment throughout treatment. At the very least, monitoring during treatment for dehydration requires regular assessment of vital signs, body weight, intake, and output.

Fluid given to the dehydrated child may be provided enterally or parenterally. Whenever possible, oral replacement therapy using oral rehydration solution (ORS) is preferred for the child with mild dehydration and for most children with moderate dehydration. Parenteral fluid therapy should be used in the child with more severe dehydration, in the setting of failure of oral therapy (eg, resulting from intractable vomiting or lethargy) despite an adequate trial, in the child in shock or impending shock, or in the child with a suspected anatomic defect, such as pyloric stenosis or ileus.

Parenteral Fluid Therapy

The parenteral management of moderate or severe dehydration can be divided into 2 phases: an initial phase (first 1–2 hours) and the main phase of rehydration. The aim of the initial phase is to restore intravascular volume, thus improving perfusion and renal function and reversing tissue hypoxia, metabolic acidosis, and increased AVP. Regardless of the type of dehydration (ie, isotonic, hypertonic, hypotonic), NS (0.9% NaCl) at 20 mL/kg per hour generally provides the most rapid and effective means of expanding the intravascular volume at acute presentation. If shock is present or imminent, treatment is more aggressive (see Chapter 74). The child should in rapid succession receive 2 to 4 boluses of 20 mL/kg of NS given over 20 to 30 minutes each. After each bolus, the child should be reassessed, and if signs and symptoms of intravascular depletion persist, the next IV bolus of 20 mL/kg of NS should be given over 20 to 30 minutes and the child admitted to the hospital for further careful evaluation, including assessment for other causes of shock (eg, sepsis). Rapid restoration of ECF volume with up to 4 boluses of NS, if necessary, in the first 4 hours is currently recommended. The physician must take care not to give excessive fluids to a child with cardiac compromise, because doing so could precipitate congestive heart failure. Administration of excess fluids also results in decreased AVP/antidiuretic hormone levels and the chances of hyponatremia in subsequent therapy even if 0.45% NaCl (0.5 NS) solutions are used rather than NS to correct the remaining deficit and maintenance therapy. The validity of rapid restoration of ECF volume with up to 4 boluses of NS, however, has not been substantiated compared with the past standard rehydration therapy in which typically only 1 or 2 boluses were used. All ORT fluids generally use hypotonic containing sodium concentrations of 45 to 75 mEq/L.

During the second phase of rehydration, the remaining fluid and electrolyte deficits are replaced based on the magnitude of these losses. These replacements are in addition to the daily maintenance requirements as well as any ongoing losses, as discussed previously, but must take into consideration the NS boluses administered during the initial phase, which may have already restored a substantial portion of the total fluid deficit. Each 20 mL/kg fluid bolus corrects 2% dehydration. Thus, in the child with moderate dehydration use of 3 boluses of 20 mL/kg of NS would correct 6% dehydration, with the result that the child may no longer have any remaining fluid deficit. Various protocols exist to restore fluid and electrolyte deficits, and approaches to treatment of dehydration vary by institution. Many of the differences in rehydration strategies lie in the composition of treatment fluid and the rate at which it is administered. Some physicians prefer to administer one-half of the total fluid needs over the first 8 hours and the remainder over the next 16 hours, whereas other physicians prefer to replace the fluid at the same rate over the entire rehydration period. The latter method is presented in the case resolution at the end of the chapter. Usually the fluid deficit is replaced within 24 hours, although noteworthy exceptions exist. The management of dehydration associated with *dysnatremia* (ie, abnormally low or high serum Na^+) should entail slower return (12 mEq serum Na^+ change per 24 hours or 0.5 mEq change per hour) to a normal range and may require 48 to 72 hours for correction.

Sodium replacement in the child with dehydration depends on the type of dehydration. In the management of isotonic dehydration, some physicians elect to replace the entire fluid deficit with NS, whereas others use a saline solution containing 110 mEq Na^+/L, and still others use 0.5 NS (77 mEq Na^+/L). We recommend NS (154 mEq Na^+/L) to replace the fluid deficit (see Case Resolution for example). This amount of sodium is somewhat more than the actual loss of sodium to the environment, which is closer to 110 mEq Na^+/L, because during isotonic dehydration some sodium lost from the ECF is shifted intracellularly to balance potassium losses and thus returns to the ECF during rehydration. To calculate the ongoing losses, although the content of excreted body fluids can be analyzed for electrolyte content for more exact replacement, the diarrheal stools are commonly replaced with 0.5 NS at 10 mL/kg

per stool. (This amount should be adequate in sodium content for most patients because diarrhea secondary to rotavirus contains approximately 30–40 mEq Na^+/L and enterotoxigenic *Escherichia coli*, 50–60 mEq/L; however, sodium stool losses in cholera are 90–120 mEq/L.)

Management of Electrolyte Disturbances

Hypernatremia and Hyponatremia

In hypernatremic/hypertonic dehydration, the patient is considered to have a relative free water deficit but usually has lost not only body water but also some sodium. The amount of free water required to restore serum sodium to normal (eg, 145 mEq/L is desired serum Na^+) is calculated as follows:

$$[\text{patient's weight in kg}] \times [\text{actual serum } Na^+ - 145] \times 4 \text{ mL/kg}$$

For serum sodium greater than 170 mEq/L, 3 mL/kg of free water is estimated to decrease the sodium to the desired level, in which case the 4 mL/kg shown in the equation is changed to 3 mL/kg. The quantity of free water provided by this equation is only part of the patient's total needs. The remainder of the patient's fluid needs include isotonic losses that occurred during the dehydration process, ongoing losses, and maintenance fluids as well. Hypertonic dehydration is corrected slowly to avoid cerebral edema, which can result in brain stem herniation and death. In hypernatremia, the various equations used for phase 2 of therapy often calculate the sodium concentration of the final solution considering the amount of free water to achieve isotonicity. We recommend initially providing 0.9% NaCl in 5% dextrose (a higher content of sodium than calculated by various equations) to ensure a slow rate of serum sodium decline and later decreasing the sodium concentration to 0.45% NaCl if the serum Na level remains high 24 to 48 hours after this treatment is begun. Serial monitoring of electrolytes at least every 6 hours and as necessary is important to ensure that the sodium level is decreasing at the expected slow rate and is not decreasing so quickly as to result in life-threatening CNS complications.

Management of hyponatremia/hypotonic dehydration also poses challenges. In addition to isotonic losses, additional sodium loss may have occurred. The amount of additional sodium (in mEq) to correct the serum sodium into a normal range (desired Na^+ level [eg, 135 mEq/L]) historically has been calculated using the following equation (where 0.6 represents the body space affected by Na^+ changes):

$$[\text{patient's weight in kg}] \times [135 - \text{actual } Na^+ \text{ level}] \times 0.6$$

This amount of sodium represents an additional need beyond a patient's isotonic losses, ongoing losses, and maintenance requirements. Although precise calculations of sodium requirement to manage hypotonic dehydration may be desirable, in most patients with hyponatremia treatment with NS (0.9% NaCl) in 5% dextrose is adequate for gradual correction of the hyponatremia. The use of hypertonic saline (3% containing 513 mEq Na^+/L) is generally reserved for the child with symptomatic hyponatremia (eg, a child who is seizing) or in the setting of serum Na level of less than 120 mEq/L. Hypertonic saline is administered as 3.0 mL/kg of 3% saline given by IV over 15 to 30 minutes or until seizures stop. This volume of 3% saline raises the serum sodium approximately 2.5 mEq/L. Based on a volume of 3.0 mL/kg of 3% saline, the child should receive volume sufficient to bring up the serum Na level to above 120 mEq/L, which is considered to be the safe level, at which improvement in serious signs and symptoms are anticipated. Recalculation is done 4 hours after the initial 3% NaCl infusion to determine the need for another infusion, if the level is still low or if there is no improvement in CNS-related symptoms. After a level of greater than 120 mEq/L is achieved or the patient is asymptomatic, any remaining deficit is corrected more slowly to avoid exceeding an increase of 12 mEq/L per 24 hours. A too rapid correction of serum sodium, particularly in the setting of long-standing hyponatremia, can potentially cause central pontine demyelination, manifested by disorientation and eventual coma.

As stated previously, hyponatremia in the hospitalized child can result from factors other than sodium loss. Arginine vasopressin release in response to hypovolemia, hypertonicity, or other stimuli followed by free water retention can result in dilutional hyponatremia (ie, water intoxication). Hyponatremia in infants given excessively diluted baby formula results from inadequate sodium intake and free water retention. Encephalopathy, brain stem herniation, and death occurring in hospitalized children with hyponatremia have been reported. The adverse effects of hyponatremia on the CNS are accentuated in the setting of hypoxemia. With rehydration and sodium administration, kidneys excrete relatively more dilute urine that can sometimes result in rapid and unpredictable increases in serum sodium levels, necessitating close monitoring of serum electrolyte levels. Consultation with a pediatric nephrologist or pediatric intensivist experienced in managing alterations in fluid and electrolyte balance is helpful.

Potassium Replacement

Potassium deficits are more difficult to determine, and no specific method exists for calculating the exact amount of potassium required by a dehydrated child. Additionally, as the acidosis that commonly accompanies moderate and severe dehydration corrects, potassium shifts intracellularly. What initially seems to be a normal serum potassium may fall into the hypokalemic zone, potentially resulting in adverse effects on neuromuscular and cardiac function. Frequent reassessment of serum potassium and adjustment of potassium content of the IV fluids may be necessary. Generally, after adequate urine output has been established, potassium may be added to the IV fluids to provide 3 to 4 mEq/kg per 24 hours. Usually, this need can be met by adding potassium chloride 20 mEq/L to the IV fluids. The child with decreased urine output or another indicator of renal impairment should not receive potassium until normal urine output has been restored. Hyperkalemia, which is a serious and life-threatening condition, may occur if a child is unable to excrete excess potassium via the kidney because of renal impairment.

Oral Rehydration

Oral rehydration therapy refers to specially prepared, balanced preparations of carbohydrates and electrolytes meant for oral consumption. Clinical trials have repeatedly shown ORT to be as efficacious as IV therapy in the treatment of the child with mild or moderate dehydration. Additional advantages of ORT over IV therapy are that it costs less, is noninvasive, and requires little technology. Oral rehydration therapy has been credited with the dramatic reduction in death associated with diarrhea in the developing world. In 2002, the World Health Organization and United Nations Children's Fund announced a new ORS with reduced osmolarity (proportionally lower Na^+ and glucose concentration) based on several clinical studies demonstrating less vomiting, lower stool output, and reduced need for IV fluids relative to the prior formulation.

In the United States, Pedialyte and generic equivalents are the most widely commercially available products. Flavored solutions and freezer pop preparations of these solutions are available and often are preferred by older children over the unflavored variety. Rice-based oral electrolyte solutions contain rice syrup solids as their source of carbohydrates. Electrolyte solutions with rice syrup solids may reduce stool output as well as replete fluid volume. It is not necessary to change to ORT in a breastfed child who is tolerating human milk; these children can continue to receive human milk for rehydration, although they may require shorter, more frequent feedings.

The composition of various ORSs is presented in Table 80.3. The cost of commercially available ORS may be prohibitive for some families. Given the simplicity of the ORS packet in the developing world and commercially available ORS in the developed world, these remain the first choice. Some solutions, such as fruit juices, ORSs, or chicken broth, do not contain the proper balance of sodium and carbohydrate to effectively rehydrate a dehydrated patient; however, these can be used at home for mild cases of diarrhea if the patient still tolerates oral fluids.

The amount of ORT fluid necessary for rehydration can be calculated in much the same fashion as for determining the parenteral fluid requirement for a dehydrated child (Table 80.4). However,

Table 80.3. Composition of Various Oral Rehydration Solutions

Solution	Carbohydrate (gm/L)	Sodium (mEq/L)	Potassium (mEq/L)	Base (mmol/L)	Osmolarity (mOsm/kg H_2O)
Appropriate for Rehydration					
Pedialyte	25	45	20	30	250
Enfalyte	30	50	25	33	160
World Health Organization–UNICEF oral rehydration solution (2002)	13.5	70	20	30	245
Not Appropriate for Rehydration					
Cola[a]	110	2	0	13	750
Apple juice[a]	120	3	32	0	730
Chicken broth[a]	0	250	8	0	500
Sports beverages	40	20	3	3	330

Table 80.5. Treatment With Oral Rehydration Therapy

Degree	*Dehydration ORT (Given Over 3–4 hours)*	*Replacement of Losses*	*Dietary Therapy*
Mild (5%) (≥13 years = 3%)	50 mL/kg of ORS	10 mL/kg for each diarrheal stool 5 mL/kg for each vomitus	Return to formula or milk as soon as vomiting resolves. Children who eat solid food can continue their regular diet.
Moderate (10%) (≥13 years = 6%)	100 mL/kg of ORS	10 mL/kg for each diarrheal stool 5 mL/kg for each vomitus	Return to formula or milk as soon as vomiting resolves. Children who eat solid food can continue their regular diet.

Abbreviations: ORS, oral rehydration solution; ORT, oral rehydration therapy.

most children with mild dehydration can be rehydrated relatively quickly and, in response to thirst, are likely to request the amount of fluid they need. Therefore, a simplified method of determining ORT fluid requirements has been developed (Table 80.5). This quantity of fluid is given over a period of 3 to 4 hours. In the child with ongoing losses, these losses should be replaced as well. Typically, it is not necessary to calculate the quantity of electrolytes that should be provided because these solutions are designed to adequately replace electrolytes in the otherwise healthy child who is dehydrated.

The parent or guardian should receive guidance about the volume (converted into common household measures [eg, 5 mL = 1 teaspoon and 15 mL = 1 tablespoon of water or ORS]) as well as the frequency and duration of ORT to be given at home. Small volumes of 5 to 15 mL administered with a syringe or teaspoon every 2 to 5 minutes are much more likely to be retained by the child who vomits larger volumes. Although this technique is labor intensive, it can be done by the parent or guardian and can deliver 150 to 300 mL/hour. As dehydration is corrected, vomiting often decreases and the child subsequently can tolerate larger volumes. With ORT, the frequency and amount of passing stool often increases during the initial period of treatment. The parent or guardian should be made aware that the primary purpose of ORT is to rehydrate the child, not to stop diarrhea, and that diarrhea will gradually decrease spontaneously. "Gut rest" (limiting oral intake) is not appropriate in most cases, and early refeeding with a return to the usual formula or milk and solids, if appropriate, should be prioritized.

Prognosis

The child with mild or moderate dehydration resulting from a self-limited childhood illness is likely to recover completely when given timely and appropriate rehydration therapy. It is more difficult to predict the prognosis of the child with severe dehydration or significant aberration in electrolyte balance. If managed appropriately, most such children also completely recover; however, despite closely monitored care, some children may experience permanent sequelae or poor outcomes.

CASE RESOLUTION

The child has moderate dehydration. Based on clinical assessment and weight change since the boy's last clinic visit, he is approximately 10% dehydrated. He does not show evidence of shock. His laboratory studies show a sodium level of 140 mEq/L, potassium of 3.7 mEq/L, chloride of 112 mEq/L, bicarbonate of 13 mEq/L, blood urea nitrogen of 13 mg/dL, and creatinine of 0.4 mg/dL. His renal status is likely to be adequate because he is urinating, and blood urea nitrogen and creatinine are normal for the patient's age. The child's serum sodium is 140 mEq/L, which is in the isotonic range. The serum potassium is 3.7 mEq/L, which is within normal range; however, this level may not accurately reflect this patient's total body potassium status. The level may decrease substantially as he is rehydrated and acidosis is corrected, indicating total body potassium depletion. His serum bicarbonate is 13 mEq/L, and his anion gap is 15 [140 – (112 + 13)], which is mildly increased and likely related to ketosis or mild lactic acidosis.

The calculation of this child's fluid and electrolyte needs is as follows, keeping in mind that his pre-illness weight was 12 kg:

Maintenance

Fluid requirement: 1,000 mL for first 10 kg + 100 mL for next 2 kg = 1,100 mL.

Deficit

Fluid replacement: 10% of the child's weight has been lost during this episode of dehydration = 1,200 mL deficit.

Ongoing Losses

Additional Fluid: Estimate this child's ongoing losses at 10 mL/kg for each stool. He had 1 loose stool while in the office, so 120 mL of additional fluid is added.

Sodium: The sodium content of diarrhea is variable; however, it is usually replaced with 0.9% NS.

Total fluid needs: 1,100 mL (maintenance) + 1,200 mL (deficit) + 120 mL (ongoing losses) = 2,420 mL/24 hours.

Electrolyte Needs

Sodium: 0.9% NS is used based on current recommendation.

Potassium: Estimate the child's maintenance and replacement needs to be 20 mEq K^+/1,000 mL fluid provided; this estimate can be modified based on follow-up laboratory values, if necessary.

Treatment

In the initial phase of therapy, provide NS 40 mL/kg per hour for approximately 2 hours. During this period, the patient's heart rate normalizes and he urinates. The initial parenteral phase provides 480 mL fluid as NS (0.9% NaCl). This amount of fluid is subtracted from the patient's total fluid needs. The remaining amount to be provided is 1,940 mL fluid. It is not necessary to prepare a special IV solution; 5% dextrose in 0.9% NS with 20 mEq/L KCl to run at 80 mL per hour is appropriate. As his GI symptoms improve, IV therapy is discontinued and ORT is instituted. The patient tolerates the ORT well and is discharged home.

CHAPTER 81

Acute Kidney Injury

Gangadarshni Chandramohan, MD, MSc, FASN, FAAP

CASE STUDY

A 10-month-old girl has a 2-day history of fever, vomiting, and watery diarrhea. The child has previously been healthy. Her diet has consisted of infant formula fortified with iron, baby food, and some table food. Since the onset of her illness, she has not been drinking or eating well, and she has thrown up most of what she has eaten. Her mother has tried to give her oral electrolyte solution and apple juice on several occasions but has had limited success. The child has had 8 to 10 watery stools without blood or mucus each day. Her temperature has varied between 37.0°C (98.6°F) and 38.8°C (101.8°F); the mother has given her daughter acetaminophen, which she has vomited up. The girl's 4-year-old brother and her parents are doing well and have no vomiting or diarrhea.

The physical examination reveals a severely dehydrated (estimated amount 15%), listless infant. Her weight is 9.4 kg (20.7 lb), her height is 74 cm (29.1 in), her temperature is 38.4°C (101.1°F), her heart rate is 168 beats per minute, her respiratory rate is 30 breaths per minute, and her blood pressure is 72/40 mm Hg with an appropriately sized cuff. Capillary refill is 2 to 3 seconds. The skin appears dry, but no rash is present. Head and neck, chest, heart, and abdominal examinations are normal. Pending the results of her blood studies, an intravenous fluid bolus of 180 mL normal saline (20 mL/kg) over 20 to 30 minutes is administered. This is followed by 2 more boluses of 180 mL normal saline each. The girl is catheterized to obtain urine and determine the urine flow rate over the next several hours. A urinalysis is performed.

Questions

1. What are the 3 stages of acute kidney injury?
2. What is the etiology of acute kidney injury?
3. How would the physician assess a patient with acute kidney injury?
4. How would the physician manage a child with acute kidney injury?
5. What are the indications for renal replacement therapy?

Acute kidney injury (AKI) is encountered in outpatient and inpatient settings and is associated with a high rate of morbidity and mortality depending on the primary cause of the insult. *Acute kidney injury* is defined as a sudden decrease in kidney function, signified by the accumulation of nitrogenous waste products (ie, blood urea nitrogen [BUN] and various other metabolic waste products) and impaired balance of fluid and electrolytes. With a better understanding of the pathophysiology of acute deterioration in renal function, the term AKI delineates the process of renal injury and encompasses the full spectrum of renal dysfunction, from early, mild renal injury with only a small elevation in serum creatinine level, to severe kidney injury requiring renal replacement therapy (ie, dialysis) as a continuum.

To better delineate the progression of AKI, in 2004 the Acute Kidney Injury Network Acute Dialysis Quality Initiative workgroup set forth the RIFLE criteria, which is based on serum creatinine level and urine output. The acronym RIFLE defines 3 stages of progressively increasing severity of renal injury (risk, injury, and failure) followed by 2 outcomes variables (loss and end-stage renal disease). These criteria, proposed in 2004 and validated in 2012 by the Kidney Disease: Improving Global Outcomes (KDIEGO) AKI workgroup, modified RIFLE for the pediatric population (pRIFLE) and its clinical use has been shown to improve outcomes in children (Figure 81.1). This classification is based in part on declining urine output; however, some children experience *nonoliguric renal failure*, in which urine output may remain normal or even increase. Decline in urine output is an essential component of risk assessment when determining severity of AKI in the pediatric patient because of the known association between the duration of oliguria and increased mortality.

The pRIFLE criteria are not applicable to newborns during the first few days after birth, however, because they may exhibit physiological oliguria during the first 24 hours after birth and their serum creatinine level initially reflects maternal creatinine values. Therefore, the pRIFLE criteria were further modified for neonates based on findings from the Assessment of Worldwide Acute Kidney Injury Epidemiology in Neonates (AWAKEN) study, which set the baseline creatinine level as the lowest level based on gestational age and set the serum creatinine threshold for stage 3 AKI at greater than or equal to 2.5 mg/dL rather than greater than 4 mg/dL.

The pRIFLE classification is intended to emphasize the reversible nature of the renal insult, which often is present in critically ill children admitted to pediatric or neonatal intensive care units (ICUs). It is anticipated that this precise and universal definition of AKI likely will enable physicians to rapidly recognize at-risk individuals and intervene promptly to improve immediate and long-term outcomes. The major limitation to the use of this classification is that it is not validated in children who present with AKI in an outpatient setting, whose etiology and outcomes often are dissimilar to those of inpatient, acutely ill children.

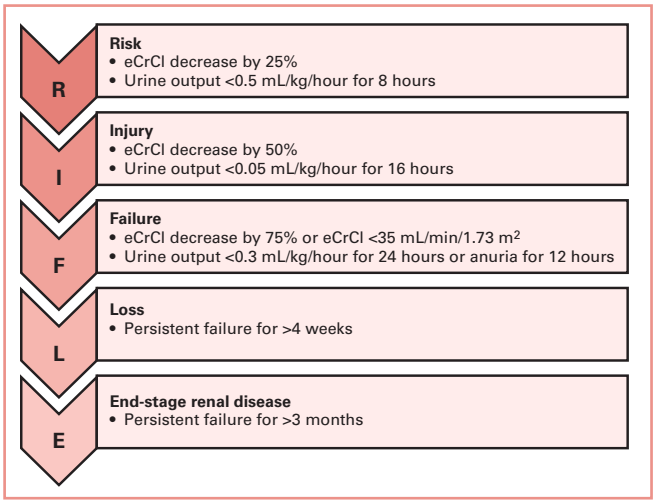

Figure 81.1. Pediatric risk for renal dysfunction, injury to the kidney, failure of kidney function, loss of kidney function, and end-stage renal disease (pRIFLE) criteria to assess the stage of renal injury.

Abbreviations: eCrCl, estimated creatinine clearance.

Epidemiology

Acute kidney injury occurs in children with a wide variety of medical or surgical conditions and especially in children who are critically ill. The exact incidence of AKI in children is unknown because it not plausible to capture all cases of AKI, particularly in children who present to outpatient settings. The prevalence of AKI varies depending on geographic and demographic factors, which are responsible for the etiology of AKI. In developed countries, AKI has been increasing over the past few decades because of the increasing number of cardiopulmonary bypass surgeries performed to manage congenital heart disease, an increase in the number of solid organ and bone marrow transplantations, and the use of newly discovered nephrotoxic agents to manage a variety of disorders. Acute kidney injury resulting from primary renal disease appears to be on the decline compared with AKI caused by other systemic illnesses or their treatments. Acute kidney injury is often observed in patients in the ICU with sepsis or major trauma with severe bleeding or in the postoperative period after major heart surgery. According to Assessment of Worldwide Acute Kidney Injury, Renal Angina and Epidemiology (AWARE) data published in 2016, of 4,683 critically ill children, 26.9% developed AKI and 11.6% had severe AKI (stage 2 and 3). Approximate 5% to 10% of patients in neonatal ICUs develop AKI, and most commonly as the result of perinatal hypoxia and postnatal hypotension.

Clinical Presentation

Most children with AKI initially present with clinical findings of the primary condition that ultimately results in the renal problem. In the critically ill child, a small increase in serum creatinine may be the first indication of AKI. However, decreased urine output, edema, hematuria, and/or hypertension may be the early sign or signs specifically related to declining renal function (Box 81.1). Additionally, hyperkalemia with cardiac arrhythmia, hyperventilation resulting from acidosis, and nausea and vomiting resulting from uremia may occur with progression of renal failure.

Etiology and Pathophysiology

Because of the recent epidemiologic shift from renal to nonrenal causes as common etiologic factors, for every child the primary care physician as well as the neonatal and pediatric intensivist should perform a risk assessment using the pRIFLE criteria and take the necessary steps to prevent AKI before the kidneys sustain serious injury. Frequently, the cause is multifactorial, and ischemic-hypoxic injury and nephrotoxic insults are important contributors; the pathophysiology of hypoxic ischemic injury and nephrotoxic insults is described herein.

The causes of AKI are usually grouped into 3 categories: prerenal, postrenal, and intrinsic renal disorders (Box 81.2 and Figure 81.2). Although prerenal failure and acute tubular necrosis (ie, intrinsic renal failure) may in fact be on opposite ends of a continuum, rather than separate entities, this classification system still aids in the conceptualization of the underlying problem and formulation of the initial treatment plan. Correspondingly, without timely intervention postrenal failure has the potential to cause renal damage and ultimately can result in intrinsic renal failure.

Prerenal Disorders

Prerenal disorders are the most common cause of AKI in pediatric patients and result in a decrease in total or effective circulating blood volume. An absolute decrease in circulating volume can be caused by blood loss from acute hemorrhage secondary to trauma or fluid loss and dehydration secondary to gastroenteritis. Heart failure or redistribution of body fluids (ie, third spacing) can result in decreased effective circulating volume. In each of these situations, the resulting decrease in the glomerular filtration rate (GFR) can be readily reversed by improving renal perfusion in its early stages. If hypoperfusion is prolonged, however, ischemic damage to the kidney occurs and intrinsic renal failure occurs.

Postrenal Disorders

In infancy and early childhood, urinary obstruction caused by posterior or anterior urethral valves or other congenital lesions involving the urinary tract can result in AKI. In the older child, kidney

Box 81.1. Diagnosis of Acute Kidney Injury

- Decreased urine output
- Hypertension
- Hematuria
- Edema
- Elevated serum creatinine level
- Blood urea nitrogen-creatinine ratio <20
- Elevated fractional excretion of sodium

Box 81.2. Etiology of Acute Kidney Injury in Children

Prerenal Disorders

- Decreased plasma volume
- Dehydration
- Hemorrhage
- Third spacing of plasma volume in the setting of burns, sepsis, bowel obstruction
- Other causes of renal hypoperfusion
- Shock
- Hypoxia
- Congestive heart failure
- Hepatorenal syndrome
- Bilateral renal artery stenosis
- Cardiac surgery

Postrenal Disorders

- Bilateral ureteropelvic or ureterovesical junction obstruction
- Posterior urethral valves
- Trauma to urethra
- Urethral stricture
- Neurogenic bladder
- Obstruction caused by kidney stone at the bladder neck or stone obstruction of both urinary tracts

Intrinsic Renal Disorders

- Vascular: renal artery or vein thrombosis, disseminated intravascular coagulation.
- Glomerular: hemolytic uremic syndrome, severe (ie, rapidly progressive) glomerulonephritis from any etiology.
- Interstitial: interstitial nephritis resulting from allergic reaction to drugs (eg, nonsteroidal anti-inflammatory drugs, oxacillin, methicillin), sepsis.
- Tubular (acute tubular necrosis): sepsis, postcardiac surgery, ischemia resulting from prolonged hypoperfusion; all causes listed in prerenal category, if sufficiently prolonged, may lead to acute tubular necrosis.
- Nephrotoxins: aminoglycoside antibiotics, indomethacin, radiocontrast agents, ethylene glycol, methanol, heavy metals.
- Pigments: myoglobinuria, hemoglobinuria.
- Uric acid: hyperuricemia, tumor lysis syndrome.
- Congenital renal anomalies (especially in newborns and young infants).
- Bilateral cystic dysplastic kidneys, reflux nephropathy, polycystic kidneys, oligomeganephronia.

stones, pelvic trauma, or complications following pelvic surgery are possible causes of postrenal failure.

Intrinsic Disorders

Intrinsic renal failure occurs because of injury to the vascular, glomerular, interstitial, or tubular components of the kidney (see Box 81.2). Intrinsic AKI can result from infection, ischemia, sepsis, or toxins. Acute kidney injury resulting from renal tubular lesions is called *acute tubular necrosis* (ATN). Histologic changes that characterize ATN include loss of brush border microvilli in tubular

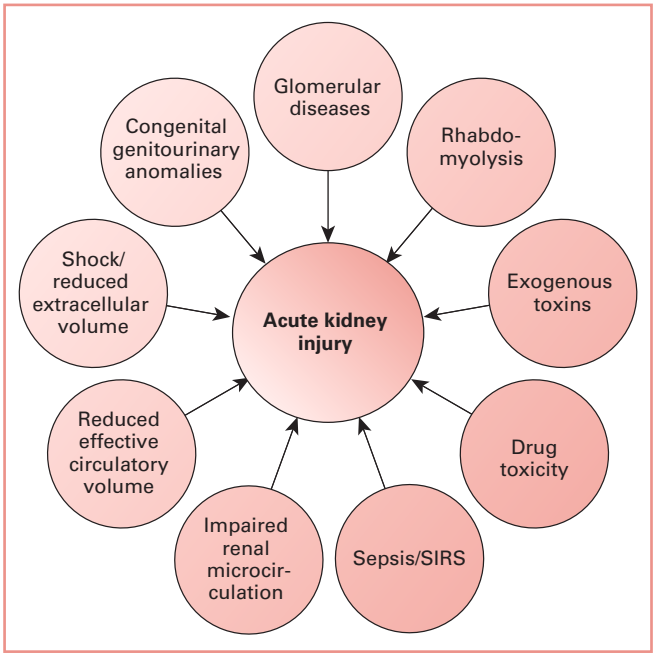

Figure 81.2. Common causes of acute kidney injury in children.
Abbreviation: SIRS, systemic inflammatory response syndrome.

cells, detachment of epithelial cells from basement membrane, and cast formation from cellular debris and protein.

The child with prolonged shock that manifests postcardiac surgery or that is caused by sepsis, trauma (ie, hemorrhage), or dehydration often develops ATN if effective circulating volume is not reestablished. This is the most frequent type of intrinsic AKI observed in children. Nonsteroidal anti-inflammatory drugs are increasingly being recognized as a cause of AKI in children, especially when used in patients with volume depletion. In the newborn or young infant, AKI may be superimposed on existing chronic congenital renal disease. In neonates, the prevalence of AKI ranges from 8% to 24% and is higher in neonates with severe asphyxia than in those with moderate asphyxia.

The pathogenesis of ATN in humans is controversial, and no single mechanism completely explains the sequence of events that results in ATN. Ischemic and toxic ATN result from a complex interplay of hemodynamic, vascular, and tubulointerstitial changes, including decreased blood flow to glomerular and tubular capillaries, resulting in reduced GFR; injury to cortical and medullary tubules with their cellular debris, resulting in tubular obstruction; and "back leak" of solute and water from the lumen to the interstitium, with further reduction in GFR. Increased production of endothelin and reduced production of nitrous oxide in the microvascular smooth muscle cells result in increased vasoconstriction and reduced perfusion, thereby perpetuating the renal injury. Renal tubular cells respond to the injury in many different ways, including no or minimal damage, sublethal injury, apoptosis, and necrosis. In the tubules, at the cellular level decreased oxygen delivery results in decreased production of adenosine triphosphate, which causes damage to cell membranes and cell cytoskeletons. Cell damage alters cell polarity, thereby promoting entry of increased amounts

of calcium into cells and increased intracellular free-radical formation. This in turn results in altered cell function, cell swelling, and apoptosis and cell death.

Certain intrinsic proteins also influence the onset of AKI, however. Low serum levels of bone morphogenetic protein 7, which is an antifibrotic, anti-inflammatory, and antiapoptotic factor that belongs to the transforming growth factor-β superfamily of ligands, is thought to play a role in the pathogenesis of postcardiac surgery–associated AKI. Acute kidney injury occurs more commonly in very low-birth-weight neonates carrying the heat shock protein 72 (1267) GG genetic variation, which is associated with low inducibility of heat shock protein 72, which itself plays an important role in ischemic renal injury. This suggests that some neonates are more susceptible to ischemic injury than others. It is hoped that with better understanding of the pathophysiology of AKI it will be possible to develop innovative, improved means of preventing, diagnosing, and managing the disease.

Differential Diagnosis

The diagnosis of AKI is established by the demonstration of a sudden increase in serum creatinine or BUN level. Decreased urine output is another helpful diagnostic factor. Identification of the clinical disorder that resulted in AKI is sometimes obvious, but at other times extensive evaluation may be necessary to discover the etiology of the primary disorder. It is also necessary to determine whether the child has chronic kidney disease or is experiencing superimposition of AKI on a preexisting renal condition (see Figure 81.2).

Evaluation

Acute kidney injury in children is among the few conditions for which laboratory and radiologic tests are often more helpful diagnostically than the history and physical examination.

History

The possibility for AKI should be anticipated in every child who is critically ill. A history of decreasing urine output, hematuria, dysuria, nausea, and vomiting should be sought in all patients. Prenatal and birth history may help identify the cause of AKI, such as oligomeganephronia in the child who was small for gestational age at birth or another complication that would have resulted in AKI. The presence of previous genitourinary disorders, delayed growth, and anemia may point to preexisting kidney conditions (Box 81.3). Family history of renal disorders can also aid in the differential diagnosis.

Physical Examination

An evaluation of physical growth, hypotension or hypertension, arrhythmia, dehydration, and edema should be made. Examination of the flank area for renal enlargement or tenderness and of the bladder for distention is necessary to help determine the etiology of AKI.

Laboratory Tests

Many biomarkers have been investigated for the early diagnosis of AKI in adults and children. The hope is that biomarkers found in the serum or urine will allow physicians to better detect early kidney injury, differentiate among multiple etiologies, and predict its severity. Many promising urinary biomarkers exist, including urinary or plasma neutrophil gelatinase-associated lipocalin, kidney injury molecule-1, interleukin-18, liver-type fatty acid binding protein, markers of cell-cycle arrest (eg, tissue inhibitor of metalloproteinases-2), and insulin-like growth factor-binding protein 7, which have been identified to correlate with AKI to variable degrees. Both neutrophil gelatinase-associated lipocalin and tissue inhibitor of metalloproteinases-1 have been shown to correlate significantly with AKI in children in ICUs with various types of predisposing conditions. Recently, consideration has been given to the potential for assessing multiple biomarkers to determine changes in kidneys during the early phase of AKI. Studies analyzing the value of this tool are ongoing. In parallel, ongoing studies are assessing the value of screening programs, such as Nephrotoxic Injury Negated by Just-in-Time Action (NINJA) and renal angina index, as a simplified alternative to already existing biomarkers. It is anticipated that in future this information will help physicians recognize at-risk individuals and intervene early to prevent progressive and permanent renal injuries.

Box 81.4 shows a list of laboratory tests recommended in all children with established or suspected AKI. If the child is not voiding frequently, temporary catheterization of the bladder is advisable (4–6 hours) to obtain urine for analysis. Residual volume should also be assessed, and the urinary flow rate (especially the response to initial fluid therapy) and presence of an outflow obstruction should

Box 81.3. What to Ask

Acute Kidney Injury

- How frequently is the child passing urine?
- Is the amount of daily urine decreased, increased, or unchanged?
- Does the child have hematuria or dysuria?
- Does the child have nausea or vomiting?
- Has the child had any previous urinary problems?
- For the older child: Does the child have a history of enuresis or nocturia?
- Is the child's physical development normal or delayed?
- Does the child have a history consistent with a primary condition that may have resulted in the acute renal failure/acute kidney injury?

Box 81.4. Laboratory Tests Recommended for Children with Established or Suspected Acute Kidney Injury

- Serum sodium, potassium, and bicarbonate levels
- Blood urea nitrogen level
- Creatinine, uric acid, calcium, and phosphorus levels
- Glucose level
- Total protein and albumin serum concentration
- Urinalysis and urine culture (if indicated)
- Spot urinary sodium and creatinine concentration and osmolality

be determined. All children with AKI and evidence of hyperkalemia should undergo electrocardiography (ECG).

Diagnosis of AKI can easily be established by laboratory tests and determination of urinary output over a specific time. *Oliguria* is defined as urine output less than 400 mL/m^2 per day or less than 1 mL/kg per hour in infants 1 year and younger, less than 0.75 mL/kg per hour in the child age 2 to 6 years, and less than 0.5 mL/kg per hour in children older than 6 years. Urinalysis, urine-specific gravity or osmolality, urine-plasma creatinine ratio, urinary sodium concentration, and fractional excretion of sodium help differentiate prerenal from intrinsic AKI (Table 81.1). Although a BUN-creatinine ratio of greater than 20:1 is suggestive of prerenal azotemia in adults, this is not necessarily true in infants and young children because they often normally have a BUN-creatinine ratio equal to or greater than 20.

Tubular epithelial cells and brown-pigmented casts are common in patients with ATN. Evidence of hematuria or proteinuria signifies glomerular disease, especially glomerulonephritis. The presence of blood on urine dipstick but absence of red blood cells (RBCs) on sediment examination is suggestive of hemoglobinuria (eg, hemolytic uremic syndrome) or myoglobinuria (eg, rhabdomyolysis) as the basis of ATN.

Although urinary indices are helpful in differentiating prerenal from intrinsic AKI, a simple clinical method can be used to distinguish between them. A therapeutic trial of volume expansion with 20 mL/kg of normal saline is administered intravenously over 30 to 60 minutes after first excluding the possibility of congestive heart failure or urinary obstruction. If oliguria persists at the end of 1 hour, furosemide (2 mg/kg) can be administered. If urinary output does not increase after furosemide administration, repeat administration of high-dose furosemide has few benefits and can cause toxicity, especially hearing loss, particularly in the preterm newborn, and should be avoided. Failure to respond to fluid and diuretic therapy is suggestive of intrinsic AKI.

Table 81.1. Diagnostic Indices in Acute Kidney Injury[a]

Test	*Prerenal Disorder*	*Intrinsic Renal Disorder*
Urinalysis	Normal, occasional granular casts	Renal epithelial cells; pigment casts
Urine osmolality (mOsm/kg H_2O)	>600	<400
Urine specific gravity	>1.020	<1.015
Urine sodium (mEq/L)	<15	>40
U-P creatinine	>40	<20
Fractional excretion of sodium (FE_{Na})[b]	<1%	>2%

Abbreviation: U-P creatinine, urine-creatinine (mg/dL) to plasma creatinine (mg/dL).

[a] Values in patients with nonoliguric acute kidney injury often overlap and fall between prerenal and renal values. Additionally, values in newborns differ from those in children older than 1 year.

[b] $FE_{Na} = (U_{Na}/U_{Cr}) \times (P_{Cr}/P_{Na}) \times 100$. U_{Na}, urinary concentration of sodium (mEq/L); FE_{Na}, fractional excretion of sodium; U_{Cr}, urinary concentration of creatinine (mg/dL); P_{Cr}, plasma concentration of creatinine (mg/dL); P_{Na}, plasma concentration of sodium (mEq/L).

Imaging Studies

Renal ultrasonography is the most useful test for differentiating postrenal from other forms of AKI. Renal ultrasonography can detect the presence or absence of kidneys, enlarged kidneys, dilated pyelocalyceal system, distended bladder, and other congenital anomalies. Other investigative tests, such as voiding cystourethrography, renal scanning, angiography, computed tomography, magnetic resonance imaging, and renal biopsy, may occasionally be necessary but generally are not indicated in the child with AKI during the initial workup. If a glomerular cause is suspected based on laboratory findings or radiologic evaluation, a biopsy is an appropriate next step. Chest radiography may also be helpful in detecting cardiac enlargement or pulmonary edema caused by fluid overload.

Management

Prevention is better than cure, and because of exponential advancement in the area of biomarkers to predict AKI in the acutely ill child, preventive measures are already in place to overcome manifestation of AKI by early intervention. The most common etiology among all children who develop AKI is prerenal azotemia. This condition is corrected by reestablishing adequate circulating volume. Prevention is particularly important because no currently available treatment can induce rapid recovery of renal function in humans after the condition has progressed to intrinsic AKI. Although low-dose dopamine and furosemide often are used in the initial management of AKI, many studies have shown that these medications do not enhance recovery of renal function. Fenoldopam mesylate, a dopamine receptor agonist, has been used in critically ill, hemodynamically unstable patients with AKI to improve renal perfusion, with some benefit in select patients. Certain drugs, such as adenosine triphosphate-magnesium chloride, thyroxine, atrial natriuretic peptide, and insulinlike growth factors, have been used in experimental animal models and some human trials without much success. The goal of therapeutic management of intrinsic AKI is maintenance of normal body homeostasis while awaiting spontaneous improvement, because proximal tubules can undergo repair and regeneration after damage.

After dehydration is corrected, if urine output is still not established daily fluid intake should be limited to replacement of insensible water loss (approximately 30%–40% of daily recommended fluid intake for age), any urinary losses, and fluid losses from nonrenal sources (eg, nasogastric drainage). Hyperhydration should be avoided in the patient with AKI because of its association with a high mortality rate and increased morbidity from edema, congestive heart failure, hypertension, hyponatremia, encephalopathy, and seizures. Recent studies have shown that fluid overload in patients in an ICU setting who did not previously have AKI can induce AKI, and in patients with AKI fluid overload can contribute to increased morbidity and mortality.

Patients with complete anuria require no sodium intake. Sodium losses, however, should be replaced daily in patients with any urinary output. Preferably, the amount of sodium required is determined by measuring daily urinary sodium losses, which can vary by individual patient.

In the patient with suspected AKI, potassium intake from all sources should be restricted. Severe hyperkalemia can often be avoided early in the course of the disease with strict adherence to potassium restriction. The level of serum potassium as well as changes on ECG should be closely monitored. The patient with mild hyperkalemia may be treated with ion exchange resin; sodium polystyrene sulfonate (eg, Kayexalate, Resonium A) may be given orally every 4 to 6 hours or by retention enema every 1 to 2 hours. Sodium polystyrene sulfonate should be mixed in water; mixtures containing polysorbate should be avoided because they may cause bowel perforation. Moderate hyperkalemia can be managed with insulin and glucose infusions or β agonists, which will drive the potassium intracellularly. In the patient with changes on ECG suggestive of hyperkalemia, such as tall T waves or widened QRS complexes, calcium gluconate should be given to stabilize the myocardium. If serum potassium continues to rise or evidence exists of cardiac instability despite conservative treatment, dialysis should be initiated to reduce the total burden on body potassium. Hypocalcemia and hyperphosphatemia are common in patients with AKI, and no treatment is required to address small alterations in levels of calcium and phosphorus. For serum phosphate greater than 8 mg/dL, a phosphate binder (eg, calcium carbonate, calcium acetate) may be used if the child can take nothing by mouth. If serum calcium is less than 8 mg/dL, intravenous (IV) or oral calcium should be administered to prevent tetany. If oral calcium supplements are given, the child will require 1,25 (OH) vitamin D (calcitriol by mouth or IV calcitriol) to enhance gastrointestinal absorption of calcium.

Mild metabolic acidosis is common in AKI and requires no treatment. If blood pH is less than 7.2 or serum bicarbonate is less than 12 mEq/L, sodium bicarbonate can be initiated and continued until renal function improves.

Adequate nutrition is important in the patient with AKI because it prevents excessive tissue breakdown. If renal failure is expected to be short in duration (3–4 days), most calories may be provided as carbohydrates. If AKI is expected to last longer, adequate calories in the form of carbohydrates along with daily protein intake of 1 g/kg should be provided.

Anemia should be identified and corrected if hemoglobin is less than 10 g/dL to improve oxygen and nutrient delivery to the tubules to facilitate regeneration of cells and establish their function. This can be achieved by maintaining an optimal hemoglobin level by transfusing packed RBCs and initiating subcutaneous or IV administration of epoetin alfa (eg, Procrit, Epogen) if renal failure is prolonged.

Many children with AKI can be managed by the conservative measures described previously. If renal failure lasts more than a few days or if complications arise, however, dialysis should be planned. The usual indications for dialysis include uncontrollable hyperkalemia or acidosis, volume overload with pulmonary edema or congestive heart failure unresponsive to diuretic treatment, progressive uremia with BUN level greater than 100 mg/dL, or creatinine clearance less than 15 mL/min/1.73 m^2. In preterm and term neonates, peritoneal dialysis is usually preferred over hemodialysis to avoid the major hemodynamic instability that often occurs with hemodialysis. In the critically ill child with overwhelming sepsis or multisystem organ dysfunction, however, early continuous venovenous hemodiafiltration is indicated for more gradual fluid removal, thereby avoiding significant fluctuations in the fluid balance and optimizing nutritional support.

Acute renal injury often can be prevented by anticipating its possible occurrence in the child with a high-risk condition, such as dehydration, trauma, sepsis, and shock, or after cardiac surgery. Prompt recognition of prerenal failure and aggressive management of it with volume expansion may prevent the manifestation of intrinsic AKI. Nephrotoxic agents, such as gentamicin, should be avoided in the high-risk patient if possible. When these drugs are used, they should be monitored meticulously, with frequent measurement of blood levels.

Prognosis

The in-hospital and long-term complications in the child with AKI can be associated with poor cardiovascular and renal prognosis. Three scenarios exist in which a child with AKI can develop chronic kidney disease. First, the initial episode of AKI may cause permanent damage to the kidneys, resulting in end-stage renal disease. Second, recovery from the initial episode may be incomplete, resulting in relatively low renal function compared with baseline function, and consequently, chronic kidney disease. Third, the child who regains near-normal or normal renal function continues to be at increased risk for developing kidney failure years later compared with the child who did not have AKI.

The duration of oliguria in AKI may be short (1–2 days) or long (a few weeks). Typically, recovery is first indicated by an increase in urinary output. Blood urea nitrogen and creatinine levels may rise during the first few days of diuresis before beginning to return to normal. During diuresis, large quantities of sodium and potassium may be lost in the urine. Serum electrolyte levels should be closely monitored, and adequate replacements should be made to prevent hyponatremia and hypokalemia.

In the child with AKI, outcomes mainly depend on the primary condition, severity of damage to other organs, and physician expertise in managing AKI. Nonoliguric AKI is consistently associated with a shorter clinical course and better prognosis than oliguric AKI. Most children with ATN recover completely. However, children with more severe kidney involvement (eg, cortical necrosis) may have residual renal impairment or chronic renal failure, and children who are critically ill have a 60% mortality rate. Studies on older children have also shown that AKI results in chronic kidney disease in a higher percentage of children than was previously appreciated.

Early recognition of potential risk factors and prompt intervention will reduce long-term sequelae of AKI, particularly the development of end-stage renal disease in the long term.

CASE RESOLUTION

A series of diagnostic studies is performed. The laboratory results are hemoglobin, 13.8 g/dL; hematocrit, 41%; white blood cell count, 12,400/mcL; neutrophils, 58%; band forms, 6%; lymphocytes, 32%; monocytes, 3%; and eosinophils, 1%. The platelet count is 277,500 platelets/mcL. Serum sodium is 136 mEq/L; potassium, 5.1 mEq/L; chloride, 110 mEq/L; bicarbonate, 10 mEq/L; BUN, 84 mg/dL; creatinine, 2.8 mg/dL; and glucose, 68 mg/dL. The urinalysis reveals a specific gravity of 1.015; trace protein, blood, white blood cell, and nitrite are all negative; and the sediment has many epithelial cells, 1 to 2 RBCs, and many granular and pigmented casts. Spot urinary sodium is 65 mEq/L, creatinine is 39 mg/dL, and fractional excretion of sodium is 3.4%.

These results, particularly the increased fractional excretion of sodium, are most consistent with a diagnosis of intrinsic AKI. The history points to prerenal failure initially, after which prolonged hypovolemia contributed to ischemia of the kidneys, resulting in intrinsic renal failure. According to the pRIFLE criteria, the laboratory results indicate that the patient is likely in stage 3 failure. Recovery may take a few days to a few weeks. The patient is admitted to the pediatric step-down unit, where fluids are adjusted according to her urine output and electrolytes are monitored frequently.

CHAPTER 82

Ingestions: Diagnosis and Management

Kelly D. Young, MD, MS, FAAP

CASE STUDY

A 2-year-old girl is found by her mother with an open bottle of pills and pill fragments in her hands and mouth. She is rushed to the emergency department. She is sleepy but able to be aroused. The vital signs are temperature of 37.1°C (98.8°F), heart rate of 120 beats per minute, respiratory rate of 12 breaths per minute, and blood pressure of 85/42 mm Hg. The pupils are 2 mm and reactive. Skin color, temperature, and moisture are normal. She has no other medical problems.

Questions

1. What history questions should be asked to help identify the substance ingested?
2. What physical examination findings can offer clues to the substance ingested and the seriousness of the ingestion?
3. What other diagnostic tests might be helpful in treating ingestion patients?
4. What are the management priorities?

Ingestions are a common problem presenting to pediatric practitioners. Three scenarios frequently encountered are accidental ingestions by preschool-age children, intentional suicide attempts by adolescents, and recreational drug use. This chapter discusses the general approach to the child who has ingested a potentially poisonous substance. Ingestions of specific substances are beyond the scope of this chapter, as is toxicity occurring by dermal, ophthalmologic, and inhalational routes. The general approach to the history, physical examination, laboratory tests and diagnostic studies, and management, especially decontamination, is useful for all ingestions, however.

Epidemiology

Most calls made to poison control centers involve pediatric patients. Poison control center data from 2016 show that pediatric patients younger than 20 years accounted for 60% of exposures and young children aged 0 to 5 years accounted for 46%. Among younger children boys were more commonly exposed, whereas girls predominated in adolescence. For children aged 0 to 12 years 3.5% of exposures are intentional, whereas for adolescents aged 13 to 19 years 27% are intentional, and for adults 69% are intentional.

The most common substances ingested overall are analgesics, including acetaminophen, nonsteroidal anti-inflammatory drugs, and narcotics; household cleaning substances; and cosmetics/personal care products. The most common fatal ingestion in children is analgesics (often narcotics that are not their own prescription). Other common pediatric fatal poisonings are stimulants and street drugs, carbon monoxide poisoning, antidepressants, and disc battery ingestions. A registry that included cases on which a medical toxicologist was consulted (presumably for serious exposures) at 31 participating centers reported on the most common agents involved for infants and toddlers age 2 years and younger: 16% cardiac drugs, 15% psychotropic drugs, 9% recreational drugs and controlled narcotics, 9% analgesics, 7% cleaning products, 5% scorpion stings, and 4% toxic alcohols.

Fatalities are uncommon overall and are more likely to occur with intentional ingestion by older children. Poison control center data from 2016 revealed 31 pediatric fatalities (age 0–12 years) and 42 adolescent fatalities (age 13–19 years). Children accounted for 2% of total toxicologic fatalities for the year, whereas adolescents accounted for 3% and adults for the remainder. Young children tend to ingest nontoxic substances or small quantities of toxic substances. Review of trends over the past few years indicates a reduction in overall calls but an increase in calls about serious exposures. Fatality rates have remained stable.

The frequency of exposures to analgesics (narcotics), cardiac drugs, and psychotropic drugs in pediatric patients is linked to an overall rise in adult prescription drug use. Cough and cold medications are an increasingly recognized source of toxicity in young children, and the US Food and Drug Administration recommends against their use in children younger than 6 years. Another new source of serious toxic exposures in children is laundry and dishwasher detergent capsules, which can have an appearance similar to candy. A rise in inadvertent pediatric marijuana exposures has been reported in states with legalized marijuana, with edible sources playing a sizeable role.

Recreational drug use is another source of serious exposures in adolescents. Narcotics, cocaine, amphetamines, and ecstasy remain popular, and newer forms of recreational drugs include energy drinks with or without alcohol, synthetic cathinones ("bath salts"), synthetic cannabinoids ("K2," "Spice"), dextromethorphan, inhalants (especially computer cleaners), and the hallucinogenic herb salvia, which is legal in many states and also has opioid effects. Contamination of street drugs with high-potency opiates, such as carfentanil, is contributing to the rise in opioid fatalities.

Clinical Presentation

The clinical presentation following an ingestion varies considerably depending on the substance ingested. Some patients may not present with a clear history of a toxic ingestion. The physician must maintain a high index of suspicion for poisoning as the cause of symptoms such as altered behavior, depressed level of consciousness, cardiac dysrhythmia, vomiting, seizure, and autonomic changes.

Pathophysiology

The pathophysiologic profile depends on the substance. Some toxins act on a particular organ system (eg, acetaminophen on the liver, ethanol on the central nervous system), whereas others act diffusely at the cellular level (eg, cyanide). Generally, drugs are absorbed, distributed within the body, metabolized, and excreted. Drug levels obtained prior to completion of absorption and distribution may not reflect the peak level. Interventions focus on preventing absorption, sometimes on preventing metabolism into a more toxic by-product, and on enhancing excretion. Toxic effects may be delayed or prolonged when an extended-release form of a drug has been ingested, with drugs likely to form concretions (eg, iron, aspirin, theophylline), or when toxicity results from an active metabolite (eg, toxic alcohols, acetaminophen, acetonitrile, dapsone). Pharmacogenetics are increasingly recognized as having an important role in individual responses to medications and toxins. Genetic variations in enzymatic activity in drug metabolism may result in toxicity through excessively rapid metabolism of a drug to its active metabolite, or through slow metabolism of a drug to its inactive metabolite. For example, a cytochrome P-450 CYP2D6 genotype has been linked to rapid metabolism of codeine to active morphine, resulting in toxicity and even fatality. The US Food and Drug Administration has added a boxed warning on codeine and a contraindication for its use after tonsillectomy or adenoidectomy in children.

Differential Diagnosis

The differential diagnosis of toxic ingestions is broad. For the patient with a history of ingestion, the differential diagnosis is narrowed to substances available to the child. If no history of ingestion is given, the physician should include ingestion in the differential diagnosis when evaluating symptoms and signs such as altered mental status, altered behavior, metabolic derangement, cardiac dysrhythmia, hypotension and shock states, seizure, respiratory distress or apnea, cyanosis, vomiting, and diarrhea (Box 82.1). In fact, almost any symptom complex may result from a toxic ingestion.

Box 82.1. Symptoms of Toxic Ingestion

- Bradycardia or tachycardia
- Hypothermia or hyperthermia
- Respiratory depression or hyperpnea
- Hypotension or hypertension
- Mydriasis or miosis
- Altered mental status or abnormal behavior
- Seizure
- Cardiac dysrhythmia
- Metabolic derangement
- Nausea, vomiting, diarrhea

Evaluation

A detailed history of what and how much the patient ingested is key to the evaluation. Physical examination should focus on identifying symptoms and serious complications. The patient should be monitored and reassessed frequently. Laboratory and other diagnostic studies can be tailored to the specific ingestion.

History

The most important questions address the ingestion (Box 82.2), such as, What did the patient ingest? What is the maximum possible amount that was ingested? When did the ingestion occur? What symptoms are occurring? History of previous medical conditions is also important to identify increased susceptibility to a particular toxin (eg, seizure disorder with ingestion of a substance that causes seizures); assess for factors that may have precipitated the ingestion, such as depression; and assess for medications that may interact with or exacerbate the toxic effects of the ingested substance (eg, acetaminophen ingestion in a patient taking a cytochrome P-450 inhibitor).

Parents and caregivers should be encouraged to bring in the container and any remains of the substance ingested. The physician should attempt to obtain the exact formulation because generic and brand name drugs may differ. The physician must also be aware of possible combination products. Investigative methods such as calling

Box 82.2. What to Ask

Toxic Ingestion

- What did the child take? (If unknown, what is available to the child?)
- How much did the child take? (If unknown, what is the maximum amount possible?)
- When did the child take it? (If unknown, how long was the child unattended or unobserved?)
- What symptoms have occurred, and when did the symptoms begin relative to the time of ingestion?
- What other medical conditions does the child have?
- What medications does the child take regularly?

or sending a family member to the home to identify the product, calling the pharmacy on a prescription label, or identifying a pill by comparing its picture and imprint to those in a pharmaceuticals reference may be necessary. Internet search engines may be used to search the imprint on a pill or identify foreign medications.

Caregivers should be questioned about all available drugs or other toxic substances in the household. Sometimes caregivers must be encouraged to mention all substances in the household, even those they do not think the child could possibly have obtained. The physician must also ask about medications used by recent visitors (eg, grandparents) and the possibility of an exposure at a recently visited household or location. It is important not to overlook herbal preparations, vitamins, alternative medications, household products (including cleaning and personal care products), gardening products, chemicals used in hobbies or work, and alcohol or illicit drugs belonging to an adult. Caregivers may initially overlook these as they concentrate only on recalling "medications." It may be helpful to interview siblings or friends of an adolescent suspected of recreational drug use. The physician must maintain a high index of suspicion for unreported co-ingestants, especially in adolescent suicide attempts.

Although often difficult, it is important to attempt to determine the quantity of drug that was available to the patient and how much is currently missing. It may be necessary to count pills or measure liquid to make the determination. For estimating liquids, the approximate volume of a swallow is 0.3 mL/kg. The physician should always assume the "worst case" (ie, the patient took all of the drug that is missing). History about the amount ingested may be inaccurate, especially when elicited from the adolescent with intentional ingestion.

The physician should attempt to determine approximately what time the ingestion occurred. Symptoms are usually expected within a defined time range. Recommended observation periods before discharge take into account expected symptoms based on the length of time since the ingestion. Timing may also be important in determining what substance was most likely ingested. For example, ingestion of mushrooms that cause a self-limited illness usually results in gastrointestinal (GI) upset within 4 to 6 hours, whereas *Amanita* mushrooms that may ultimately result in hepatic failure typically present with GI upset in 6 to 12 hours.

The physician should ask about current symptoms and when they started relative to the time of the ingestion. In a patient without a definite history of ingestion, certain *toxidromes* (ie, recognizable combinations of symptoms suggestive of a certain class of medications or toxins) may be suggestive of a specific substance or class of substances. Whether the patient is symptomatic and what symptoms are present may guide the workup for an unknown ingestion, determine whether hospitalization is necessary, or dictate therapy.

Physical Examination

If the substance ingested is known, the physical examination should be focused on identifying expected symptoms of toxicity. A general physical examination should always be performed, however, because co-ingestion of another undisclosed substance must be considered. Particular attention should be paid to all 4 vital signs (ie, temperature, respiratory rate, heart rate, blood pressure); pupillary size and reaction; breathing (eg, Kussmaul respiration that occurs with acidosis); mental status; distinctive breath odors; presence or absence of bowel sounds; and skin color, temperature, and moisture. The patient's weight should be measured, because toxicity is often estimated based on milligrams of drug ingested per kilogram of body weight. Because symptoms may develop or worsen if peak levels of the toxic substance have not been reached at the time of initial evaluation, continual reassessment and cardiorespiratory monitoring are imperative. If a symptomatic patient is noted to have a typical toxidrome, therapy may be initiated based on the toxidrome without confirmation of the exact substance ingested. Some common toxidromes and their treatments are listed in Table 82.1.

Laboratory Tests

Qualitative drug screening (reporting only the presence or absence of the drug) of urine or blood often is done when poisoning is part of a broader differential diagnosis for symptoms such as altered mental status or acute behavioral changes. Such drug screening is rarely helpful in the patient with acute poisoning because typically results are not rapidly reported, testing can be done for only a limited number of substances, and false-positive and -negative results may occur. Given the frequency of narcotic ingestions, it is important to note that synthetic opioids (eg, fentanyl, methadone, oxycodone, hydrocodone) are not detected by typical hospital immunoassay "tox screens." Laboratory tests and diagnostic studies to consider for the patient with known or suspected toxic ingestion are listed in Box 82.3.

Quantitative drug levels for specific drugs can be helpful to estimate severity of expected symptoms or to rule out ingestion of that drug, however. Examples include acetaminophen, salicylate, ethanol, methanol, ethylene glycol, iron, theophylline, lithium, anticonvulsants, and levels of carboxyhemoglobin or methemoglobin by blood gas analysis. With the exception of acetaminophen and ethanol, such levels should be measured only when suggested by the history or physical examination. Many toxicology experts feel that because acetaminophen overdose produces few acute symptoms, may lead to fulminant hepatic failure, and is readily treatable with an antidote, and because acetaminophen is a frequent ingredient in combination products, acetaminophen level should be determined for all patients with a history of ingestion. In adolescents and adults, ethanol is a common co-ingestant, and ethanol levels are routinely measured. Routine salicylate levels are likely to be low yield in the absence of suspicion based on history or physical examination, although some physicians do obtain them as well.

Serum chemistries and osmolarity may offer clues about what was ingested when the substance is unknown. The *anion gap* is calculated as $[Na] - ([Cl] + [HCO_3])$ and is normally 8 to 12 mEq/L. An elevated anion gap indicates the presence of metabolic acidosis and occurs in ingestions and conditions identified by the MUDPILES mnemonic: methanol, uremia, diabetic ketoacidosis, paraldehyde

Table 82.1. Toxidromes

Toxidrome	*Toxins/Drugs*	*Symptoms*	*Treatment*
Narcotic or opiate	Oxycodone, hydrocodone, methadone, fentanyl, heroin, codeine, morphine	Nausea/vomiting, respiratory depression, miosis, altered mental status, coma	Naloxone, respiratory support
Cholinergic (parasympathomimetic)	Organophosphate and carbamate pesticides	Diarrhea, urination, miosis, bronchorrhea and bronchospasm, emesis, lacrimation, lethargy, salivation (ie, DUMBELLS)	Atropine, pralidoxime (ie, 2-PAM)
Anticholinergic	Antihistamines, jimson weed, antipsychotic agents, some antidepressants, Parkinson medications	Flushing ("red as a beet"), dry skin and mucous membranes ("dry as a bone"), hyperthermia ("hot as a hare"), delirium ("mad as a hatter"), mydriasis ("blind as a bat"), tachycardia, urinary retention, ileus/decreased bowel sounds	Supportive care
Sympathomimetic	Cocaine, amphetamines, ephedrine	Mydriasis, anxiety, tachycardia, hypertension, hyperthermia, diaphoresis	Quiet environment, benzodiazepines
Sympatholytic	Clonidine, beta blocker (eg, propranolol)	Bradycardia, hypotension, miosis, possibly lethargy	Supportive care, fluids and pressors if necessary for hypotension, atropine for symptomatic bradycardia
Tricyclic antidepressant	Imipramine, amitriptyline[a]	Seizure, tachycardia, prolonged QRS complex, altered level of consciousness, cardiac dysrhythmia	Sodium bicarbonate
Salicylate	Aspirin, methyl salicylate, oil of wintergreen	Hyperventilation, nausea/vomiting, tinnitus, hyperthermia, metabolic acidosis	Alkalinization with sodium bicarbonate (ie, $NaHCO_3$; confirm salicylate level)
Serotonin syndrome	Selective serotonin reuptake inhibitors[a]	Altered mental status, neuromuscular rigidity, tremors, or hyperreflexia; autonomic instability: hyperthermia, mydriasis, tachycardia, hypertension or hypotension	Supportive care

[a] Not an exhaustive list.

Box 82.3. Laboratory Tests and Diagnostic Studies to Consider for Toxic Ingestion

- Specific drug levels as indicated
- Qualitative urine or blood toxicology screening
- Acetaminophen level; consider ethanol and salicylate levels
- Serum chemistries (ie, calculate serum anion gap)
- Serum osmolarity (ie, calculate osmolar gap)
- Liver function panel and renal function tests
- Rapid bedside glucose test
- Urine pregnancy test
- Pulse oximetry
- Electrocardiography
- Arterial blood gas with carbon monoxide and methemoglobin levels
- Urinalysis
- Creatinine phosphokinase level
- Chest radiography
- Abdominal radiography for radiopaque tablets

and phenformin, iron and isoniazid, lactic acidosis, ethylene glycol and ethanol, and salicylates and solvents (eg, toluene). The *osmolar gap* is the difference between the measured serum osmolarity and the calculated osmolarity (given by the formula 2[Na] + [glucose]/18 + [BUN]/2.8). The normal osmolar gap is less than 10 mOsm. An elevated osmolar gap occurs with ingestion of alcohols such as ethanol, methanol, ethylene glycol, and isopropanol.

Depending on the level of suspicion for acidosis, hypoxemia, or abnormal hemoglobins (ie, carboxyhemoglobin and methemoglobin), arterial blood gas analysis may be indicated. Because hypoglycemia may be noted with some ingestions and is easily treated, a rapid bedside glucose test should be done on all patients. Urinalysis and creatinine phosphokinase level tests may be performed to evaluate for signs of rhabdomyolysis if the patient is deemed at risk. All females of childbearing age should undergo a urine pregnancy test. Assessment of liver and renal function is often important because many substances are metabolized by these routes.

Diagnostic Studies

Pulse oximetry and cardiorespiratory monitoring should be instituted for all serious ingestions. Electrocardiography may be indicated if cardiac toxicity is expected. Other studies are tailored to the specific ingestion, such as endoscopy after ingestion of caustic acids or alkalis.

Imaging Studies

Specific imaging studies may be indicated for certain ingestions, such as chest radiography in the case of hydrocarbon ingestion to look for signs of aspiration. An abdominal radiograph may be helpful in identifying ingestion of radiopaque substances and monitoring the effectiveness of GI decontamination procedures for removing such substances. The mnemonic CHIPS can be used for remembering which medications are radiopaque: chloral hydrate, heavy metals, iron, phenothiazines, and slow-release (ie, enteric-coated) medications. In practice, abdominal radiography is primarily used in iron ingestion and suspected body-packing with illicit drugs.

Management

Management strategies are specific to the substance ingested. The regional poison control center should be consulted for advice on treatment and length of time to observe the asymptomatic patient. A single telephone number, 1-800-222-1222, automatically routes the caller to 1 of the appropriate 55 regional poison control centers in the United States. Generally, the approach to management includes attention to the basics of resuscitation (circulation, airway, breathing), decontamination methods, specific antidotes when available and indicated, and meticulous supportive care, often in an intensive care unit.

Decontamination

Decontamination techniques are used to prevent or minimize absorption of the toxic substance and to enhance its elimination. They are a critical part of the treatment of the acutely poisoned patient and should be used whenever a significant ingestion is suspected (Table 82.2).

Historically, ipecac syrup was commonly recommended for home use to induce vomiting in the event of an accidental ingestion. The American Academy of Pediatrics released a policy statement in 2003 stating that ipecac syrup should no longer be kept in homes and is not recommended because studies showed that its use resulted in no difference in outcomes. Gastric lavage, in which a large nasogastric tube is placed and the stomach is washed with normal saline theoretically removes toxic substance from the stomach, thereby preventing absorption. At best (ie, immediate performance after ingestion), however, less than one-third of gastric contents are removed by this method. Additionally, this technique may interfere with the use of activated charcoal, which usually is a more effective therapy. Gastric lavage is technically difficult to perform in young children because of the need to pass a large-bore tube. Gastric lavage also has a high rate of complications, such as aspiration and esophageal trauma. Gastric lavage is not recommended for routine use. The American Academy of Pediatrics released a policy statement in 2003 stating that ipecac syrup should no longer be kept in homes. Ipecac syrup was administered in 0.01% of pediatric ingestions in 2011.

Table 82.2. Summary of Gastric Decontamination Techniques

Technique	*Dose*	*Contraindications*
Gastric lavage	15 mL/kg aliquots normal saline to maximum of 400 mL until lavage fluid is clear (may be several liters)	ALOC with unprotected airway Caustics: acids and alkalis Hydrocarbons Expected ALOC >1 hour since ingestion
Activated charcoal	1–2 g/kg or <6 years: 25–50 g ≥6 years: 50–100 g	ALOC with unprotected airway Absent bowel sounds or bowel obstruction Substance not bound by charcoal
Cathartics	Magnesium citrate 4 mL/kg 70% sorbitol 1 g/kg	Not recommended for routine use Repeated doses can cause dehydration or electrolyte imbalances
Whole-bowel irrigation	Toddler and preschool age: polyethylene glycol solution 500 mL/hour 6–12 years: 1,000 mL/hour Adolescent and adult: 1.5–2 L/hour Continue until rectal effluent is clear	Bowel obstruction, ileus, perforation, or hemorrhage ALOC with unprotected airway
Lipid emulsion 20%	1.5 mL/kg initial bolus intravenous, then 0.25 mL/kg/minute for 30–60 minutes	For lipophilic drug overdose with severe cardiotoxicity

Abbreviation: ALOC, altered level of consciousness.

Activated charcoal is the mainstay in decontamination therapy of ingestion. Charcoal binds toxins, and because it is not absorbed in the GI tract, the charcoal-toxin complex passes through and is eliminated. Its efficacy decreases with increasing time since ingestion, and ideally it should be started within 1 hour of the ingestion. The optimal dose of charcoal is 10 times the amount of substance ingested. Because the exact amount of toxin ingested is often unknown, activated charcoal is usually dosed at 1 to 2 g/kg (teenagers and adults, 25–100 g). The amount of charcoal given is limited only by what the child can tolerate. Only a few substances are not absorbed by activated charcoal, and the mnemonic PHAILS can be used to remember them: pesticides; hydrocarbons and heavy metals; acids, alkalis, and alcohols; iron; lithium; and solvents. The main complication of charcoal administration is aspiration pneumonitis, which mainly occurs in patients with altered level of consciousness and an unprotected airway. If charcoal is not voluntarily taken by the child, it may be administered via nasogastric tube. Endotracheal intubation (preferably with a cuffed tube) to protect the airway first may be necessary in the patient with altered mental status, because charcoal aspiration can result in severe chemical pneumonitis. It is imperative that nasogastric tube placement in the GI tract (as opposed to the respiratory tract) be confirmed before charcoal administration.

Cathartics (most commonly sorbitol) have been used to decrease transit time and improve elimination of the toxin through the GI tract and to counteract activated charcoal-induced constipation. The cathartic is often mixed with the activated charcoal and may serve to improve the palatability of the charcoal. A significant benefit from cathartic use has never been demonstrated, however, and a risk of dehydration and electrolyte disturbances exists, particularly in young children. The American Academy of Clinical Toxicology recommends against use of cathartics. Under no circumstances should repeat doses of cathartics be administered.

Multiple-dose charcoal, which has been called "GI dialysis," may remove drugs from the bloodstream by promoting diffusion back into the GI tract and subsequent binding to charcoal. Activated charcoal at the same dose previously used is repeated approximately every 4 hours. Cathartics should not be mixed with the charcoal for repeat doses. Multiple-dose charcoal is useful for a small number of drugs, such as phenobarbital, theophylline, carbamazepine, dapsone, and quinine. It should be used only if a potentially life-threatening amount has been ingested. It should not be used for drugs that can cause an ileus (eg, tricyclic antidepressants).

Whole-bowel irrigation involves infusion of a solution usually used for cleansing of the bowel prior to GI surgery (eg, polyethylene glycol). It is especially useful for slow-release medications, for tablets that dissolve slowly and may cause concretions (eg, iron), and in ingestions for which charcoal is not likely to be effective (eg, heavy metals). A nasogastric tube is used to infuse the solution at a rate of 500 mL/hour in young children and 1 to 2 L/hour in older children and adolescents. Clear rectal effluent is the end point; a bedpan may be necessary. Whole-bowel irrigation should not be used in the setting of bowel obstruction, ileus, perforation, or hemorrhage or altered mental status with an unprotected airway.

Hemodialysis may be used for serious ingestions of ethylene glycol, methanol, phenobarbital, lithium, salicylate, or theophylline. Charcoal hemoperfusion, in which blood passes through a charcoal cartridge rather than a dialysis machine, is used rarely for severe theophylline poisoning. Urinary alkalinization (by administration of sodium bicarbonate) can increase elimination of weak acids by keeping the drug in its ionic state, thus preventing reabsorption in the renal tubule. It is used mainly for significant salicylate, phenobarbital, and isoniazid poisonings.

Lipid emulsion (eg, Intralipid) is becoming recognized as a potential treatment for lipophilic drug overdoses and has been used successfully for managing severe cardiotoxicity from bupivacaine hydrochloride, haloperidol, and verapamil hydrochloride overdoses. It is unclear by what method this agent works. Although ideal dosing and indications have not been established, 1 suggested treatment protocol to consider is 1.5 mL/kg of 20% lipid emulsion initial bolus, followed by 0.25 mL/kg per minute for 30 to 60 minutes. Boluses may be repeated in the setting of severe cardiotoxicity and dysrhythmias.

Supportive Care

Attention to the basics of resuscitation (circulation, airway, breathing) is always the first step in management. Hypoglycemia must be assessed and managed as soon as possible. Dextrose 0.5 to 1 g/kg intravenously is administered for hypoglycemia; glucagon may be used if dextrose cannot be given. Seizure generally is treatable with benzodiazepines. Glucose and electrolyte levels should be normalized. For the patient with seizure caused by isoniazid ingestion, pyridoxine is indicated. Shock requires aggressive fluid resuscitation. Fluid-resistant shock may require vasopressors, most commonly dopamine, epinephrine, or norepinephrine. Resistant shock in the setting of beta blocker ingestion may respond to glucagon, and in the setting of a calcium channel blocker ingestion to insulin plus glucose. Dysrhythmias generally should be managed by following pediatric advanced life support (PALS) protocols, although specific ingestions may respond to specific therapies. Sodium bicarbonate is the first-line treatment for dysrhythmias associated with ingestions of antihistamines, class 1 antiarrhythmic drugs (ie, lidocaine, quinidine, procainamide hydrochloride), cocaine, and tricyclic antidepressants. Beta blocker ingestions may respond to atropine and glucagon, whereas ingestions of calcium channel blockers are managed with calcium. Procainamide hydrochloride, which is found on PALS algorithms, should be avoided for patients with dysrhythmia resulting from overdoses of antihistamines, quinidine and other class 1 antiarrhythmic drugs, digoxin, quinine, and tricyclic antidepressants. Amiodarone hydrochloride, another agent found on PALS algorithms, should also be avoided in the management of antihistamine ingestions. Electrolyte imbalances should be assessed and corrected. Suicidal ideation should be assessed, often in conjunction with a mental health professional.

Antidotes

Antidotes or medications that counteract the pathophysiologic mechanisms of the toxin are available for only a few ingestions (Table 82.3). Important antidotes are N-acetylcysteine for acetaminophen, naloxone hydrochloride for narcotics, oxygen for carbon

Table 82.3. Select Antidotes for Specific Ingestions

Toxin	*Antidote*
Acetaminophen	N-acetylcysteine
Anticoagulants (warfarin-like)	Vitamin K
Anticholinergic	Physostigmine
Benzodiazepine	Flumazenil
Beta blocker	Glucagon
Calcium channel blocker	Calcium, insulin + glucose
Carbamate pesticide	Atropine
Carbon monoxide	Oxygen
Cyanide	Cyanide antidote kit
Digoxin	Digoxin immune Fab (ovine; Digibind)
Ethylene glycol	Fomepizole, ethanol
Iron	Deferoxamine
Isoniazid	Pyridoxine
Lead	Dimercaprol (ie, BAL), ethylenediaminetetraacetic acid, DMSA
Mercury	BAL, DMSA
Methanol	Fomepizole, ethanol
Methemoglobinemia	Methylene blue
Narcotics	Naloxone hydrochloride
Organophosphate pesticide	Atropine, pralidoxime (ie, 2-PAM)
Rattlesnake bite	Crotalidae polyvalent immune Fab (ovine; CroFab)
Sulfonylurea oral hypoglycemic	Dextrose, octreotide
Tricyclic antidepressant	Sodium bicarbonate

Abbreviations: BAL, British antilewisite; DMSA, dimercaptosuccinic acid.

monoxide poisoning, sodium bicarbonate for tricyclic antidepressant cardiotoxicity, digoxin immune fab (eg, Digibind, DigiFab) for digoxin, and deferoxamine for iron. Antidotes are not without adverse effects themselves and should be given only in cases of symptomatic or, as in the case of acetaminophen, potentially symptomatic ingestions of significant amounts. The poison control center staff can be quite helpful in guiding physicians in the use of antidotes.

Anticipatory Guidance and Prevention

Most ingestions are nontoxic and require only observation for a few hours. These episodes do, however, provide an excellent opportunity to discuss poisoning prevention with parents and caregivers. Possible toxins, including prescription and over-the-counter medications, cleaning and household products, cosmetics and nail care products, toxic plants, gardening and hobby chemicals, and kitchen items (eg, alcohol) should be kept out of reach of children. Visitors to the household should also be cautioned to keep medications out of reach of children. Substances should never be stored in unmarked containers, particularly in containers that typically hold beverages (eg, old soda bottles, cups). Medications should not be referred to as "candy" to entice youngsters to take them. Family members and visitors should be asked to store medications out of the child's reach and to dispose of leftover medications and used transdermal patches safely. Used transdermal patches may still contain up to 75% of the medication dose. Additionally, chewing on patches, as toddlers may do, releases the medication much faster. Parents and caregivers should have the universal telephone number for the poison control center and telephone numbers for local emergency departments readily available. Carbon monoxide detectors should be placed near children's bedrooms. Activated charcoal for home use is controversial and not currently recommended, although it is available without prescription from many pharmacies. Parents should not give activated charcoal without first speaking to poison control center staff or medical personnel.

Prognosis

Prognosis depends on the toxicity of the substance ingested. For a few substances, a small amount can be fatal (Box 82.4), whereas for others, even large ingestions are generally benign. Prognosis is generally excellent; fatalities in children are rare. Prognosis is worse for intentional ingestions, often because patients delay or do not reveal that they attempted overdose.

Box 82.4. Substances Potentially Fatal in 1 to 2 Pills or Teaspoons

- Camphor (found in Vicks VapoRub, Campho-Phenique, Tiger Balm)
- Imidazoline decongestants (found in over-the-counter nasal drops and eyedrops)
- Acetonitrile nail glue remover
- Clonidine hydrochloride (also available in transdermal patches)
- Opiates (also available in transdermal patches)
- Methyl salicylate (oil of wintergreen, Bengay)
- Calcium channel blockers
- Toxic alcohols (ie, methanol, ethylene glycol, ethanol, isopropanol)
- Tricyclic antidepressants
- Diphenoxylate and atropine (eg, Lomotil)
- Sulfonylurea oral hypoglycemics
- Chloroquine and hydroxychloroquine sulfate antimalarial agents
- Hydrofluoric acid
- Selenious acid (gun bluing solution)
- Buffered saline solution
- Benzocaine-induced methemoglobinemia

CASE RESOLUTION

Because the respiratory rate of this 2-year-old is slow and the child exhibits symptoms of miosis and altered level of consciousness narcotic ingestion is suspected, and naloxone is administered. The child becomes more alert, and respiratory rate increases to 24 breaths per minute. The father is instructed to retrieve the bottle, and the substance is found to be a prescription narcotic analgesic left in the house by a recent visitor. The child is given activated charcoal, observed overnight in the hospital, and discharged on the following day without sequelae.

CHAPTER 83

Disaster Preparedness

Ireal Johnson Fusco, MD, FAAP, and Katherine E. Remick, MD, FACEP, FAEMS, FAAP

CASE STUDY

A family comes in for a well-child visit with their 7-year-old son and 9-month-old daughter, the latter of whom has complex congenital heart disease. The mother is concerned after a recent tornado in the next town resulted in prolonged power outages. She is wondering what the family might do in this situation. The daughter needs daily breathing treatments and often requires oxygen at nighttime. She is on multiple medications and a special formula. All her specialty doctors are at the children's hospital, which is more than an hour from their house. She is also concerned because her husband has a seizure disorder that requires medication. She asks whether the family should stay together in a disaster or separate to get her daughter to the children's hospital.

Questions

1. What are the 4 phases of disaster preparedness with which the pediatrician should be familiar?
2. What should be included in disaster preparedness kits? How should medications for all family members be included?
3. When should a family consider getting a backup generator?
4. What is the role of the local hospital and emergency medical services for the family with a child or children with special health care and critical medical needs?
5. What should the pediatrician recommend to the family about children's immunization records and important medical history?
6. How does the physician assess for the effect of traumatic events on children and their families?

Disaster preparedness has become an increasingly relevant topic for children and their families. Although natural disasters, war, and pandemic infections have always threatened human populations, increasing population density, global warming, international trade, and terrorist threats have heightened our awareness of disasters and the need for preparedness. State and federal systems are an essential component of disaster preparedness, but significant delays in the delivery of resources can occur. Because of a growing need to address the availability of resources and inherently delayed response times of the state and national systems, disaster preparedness is important for families and local communities. Recent major disasters, whether human-induced events, such as the 2013 bombing during the Boston Marathon, or natural events, such as Hurricane Harvey, which devastated Houston, Texas, in 2017, demonstrate the vulnerability of communities and the need for extensive local preparation. In the first hours to days after a disaster, community response is vital to well-being, and the community needs to be prepared to play a greater role than was historically anticipated. As frontline health care providers and advocates for children, pediatricians have a particular responsibility to maintain a baseline understanding of chemical, biological, and radioactive exposures as well as emerging pandemic infections to provide guidance to families in the event of such disasters.

In addition to large-scale disasters, incidents in which local emergency medical services (EMS) are overwhelmed by the number and severity of casualties, termed *mass casualty incidents*, also have the potential to overwhelm community resources. These may include catastrophic events, such as multiple-vehicle collisions, mass shootings, and hazardous materials spills. Patients must be quickly triaged, treated, and transported. Typically, local government facilitates the initial response in accordance with emergency preparedness policies and procedures. This may include coordinating efforts with surrounding communities as per regional preparedness plans, along with additional assistance as necessary from state government. A public health emergency is declared only when an event exceeds the ability of local, regional, and state resources to provide routine care as the result of any incident that poses substantial risk for human fatalities or long-term disabilities. Preparedness experts suggest evaluating public health emergencies from what is called an *all-hazards approach*, which focuses on the key elements necessary to ensure the provision of routine care during any type of disaster or mass casualty incident. Specific scenarios that occur rarely, such as chemical or radiation exposure, require access to specialized resources that may be impractical to stockpile or are limited in availability. From a practical standpoint, the all-hazards approach is more effective.

Multiple factors make children more vulnerable than adults during a disaster. In the United States, children make up approximately 25% of the population. Younger children, especially, are reliant on others for food, shelter, and, importantly, psychological support. Their unique nutritional needs put them at risk for malnourishment if specific dietary requirements are not available. Additionally, children often have less mature immune systems. In a setting of physical stress and unreliable sanitation, children are at increased

risk for infection. Moreover, decreased fluid reserves make children more susceptible to blood loss or dehydration from agents that cause diarrhea and vomiting. In the setting of a blast or fall, children are at increased risk for traumatic brain injury because of their large head-to-body ratio. Their more pliable skeleton also increases the likelihood for internal organ injury. Furthermore, children are at increased risk for exposure from chemical, biological, and radiation disasters because of their unique physiology. Infants and children have higher minute ventilation, resulting in increased inhalation of aerosolized agents. Their smaller height increases their exposure to high-vapor density agents, which are in higher concentrations closer to the ground. Additionally, the skin of infants and children is more permeable because of lesser keratinization compared with adults, and infants and children have a larger surface area-to-body mass ratio. As a result, exposed children receive a higher dose of transdermally absorbed toxins than adults exposed under identical circumstances. This larger surface area-to-body mass ratio also complicates treatment, because children are at increased risk for hypothermia during the decontamination process. Finally, the psychological effect of being separated from family and experiencing other disaster-related trauma can be devastating in the short- and long-term.

The 4 phases that the pediatrician should understand when it comes to disaster preparedness and the importance of advocating for children at each of these steps are planning, rescue, recovery, and mitigation. *Planning* includes training and education as well as identifying specific local risks. For example, some communities might need to anticipate hurricanes and flooding, whereas others are more concerned about earthquakes or blizzards. This is a key area in which the pediatrician can intervene and both work with families to develop disaster plans and interact with the local disaster response community to improve the capacity to care for children. *Rescue* refers to the actions taken during a disaster, and this is typically what receives the most attention in the media and by the public. *Recovery* is the process that begins immediately after the disaster occurs—often simultaneously with the rescue phase—in which the community works toward returning to normal routines. This is also the phase during which mental health problems begin to emerge. *Mitigation* is an important and often overlooked phase in which individuals and the community learn from the response to the disaster to prevent future occurrences or improve on the response to decrease the effect of future disasters.

Unfortunately, many disaster response teams lack pediatric training, protocols, and equipment. Recently, various public health and disaster organizations have lobbied for states to mandate disaster preparedness regulations for children. Specifically, many states lack basic emergency preparedness regulations for schools and child care facilities. The developmental vulnerabilities of infants, toddlers, and young children make them physically less able to escape a disaster scene and cognitively less able to recognize the need to flee and follow directions from authorities. Children with special health care needs, whether because of physical or cognitive disabilities, require specific attention. The pediatrician can assist schools and child care centers in developing disaster preparedness plans. All child care facilities should have a plan in place that addresses all-hazards safety, medical needs, evacuation and transportation, and reunification with families. The idea of family-centered care that seeks to keep family units together even as care is needed for individual members is important for the immediate physical health and long-term mental health of children during and after disasters.

The Role of the Pediatrician With Families

The pediatrician serves as an important resource for disaster preparedness planning for families. The pediatrician should consider assessing a family's level of readiness for a disaster and then tailor anticipatory guidance accordingly. Families must stay informed and realize that everyone is susceptible to some type of disaster. The pediatrician can also ensure that families understand the importance of preparation and the special needs of children during a disaster. The US Federal Emergency Management Agency (FEMA) offers a free smartphone application (www.fema.gov/smartphone-app) that includes specific information on various types of natural disasters, how to build a disaster kit, resources for victims of disasters, and a disaster reporting feature. Families should prepare an emergency kit that provides up to 3 days of basic necessities, including food, water, and clothing. Families of newborns and infants must include formula and diapers as well as any daily medications for all family members. Copies of immunization and general medical information are useful as well as pictures of family members in case the family unit is separated. Parents must be prepared to handle nonemergent problems, because formal medical care may be limited to the seriously ill and injured during a disaster. If a family needs acute medical care, it may be necessary to treat children in adult facilities; alternatively, for the family unit to remain together it may be necessary for adults within the family to undergo treatment in pediatric facilities. The more information families can provide about any medical conditions requiring attention, the easier it will be to receive appropriate care in a disaster.

Families of children with special needs are especially vulnerable after a disaster because access to routine medical care may not be available. Experience in Japan during the 2011 earthquake and subsequent tsunami showed increased mortality among children with special needs and increased hospitalizations for children who were technology dependent. Not only should families have a sufficient supply of medication, they should have a surplus of necessary medical equipment and nutritional supplements. Common supplies, such as a feeding tube or catheters, may be in short supply or unavailable during a disaster. Families with a child on a ventilator or one who is oxygen dependent should notify local utilities to flag their address for priority status during power outages. They should consider the benefits of backup battery units and a backup generator at their home. These families would also benefit from notifying their local EMS agency and hospital of their child's medical needs, because some EMS systems keep a registry of children with special

needs. Some communities have developed systems in which posters are disseminated for placement in a window of the home specifying if any occupant may require special services from EMS in the event of a disaster or terrorist attack. Additionally, the American Academy of Pediatrics (AAP) and American College of Emergency Physicians offer an emergency information form that can be completed with the pediatrician and should be part of the emergency preparedness kit. The emergency information form contains information on diagnoses, procedures, medications, common presenting problems, and suggested medical management (see Online Resources). The family of a child with special needs can also contact the National Organization on Disability (www.nod.org) or Family Voices (www.familyvoices.org) for more detailed information on preparing for a disaster.

During the recovery phase after a disaster, children and adolescents may develop chronic medical problems as a result of injuries sustained during the event. Beyond physical injuries, all disasters have a psychological effect on children. The experiences and effects of disaster are unique to each patient, and the pediatrician must individualize treatment accordingly. Multiple studies of various types of disasters demonstrate the increase in mental health symptoms among children and adolescents exposed to a disaster. This is true even if a family is not directly affected by the disaster but is exposed to the event within the community, on television, or through the internet and social media. A child may present with somatic symptoms, such as headaches and abdominal pain, or may not want to participate in his or her normal activities. Long-term effects include depression, anxiety, aggression, and substance abuse. Age-appropriate discussions should be encouraged along with validation of the child's concerns while assuring the safety of the individual child. Posttraumatic stress disorder should be considered in the differential diagnosis of the patient with persistent symptoms that do not respond to family support. Families and health professionals can obtain further information through the AAP (www.aap.org) and the Substance Abuse and Mental Health Services Administration (www.samhsa.gov).

The Role of the Pediatrician in the Community

Many state and regional disaster preparedness plans are tailored for an adult population and may not consider the special needs of children. The pediatrician can participate in the development of a community-wide disaster preparedness plan (eg, identifying emergency meeting locations) as well as surveillance to identify potential disasters as part of the planning phase of disaster response. From an operational standpoint, it is more effective to have 1 plan that can take into consideration the needs of multiple vulnerable populations rather than a separate disaster preparedness plan for each population. The pediatrician should serve as a consultant about local preparation and provide guidance about the unique medical, nutritional, and psychological needs of children. For example, increased staffing needs should be anticipated when caring for younger children and infants. Depending on availability of human milk, newborns and infants may require formula and a sterile water supply. The food needs of young children differ from those of adults. Stockpiling of medications for biological, chemical, or radiation disasters must take into consideration dosing differences for children compared with adults. It is necessary to make available suspensions of medications in addition to pill forms. Furthermore, many recommended antidotes and treatments are not approved for use in the pediatric population, and policies on the risks and benefits of their use in disasters should be established.

Emergency medical services systems are charged with the initial and rapid triage of all victims. Various well-known triage algorithms are available, including sort, assess, lifesaving interventions, treatment/transport (SALT) and simple triage and rapid treatment (START). Common to all is the rapid sorting of patients based on ability to ambulate followed by assessment of respiratory status, circulation/perfusion, and motor skills. Although multiple triage tools exist, the physiologic parameters and mental status assessments used in adult-based algorithms may not be suitable for children of all ages. Triage systems must take into account physiological differences of children as well as their psychological response to strangers. For example, young children may not be able to communicate their complaint, and because their vital signs are normally different from those of adults, medical personnel accustomed to working with adults may misinterpret physical findings and overtriage children. JumpSTART is a widely recognized pediatric-specific disaster triage tool that parallels START but is customized to address a child's developmental ability and age-appropriate vital signs. However, it fails to capture children who are dependent on technology or those with special health care needs. Whether or not a triage tool is readily available, clinical decision making can be relied on to help sort and triage victims in a disaster.

Ideally, children should remain with their caregiver as part of family-centered disaster care. If this is not possible, it is necessary for a child advocate to be with the child at all times, although the nature of disaster response may make this challenging if not planned in advance. Additionally, incorporation of child life specialists and techniques for distraction during medical procedures should be encouraged. Children may not respond well to new environments and disaster protocols. The simple process of decontamination can be devastating to a young child without the presence of a parent or other familiar caregiver. A child may have concerns about being sprayed with water or may refuse to disrobe in front of strangers, which may affect the success of decontamination for children and adolescents. It is assumed that adults will comply with protocols, but such compliance is less predictable in a pediatric population. A child may be afraid of strangers or may simply wander off before triage is complete. Nonmedical personnel or bystanders may be called on to assist with supervising ambulatory children.

Facility-based issues must also be addressed in regional disaster preparedness plans. These include providing for increased staffing in adult facilities caring for children as well as the need for stockpiling of pediatric supplies at those facilities. Similarly, parents may be triaged with their children, so pediatric facilities should be prepared

to manage adult victims as well. Additionally, facilities need to plan for children arriving without a caregiver and establish an identification system that allows children to be reunited with their families. This was a significant problem for children displaced during Hurricane Katrina. Strategies to address this include using digital cameras to photograph children on arrival with their original clothing as a means of facilitating family reunification.

The Role of the Pediatrician in Disaster Surveillance and Management

Pediatricians function as key public health workers. Their knowledge and diligence aids in local and regional surveillance for potential chemical, biological, and radiation disasters. Families may seek care from their pediatrician rather than an emergency department for early symptoms during and after a disaster. Although it is beyond the scope of this chapter to provide details about signs and symptoms after every type of disaster, important concepts in identifying and treating patients with exposures to chemical and biological agents as well as radiation are highlighted herein.

Chemical exposures usually result in immediate symptoms and require special protection for emergency personnel as well as decontamination for the victims. These exposures can occur from terrorism as well as (more commonly) industrial accidents. Insecticides, herbicides, and nerve gases are organophosphates that inhibit the enzyme acetylcholinesterase. This results in the accumulation of acetylcholine and excessive cholinergic stimulation at muscarinic and nicotinic receptors. Symptoms include the muscarinic SLUDGE toxidrome (increased salivation, lacrimation, urination, diaphoresis, gastric distress, and emesis) as well as the MTWHF nicotinic toxidrome (mydriasis, tachycardia, weakness, hypertension, and fasciculation). Vesicant exposure, such as mustard gas and lewisite, causes irreversible damage to mucous membranes, skin, and the respiratory system soon after exposure. Cyanide is another common chemical agent, known for its bitter almond taste. Cyanide inhibits cellular metabolism and causes rapid hypotension, coma, seizures, and death. Agents other than nerve agents usually do not result in severe mortality but rather incapacitate the victim. Many other chemical agents from industrial accidents can cause a variety of skin and pulmonary symptoms.

Biological agents include bacteria, viruses, and preformed toxins. These agents may be easy to disperse and can affect large populations. Unlike in chemical exposures, the onset of symptoms is delayed by hours to days, and symptoms are more difficult to distinguish from common ailments. Secondary transmission of the infection is also of concern with some agents. Management of biological disaster requires detailed surveillance and containment of exposed populations.

Although there are too many biological agents to discuss in any detail in this brief chapter, a few of particular relevance to disaster planning are mentioned here. Anthrax, from *Bacillus anthracis,* is a gram-positive sporulating rod. When used as a bioterrorism agent in its inhaled form, victims present with severe influenza-like symptoms with an associated high fatality rate. Fever and dyspnea associated with a widened mediastinum are common and may progress to shock. Ciprofloxacin and doxycycline are recommended for prophylaxis and treatment among adults. Despite the risks to bone and cartilage that generally restrict its use to healthy children, ciprofloxacin is approved by the US Food and Drug Administration (FDA) for use in children with inhalational anthrax exposure. Doxycycline should generally be avoided in children younger than 8 years, although it may be considered on a case-by-case basis. The physician must consider consulting with experts to assist in assessing the risks and benefits associated with using these medications. Among the viruses, variola, more commonly known as smallpox, is an agent of concern. After its global eradication in 1980, children were no longer immunized, leaving all children and most adults susceptible to the virus. Similar to varicella (ie, chickenpox), it presents with vesicles with umbilicated centers but is associated with a higher mortality rate of 3% to 30% among nonimmunized individuals. Exposure to the potent botulinal toxin results in cranial nerve disturbances, descending paralysis, and respiratory distress. Ricin, which is derived from the castor bean, is another potent toxin. Inhalation results in fever, cough, and pulmonary edema, often resulting in death within days. Ingestion presents with severe vomiting and diarrhea, resulting in hypovolemic shock. For a complete list of biological agents, presenting symptoms, and potential treatment or prophylaxis, physicians should consult the Centers for Disease Control and Prevention.

Radiation exposure may occur as a result of damage to a facility containing nuclear material, detonation of a nuclear weapon, or dispersal of nuclear material by a radioactive dispersal device. Ionizing radiation presents the greatest health risk because of its high-frequency energy. It causes chromosomal breaks in cells that can cause long-term damage and increased risk of cancer. The 5 types of ionizing radiation with specific characteristics, behaviors, and toxicities are alpha particles, beta particles, gamma rays, x-rays, and neutrons. Alpha particles have limited ability to penetrate but when inhaled or ingested can cause internal damage. Beta particles are most commonly found in a medical setting, and they have greater penetration than alpha particles. Beta particles can cause skin damage as well as damage when ingested. Gamma rays and x-rays are part of the electromagnetic spectrum. Gamma rays are high energy and cause significant damage. This type radiation would be seen after a nuclear detonation or from radioactive materials. Much less common are neutrons, which induce radioactivity. Exposure to radiation is classified as external, internal, whole body, and partial body. The effects of radiation can directly damage the target tissue, or the effects can be indirect, caused by the creation of free radicals. Tissue sensitivity is based on the cellular rate of division and level of differentiation. The most sensitive to least is as follows: lymphoid, gastrointestinal, reproductive, dermal, bone marrow, nervous system. The severity of exposure is also dependent on the dose of radiation, type of radiation, and age of the victim.

Radiation exposure is quantified by the amount of energy absorbed (ie, rad [radiation absorbed dose]) and the relative

biological effectiveness of doses (RBE) based on the type of ionizing radiation. The rem is the product of the rad and RBE. Under the International System of Units, the rad and rem are being replaced by the gray (1 Gy = 100 rad) and sievert (1 Sv = 100 rem). Typically, doses for common radiation exposures are given in millisieverts (1 mSv = 0.001 Sv). Radiation exposure from common radiographic procedures can range from 0.1 mSv for a chest radiograph to 2 to 20 mSv for a computed tomography scan.

Symptoms associated with radiation exposure depend on the total exposure. Nausea and vomiting can present with exposures of 0.75 to 1 Gy and lymphoid and bone marrow suppression with exposures of 1 to 6 Gy. The mean lethal dose, the radiation dose for which one-half of the population is expected to die within 60 days, is 4 Gy. Long-term effects of radiation include increased incidence of cancer and psychological distress. Evacuation is the ideal intervention to decrease exposure, but this may not be feasible in a timely fashion in highly populated areas.

Seeking shelter can greatly decrease the level of exposure, with large cement structures providing the best protection. The use of potassium iodide is effective in exposures to radioactive iodine, which is associated with nuclear power facilities. It can be dispensed in a pill and in suspension form. Dosage is based on level of radiation exposure and patient age, and physicians should consult the FDA (www.fda.gov) or the US Nuclear Regulatory Commission (www.nrc.gov) to determine the appropriate dosage of potassium iodide depending on the level of radiation exposure. For individuals seeking medical care, containment and decontamination are essential. Removal of clothing and washing the skin with warm water is quite effective. Supportive medical care is essential in managing patients with radiation exposure. Radiation results in significant immune suppression, neutropenia, and lymphocytopenia, which last for weeks and need close monitoring. The physician should be aggressive in managing infections and consider treatments to increase bone marrow regeneration. Expert consultation in radiation sickness would be prudent.

In addition to caring for patients, pediatricians need to take into consideration the well-being of their own family as well as that of office staff. During a disaster, office staff may not be able to get to work. For those able to report to work, extra supplies of food and water must be available in case staff cannot return to their homes. An office disaster plan should be implemented with emergency contacts and preparation for the staff's basic needs. Basic medical supplies should be available to care for patients during a disaster. Depending on the type and severity of the disaster, access to the office facility may be prohibited. Plans for backing up patient medical records should be implemented as well as for alternative sites in which medical services can be delivered.

Physicians need to review their medical liability policies addressing the provision of care in a disaster situation. Most policies only provide coverage for care that is provided in the office setting. Good Samaritan laws vary in each state about what level of protection is provided to the health professional. The AAP recommends that during a disaster situation, pediatricians who volunteer do so under the auspices of an official disaster agency or recognized relief organization to ensure the greatest protection from liability.

Conclusion

The pediatrician has a vital role in predisaster, disaster, and postdisaster management on the local, regional, state, and national level, not only as a medical service professional but also as an advocate for the special needs of children and their families. The essential components of disaster management are to provide for all basic human requirements, reduce an individual's vulnerability to disasters, and, after a disaster has occurred, reduce the exposure risk. The pediatrician can educate and assist families in preparing for disasters. Additionally, the pediatrician can guide communities in their disaster preparedness planning to accommodate the particular vulnerabilities of children. As with other health professionals, pediatricians can also contribute to the essential medical and public health workforce during a disaster. Pediatricians can access the most current guidelines and recommendations through multiple professional and governmental resources. It is imperative for the physician to have easy access to telephone numbers and websites specific to pediatric disaster preparedness and response for the relevant local, state, and federal agencies.

CASE RESOLUTION

The family is relieved to discuss the importance of preparing for a disaster. They now have an idea of what is involved in disaster preparation and feel less vulnerable. They plan to create and store an emergency kit with a 3-day supply of food, water, and medications as well as a first aid kit. Additionally, they will refer to the FEMA application for further recommendations. Together with their pediatrician, they complete an emergency information form for the kit. In the event of a disaster, they plan to stay together. The mother also shares her plan to call their local utility company to identify their house as a priority during a power failure and indicates she will consider purchasing a backup generator. Before leaving the office, the mother shares that her son has been sleeping less since the tornado and does not want to go to school because he is afraid of being away from the family. The pediatrician encourages the family to discuss the boy's fears while ensuring his safety. Having the son participate in making the emergency kit and creating a family plan may help. A follow-up visit is scheduled to reassess his symptoms and decide if further intervention is needed.

PART 6

Head, Neck, and Respiratory System

CHAPTER 84

Approach to the Child With Dysmorphism

Henry J. Lin, MD, and Moin Vera, MD, PhD

CASE STUDY

A 13-year-old boy presents to the office for the first time for an evaluation after moving to the area. His parents note that he has unexplained intellectual disability and has had problems with hyperactivity in school. The pregnancy was uncomplicated and the mother, who was a 32-year-old gravida 1, para 1 at the time of the child's birth, denies alcohol or drug use or exposure to any teratogens during pregnancy. Delivery was by cesarean section secondary to cephalopelvic disproportion, but the Apgar score was 8 at 1 minute and 9 at 5 minutes. As a newborn the patient was noted to have macrocephaly and to be large for gestational age. He did well in the newborn period and had no feeding problems. Subsequently, he had no significant medical illnesses, including no seizures, but at 1 year of age he was noted to be developmentally delayed. This delay continued, and he has been in special education classes throughout his schooling. Family history is negative for any relatives with disabilities.

On physical examination, the boy is at greater than the 90th percentile for height and weight. He exhibits mild prognathism with large ears. His fingers are hyperextensible. A complete physical examination reveals that his testicles appear large (6 cm), and his sexual maturity rating (ie, Tanner stage) is 3. The rest of the examination is normal.

Questions

1. What history is important to elicit in evaluating a child with dysmorphic features?
2. What are the possible causes of errors in morphogenesis?
3. What clues on physical examination can aid in establishing a specific diagnosis?
4. What laboratory tests can confirm a diagnosis?
5. When is it appropriate to obtain a genetics consultation or refer a patient for genetic counseling?
6. What are the benefits of establishing a specific diagnosis?

Evaluation for structural anomalies is an essential part of all pediatric examinations. Visible errors in morphogenesis are a source of potentially useful information in the evaluation of a patient with abnormal symptoms, such as seizures. Additionally, major malformations frequently require treatment, and the presence of 1 anomaly suggests that others may also exist.

The study of congenital defects was termed *dysmorphology* by David Smith, MD, in 1966. The anomalies fall into 2 categories: minor and major. Minor malformations are those of "no medical or cosmetic consequence to the patient." An example is a supernumerary nipple that appears as a hyperpigmented papule along the nipple line. Identification of minor malformations is important, because they may indicate the presence of a more generalized pattern of malformation. Major malformations are those that have "an adverse effect on either the function or social acceptability of the individual." Cleft lip and palate are major malformations that have functional as well as cosmetic relevance to the patient's health. Severe congenital malformations as defined by the Centers for Disease Control and Prevention are "defects that cause death, hospitalization or intellectual disability; necessitate significant surgical procedures; are disfiguring; or interfere with physical performance."

Epidemiology

Structural anomalies are common in the general population. Most are minor. In the first comprehensive analysis of minor structural anomalies, Marden in 1964 reported that 7% to 14% of newborns have at least 1 minor anomaly on surface examination. Other studies indicate that up to 40% of newborns have 1 anomaly. The presence of 3 or more minor malformations has predictive value in identifying a major malformation. Among newborns, 0.8% have 2 minor malformations, and 11% of these patients have a major malformation. Three or more minor malformations occur in 0.5% of newborns, and 90% of these patients have a major malformation. Data from the National Collaborative Perinatal Project revealed that 44.8% of these anomalies were craniofacial manifestations and 45.3% were skin abnormalities. Autopsies of expired fetuses show an increased incidence of minor and major malformations. Males are affected with minor malformations more often than females. Frequencies of minor

and major malformations vary along racial lines, depending on the specific malformations. For example, postaxial polydactyly occurs in 16 of 10,000 births among whites and in 140 of 10,000 births among blacks. Hemangiomas occur in 350 of 10,000 births among whites, whereas the frequency among blacks is 100 in 10,000 births.

Three percent of all pregnancies produce a child with a significant genetic disease or birth defect. These malformations account for a great proportion of morbidity and mortality in the pediatric population. Of all pediatric hospital admissions, 33% to 50% involve a child with a disease with a genetic component.

Clinical Presentation

With the advent of various prenatal tests and diagnostic modalities, detection of anomalies may occur during pregnancy. Abnormalities on routine prenatal screening raise the possibility of finding an anomaly in the newborn. For example, an elevated maternal α-fetoprotein may be indicative of a neural tube defect. Amniocentesis or chorionic villus biopsy may reveal abnormal chromosomes associated with malformations. Standard prenatal ultrasonography examinations can demonstrate structural defects in utero, which can be further delineated on specific fetal ultrasonography examinations. More recently, maternal plasma cell-free DNA has been used for noninvasive prenatal testing for trisomy syndromes.

Most structural anomalies develop during the first trimester of gestation and, if not detected prenatally, are noted in the delivery room or newborn nursery (see Chapter 25). Many major congenital defects are obvious on a thorough physical examination. Other major defects, such as a tracheoesophageal fistula, are not evident on clinical examination but become readily apparent as the neonate adapts to extrauterine life and experiences difficulties with feeding. Minor anomalies may be overlooked on initial newborn examination. If developmental disability manifests by age 6 months in an infant who exhibited minor anomalies as a newborn, however, the physician should thoroughly evaluate the infant for minor anomalies that may aid in identifying the cause of the condition.

Sometimes dysmorphic features are not present at birth but become apparent as the child grows and develops. Such features may be associated with dysplasias, that is, defects in cellular metabolism that manifest after birth (eg, skeletal dysplasia that becomes more apparent as the bones grow).

Pathophysiology

In terms of pathophysiology, structural defects can be separated into 4 different types of errors in morphogenesis: malformation, deformation, disruption, and dysplasia (Box 84.1). All these types of errors can result in a sequence of abnormalities.

Previously, the term "malformation" was used descriptively to denote an anomaly; however, it is also used to denote a specific pathogenic mechanism. A *malformation* is a permanent defect in a structure caused by an intrinsic abnormality in the development of that structure. An example of a malformation is an endocardial cushion defect in a patient with Down syndrome. Malformation syndromes frequently are caused by chromosomal abnormalities, single-gene disorders involving genes that program for structure, or environmental teratogens. Teratogens interfere with organ development during a critical period in embryogenesis, resulting in organ dysgenesis. Alcohol, certain drugs, x-ray irradiation, viral infections, and other environmental exposures can all be teratogens. More than 30 drugs have been proven to be teratogenic.

Box 84.1. Pathophysiology of Structural Defects

Malformation
- Chromosomal abnormality
- Single gene disorder

Deformation

Disruption
- Vascular compromise
- Viral infection
- Mechanical (eg, amniotic bands)
- Teratogens (eg, alcohol, drugs, irradiation)

Dysplasia
- Metabolic or structural protein disorder

Deformation results from exertion of mechanical pressure by external forces on the developing fetus. This mechanism involves no intrinsic defect of the fetus. Deformation associated with intrauterine forces can be caused by uterine constraint, an abnormally shaped uterus, or multiparous pregnancy. For example, flexible talipes equinovarus (ie, clubfoot) is a deformation caused by uterine constraint. Postnatal deformations can also occur, such as plagiocephaly caused by an infant sleeping on his or her back.

With *disruption*, an agent outside the fetus causes cell death, resulting in a permanent defect in fetal development. Disruptive events result in tissue destruction. Examples of disruptive events are tissue ischemia secondary to vascular compromise, viral infection at a critical gestational age (eg, Zika virus infection), and mechanical interference with normal development. An amniotic band is an example of a mechanical disruptive agent; an amniotic band can cause amputation of a developing limb by restricting blood flow to it.

Dysplasias, which often are caused by a single-gene defect, are structural abnormalities that occur as the result of abnormal cellular metabolism and/or organization. Dysplasia can be apparent in utero (and therefore at birth [eg, skeletal dysplasia]) or later. Mucopolysaccharidosis type I causes dysplasias that manifest postnatally secondary to absence of the lysosomal hydrolase, α-L-iduronidase. Glycosaminoglycans accumulate in parenchymal and mesenchymal tissues after birth. Affected children develop coarse facies, an enlarged tongue, misshapen bones, and hepatosplenomegaly, among other features.

Differential Diagnosis

In generating an appropriate differential diagnosis for a child with dysmorphism, it is essential to identify all minor and major malformations. The differential diagnosis varies depending on the specific findings. A thorough patient history and physical examination are necessary to aid in establishing the list of conditions to consider. For the patient with multiple anomalies, identifying the most specific and rarest anomaly can direct the health professional to a narrower list of possible diagnoses. For example, nail hypoplasia, which occurs in fetal hydantoin syndrome, is much rarer than congenital cardiac disease, which occurs in multiple syndromes. The health professional should be familiar with the prominent features of the more common syndromes. Reference texts, such as *Smith's Recognizable Patterns of Human Malformation,* are helpful in establishing differential diagnosis lists and in finalizing diagnoses. In addition, several helpful websites are available, such as OMIM (Online Mendelian Inheritance in Man), PubMed, Google and Google Scholar, and others that were specifically developed for the delineation of syndromes and genetic disorders.

In evaluating a neonate or an infant with congenital anomalies, the physician should attempt to separate the findings into 1 of 5 categories: an isolated defect, a developmental field defect, a birth defect association, a sequence pattern, or a dysmorphic syndrome. The first step is to determine whether the anomaly is isolated. If so, does it represent a failure in development in 1 location, such as a cleft lip? Most *isolated anomalies* are believed to have a multifactorial inheritance, representing the interaction between multiple genes and unknown external influences. Typically, the risk of recurrence for isolated anomalies in future pregnancies is 2% to 5%.

A *developmental field defect* is a pattern of anomalies that occurs in structures that are in close physical proximity during embryologic development. The defects may involve a limited region and may be the result of a single disruptive event (eg, vascular compromise); thus, the risk for recurrence in subsequent pregnancies is low. One example of such a defect is hemifacial microsomia (ie, oculoauriculovertebral defect), which is believed to be caused by disruption of vascular flow to the first and second branchial arches. The disruption results in hypoplasia of the malar, maxillary, and mandibular region on 1 side with associated microtia and vertebral defects.

Birth defect associations are those in which a combination of anomalies occurs together frequently but the pattern does not fit a known field defect or syndrome. Etiologies of association defects may be unknown, and risk for recurrence in subsequent pregnancies may be low. One of the more common associations is the VACTERL association (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, renal defects, and limb defects).

A *sequence pattern* of anomalies occurs when 1 malformation results in multiple dysmorphic features. For example, oligohydramnios sequence with Potter facies results from renal agenesis. The renal malformation causes oligohydramnios, which in turn causes fetal joint contractures, pulmonary hypoplasia, and a flattened face.

A *syndrome* is a constellation of anomalies that are pathogenetically related. Chromosomal abnormalities (eg, trisomy 21), single-gene disorders, and teratogens can produce syndromes. Alcohol is the most common teratogen to which fetuses may be exposed. Alcohol exposure in utero causes growth failure, intellectual disability, microcephaly, a short nose, and small distal phalanges (see Chapter 147). Children with intellectual disability and structural anomalies are at increased risk for having a syndrome and should undergo genetic or genomic testing.

Evaluation

History

A complete history is essential (Box 84.2). The history begins prenatally with information from the mother on duration of pregnancy, possible teratogen exposure, fetal activity, diagnostic test results, and any complications of pregnancy. The delivery history should include information on the type of delivery, newborn presentation, and size at birth, including growth percentiles. Neonatal adaptation and feeding patterns are important parameters to assess. The subsequent medical history also should be obtained. The identification of associated intellectual disability is an essential part of the history.

A thorough family history is equally important, including a pedigree. Specifically, the family should be questioned about parental ages, information pertaining to possible consanguinity, and any history of fetal loss or early infant deaths. Family histories of birth defects or disabilities should be documented.

Physical Examination

The physical examination should be extremely thorough, and all morphologic findings should be noted. As previously mentioned, the craniofacial area and skin are common sites for anomalies, but all organ systems should be extensively evaluated. Even minor anomalies, such as a supernumerary nipple or clinodactyly, may have

Box 84.2. What to Ask

Child With Dysmorphism

- How long was the pregnancy?
- Did the mother take any medications, smoke cigarettes, or use alcohol or any illicit drug?
- What was the fetal activity?
- Were there any complications of pregnancy?
- What was the type of delivery and presentation of the baby?
- What was the newborn's size at birth?
- How did the newborn feed?
- What is the subsequent medical and developmental history?
- Are the parents related?
- What are the ages of the parents?
- Is there a history of fetal or infant deaths?
- Is there a history of birth defects in the family?
- Do any family members have disabilities?

significance. Objective measurements should be obtained when possible. Normal growth curves are available for evaluating measurements of the face (and other body parts), such as inner canthal distances, palpebral fissure lengths, and ear lengths. Unusual hair whorl patterns and dermatoglyphics (eg, appearance of the palmar creases) should be noted. Physical data, including height, weight, and head circumference, should be plotted and the growth percentiles checked. A complete ophthalmologic evaluation may be indicated to detect abnormalities such as cataracts or cherry-red spots.

Laboratory Tests

In assessing children who appear dysmorphic, the physical examination is the most important part of the evaluation. Findings on physical examination help guide selection of laboratory tests. Additional studies may then confirm a suspected diagnosis. Similarly, when prenatal screening detects an abnormality, specific prenatal tests may be used to assess the fetus for associated disorders.

Cytogenetic testing has been a major tool for evaluating children suspected of having a chromosome disorder, and it also has been used for children with malformations and intellectual disability. Chromosomal microarrays have largely replaced standard chromosomal analysis, because microarrays are better for detecting copy number variants, such as chromosome deletions or duplications. The older methods (eg, G-banded karyotyping, fluorescence in situ hybridization) are still used in certain situations, however, such as in distinguishing between trisomy 21 versus Down syndrome involving a translocation.

Whole-exome sequencing and gene sequencing panels have become important components of dysmorphology evaluations and are often performed as first-line testing. Whole-exome sequencing is a powerful tool for uncovering single-gene disorders and has also been used to detect Turner syndrome, which is a chromosomal disorder (45,X). Whole-genome sequencing is starting to be used clinically and offers greater detection ability compared with whole-exome sequencing, because sequences obtained are not limited to coding regions. Consultation with a medical geneticist is helpful in selecting the most appropriate tests for specific situations. Also, the possibility of detecting findings of unknown clinical significance needs to be addressed, before whole-exome or -genome sequencing is used.

Some syndromes can be detected by metabolic testing. For example, Smith-Lemli-Opitz syndrome is a malformation syndrome caused by a disorder in cholesterol metabolism. Plasma amino acids, urine organic acids, and a plasma acylcarnitine profile are examples of metabolic tests that are widely available. Many of the analytes on these tests are also included in state newborn screening protocols.

Imaging Studies

Imaging studies are extremely useful in deriving information on internal malformations. Radiographs, including skeletal surveys, may detect skeletal anomalies. Echocardiography, renal ultrasonography, computed tomography, and magnetic resonance imaging studies all can be used when appropriate. With the findings of anomalies and global developmental delay in a patient, the American Academy of Neurology recommends routine neuroimaging with magnetic resonance imaging.

Management

Children who present with dysmorphic features should be evaluated to determine a specific diagnosis, if possible. Obtaining a diagnosis is of vital importance for patient care and parental counseling. Knowing the diagnosis can direct testing for associated abnormalities. Treatment options may be available, and a prognosis can be established. Defining the developmental prognosis for children is essential for school planning. If intellectual disability is not associated with the diagnosis, such as with cleft lip and palate, the primary care physician should reassure the parent or parents of that. Parents also need to know the risk for recurrence for future children. Occasionally, further testing of parents may be needed to accurately determine recurrence risks. For example, the risk for a chromosomal abnormality in a subsequent child is increased if 1 of the parents is a carrier of a balanced chromosome translocation.

Health supervision strategies have been established for specific disorders. For instance, published guidelines recommend hearing, ophthalmologic, and thyroid screening, among other tests, for patients with Down syndrome. The field of genetic diseases advances rapidly, and it is often difficult for the primary care physician to stay informed. A geneticist can provide guidance on up-to-date recommendations.

Parents may wish to be referred to support groups for specific conditions. Such groups can be invaluable in helping parents understand their child's condition and adjust to the disorder. They can also advise parents about community and educational resources and help parents advocate for their child's unique needs.

Referral to a genetic counselor can provide parents with information about prenatal testing, recurrence risk, and alternatives for addressing recurrence risks. Counseling is extremely useful in helping parents understand the mode of inheritance.

Prognosis

As with management, defining an accurate prognosis for each patient depends on recognition of the specific condition. Some conditions, such as trisomy 13, are lethal, whereas other conditions allow for a normal life span.

Malformations are permanent defects that generally have a recurrence risk. They may be correctable with surgery or treatment, but frequently there will be residual disability.

Deformations usually resolve with treatment and have no recurrence risk, except in cases in which the deformation is secondary to a uterine abnormality (eg, bicornuate uterus).

A disruption may be treated with surgery or therapy to improve function; however, as with malformations, residual disability frequently remains. For disruption resulting from tissue ischemia or a mechanical agent, no recurrence risk is expected. For disruption resulting from a teratogen, however, the disruption may recur with exposure to the same teratogen.

Dysplasias tend to persist or worsen with time, unless a specific treatment is available. Generally, a risk for recurrence exists. Specific treatments are available for only a limited number of diseases, although progress is being made, such as in the area of enzyme replacement therapy.

CASE RESOLUTION

The child has features that are suggestive of a dysmorphic syndrome. The most specific finding on examination is macro-orchidism. This finding is associated with fragile X syndrome. The patient is referred to a genetic specialist for diagnosis and counseling. Specific DNA-based molecular analysis is performed and is positive for a fragile site on the X chromosome at Xq27.3.

The parents are counseled that this condition has an X-linked inheritance mode. The child will have a normal life span but may need early intervention services as well as a special education program later in his schooling. He may not be capable of independent living as an adult. The primary care physician will be notified of the diagnosis and coordinate further services. The parents are encouraged to attend a parents' support group and consult with experts to learn how their child's full potential may be realized.

CHAPTER 85

Craniofacial Anomalies

Carol D. Berkowitz, MD, FAAP

CASE STUDY

A boy weighing 3,500 g (7.7 lb) is born by normal spontaneous vaginal delivery to a 28-year-old gravida 3, para 3 mother after an uncomplicated term gestation. Apgar scores are 9 and 10. On physical examination, the newborn is well but has an incomplete, left-sided unilateral cleft of the lip and palate.

No other family member has such a deformity, but the mother and father are distantly related. The mother had prenatal care. During the pregnancy she had no illnesses, took vitamins but no other medications, and did not smoke, drink alcohol, or use illicit drugs.

The mother is planning to feed the newborn with formula and wonders if she should do anything special. She is also wondering if her son's lip deformity can be repaired before she takes him home from the hospital. Except for the cleft, the physical examination is normal.

Questions

1. What craniofacial anomalies are common in infants and children?
2. What are feeding considerations in the newborn with cleft lip or palate?
3. What is the appropriate timing of surgery for the more common craniofacial anomalies?
4. What are the major medical problems that children with craniofacial anomalies, particularly clefts of the lip or palate, experience?
5. What is positional plagiocephaly? How is its prevalence related to supine sleeping?

A neonate may be born with a readily apparent craniofacial anomaly, such as cleft lip, cleft palate, or microtia, or anomaly may emerge as an infant ages. The latter includes conditions that may be genetically based but do not manifest until later, such as facial asymmetry (ie, hemifacial microsomia) and premature closure of 1 or more sutures. Alternatively, these anomalies may be environmentally influenced, such as positional or deformational plagiocephaly. *Deformational plagiocephaly* is defined as a condition in which an infant's head and sometimes face are misshapen as a result of prenatal and, in recent years, postnatal external molding, which occur on the infant's malleable cranium.

Epidemiology

The overall prevalence of cleft lip with or without cleft palate is 1 in 1,000 and that of isolated cleft palate is 1 in 2,500 live births. Cleft lip with or without cleft palate is the second most common birth defect in the United States, after Down syndrome, with nearly 7,000 infants with clefts born annually. Racial, ethnic, and geographic variation exists in the prevalence of clefts. For example, the prevalence of clefts in parts of the Philippines is 1 in 200. Similarly, cleft lip with or without cleft palate is most common among Asians and Native Americans (1 in 500) and least common among blacks (1 in 22,500). The sex distribution varies with the type of cleft. Isolated clefts of the palate occur twice as frequently in girls, but clefts of the lip with or without clefts of the palate appear twice as often in boys.

The type of cleft, the sex of the child, and whether a parent or sibling(s) is similarly affected influence the risk for recurrence of clefts in subsequent offspring. Generally, the risk for recurrence of clefts is 4% to 7% for cleft lip with or without cleft palate and 3% for isolated cleft palate.

Clefts may occur as isolated findings or as part of syndromes or sequences. In Van der Woude syndrome, clefts of the lip or palate are associated with lip pits. This condition is inherited in an autosomal-dominant manner and is the most common cause of syndromic cleft lip. Currently, more than 500 Mendelian syndromes are associated with clefts, with approximately 30% of newborns with clefts having other congenital anomalies associated with specific syndromes. Pierre Robin sequence includes micrognathia and glossoptosis (ie, retrodeviated tongue) and a distinct U-shaped cleft. One theory relates the sequence to failure of the fetal neck to extend normally, resulting in compression of the mandible on the chest, thereby restricting its growth and causing malposition of the tongue, thus preventing closure of the palate.

True craniosynostosis occurs in approximately 1 in 2,000 to 3,000 live births, and this prevalence is the same in all ethnic groups. Sex variation exists among the different types of craniosynostosis. Deformational plagiocephaly is reported in 25% to 45% of infants. The term *plagiocephaly* comes from the Greek *plagio,* meaning oblique, twisted, or slanted, and *kephale* for head. Firstborn and male sex increase the risk of deformational plagiocephaly at birth. Most cases of deformational plagiocephaly resolve over time without specific medical intervention.

Microtia is less common and occurs in 1 in 6,000 to 8,000 live births. Other ear malformations, such as auricular dystopia (ie, ear located on the check) or total atresia of the external area, are less

common and can be associated with other syndromes. Other ear anomalies involve protuberant ears (sometimes referred to as "outstanding ears") or pinna with folds or flattened components (eg, antihelix).

Clinical Presentation

Most craniofacial anomalies are readily apparent (Box 85.1). Some anomalies, such as cleft lips or microtia, are noted immediately in the delivery room. Other anomalies, such as craniosynostosis, develop over time. Because the onset of craniosynostosis may be gradual, the parent(s)/guardian(s) may not recognize the condition, which usually appears as asymmetry of the face or skull. Deformational plagiocephaly also evolves over time and is more often noted by the physician rather than the parent or guardian.

The child with craniofacial anomaly may also have medical problems that occur secondary to the deformity. The newborn or infant with cleft palate may present with failure to thrive because of difficulty feeding. The older infant or the child may experience recurrent otitis media, speech impairment, or psychosocial stress. Nasal regurgitation of liquids may occur in the child with obvious palatal cleft or more subtle deformity, such as submucosal cleft of the soft palate.

Pathophysiology

Clefts of the lip and palate (Figure 85.1) are believed to develop as a result of an interruption in the merging of the middle and lateral portions of the face during the sixth to seventh week of gestation. The palate normally closes with an anterior to posterior progression. Any interference with this progression (eg, tumor or encephalocele in the roof of the mouth) leads to a cleft. A vascular disruption may also result in ischemia in the involved areas. Although the etiology of clefts is not fully determined, it is felt to be multifactorial. Multiple genetic risk loci have been associated with nonsyndromic cleft lip with or without cleft palate. The interferon regulatory factor 6 (*IRF6)* gene is consistently associated with nonsyndromic cleft lip and palate. As with other clinical conditions, genetic predisposition interacts with environmental factors to increase the risk of the emergence of a disorder. A newborn with the A2 form of the transforming growth factor-α (*TGFA*) gene is 8 times more likely to have a facial cleft if the mother smokes. Other environmental teratogens associated with clefts include hydantoin, alcohol, warfarin, trimethadione, thalidomide, aminopterin, and topiramate.

Box 85.1. Diagnosis of Craniofacial Anomalies

- Cleft of the lip or palate
- Small, atretic, or malformed ear
- Asymmetry of the face
- Misshapen skull
- Recurrent otitis media
- Speech impairment
- Nasal regurgitation of liquids or foods

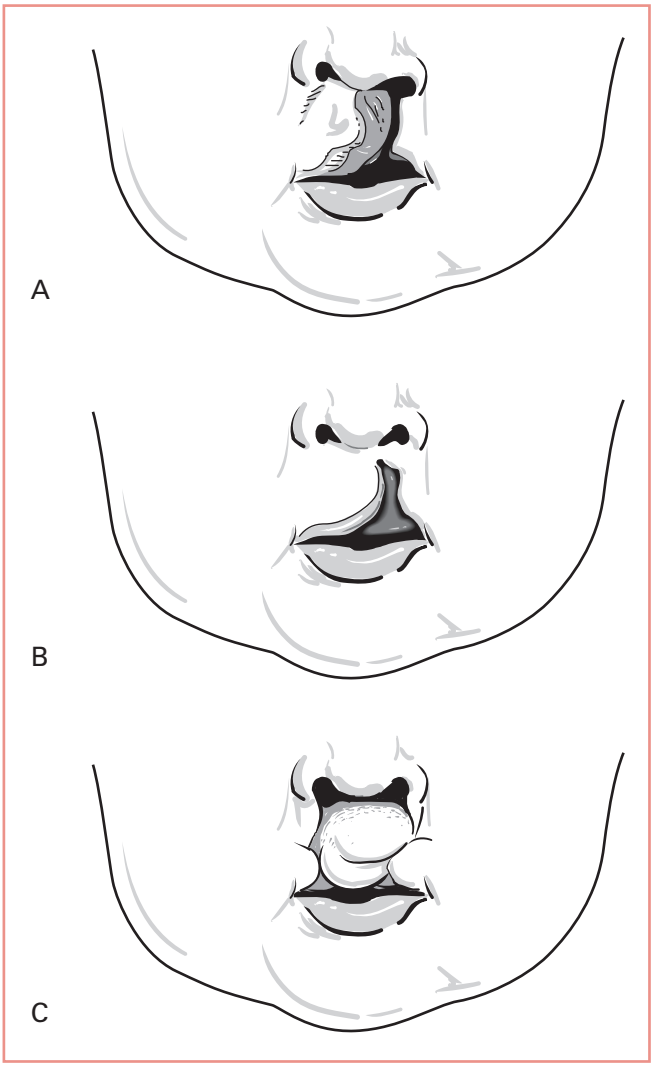

Figure 85.1. Cleft lips. A, Unilateral, complete cleft lip. B, Unilateral, incomplete cleft lip. C, Bilateral, complete cleft lip.

The presence of a cleft palate affects normal oropharyngeal functioning, including sucking and speech. A child may exhibit hypernasal speech caused by the escape of air through the nose and have articulation problems. Recurrent otitis media seems to be related to dysfunction of the eustachian tube.

Facial asymmetry may be the result of hemifacial microsomia either in isolation or as part of a syndrome. Facial asymmetry that is only noted with crying is referred to as "asymmetric crying facies." The condition is present at birth and caused by congenital hypoplasia of the depressor anguli oris muscle (CHDAOM). Although the disorder may occur in isolation, it may also occur in association with other anomalies, including congenital heart disease (40%–50%), head and neck anomalies (45%–50%), skeletal defects (22%), and genitourinary anomalies. Syndromes with which CHDAOM has been associated include CATCH 22, Cayler cardiofacial, VACTERL, and DiGeorge. As with other craniofacial anomalies, the presence of CHDAOM indicates the need for a thorough physical examination for other findings.

Microtia, a small atretic pinna of the ear, results from failure of development of the pinna and portions of the external auditory canal.

It is most likely caused by a vascular accident during the 12th week of gestation. Similar anomalies have been created in laboratory animals by ligature of the stapedial artery. Microtia is considered in the spectrum of branchial arch defects.

Craniosynostosis refers to the premature closure of the sutures, which should remain open until 2 to 3 years of age. The newborn skull consists of membranous bones that meet at the suture lines. The newborn skull is therefore moldable, can change during the birthing process, and can expand in response to growth of the brain. Premature closure of the sutures is a pathologic process. What initiates this pathologic ossification is unclear. Some evidence exists to suggest that skull compression, such as that which occurs in utero with breech presentation or twins, contributes to the process. The presence of other associated anomalies, such as syndactyly, is suspicious for embryologic disturbances in fibrocartilaginous development. Abnormalities in 1 region of chromosome 10 are implicated in syndromic synostosis. Genes associated with fibroblast growth factor receptor have been implicated in some genetic syndromes with craniosynostosis. Any or all of the sutures can be affected, and the closure may result in asymmetry of the skull or microcephaly. Single suture synostosis is classified as simple; multiple synostosis is classified as compound. When closure is related to pathology at the suture, the condition is primary. In the presence of underlying brain pathology, the disorder is secondary. Premature closure of all sutures is often associated with diseases of the central nervous system, with failure of the brain to grow.

Microcephaly may result from premature closure of some or all of the sutures as a primary event or from impairment of the brain and its growth related to some other problem, such as hypoxic encephalopathy or congenital infection. Other disorders involving head size include *macrocephaly*, in which the head circumference is greater than the 97th percentile. Macrocephaly has numerous causes, including hydrocephalus, characterized by enlargement of the ventricular system, and macrencephaly, the latter of which may be caused by enlargement of the brain from anatomic or metabolic conditions, including mucopolysaccharidoses. The child with a large head and who is neurologically normal has *benign* or *idiopathic macrencephaly*. Measuring parental head size is frequently a clue to the correct diagnosis.

Fusion of individual sutures prevents growth of the skull perpendicular to the suture, and skull expansion proceeds in an axis parallel to that of the suture (Figure 85.2). If the sagittal suture fuses prematurely, the head is long and narrow, a condition referred to as *scaphocephaly* ("boat head"). This is the most common type of craniosynostosis, occurring in approximately 54% to 58% of cases of craniosynostosis. If the coronal sutures fuse too soon, the head is flattened; this condition is called *brachycephaly* and occurs in 18% to 29% of cases of craniosynostosis. The prevalence is 1 in 10,000 live births. Unilateral fusion of a coronal suture produces facial asymmetry and a characteristic appearance of the orbit on the affected side, called a *harlequin deformity*, noted on facial radiography. Premature closure of the metopic suture results in the triangular-shaped head characteristic of *trigonocephaly*, reported in 4% to 10% of case of craniosynostosis. Familial cases have been reported, as well as abnormalities of chromosomes 3, 9, and 11. The *FGFR3*P250R mutation has been reported in patients with nonsyndromic craniosynostosis, particularly with coronal or multisuture synostoses.

Premature closure of the lambdoid sutures results in *plagiocephaly* (ie, oblique head) (Figure 85.3). Plagiocephaly may also result from malpositioning in utero or after birth, a condition referred to as nonsynostotic, deformational, or positional plagiocephaly. The skull has been likened to a parallelogram in appearance in cases that also include involvement of the facial structures. Torticollis, which often is attributed to injury to the sternocleidomastoid muscle at birth (see Chapter 119) and abnormal positioning after birth, contributes to plagiocephaly. Plagiocephaly-torticollis sequence occurs in 1 in 300 live births. Malar and contralateral occipital flattening related to preferential positioning by infants are characteristically seen in affected infants. Some affected babies also have hip dislocation or positional talipes (ie, clubfoot) from in utero constraint (see Chapter 113).

Since 1994 with the advent of the Back to Sleep campaign (currently called the Safe to Sleep campaign), the prevalence of positional plagiocephaly has increased significantly, with estimates of between 25% and 45% of infants affected. Most cases are mild and correct over time. Positional plagiocephaly may encompass positional *occipital plagiocephaly* (ie, unilateral flattening of parieto-occipital region, compensatory anterior shift of the ipsilateral ear, bulging of the ipsilateral forehead) and *positional brachycephaly* (ie, symmetric flattening of the occiput, foreshortening of the anterior dimension of the skull, compensatory biparietal widening) or any combination of these 2 deformities. An important strategy to help minimize the development of positional plagiocephaly is to recommend "tummy time," placing an infant in a prone position while awake (eg, with each diaper change) to help develop the muscles of the neck.

Differential Diagnosis

Typically, the differential diagnosis of clefts of the lip and palate presents few problems. Submucosal clefts may be more difficult to diagnose, however. The child with such a cleft may present with recurrent otitis media, hypernasal speech, or nasal regurgitation of liquids. Physical examination may reveal a bifid uvula and occasionally a notch at the junction of the hard and soft palates.

Determining whether any physical finding represents an isolated anomaly or is part of a genetic syndrome may be challenging. Any associated anomalies (eg, syndactyly, atrial septal defect) suggest the possibility of a genetic problem (Boxes 85.2 and 85.3).

Microtia does not present a diagnostic dilemma. The anomaly usually appears sporadically as an isolated condition, although, like a cleft, it may be part of some other syndrome. Microtia is associated with midfacial hypoplasia and antimongoloid slant to the eyes in Treacher Collins syndrome. Microtia may also occur in oculoauriculovertebral dysplasia (ie, Goldenhar syndrome), which is characterized by several associated findings, including hemifacial microsomia (ie, 1 side of the face smaller than the other), epibulbar dermoids, hemivertebrae, microphthalmos, and renal and cardiac anomalies.

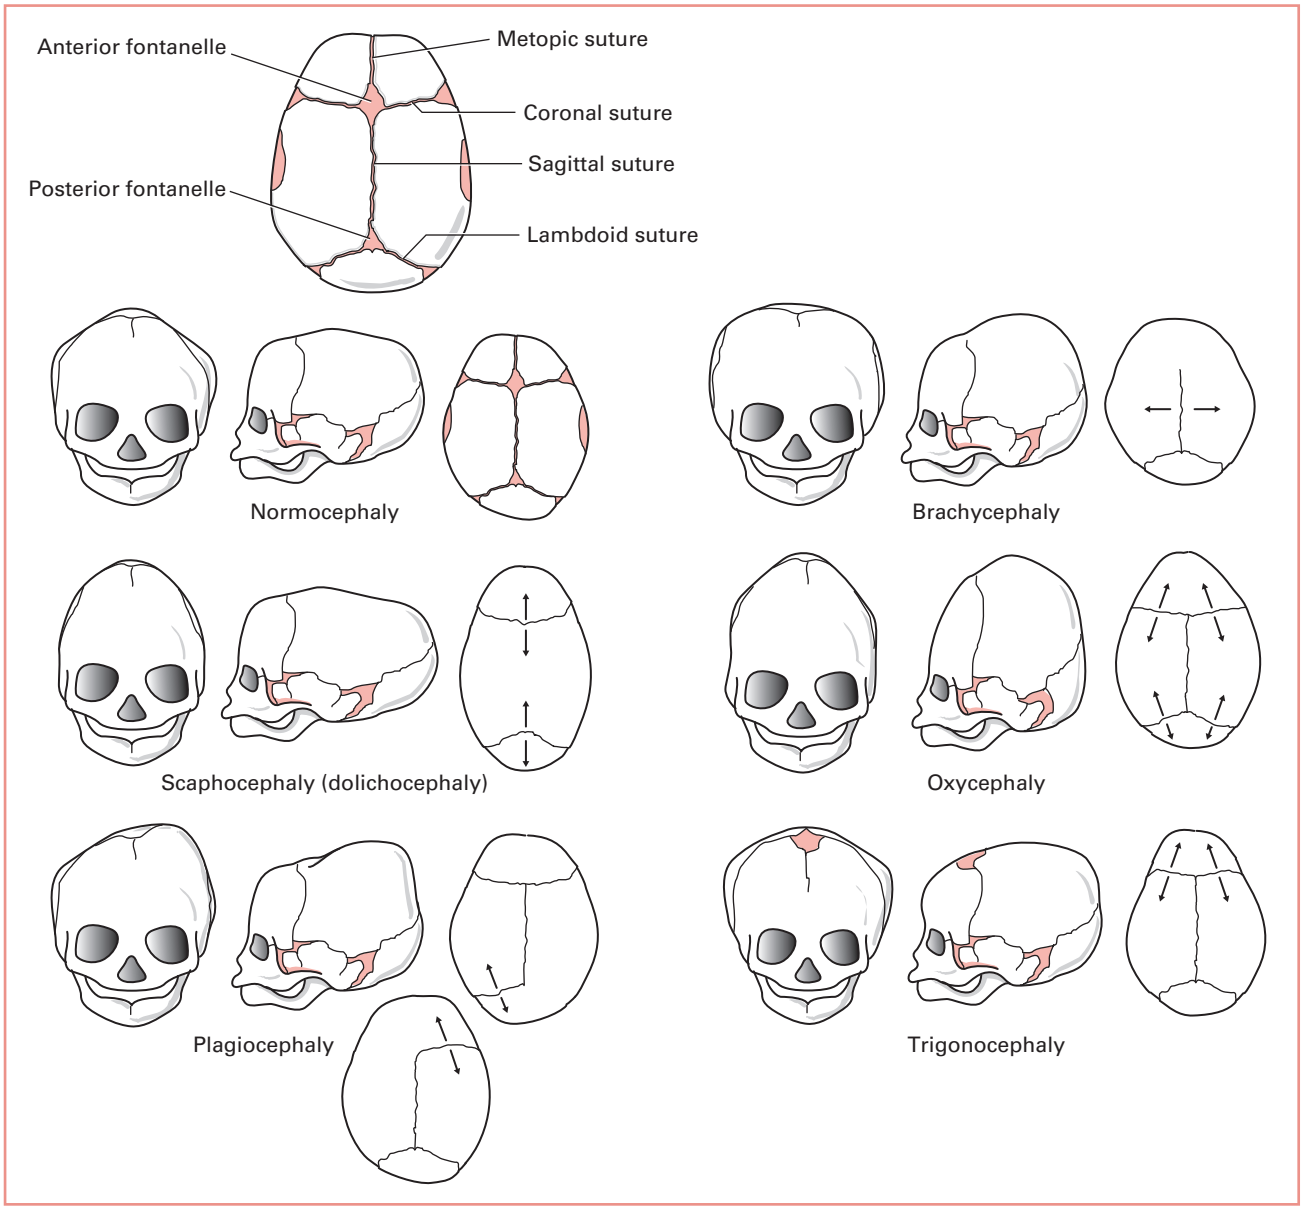

Figure 85.2. Changes in the shape of the skull when sutures fuse prematurely. Growth occurs parallel to the fused suture.

Craniosynostosis may also be an isolated finding or associated with a condition such as Apert syndrome, in which clefts of the palate are also seen (Box 85.4). A careful neurodevelopmental assessment helps determine whether microcephaly is related to an underlying neurodevelopmental disorder. Plagiocephaly may present a diagnostic dilemma: Is the condition related to unilateral craniosynostosis, torticollis, or supine sleeping? A careful assessment of the neck for masses or mobility helps determine the role of the neck musculature in cranial flattening and defines the management approach (eg, neck exercises).

Evaluation

Care must be taken to assess the child and determine if the anomaly is an isolated finding or a component of a syndrome. This information is important in terms of patient care and genetic counseling for the parent(s) on the likelihood of having future offspring with similar anomalies.

History

A medical, family, and psychosocial history should be obtained (Box 85.5). Whether the condition appeared at birth or some time later is particularly significant in lesions affecting the skull, such as craniosynostosis. Maternal use of certain medications, such as diazepam, phenytoin, and isotretinoin (eg, Accutane, Claravis), and alcohol is associated with an increased incidence of clefts of the lip and palate. Maternal smoking also increases the risk of clefting, especially in a genetically vulnerable population. Maternal smoking and high altitude are associated with an increased occurrence of craniosynostosis.

Physical Examination

Height, weight, and head circumference should be measured and plotted at each visit. Head circumference is especially important in the child with craniosynostosis or facial asymmetry. The skull should be palpated to detect perisutural ridging. Inner canthal distance

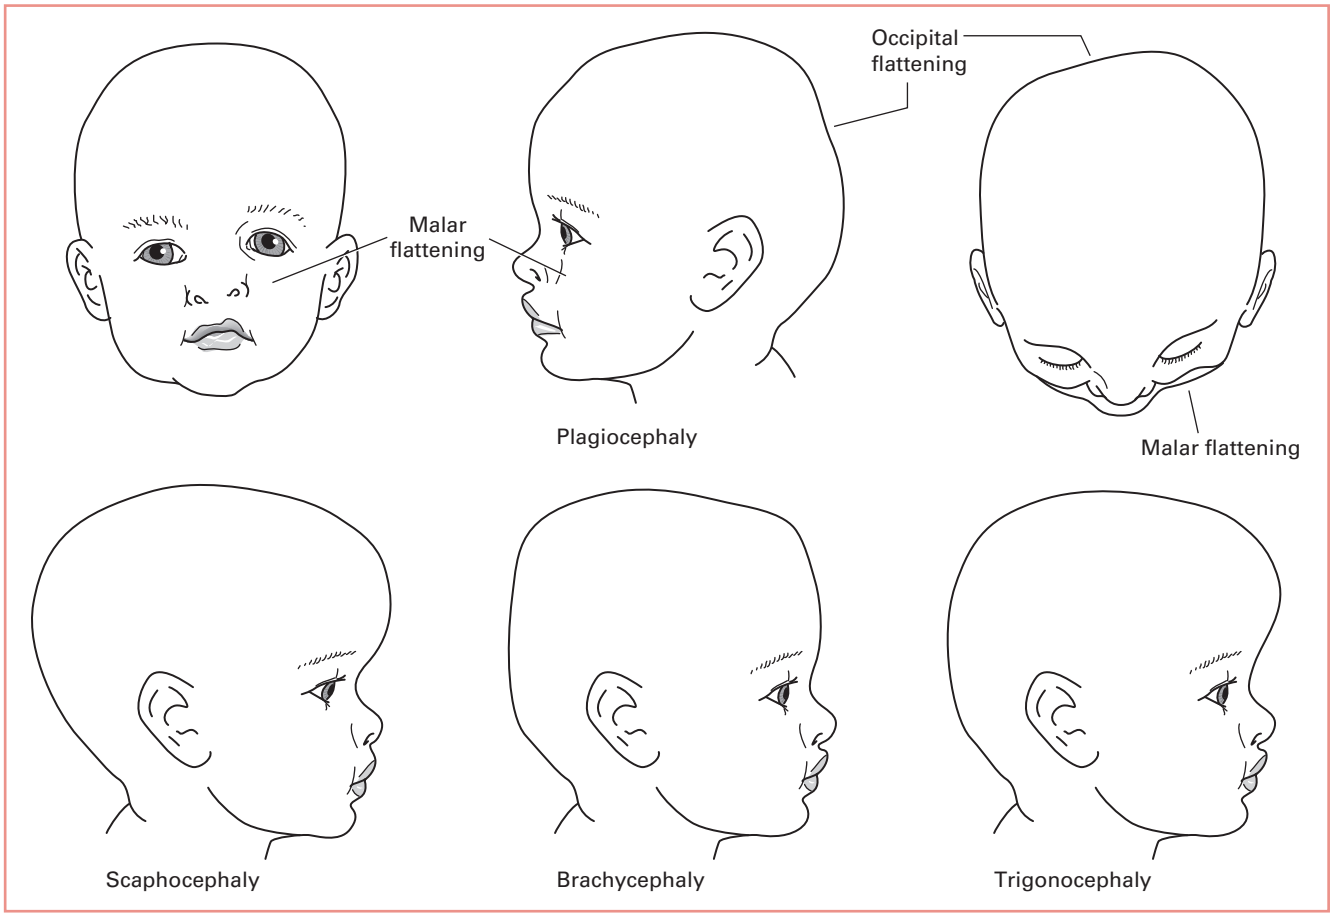

Figure 85.3. **Top row, Classic appearance of an infant with facial asymmetry secondary to plagiocephaly. Bottom row, Classic appearance of infants with craniosynostosis.**

may reveal hypotelorism, a finding that occurs in trigonocephaly. The child's face should be assessed when neutral and when crying or smiling to evaluate the status of the depressor anguli oris muscle. The neck should be palpated for masses and neck range of motion assessed. The growth of the child with craniofacial anomaly must be carefully monitored. Problems with adequate weight gain are frequently experienced by newborns and infants with clefts.

Box 85.2. Genetic Syndromes Associated With Clefts

- Apert
- Ectrodactyly–ectodermal dysplasia–clefting
- Goldenhar (ie, oculoauriculovertebral dysplasia)
- Meckel
- Opitz
- Oral-facial-digital, type I
- Popliteal web
- Stickler (ie, hereditary progressive arthro-ophthalmopathy)
- Treacher Collins
- Van der Woude

Box 85.3. Anomalies Associated With Cleft Lips and Palates

- Anencephaly
- Aniridia
- Ankyloblepharon filiforme adnatum
- Aplasia of trochlea
- Cleft larynx
- Congenital heart disease
- Congenital neuroblastoma
- Congenital oral teratoma
- Foot deformities
- Forearm bone aplasia
- Laryngeal web
- Lateral proboscis
- Nasal glioma or encephalocele
- Oral duplication
- Persistent oropharyngeal membrane
- Polydactyly
- Sacral agenesis
- Spina bifida
- Thoracopagus (ie, conjoined twins)

Box 85.4. Genetic Disorders With Craniosynostosis

- Apert syndrome
- Crouzon syndrome
- Jackson syndrome
- Pfeiffer syndrome

Box 85.5. What to Ask

Craniofacial Anomalies

- What was the birth like?
- Was the delivery vaginal or by cesarean section?
- Were forceps used during the delivery?
- Was the fetus in an abnormal position (eg, breech) in utero?
- What is the child's usual sleeping position?
- Have the findings been present since birth, or did they appear later?
- Has the child experienced other symptoms, such as recurrent ear infections or speech difficulties?
- Does the child have any family history of craniofacial anomalies?
- Does the mother have a history of illness during pregnancy?
- Was the mother exposed to any medications, particularly teratogenic agents, during pregnancy?
- Did the mother use alcohol during pregnancy?
- Did the mother smoke during pregnancy?
- Is the child experiencing difficulties in school (eg, teasing)?
- How is the child performing in school?
- Is development progressing normally? What are the child's milestones?
- Is the child's speech understandable?
- Does the child have any trouble with eating or drinking? Are fluids expelled through the child's nose with swallowing?

The physical examination should focus on defining the extent of the anomaly and determining if associated abnormalities are present. Such abnormalities may involve the face or other parts of the body, including the skeleton. The pharynx should be carefully examined for mobility of the palate. Although some children with nasal regurgitation have a structural deformity, such as a submucosal cleft, others, including infants with DiGeorge syndrome (ie, 22q11 deletion syndrome), have functional impairment with decreased palatal mobility. In the child with microtia, the position of the ear should be noted. When the ear is displaced to the cheek, the condition is called *auricular dystopia.* Cardiac murmur may be noted in the child with cleft, and the murmur should be carefully evaluated.

The child with cleft should be carefully assessed for the presence of otitis media at each visit. Periodic hearing assessments should be carried out in the child with cleft or microtia. Speech and development should also be evaluated.

Laboratory Tests

Routine laboratory tests are not indicated in most children with craniofacial anomalies. Genetic studies are indicated if a genetic disorder is suspected (see Chapter 20). Referral to a geneticist is warranted to ensure testing for recently identified gene associated with craniofacial conditions and for genetic counseling with the parent or parents.

Imaging Studies

Radiographs and imaging studies may be indicated in children with facial asymmetry, microcephaly and macrocephaly, and craniosynostosis. Three-dimensional computed tomography of the skull is particularly helpful in defining which, if any, sutures are fused but is not warranted in the child with suspected positional plagiocephaly. Such studies are helpful in differentiating craniosynostosis and deformational disorders that will resolve on their own. Renal ultrasonography may be indicated in the child with microtia or other ear anomaly because of the association between ear and renal anomalies. Renal ultrasonography is usually normal in the child with isolated microtia but is abnormal in approximately 30% of children with auricular as well as other congenital anomalies, particularly when associated with certain syndromes.

Management

The management of the child with craniofacial anomaly usually requires the expertise of a multidisciplinary team, including a pediatrician, plastic surgeon, otolaryngologist, speech pathologist, social worker, psychologist, orthodontist, and prosthodontist. The primary care physician who is not part of the team can receive information about appropriate patient care and follow-up. It is important for the primary care physician to be familiar with the appropriate nomenclature to be able to communicate with consultants. In brief, clefts of the lip are unilateral or bilateral and complete or incomplete. A complete cleft extends into the nares (Figure 85.1). Clefts of the palate may involve the entire palate or be confined to the secondary or soft palate.

Routine well-child care, including monitoring of growth and administration of immunizations, is most important in the treatment of the child with craniofacial anomaly. Some newborns and infants with clefts are slow feeders. Mothers should be told that although breastfeeding can be carried out, it may present unique challenges; however, the compliancy of the breast tissue creates a natural seal for the lip and palate. If difficulties are encountered, consultation with a lactation specialist may be especially helpful (see Chapter 29). Some formula-fed newborns and infants require the use of special adaptive nipples or feeders. A specific cleft palate feeder, which consists of a plastic bottle that allows for compression of the unit during feeding, is available. A soft nipple typically used by a preterm neonate can also be used. Long nipples, such as lamb's nipples, which are used to feed baby lambs, are not routinely recommended because they cause newborns and infants to gag. The newborn or infant who gains weight slowly may need to be given concentrated formula (see Chapter 146).

Hearing and speech should be monitored. Chronic prophylactic antibiotics or the insertion of pressure equalization tubes may be necessary to manage recurrent otitis media (see Chapter 87). Speech

problems require the expertise of a speech pathologist and placement of the child in speech therapy in the community or school.

Surgical correction is indicated for many anomalies. Clefts usually are repaired as staged procedures during the first 2 years after birth. Repair of the cleft lip, the first procedure, is traditionally scheduled when an infant weighs 10 lb and is 10 weeks of age and the hemoglobin is 10 (ie, rule of 10s). Infants, particularly those with widely separated complete bilateral clefts, may require taping or a prosthetic device to bring tissues in close proximity before surgery is attempted. Appropriate weight gain is therefore critical to ensure timely surgery. If skilled anesthesiologists and nurses are available, cleft lip repair can be carried out within the first 2 weeks after birth. Early repair is recommended at some centers. Repair of the cleft palate, the second procedure, is usually undertaken when the child is between 12 and 18 months of age. Better speech develops with earlier palatal repair. Surgical correction of clefts does not alter a child's propensity to otitis media, although the incidence of otitis media appears to have decreased among children with clefts following the use of conjugated pneumococcal vaccine. The incidence of otitis media decreases as children age, however. Refinement of the cosmetic results, including rhinoplasty, occurs throughout childhood. Orthodontia is frequently a key component to achieve a cosmetically acceptable result and appropriate occlusion of the dentition for speech and chewing. Approximately 10% to 20% of children will develop velopharyngeal insufficiency after repair of a cleft palate. In these cases, the posterior soft palate fails to make a tight seal with the pharynx. A child may experience nasal regurgitation of food or hypernasal speech. Surgical correction of velopharyngeal insufficiency involves lengthening the shortened palate. Additional surgery may also be required for the child with significant jaw deformity. These may include the placement of bone grafts or maxillary advancement.

The child with isolated unilateral microtia often hears, and surgery is recommended to restore a normal anatomic appearance, even if hearing in the affected ear is not improved. Surgical correction of microtia usually is initiated when the child is 5 years of age, before the child starts school. At this time, the ear has achieved 90% of its growth, and the child is spared the potential embarrassment of the deformity in the school setting. Surgical reconstruction can involve the implantation of the child's costal cartilage or a porous polyethylene framework shaped like the pinnae. In either case, several surgical procedures usually are necessary. For the child with other facial anomalies as well, more extensive reconstructive surgery is indicated. The infant with "outstanding ears" may benefit from taping the ears back to the mastoid area early on while the ear cartilage is soft and malleable. Other ear anomalies may be amenable to molds that reshape flattened or folded areas.

Craniosynostosis can be corrected surgically, and such correction is best carried out before 1 year of age. Endoscopic craniosynostosis repair (ie, endoscopic-assisted strip craniectomy) is minimally invasive and requires shorter surgical time (average time, <1 hour) and a reduced length of hospital stay. Discharge can be as early as the first postoperative day. It is the preferred approach in many centers. The age of the infant and the site of the synostosis influence the complexity of the surgical procedure, although a move is afoot to perform endoscopic surgery in infants younger than 16 weeks. Endoscopic strip craniectomy is usually followed by the use of a custom-made molding helmet for up to 7 months. A controversy about whether neurodevelopmental problems are related to craniosynostosis or whether they represent a preexisting condition has arisen. In the developmentally normal child with evidence of closure of all sutures, surgical repair is believed to be warranted. In other cases, the procedure is thought to be reconstructive because it normalizes the appearance of the child with a deformation.

In the newborn or infant with plagiocephaly, when the deformation is believed to be related to torticollis, passive stretching of the neck 5 to 6 times a day (with each diaper change) is used to manage the condition. Additionally, it is recommended that bright objects, such as mobiles, be placed over the child's crib to encourage head turning. Changing the crib position or the position of the newborn or infant in the crib may also encourage movement of the head. Studies have shown that 90% of newborns and infants with congenital torticollis improve with manual stretching. The infant who does not improve with stretching, who has a developmental delay in which the infant does not develop normal neck muscle strength or tone, or who has a deformity that is still present at 6 months of age may benefit from the use of a specially designed helmet or band, referred to as a *dynamic orthotic cranioplasty device,* that reshapes the skull. The device is not used before 6 months of age and generally is worn for a minimum of 4 months.

In an effort to reverse the trend of increasing positional plagiocephaly related to supine sleeping, the American Academy of Pediatrics has recommended that parents and guardians rotate their infant's position when they are awake and allow for tummy time, which is time when the infant is placed prone, sometimes with a rolled receiving blanket under the upper chest. Tummy time can be recommended with each diaper change. This promotes the development of the neck musculature and head control. Most positional plagiocephaly secondary to supine sleeping resolves over time as the infant develops head control and spends less time in a supine position. In 2016 the Congress of Neurological Surgeons released guidelines about the management of positional plagiocephaly that were later endorsed by the American Association of Neurological Surgeons and the American Academy of Pediatrics. These guidelines were based on an extensive review of the existing literature. The guidelines note that imaging studies are rarely indicated. Repositioning of infants is effective, although the evidence supports the use of physical therapy as preferred. Helmets can be used in refractory cases with persistent moderate to severe plagiocephaly. Early initiation of a dynamic orthotic cranioplasty device is usually indicated in the child with developmental delay, including Down syndrome, because of their failure to achieve neuromuscular control that precludes persistent supine posture.

Psychological counseling should be available to affected children and their families to help them adjust to anomalies and the reactions of society. The parent(s)/guardian(s) may be referred to

national agencies and support groups, such as the American Cleft Palate-Craniofacial Association (https://cleftline.org) to help them cope with the potential stress related to giving birth to a child with this anomaly and to advise them about the medical and surgical interventions that are available. FACES: The National Craniofacial Association (www.faces-cranio.org) is another referral source for parents.

Prognosis

Some anomalies, such as deformational plagiocephaly, resolve spontaneously or with exercise and positioning. Most other anomalies can be surgically corrected, leaving little residual evidence of the deformity. School success and psychological well-being may be more resistant to remediation and are highly dependent on the supportiveness of the family and its emotional resources. Children who grow up in settings in which the deformity is thought to be embarrassing have long-term problems with low self-esteem.

CASE RESOLUTION

The newborn has a cleft of the lip and palate. The mother is advised that her newborn can be given formula, and she is given a supply of special feeders. She is also given contact information for a parents' support group and meets other parents of children with similar anomalies. During her visit to the local craniofacial team, she views pictures of children who have undergone a repair and feels relieved.

The mother is advised about the timing of surgery and told that the surgery will be scheduled when the infant is approximately 10 weeks of age. A follow-up appointment in approximately 2 weeks is arranged. Weight gain is monitored, and the adjustment between the mother and the newborn is assessed.

CHAPTER 86

Common Oral Lesions

Charlotte W. Lewis, MD, MPH, FAAP

CASE STUDY

A 7-year-old girl is brought to the office for evaluation of a swelling on the inside of her lower lip of 4 to 6 weeks' duration. Her mother reports that it increases and decreases in size. The girl states that the swelling is not painful, and she cannot remember hurting her lower lip. On examination, a raised, bluish, nontender swelling measuring 0.8 × 0.7 cm (0.31 × 0.28 in) is apparent on the mucosa of the lower lip.

Questions

1. What is the differential diagnosis of lip masses and other oral lesions?
2. What laboratory tests or radiologic studies are useful in the evaluation of oral lesions?
3. What management strategies are used to treat cyst-like and other intra-oral lesions?
4. When should children with oral lesions be referred to subspecialists?

Primary care physicians commonly evaluate lesions in the oral cavity. Knowledge of common congenital, developmental, infectious, traumatic, and neoplastic conditions that affect the mouth and its structures can help physicians recognize and manage these lesions appropriately. Although many oral lesions are benign or represent normal variants, others may require specific medical or surgical treatment. Some oral lesions offer clues to underlying syndromic diagnosis, indicate more serious infectious or systemic disease, or occur as side effects of certain medications.

Epidemiology

Oral pathology is common and covers a broad range of lesions. Benign oral lesions, such as gingival cysts, occur in approximately 75% of newborns. Approximately 20% of the population has at least a small *torus palatinus*, a benign bony overgrowth of the palate that usually begins in childhood. Ankyloglossia, commonly referred to as tongue-tie, affects approximately 5% of newborns. Fissured tongue affects approximately 2% of the population. Fissured tongue may be associated with benign migratory glossitis (ie, geographic tongue), which occurs in approximately 1% to 2% of children. Tobacco-associated keratosis occurs at the site of habitual placement of snuff or chewing tobacco and is estimated to affect more than 300,000 children in the United States. Leukoplakia, a premalignant condition associated with smokeless tobacco, occurs in approximately one-half of users. Although the resulting oral cancer is often diagnosed in the sixth or seventh decade of life, the habit of oral tobacco use typically starts in childhood—typically between 9 and 16 years of age. Among US high school students surveyed in 2017, 5.5% report current use of a smokeless tobacco product; use is higher in boys than girls and in whites as well as American Indians/Alaska Natives relative to other racial/ethnic groups.

Aphthous ulcers, commonly known as canker sores, are among the most common oral lesions in developed countries, with typical onset early in childhood. Approximately 20% to 25% of the US population experiences recurrent aphthous stomatitis (RAS). Oral lesions resulting from infections are also common. Approximately 35% of newborns and young infants develop oral candidiasis, commonly known as thrush. Oral herpes lesions are also common and are caused by human herpesvirus, usually type 1. By young adulthood, more than 50% of US individuals are seropositive for human herpesvirus 1. Approximately 20% to 40% of the population has experienced oral herpes at least 1 time.

Chronic ("ordinary") gingivitis usually has its onset in the peripubertal age group, and it ultimately affects as many as 90% of adults. Smoking is a major risk factor for gingivitis and its sequelae–periodontal disease. In 2017, 20% of high school students reported current use of a tobacco product.

Clinical Presentation

Oral lesions may come to the attention of the physician in any number of ways. Some may be obvious at birth, such as a congenital epulis (also called congenital granular cell tumor), which typically presents as a mass arising from the maxillary alveolar ridge and protruding from the oral cavity in a neonate, potentially interfering with breathing or eating. Oral lesions may be an incidental finding on physical examination. For example, in examining a newborn, the pediatrician may notice small (approximately 2–3 mm in size) yellow-white papules along the palatal midline and can reassure the family that these are Epstein pearls, common lesions of no clinical significance. Most oral vascular malformations are present at birth, become more noticeable over time, and rarely regress. One of 3 vessel types usually predominates in such malformations: arterial, venous, or lymphatic. Microcystic lymphatic malformations often affect the tongue and surrounding soft tissue, can be friable, may interfere with eating and speaking, and can result in overgrowth of adjacent bones. When these lesions become infected, they rapidly enlarge and may compromise the airway.

The physician or parent/guardian may be the first to notice thrush. The incidence of oral candidiasis peaks around the fourth week after birth; thrush is uncommon in infants older than 6 to 9 months. Thrush can occur, however, at any age in predisposed patients (ie, immunosuppressed or deficient) and can affect the esophagus as well as the oropharynx. *Candida albicans* in combination with contact irritation has been implicated in *angular cheilitis*, which appears as crusty or scaling erythematous fissures at the corners of the mouth. Other benign oral lesions, such as benign migratory glossitis, are brought to the attention of the physician because parents or guardians are concerned that they represent pathology; however, reassurance is appropriate.

Concerns for ankyloglossia may arise when a newborn has difficulty breastfeeding, particularly when the mother has persistent pain or trauma to her nipple with breastfeeding. Clinically significant ankyloglossia interferes with an effective latch and with normal tongue movement needed to efficiently transfer milk from the breast. Anterior ankyloglossia refers to a sublingual attachment to the underside of the tongue that is close to the tongue tip. In posterior ankyloglossia, the sublingual attachment is farther back on the tongue underside, but it still restricts motion of the tongue. The maxillary labial frenulum can appear quite prominent in infants and young children; however, it usually becomes much less obvious by the time the permanent central incisors erupt.

Physicians may be the first to note swollen, friable, erythematous gingiva along with plaque buildup on and between the teeth representing the initial presentation of chronic gingivitis. Chronic gingivitis is the first and only reversible stage of periodontal disease. Onset is typically in peripubertal children. Although young children experience gingivostomatitis from other causes, they do not usually harbor *Actinobacillus actinomycetemcomitans* or *Porphyromonas gingivalis* and thus do not commonly experience chronic gingivitis or periodontal disease.

Thickening of the mucosa, usually in the labial vestibule, offers clues to smokeless tobacco use. The severity of tobacco-related oral lesions demonstrates a dose-response relationship with the amount, frequency, and duration of smokeless tobacco exposure. *Tobacco-associated keratosis* is a predictable lesion that manifests as an area of thickening at the site of habitual placement of snuff or chewing tobacco. Chronic exposure to smokeless tobacco can result in the development of opaque-white to yellow-brown lesions with a wrinkled appearance, known as leukoplakia and which is considered to be a premalignant condition.

Recurrent oral mucosal trauma, such as habitual biting of the inside of the lip or recurrent irritation from orthodontics, can induce oral lesions anywhere in the mouth but most often does so on the buccal or labial mucosa. One such lesion is a *mucocele*, which is a saliva-filled cyst that is usually less than 1 centimeter in diameter, round, painless, and opaque white or slightly blue in color. *Pyogenic granuloma* is another lesion that can occur at a site of recurrent mucosal or skin irritation. These lesions are blood red or reddish-brown, and they bleed easily. Although they can be protuberant and look scary to parents/guardians, both mucoceles and pyogenic granulomas are benign.

Other oral lesions may present in conjunction with other symptoms. Acute onset of "strawberry tongue," indicating glossitis, often occurs with scarlet fever or Kawasaki disease. The initial herpes simplex virus oral infection–primary herpetic gingivostomatitis–which typically affects infants and young children, is characterized by multiple oral vesicular or ulcerative lesions, fever, malaise, cervical lymphadenopathy, and decreased oral intake. Reactivation of prior human herpesvirus 1 infection often affects the vermillion border of the lip, which is known as *herpes labialis*. Oral lesions may also indicate underlying serious systemic illness, such as Crohn disease, systemic lupus erythematosus, or acute myelogenous leukemia.

Some life-threatening, rapidly progressive infections begin in the mouth. *Ludwig angina* (see Chapter 89) is a painful, rapidly progressive, infectious process of the submandibular space, often presenting as induration and swelling of the floor of the mouth, neck swelling, a superiorly and posteriorly displaced tongue, difficulty swallowing, and subsequent airway obstruction. Ludwig angina is a potential complication of a dental infection; in children, however, Ludwig angina can occur without a clear etiology, or it can complicate oral trauma or gingivostomatitis. *Vincent infection* or *acute necrotizing ulcerative gingivitis* is painful, edematous, bleeding gums with ulcers, necrosis, and pseudomembrane formation in affected areas. When this spreads to the pharynx and tonsils, the condition is referred to as Vincent angina (also called trench mouth). Like Ludwig angina, Vincent angina can progress to life-threatening airway obstruction.

Some genetic syndromes are first detected because of oral lesions. For example, lip pits or mounds in conjunction with cleft lip and/or cleft palate are virtually pathognomonic of Van der Woude syndrome, an autosomal-dominant cause of orofacial clefting. Hyperpigmented lesions (brown or dark blue, similar to freckles) on the lips or buccal mucosa may provide a clue in the diagnosis of Peutz-Jeghers syndrome, an autosomal-dominant condition of multiple intestinal hamartomas. Patients with Peutz-Jeghers syndrome may experience recurrent abdominal pain, intestinal obstruction, or bleeding, and have a 15-fold increased risk of intestinal cancer.

Pathophysiology

Neonatal and Other Developmental Lesions

Gingival cysts in the neonate include Epstein pearls, Bohn nodules, and dental lamina cysts; these are caused by entrapment of tissues during embryologic development. Congenital epulis of the newborn is a rare, gingival tumor of unclear etiology that occurs more commonly in the maxilla than the mandible, with female predilection (8:1), and may occur as a single tumor or multiple tumors. The etiology of fissured tongue and geographic tongue are unknown. Fissured tongue tends to cluster in families, suggesting a genetic etiology, and can also occur in Down syndrome. Benign migratory glossitis results from the loss of the tiny fingerlike projections, called papillae, on the surface of the tongue, giving the tongue a map-like appearance. The inciting factors responsible for oral vascular malformations are

not well understood. Ankyloglossia is thought to result from a localized failure of apoptosis.

Traumatic

Some of the most common oral lesions noted on physical examination result from minor accidental self-bites to the lip or buccal mucosa. Most of these lesions resolve quickly, but recurrent trauma may result in pyogenic granuloma or fibroma formation. A mucocele results from traumatic rupture of a minor salivary gland with subsequent cyst formation.

Infectious

Although an infectious etiology to aphthous ulcers has been proposed, their true etiology remains unclear. Oral herpes lesions usually are the result of infection with human herpesvirus 1. Herpangina results from coxsackievirus A infection. *Candida albicans* causes oral candidiasis. Thrush occurs when normal host immunity is immature (as in neonates) or suppressed (eg, during steroid treatment) or when normal flora is disrupted (eg, while on antibiotics). Newborns may be colonized with *C albicans* during birth. Other sources of transmission to neonates include colonized maternal skin in contact during breastfeeding, pacifiers, and bottle nipples.

Chronic gingivitis occurs after buildup of bacterial plaque on the teeth, adjacent gingiva, and pockets between teeth and gums. Bacteria within plaque release toxins that cause an inflammatory response; the most commonly involved species are gram-negative anaerobic bacteria, including *A actinomycetemcomitans* and *P gingivalis*.

Both Ludwig angina and Vincent infection/angina result from polymicrobial infection, including anaerobes.

Other

Drug-induced gingival hyperplasia can occur in patients taking corticosteroids, phenytoin (most common cause in children), cyclosporine A, or nifedipine. It results from fibrous tissue overgrowth but, much like ordinary gingivitis, is exacerbated by poor oral hygiene and presence of plaque.

Differential Diagnosis

Age at onset, location and characteristics of the lesion, and accompanying signs and symptoms often help narrow the differential diagnosis. The appearance of 1- to 3-mm cysts in the mouth of a neonate is indicative of Epstein pearls, which are the most common and usually are present along the palatal midline; dental lamina cysts, which usually are located bilaterally along the crest of the dental ridge about where the first molars typically erupt; or Bohn nodules, which are found on the buccal and lingual aspects of the ridge, away from the midline. A protuberant mass from the anterior maxillary ridge of a newborn should prompt suspicion for a congenital epulis; however, examination by a pathologist after resection is important to confirm the diagnosis. A mucocele is a painless, clear or bluish, fluid-filled cyst that results from damage to the salivary duct, resulting in extravasation of mucus from the gland into the surrounding soft tissue.

White plaques involving the buccal, lingual, and palatal mucosa are suggestive of oral candidiasis. Thrush can sometimes be confused with milk remaining in the child's mouth after feeding. Scraping the lesion to determine if the white substance is readily removed (as milk is) helps differentiate this from oral candidiasis, in which the white plaques do not easily scrape off; additionally, after scraping, the base of the thrush lesion may be erythematous or may bleed. Some infants and young children have a white coating to the tongue as a normal variant. The lack of white patches on other mucosal surfaces should call into question the diagnosis of thrush. In fissured tongue, grooves that vary in depth are noted along the dorsal and lateral aspects of the tongue.

In scarlet fever, the tongue initially has a white coating overlying the red swollen papillae of the tongue—the "white strawberry tongue," which desquamates at approximately day 4 or 5 of illness, leaving the "red strawberry tongue." In Kawasaki disease, initial presentation usually includes a bright red strawberry tongue and red, dry, cracked lips. Other clinical features and select laboratory testing help differentiate Kawasaki disease from scarlet fever. Both Kawasaki disease and scarlet fever require specific treatment to avoid long-term complications. For scarlet fever, treatment is with penicillin to avoid rheumatic fever, and for Kawasaki disease, treatment is with intravenous immunoglobulin to prevent coronary artery aneurysms.

Common oral ulcers include aphthous ulcers, herpes gingivostomatitis, and herpangina. Oral herpes may be characterized by multiple vesicular lesions, which, after rupture, appear as ulcers involving the lips, skin around the mouth, tongue, and mucosal membranes, typically in the anterior portion of the mouth. The initial infection may occur between 1 and 3 years of age. Aphthous ulcers also involve the anterior mouth, typically along the wet vermillion; however, they usually first appear at a somewhat older age (ie, in the preschool years or later) and with fewer lesions than oral herpes. Factors that may predispose to the development of RAS include familial tendency, trauma, hormonal factors, food or drug hypersensitivity, immunodeficiency, celiac disease, inflammatory bowel disease, and emotional stress. Herpangina may present similarly to herpes, but it more typically involves the posterior pharynx and the palate. Similar lesions on the hands or foot, as in hand-foot-and-mouth disease, may lend support to coxsackievirus A as the etiology.

Trauma to the salivary duct may result in a mucocele. In contrast, a *pyogenic granuloma* is an erythematous, nonpainful, smooth or lobulated mass that often bleeds easily when touched, whereas a fibroma is a moderately firm, smooth-surfaced, pink, sessile or pedunculated nodule, usually noted on the buccal mucosa in the occlusal plane. When located on the gingiva, a pyogenic granuloma can be confused with a *periapical abscess*, which is an erythematous, pus-filled cyst that occurs when infection spreads from the root of an infected tooth to surrounding tissues (also called a gum boil or a parulis). If the abscess ruptures, it often leaves a periapical fistula.

Erythematous and friable gums often indicate the presence of chronic gingivitis. Typically, plaque is seen on and between the teeth. In contrast with plaque-associated chronic gingivitis, which

is usually painless or only mildly uncomfortable, acute necrotizing ulcerative gingivitis (Vincent infection) is quite painful, acute in onset, and associated with ulcers, necrosis, and pseudomembrane formation in affected areas. Swollen and inflamed gingiva can be presenting signs of leukemia in an ill-appearing child with an abnormal complete blood count.

Evaluation

History

The history is very important in evaluating oral lesions and determining the need for further treatment or referral. Key factors to include in the history are age at onset, duration, inciting factors, other medical problems, medications, tobacco use, family history, ill contacts, and associated or systemic symptoms and signs, such as fever (Box 86.1).

Physical Examination

Physical examination of the oral structures should start with the lip (dry and wet vermillion) and surrounding skin (the "white lip"). The examination should then turn to the mucosa, gingiva, teeth, and palate; all aspects of the tongue (ie, superior, inferior, both sides); sublingual structures; frena; and posterior pharynx. The physician should note the number, size, location, and characteristics of the lesions, because this information can be helpful in narrowing the differential diagnosis. The presence and duration of fever should be ascertained. The rest of the body should be examined with specific attention to the presence of other lesions, rashes, lymphadenitis, or arthritis.

Anterior ankyloglossia may be obvious because of a notched or heart-shaped tip of tongue. In more severe cases, the tight and short sublingual frenum makes it difficult to pass a finger under the tongue. Difficulty lifting the tongue to the middle of the mouth and/or difficulty extruding the tongue past the gingiva are other characteristics suggestive of anterior or posterior ankyloglossia.

Laboratory Tests

In otherwise healthy children who present with oral ulcerative lesions, supportive care is typically implemented without pursuing a definitive etiology. If a specific diagnosis is required, human herpesvirus and coxsackievirus can be identified and differentiated with polymerase chain reaction testing. Likewise, oral candidiasis in an otherwise healthy infant usually is managed without diagnostic tests. However, a potassium hydroxide 10% microscopic slide preparation of scrapings from the lesion should demonstrate the characteristic spherical budding yeasts and pseudohyphae. An excisional biopsy or resection may be necessary to determine histology and diagnosis of other oral lesions.

Laboratory tests, including a complete blood cell count, may be helpful in the initial evaluation of the ill-appearing child with oral lesions or in cases in which serious infection, systemic illness, or inflammatory conditions are suspected.

Box 86.1. What to Ask

Common Oral Lesion

- How long has the child had the lesion?
- Is the lesion painful?
- Did the child recently injure the affected area?
- Has the child had any fever?
- Is the child eating as usual?
- Does the child have any other lesions?
- Is the child currently taking any medications? Has the child recently taken any medications?

Imaging Studies

Imaging studies are not indicated in the evaluation of most oral lesions unless the lesions are related to problems of dentition, such as a periapical abscess, in which case radiographs are usually obtained by the dentist rather than the physician. Magnetic resonance imaging may be used for evaluation of oral vascular malformations.

Management

Many of the common oral lesions are developmental or normal variants or are self-limited, and management entails observation to ensure the lesions follow their expected course. For example, gingival cysts in newborns typically regress spontaneously. Oral lesions such as torus palatinus or benign migratory glossitis do not require treatment. Although human herpesvirus 1 gingivostomatitis is self-limiting, primary infection can cause considerable pain and result in decreased oral intake. Early (within 72 hours) antiviral therapy in the form of acyclovir 5 to 10 mg/kg/dose 5 times per day for 7 to 10 days has been shown to shorten the duration of fever, lesions, and odynophagia. Other oral lesions respond well to supportive care. For example, a child with herpangina may benefit from regular ibuprofen or acetaminophen; topical application of a 1:1 mixture of attapulgite (eg, Kaopectate, Donnagel) and diphenhydramine elixir (eg, Benadryl) to form a protective coating over the lesion; avoidance of acidic beverages, such as orange juice, that may cause pain on contact with the ulcers; and close attention to fluid intake and signs or symptoms of dehydration. Amlexanox 5% oral paste or triamcinolone acetonide dental paste reduces pain associated with, duration of, and size of aphthous ulcers and is used in adults with RAS; however, safety of these treatments in children has not been established. Viscous lidocaine has been associated with systemic absorption and subsequent dysrhythmia or seizure and should not be used in children.

Complicated vascular and lymphatic malformations of the oral cavity require specialty consultation with a team experienced in the care of these lesions. Unlike infantile hemangiomas, complicated vascular malformations usually do not involute. Typically, surgical resection is the treatment of choice for lymphatic malformations; however, microcystic lymphatic malformations are difficult to remove and may recur even after resection. Sclerosing therapy and laser treatment are options in some cases. Supportive care includes

treatment with antibiotics when the lesion becomes infected as well as ongoing, aggressive preventive oral hygiene.

Other oral lesions require specific therapy. Thrush is typically treated with nystatin suspension (100,000 units/mL) as 1 mL swabbed to lesions 4 times per day until lesions are resolved. It is important to consider the possibility of an underlying immunodeficiency when thrush occurs outside of infancy or without a reasonable explanation. Angular cheilitis can be managed with nystatin cream or ointment and a low-potency hydrocortisone cream. Some oral lesions, including congenital epulis, mucocele, pyogenic granuloma, and fibroma, are best managed with resection.

Treatment of gingivitis should start with ensuring that a child follows a regular home oral hygiene program, including twice-daily toothbrushing with fluoride toothpaste and flossing, and referral for professional dental care. Regular rinsing with a mouthwash containing essential oils (eg, Listerine Ultraclean, Vita-Myr Mouthwash) or chlorhexidine gluconate oral preparation has been shown to decrease plaque and inflammation. The goals of therapy for gingivitis are to reduce clinical signs of inflammation and gingival bleeding and arrest or reduce the risk of progression of the periodontal disease and maintain dentition. Drug-induced gingival hyperplasia requires therapy similar to that for ordinary gingivitis. Additionally, if the causative medication cannot be discontinued or changed, patients can be referred for surgical removal of excess gingival tissue and fitting of a positive-pressure mouth guard to inhibit further tissue growth. Acute necrotizing ulcerative gingivitis should be managed with débridement and penicillin or metronidazole.

Vincent infection should be managed with débridement and penicillin or metronidazole. Ludwig angina requires surgical drainage as well as treatment with broad-spectrum antibiotics covering gram-negative, gram-positive, and anaerobic bacteria (eg, ampicillin, sulbactam). Securing the airway should be prioritized in both Vincent angina and Ludwig angina.

When a woman reports persistent pain or experiences bruising or bleeding of the nipple with breastfeeding, prompt consideration should be given for clinically significant ankyloglossia, either anterior or posterior. Consultation with a lactation consultant is often helpful as a first step when questions arise about whether ankyloglossia is contributing to breastfeeding difficulty. Not all infants with ankyloglossia have difficulty breastfeeding. Systematic review indicates that sublingual frenotomy reduces maternal pain with breastfeeding and increases breastfeeding efficacy. Sublingual frenotomy, which involves incising the sublingual frenum, is indicated when ankyloglossia is interfering with effective breastfeeding. Longitudinal data are insufficient to warrant sublingual frenotomy in infancy as a means to prevent speech problems in later childhood. No research evidence exists to support incising the superior (upper lip or maxillary) labial frenum in infancy to improve breastfeeding, prevent dental caries, or prevent future orthodontic problems. Cosmetic interventions for a prominent superior labial frenum and/or concerns for a diastema should be delayed until after the permanent maxillary (upper) incisors erupt.

Management of oral lesions may require consultation and collaboration with colleagues in dental, oral surgery, otolaryngology, or other subspecialties. The recommended treatment of a congenital epulis is early resection; however, if a large lesion with potential to obstruct the newborn's airway is diagnosed antenatally, it may be necessary to perform an ex-utero intrapartum procedure to establish an airway before interruption of the fetomaternal circulation. If the etiology of a lesion is unclear or if an oral lesion does not follow its expected course, referral is essential to ensure appropriate diagnosis and treatment.

Prognosis

Most oral lesions in children respond to appropriate intervention without residual problems. However, oral lesions can signal the onset of or occur in association with serious systemic conditions. Although uncommon, rapidly progressive polymicrobial infections of oral structures, such as Vincent angina or Ludwig angina, can be life-threatening. Chronic gingivitis represents the first and only reversible stage of periodontal disease, which is the leading cause of tooth loss in adulthood. Because chronic gingivitis has its onset during childhood, physicians can play an important role in the prevention of periodontal disease by promoting oral hygiene early in life. After periodontal disease extends beyond the gums, it is no longer reversible and gradually destroys the bone and tissue that support the teeth, resulting in halitosis and tooth loss.

CASE RESOLUTION

The child seems to have a mucocele. Mucoceles may spontaneously regress; however, if the lesion persists the child should be referred to an oral surgeon or head and neck surgeon for surgical excision of the lesion.

CHAPTER 87

Otitis Media

Nasser Redjal, MD

CASE STUDY

An 18-month-old boy is brought to your office with a 2-day history of fever and decreased food intake. He has had symptoms of an upper respiratory infection for the past 4 days but no vomiting or diarrhea. Otherwise, he is healthy.

The child appears tired but not toxic. On physical examination, the vital signs are normal except for a temperature of 38.3°C (101°F). The left tympanic membrane is erythematous and bulging, with yellow pus behind the membrane. The light reflex is splayed, and mobility is decreased. The right tympanic membrane is gray and mobile, with a sharp light reflex. The neck is supple with shotty anterior cervical adenopathy, and the lungs are clear.

The child has a 10- to 15-word vocabulary, and no one smokes in the household.

Questions

1. What are the differences between acute, persistent, and recurrent otitis media?
2. What factors predispose to the development of ear infections?
3. What are the most common presenting signs and symptoms of ear infection in infants and children?
4. How do the treatment considerations differ between acute, persistent, and recurrent ear infections?
5. What are some of the complications of otitis media?

Otitis media (OM) is the second most common reason after well-child care for a visit to the pediatrician and the most common reason for which antibiotics are prescribed for children. An estimated 30 million office visits per year are for the evaluation and treatment of OM in the United States. More than 25% of all prescriptions written each year for oral antibiotics were for the treatment of middle ear infections. Many surgical procedures, such as myringotomy with tympanostomy tube placement or adenoidectomy, were performed on children for treatment of recurrent disease. However, a dramatic decline has occurred in the prevalence of OM from the prepneumococcal conjugated vaccine (PCV) 7 era to the post-PCV13 era, from 9.5% of office visits to 5.5%, respectively, and from 826 per 1,000 children to 387 per 1,000 children, respectively. Despite this decline, the primary care physician must have a good understanding of these pediatric conditions, which remain quite common.

Otitis media can be classified into the following 5 categories: acute OM (AOM), OM with effusion (OME), recurrent AOM, chronic OME, and chronic suppurative OM. It is important to distinguish between each of these entities because their presentation and management differ.

Acute OM (ie, acute suppurative or purulent OM) is the sudden onset of inflammation of the middle ear, which is often accompanied by fever and ear pain (ie, *otalgia*). The clinical findings of inflammation noted on otoscopic examination are bulging of the tympanic membrane (TM), limited or absent mobility of the TM, air-fluid level behind the TM, and otorrhea not resulting from acute otitis externa (Box 87.1). *Otitis media with effusion* or *serous OM* is the persistence of nonpurulent middle ear fluid after antimicrobial treatment following resolution of acute inflammatory signs. Fluid may persist for 2 to 3 months but usually resolves within 3 to 4 weeks in 60% of cases. *Recurrent OM* is defined as frequent episodes of AOM with complete clearing between each episode, although a more specific definition of recurrent OM is 3 new episodes of AOM requiring antibiotic treatment within a 6-month period or 4 documented infections in 1 year. This condition affects approximately 20% of children with a propensity to otitis; such children typically have their first infection at younger than 1 year. *Chronic OME*, which is also known as serous OM, secretory OM, nonsuppurative OM, mucoid OM, and glue ear OM, is characterized by persistence of fluid in the middle ear for 3 months or longer. The TM is retracted or concave with impaired mobility but without signs of acute inflammation. The affected child may be asymptomatic. The child with chronic OME is at increased risk for developing hearing deficits, speech delay, and learning problems. *Chronic suppurative OM* implies a non-intact TM (ie, perforation or tympanostomy tube present) with at least 6 weeks of middle ear drainage.

Epidemiology

The prevalence of OM peaks in children 6 to 24 months of age. An additional smaller peak occurs at approximately 4 to 6 years of age. Otitis media is relatively uncommon in older children and adolescents. The condition is more common in boys than girls.

Several epidemiologic risk factors for OM have been identified, including age younger than 2 years; first episode before 6 months; familial predisposition; siblings in the household; low socioeconomic status; infant not breastfed; altered host defenses (ie, acquired or congenital immunodeficiencies); environmental factors (eg, cigarette smoke); child care attendance; and the presence of

Box 87.1. Components of Acute Otitis Media

Definition

A diagnosis of acute otitis media requires the following:

- A history of acute onset of signs and symptoms
- The presence of middle ear effusion
- Signs and symptoms of middle ear inflammation

Findings on Examination

- The presence of middle ear effusion that is indicated by any of the following:
  - — Bulging of the tympanic membrane
  - — Limited or absent mobility of the tympanic membrane
  - — Air-fluid level behind the tympanic membrane
  - — Otorrhea (not resulting from acute otitis externa)

Derived from Lieberthal AS, Carroll AE, Chonmaitree T, et al. The diagnosis and management of acute otitis media. *Pediatrics.* 2013;131(3):e964–e999.

an underlying condition, such as allergic disease of the upper airway, chronic sinusitis, a cleft palate, or other craniofacial anomalies. Children with Down, Goldenhar, or Treacher Collins syndrome and ciliary dysfunction also are at increased risk for OM. American Indian/Alaska Native individuals have a higher incidence of AOM than whites. Otitis media usually occurs during the winter and early spring, coinciding with peaks in the incidence of viral upper respiratory infections (URIs).

Worldwide, OM results in an estimated 50,000 deaths per year in children younger than 5 years because of the complications of chronic suppurative OM. Otitis media is estimated to affect 65 million to 133 million individuals worldwide, 60% of whom experience significant hearing loss. Chronic suppurative OM is a rare entity in developed countries, in which most instances of OM are of the acute presentation or with effusion.

Etiology

In general, 50% to 90% of cases of AOM culture are bacterial, 20% to 50% are viral, and 66% are both. Until the widespread immunization of children with PCV, the causative microorganisms for AOM were *Streptococcus pneumoniae* (25%–50%), non-typable *Haemophilus influenzae* (15%–30%), and *Moraxella catarrhalis* (3%–20%). Other less common causative organisms include group A streptococcus, *Staphylococcus aureus,* α-hemolytic *Streptococcus, Pseudomonas aeruginosa,* anaerobic bacteria, *Mycoplasma pneumoniae,* chlamydia, and *Mycobacterium tuberculosis.* Bullous myringitis has shown a 97% bacterial-positive rate, primarily with *S pneumoniae*, in contrast to the previous belief that mycoplasma was the causative agent in this condition. Respiratory viruses, such as respiratory syncytial virus, adenovirus, rhinovirus, parainfluenza, coronavirus, and influenza (A and B), also play a role. Respiratory syncytial virus, adenovirus, and coronavirus are associated with an increased rate of AOM, with 50% of children with URI caused by these viruses developing AOM; in contrast, only 33% of patients who have URIs caused by rhinovirus, influenza, parainfluenza, or enterovirus develop AOM. The bacterial pathogens causing AOM in the first 6 weeks after birth are essentially the same as those in older children. However, 10.5% of neonates with AOM have gram-negative bacilli.

Currently, approximately 50% of *H influenzae* and 100% of *M catarrhalis* isolated from the upper respiratory tract are positive for β-lactamase, and 15% to 50% (average, 30%) of *S pneumoniae* are not susceptible to penicillin. The mechanism of penicillin resistance among isolates of *S pneumoniae* is associated not with β-lactamase production but with an alteration of penicillin-binding proteins. This effect varies widely by geographic location and results in resistance to penicillins and cephalosporins.

Clinical Presentation

Children with AOM often have a history of fever and ear pain. Associated symptoms include URI, cough, vomiting, diarrhea, and nonspecific symptoms, such as decreased appetite, waking at night, generalized malaise, lethargy, and irritability. Purulent otorrhea with minimal ear pain and hearing loss may also occur and signifies rupture of the TM. Fever occurs in approximately 30% to 50% of patients. Temperatures exceeding 40°C (104°F) are uncommon and are suggestive of bacteremia or another complication. Verbal children may report tinnitus, vertigo, and hearing loss; Bell palsy is a rare finding. Nonverbal children may appear ataxic on physical examination.

Pathophysiology

The most important factor in the pathogenesis of OM is abnormal function of the eustachian tube (Figure 87.1). Eustachian tube dysfunction occurs for 2 main reasons: abnormal patency and obstruction of the tube. Obstruction is functional (secondary to collapse of the tube), mechanical (from intrinsic or extrinsic causes), or both. Functional obstruction or collapse of the eustachian tube is common in infants and young children because the tube is less cartilaginous and therefore less stiff than in adults; the tube is also more horizontal and shorter in infants and young children. Additionally, the tensor veli palatini muscle is less efficient in this age group. Extrinsically, the presence of lymphoid follicles (eg, adenoidal enlargement) or, rarely, tumors surrounding the opening of the tube contributes to reflux, aspiration, or insufflation of nasopharyngeal bacteria into the middle ear. Intrinsic mechanical obstruction of the eustachian tube occurs as the result of inflammation secondary to a URI or allergy in patients older than 5 years. Viral infections may occur up to 6 to 12 times per year in children younger than 3 years. Subsequently, viral respiratory infections contribute to eustachian tube dysfunction, resulting in negative middle ear pressure, which occurs in 75% of children who have viral URIs. The presence of a viral URI enhances the ability of bacterial pathogens to adhere to and ascend from the nasopharynx to the middle ear via the eustachian tube. Viruses also can affect the local host immune response by impairing leukocyte function, exposing receptors for bacteria, and decreasing the effectiveness of the mucociliary escalator (Figure 87.1).

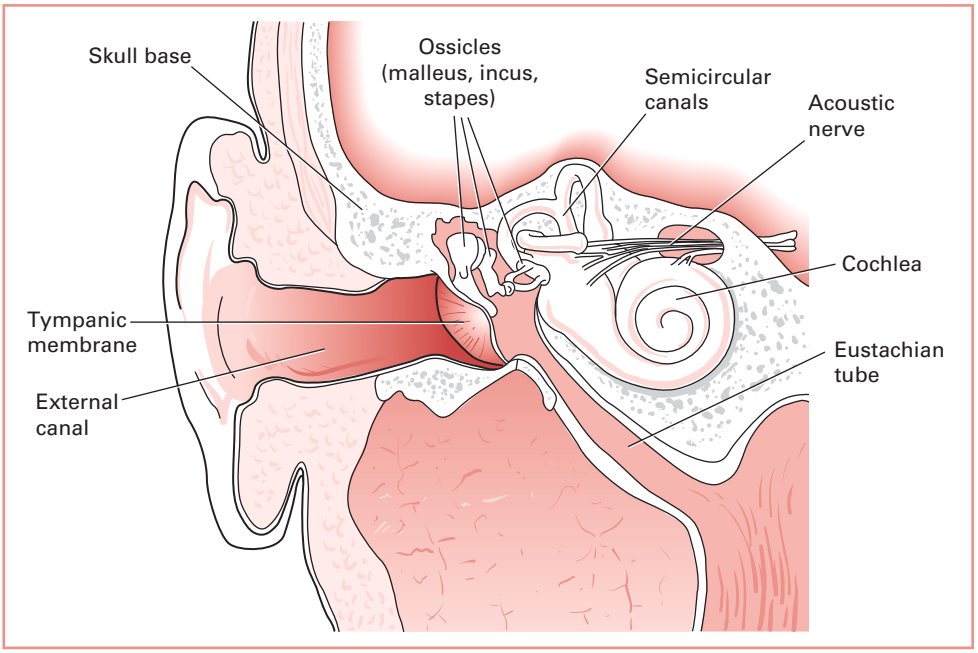

Figure 87.1. Relationship of middle ear to external and inner ears.

Hematogenous spread of microorganisms also can result in OM. Less often, primary mucosal disease of the middle ear from allergies or abnormal cilia contributes to OM.

Differential Diagnosis

The most common cause of otalgia is AOM. Other causes include mastoiditis, which is almost always accompanied by OM; otitis externa; and referred pain from the oropharynx, teeth, adenoids, or posterior auricular lymph nodes. A foreign body in the canal can produce similar symptoms. In the child with ear pain, a search for any of these other conditions must be undertaken if the TM appears completely normal.

Evaluation

History

The history should carefully delineate the symptoms of OM and differentiate from those indicating a more serious condition, such as meningitis (Box 87.2).

For the infant or child with a history of persistent or recurrent OM, it is important to discern when the last documented infection occurred and what treatment, if any, was administered. It is also critical to monitor development, particularly speech.

Physical Examination

To diagnose OM, the TM must be completely visualized and its mobility assessed. Occasionally, this may be difficult because of the presence of cerumen or otorrhea. In such cases, diagnosis is made on the basis of the history, and treatment may be initiated without confirmation by physical assessment. In all other cases, the position, color, degree of translucency, and mobility of the TM are evaluated. Classically, in AOM the TM is full, bulging, hyperemic, opaque, or has an air-fluid level, with limited or no mobility. Typically, the light reflex is distorted or absent. In the case of persistent or chronic OM, signs of inflammation usually are absent and the TM may be retracted, with limited or no mobility. Smartphone apps exist that can be used in assessing the mobility of the TM and can assist in diagnosing OM.

Box 87.2. What to Ask

Otitis Media

- Does the infant or child have fever, ear pain, hearing loss, or otorrhea?
- Is the infant or child inconsolable or lethargic?
- Has the infant or child had a previous ear infection? If so, when?
- Did the child complete the course of prescribed antibiotics?
- How many ear infections has the child had in the past year?
- Is the child taking any medication to prevent recurrent otitis media?
- Does the child attend child care?
- Is the child exposed to passive smoke?
- Is the infant breastfed?
- Does the child seem to hear?
- Is the child's speech development normal?

Associated physical findings with an uncomplicated middle ear infection may include posterior auricular and cervical adenopathy. Other significant findings on physical examination are pain on movement of the pinna, anterior ear displacement, posterior auricular pain, and, rarely, evidence of peripheral facial nerve (ie, seventh cranial nerve) paralysis. The presence of these findings suggests other diagnoses, such as an associated otitis externa or mastoiditis.

Positioning of the infant or young child for evaluation of the ear is critical for an adequate examination. Several methods have been described, including restraining the child on the examination table or allowing parents or guardians to hold the child in their arms or on their laps (Figure 87.2). In the infant, it may be difficult to visualize the TM because the external auditory canal is slightly angulated. Lateral retraction of the pinna may help correct this problem.

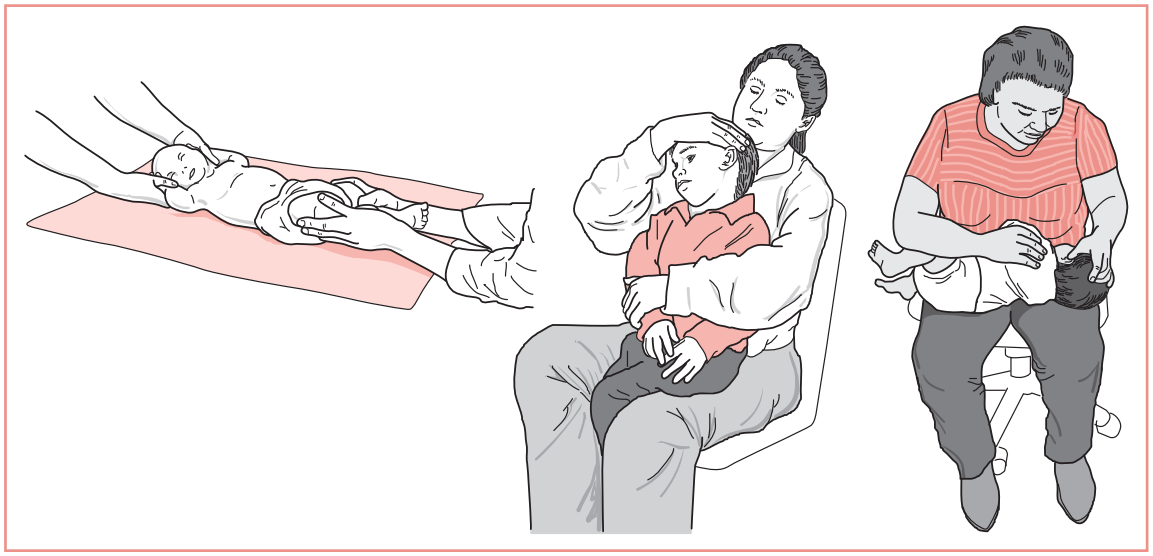

Figure 87.2. Three methods of positioning an infant or child for examination of the ear. Left, Restraining the infant on the examination table. Middle, Holding the child in the arms. Right, Holding the child on the lap.

Laboratory Tests

Although the diagnosis of OM is suspected on the basis of the history and verified on physical examination, tympanometry may be helpful in distinguishing the normal ear from the ear with effusion. In acute cases, audiometry is of limited diagnostic value; however, it is helpful in evaluating the effects of a persistent, recurrent, or chronic middle ear effusion (MEE) on hearing.

Tympanocentesis is the most definitive method of verifying the presence of middle ear fluid and of recovering the organism responsible for the infection. Indications for tympanocentesis or myringotomy are listed in Box 87.3. Nasopharyngeal cultures are not helpful because they do not correlate with middle ear fluid cultures.

Prevention

During infancy and early childhood, the incidence of respiratory tract infections and recurrent OM can be reduced by altering child care center attendance patterns.

Box 87.3. Indications for Tympanocentesis or Myringotomy in the Child With Otitis Media

- Otitis media in the patient with severe ear pain, serious illness, or appearance of toxicity
- Onset of otitis media in the child receiving appropriate and adequate antimicrobial therapy
- Otitis media associated with confirmed or potential suppurative complications, such as facial paralysis, mastoiditis, or meningitis
- Otitis media in the newborn, ill neonate, or immunodeficient patient, in each of whom an unusual organism may be present
- Otitis media in the patient with severe illness in whom second-line antibiotic management has been unsuccessful
- Otitis media in the patient with penicillin allergy in whom the first-line agent was unsuccessful

Immunoprophylaxis with influenza vaccine and PCV has proven effective in reducing the prevalence of OM. Avoiding supine bottle-feeding (ie, bottle propping) and reducing or eliminating pacifier use between age 6 and 12 months, as well as eliminating exposure to passive tobacco smoke, decreases the incidence of AOM.

Breastfeeding, which provides infants with immunologic protection against URIs, other viral and bacterial infections, and allergies, also has a protective effect. Facial musculature may mature differently in breastfed infants, thus influencing eustachian tube function and reducing the risk of aspiration of fluid into the middle ear. Positioning during breastfeeding also has some protective effect, although immune factors in human milk may serve as the most important mechanism for the reduced prevalence of OM.

Increased antibiotic resistance has eliminated the utility of routine antibiotic prophylaxis for recurrent AOM as a means of disease prevention.

Management

In 2013, the American Academy of Pediatrics released clinical guidelines on the management of OM (Box 87.4). One of the perhaps more controversial recommendations was to, depending on the clinical findings in the child between 6 and 24 months of age, not routinely initiate antibiotics but instead observe the child. The American Academy of Pediatrics has not revised these guidelines. Some physicians, based on several subsequent meta-analyses detailing the risk of serious complications, including TM perforation, seventh cranial nerve palsy, subperiosteal abscess, mastoiditis, sinus vein thrombosis, labyrinthitis, bacteremia, and bacterial meningitis, have opted to start antibiotics at the initial encounter.

High-dose amoxicillin is recommended as the first-line treatment in most patients with AOM, although several medications are clinically effective (Table 87.1). The justification for the use of amoxicillin relates to its effectiveness against common AOM bacterial pathogens as well as its safety, low cost, acceptable taste, and narrow microbiological

Box 87.4. Indications for Antibiotics in the Management of Otitis Media

Criteria for Antibacterial Treatment or Observation in the Child with Non-Severe Illness

1. Younger than 6 months: antibacterial treatment
2. Six to 24 months: antibacterial treatment with certain diagnosis or severe illness; observation with unilateral acute otitis media without otorrhea, although a 2015 meta-analysis showed better outcome with antibiotics
3. Two years and older: antibacterial treatment with severe illness or observation in the setting of uncomplicated unilateral or bilateral acute otitis media

Observation is an Appropriate Option if All of the Following Are Present:

A. Caregiver is informed and agrees
B. Caregiver can monitor the child and return should condition worsen
C. Systems are in place for ready communication with the physician, reevaluation, and obtaining medication, if necessary

Adapted with permission from Lieberthal AS, Carroll AE, Chonmaitree T, et al. The diagnosis and management of acute otitis media. *Pediatrics.* 2013;131(3):e964–e999.

spectrum. In children with a history of recurrent AOM or who have taken amoxicillin in the previous 30 days, those with concurrent conjunctivitis, or those for whom coverage for β-lactamase-positive *H Influenzae* and *M catarrhalis* is desired, therapy should be initiated with high-dose amoxicillin-clavulanate (90 mg/kg per day of amoxicillin with 6.4 mg/kg per day of clavulanate in a ratio of amoxicillin to clavulanate of 14:1, given in 2 divided doses; this preparation is less likely than other amoxicillin-clavulanate preparations to cause diarrhea).

Alternative initial antibiotics include cefdinir (14 mg/kg per day in 1 or 2 doses), cefuroxime (30 mg/kg per day in 2 divided doses), cefpodoxime (10 mg/kg per day in 2 divided doses), or ceftriaxone (50 mg/kg, administered intramuscularly). Alternative antibiotics vary in their efficacy against AOM pathogens. For example, recent data from the United States on in vitro susceptibility of *S pneumoniae* to cefdinir and cefuroxime indicate efficacy of only 70% to 80%, compared with 84% to 92% amoxicillin efficacy. In vitro efficacy of cefdinir and cefuroxime against *H influenzae* is approximately 98%, compared with 58% efficacy of amoxicillin and nearly 100% efficacy of amoxicillin-clavulanate. A multicenter double tympanocentesis open-label study of cefdinir in recurrent AOM attributable to *H influenzae* showed eradication of the organism in 72% of patients.

For children allergic to penicillin, recent data suggest that cross-reactivity among penicillins and cephalosporins is lower than historically reported. Cross-reactivity is higher between penicillins and first-generation cephalosporins but is negligible between penicillins and second- and third-generation cephalosporins. According to the Joint Council of Allergy, Asthma & Immunology, cephalosporin treatment of patients with a history of mild delayed penicillin allergy (ie, maculopapular or morbilliform eruption after 6 hours of taking penicillin) shows a reaction rate of less than 0.1% to cephalosporin antibiotics and can be prescribed to this subset of patients. This treatment is not appropriate for individuals with severe reaction histories to penicillin (eg, anaphylaxis urticaria, angioedema, bronchospasm, serious delayed reaction [eg, Stevens-Johnson syndrome, toxic epidermal necrolysis, hemolytic anemia]) or uncertain type of reaction where treatment with another antibiotic (azithromycin, clarithromycin, or erythromycin-sulfisoxazole) is recommended.

Currently, tympanocentesis is rarely performed before the initiation of antibiotics. Indications for tympanocentesis include toxic appearance or severe ear pain, because the procedure provides relief through decompression. Tympanocentesis is occasionally performed in a child who has been receiving appropriate and adequate antimicrobial therapy but in whom such treatment does not result in improvement; in the setting of confirmed or potential suppurative complications, such as facial paralysis, mastoiditis, or meningitis; or in the newborn, ill neonate, or immunodeficient patient in whom an unusual organism may be present (Box 87.3).

Table 87.1. Recommended Antibiotics for Initial or Delayed Treatment and for Patients Who Have Failed Initial Antibiotic Treatment

Initial Antibiotic Treatment at AOM Diagnosis or After Observation		*Antibiotic Treatment After 48–72 Hours of Initial Antibiotic Treatment Failure*[a]	
Recommended First-Line Treatments	***Alternative Treatments***	***Recommended First-Line Treatments***	***Alternative Treatments***
Amoxicillin (80–90 mg/kg per day) OR Amoxicillin–clavulanateb (90 mg/kg per day of amoxicillin, with 6.4 mg/kg per day of clavulanate)	Cefdinir (14 mg/kg per day in 1 or 2 doses) Cefuroxime (30 mg/kg per day in 2 divided doses) Cefpodoxime (10 mg/kg per day in 2 divided doses) Ceftriaxone (50 mg/kg per day IM or IV for 1–3 days)	Amoxicillin–clavulanate (90 mg/kg per day of amoxicillin, with 6.4 mg/kg per day of clavulanate) OR Ceftriaxone (50 mg/kg per day IM or IV for 3 days)	Clindamycin (30–40 mg/kg per day in 3 divided doses), with or without second- or third-generation cephalosporin[b]

[a]If no improvement with second course of antibiotics, consider tympanocentesis and consultation with an otolaryngologist.

[b]May be considered in patients who have received amoxicillin in the previous 30 days or who have the otitis–conjunctivitis syndrome.

Abbreviations: IM, intramuscular; IV, intravenous.

Adapted with permission from Lieberthal AS, Carroll AE, Chonmaitree T, et al. Erratum. The diagnosis and management of acute otitis media. *Pediatrics* 2014;133(2):346–347 DOI: https://doi.org/10.1542/peds.2013-3791.

Adjunctive medications, such as topical analgesics (antipyrine and benzocaine ear drops) and antipyretic agents are important therapeutic options and should be prescribed for the child with significant pain or fever. Antihistamines, decongestants, or steroids have no documented role in the management of OME. Most resolving MEEs that occur after AOM in otherwise healthy children do not need to be treated; the wait-and-watch approach is recommended.

Failure of antibiotic treatment and chronic effusions warrant a referral to an otolaryngologist for further evaluation for pressure equalization tubes, especially if an effusion is present for more than 3 months and associated symptoms, such as vestibular symptoms, school or behavioral problems, ear discomfort, or decreased quality of life, are present. The physician may recommend pressure equalization tubes to manage recurrent OM (3 episodes in 6 months or 4 episodes in 1 year, with 1 episode in the preceding 6 months). Episodes of recurrent OM should be well documented as separate acute infections. Other indications for consultation include hearing loss; any anatomic abnormality, such as a defect of the TM (eg, perforations, cholesteatomas) or intranasal problems (eg, deviated septum, polyp); signs and symptoms of an OM but normal physical examination; and a predisposition to chronic recurrent OM (eg, child with a cleft palate or Down syndrome).

Duration of Therapy

For the child younger than 2 years and any child with severe symptoms, a standard 10-day course of oral antibiotics is recommended. A 7-day course of oral antibiotic appears to be equally effective in children 2 to 5 years of age with mild or moderate AOM. For the child 6 years or older with mild to moderate symptoms, a 5- to 7-day course of oral antibiotics is adequate.

Follow-up of the Patient With Acute Otitis Media

The physician may choose to reassess some children in 10 to 14 days, such as the young child with severe symptoms or recurrent AOM or when specifically requested by the child's parent or guardian.

Persistent MEE is common and can be detected by pneumatic otoscopy (with or without verification by tympanometry) after resolution of acute symptoms. Two weeks after successful antibiotic treatment of AOM, 60% to 70% of children have MEE; this percentage decreases to 40% at 1 month and to 10% to 25% at 3 months after successful antibiotic treatment.

Complications

Complications associated with OM are uncommon with appropriate antibiotic therapy and follow-up. Such complications are either extracranial or intracranial. Extracranial complications include perforation of the TM, conductive and sensorineural hearing loss, ossicular fixation or discontinuity (eg, adhesive OM), cholesteatoma, mastoiditis, petrositis, facial nerve (ie, seventh cranial nerve) paralysis, osteomyelitis of the temporal bone, and Bezold abscess. Intracranial complications are meningitis, extradural as well as subdural abscesses, lateral venous sinus thrombosis, brain abscess, carotid artery thrombosis, and hydrocephalus.

CASE RESOLUTION

The child displays the classic signs and symptoms of AOM: fever, URI, decreased appetite, and an abnormal TM on physical examination. Because of his age and fever and the certainty of diagnosis, he should be treated for 10 days with oral amoxicillin. The prognosis is good given his normal speech development.

CHAPTER 88

Hearing Impairments

Patricia Padlipsky, MD, FAAP

CASE STUDY

A 15-month-old girl is brought to the office because her parents are concerned that she has not yet begun to speak. The child was the product of a term uncomplicated pregnancy. Her 25-year-old mother, who began to receive regular prenatal care during the second month of gestation, had no documented infections during the pregnancy, took no medications, and denies using illicit drugs or alcohol. The child was delivered at home by a midwife, and a newborn hearing screening was never done. The 27-year-old father is reportedly healthy. The family history is negative for deafness, intellectual disability, and consanguinity.

The child, who is otherwise healthy, has never been hospitalized, but she has had 3 documented ear infections. She rolled over at 4 to 5 months of age, sat at 7 months, and walked at 13 months. She can scribble. The parents report that their daughter smiles appropriately, laughs occasionally, and plays well with other children. As an infant, the girl cooed and babbled, but she now points and grunts to indicate her needs. She does not respond to loud noises by turning her head.

The child's growth parameters, including head circumference, are normal for age. The remainder of the physical examination is unremarkable.

Questions

1. When should deafness be suspected in infants and children?
2. What is the relationship between hearing loss and language development?
3. What are the major causes of deafness in children?
4. Which neonates are at risk for the development of hearing deficits?
5. What methods are currently available for evaluating hearing in infants and children?
6. What are the important issues to address with families who have infants or children with suspected hearing impairment?

Any amount of hearing loss, whether unilateral or bilateral, can cause a significant childhood disability that can compromise speech and language development, academic performance, and social and emotional development. It is essential to identify hearing loss as soon as possible to implement early intervention, which has been shown to prevent many adverse consequences. Children may be born with a hearing deficit (ie, *congenital deafness*), or they may acquire the condition during childhood (ie, *late-onset deafness*). Hearing loss also may be progressive and not identified on early screening. Hearing loss can be classified as conductive, sensorineural, mixed, or auditory neuropathy spectrum disorder (ANSD). Hearing loss is further described by the degree of loss, whether mild (26–40 dB loss), moderate (40–70 dB loss), severe (71–90 dB loss), or profound (>90 dB loss). The most important period for speech and language development is from birth to 3 years of age. Reduced hearing acuity in both ears or even 1 ear during this time can significantly interfere with this important process (see Chapter 33). Therefore, the primary care physician must have a clear understanding of when to suspect impaired hearing in infancy and early childhood and must be familiar with the identification of, evaluation methods for, and treatment options for hearing loss.

Epidemiology

The prevalence of congenital deafness in children is approximately 0.1%. In other words, 1 in 1,000 children is born with severe to profound hearing loss. The prevalence increases to 6 in 1,000 when all degrees of hearing loss, mild to profound, are considered. By age 18 years, it is estimated that 17 in 1,000 children have some degree of permanent hearing loss. This increase over time reflects the addition of patients with progressive, acquired, or late-onset genetic causes. Diagnostic findings for ANSD often are not conclusive in newborns because language skills are still developing and not aberrant at the time of newborn screening.

Prior to the initiation of newborn hearing screening, the average age at diagnosis of most children who were born with hearing impairment was 2 to 3 years. Since the advent of such screening, however, the average age at diagnosis has dropped to 2 to 3 months. Currently, all 50 states have a universal newborn hearing screening as well as early hearing detection and intervention programs. More than 95% of all newborns are screened, and 74% of those found to have hearing impairment have entered an intervention program by 6 months of age. As with any screening program, however, some newborns are missed, especially with at-home births.

Additionally, as many as 40% of identified newborns are currently lost to follow-up, and some forms of early-onset hearing loss are not apparent at birth. Therefore, careful assessment of hearing and language development by the medical professional is essential at each patient encounter.

More than 90% of children with deafness are born to hearing parents. An estimated 20% to 30% of children with hearing impairment develop the condition during childhood. Of these, 70% of children with acquired hearing loss are initially identified by parents rather than physicians. Any concern by parents that their child might have a hearing problem should be taken seriously by the physician and objective testing performed. Risk factors for acquired hearing loss in childhood include persistent otitis media with effusion, history of head trauma, bacterial meningitis, and identification of syndromes or neurologic disorders associated with hearing loss.

Graduates of the neonatal intensive care unit are at significantly increased risk for sensorineural hearing loss (SNHL) and ANSD, with reported rates of SNHL and ANSD of 16.7 and 5.6 per 1,000 infants, respectively, compared with an estimated incidence of ANSD in a well-baby population of 0.06 per 1,000 infants. Diagnostic findings for ANSD often are not conclusive in newborns because language skills are still developing and not aberrant at the time of newborn screening. Associated factors, such as preterm birth (birth weight <1,500 g [<3.3 lb]), hyperbilirubinemia, prolonged mechanical ventilation, extracorporeal membrane oxygenation treatment, perinatal asphyxia, exposure to ototoxic drugs, and neonatal sepsis increase the risk for ANSD. Other factors associated with deafness in childhood include meningitis, parental consanguinity, craniofacial malformations, congenital viral infections, exposure to chemotherapy, and a family history of deafness.

Box 88.1. Risk Factors for Hearing Impairment

- Family history of congenital or early SNHL
- Congenital infection known to be associated with SNHL
- Craniofacial anomalies
- Birth weight <1,500 g (<3.3 lb)
- Hyperbilirubinemia over the exchange level
- Infectious diseases associated with SNHL
- Exposure to ototoxic medications
- Bacterial meningitis
- Low Apgar scores at birth
- Prolonged mechanical ventilation in neonatal period
- Findings of a syndrome associated with SNHL
- Any parental/caregiver concern about hearing, speech, language, or developmental delay
- Head trauma, especially with fracture of the temporal bone
- Neurodegenerative disorders

Abbreviation: SNHL, sensorineural hearing loss.

Clinical Presentation

The newborn may present to the primary care physician having had an abnormal newborn hearing screening test. The initial newborn screening is mandated by 1 month of age, with definite testing by an audiologist for abnormal tests by 3 months of age. Intervention should begin by 6 months. For the infant who passes hearing testing but has positive risk factors for hearing impairment (Box 88.1), communication skills should be assessed at every well-child visit and diagnostic audiologic assessment should be done by 24 to 30 months of age.

In the unscreened population or for children with progressive or acquired hearing loss, parents are often the first to suspect hearing loss. A parent may be concerned that the toddler is indicating needs by grunting and pointing rather than using words or that the child does not seem to respond to sounds. Children with hearing impairments frequently present to physicians with delayed speech or speech impediments; children produce what they hear.

Normal speech volumes range from 30 to 50 dB, whereas typical street traffic volume is approximately 60 dB. Standard telephone rings and shouts are approximately 80 dB, and lawnmowers are approximately 90 dB. Therefore, children with a 50-dB hearing loss may hear their mother when she yells at them and may startle when the telephone rings. However, they do not hear most conversational speech, and they may not always hear the teacher in a classroom, especially if they are not in the front and in the setting of significant extraneous noise. This can result in behavioral problems, such as inattention, temper tantrums, and aggressive play with other children (Box 88.2).

Worsening speech or school performance may herald longstanding or progressive mild-to-moderate hearing loss. Other presentations of mild or progressive hearing loss may consist of either withdrawal from social activities and playing alone or playing the television and music at increasingly loud volumes.

Hearing impairment can be particularly difficult to recognize in infants younger than 6 months because they may have no obvious symptoms of a hearing deficit. They may startle to moderately loud noises and begin to vocalize as other infants do (Figure 88.1). If the history is suggestive of a hearing deficit or a parent or caregiver expresses concern, audiologic testing should be performed.

Box 88.2. Diagnosis of Hearing Impairment in the Pediatric Patient

- Parental concern or suspicion of hearing loss
- Delayed speech and language development
- Associated risk factors, including preterm birth, exposure to ototoxic drugs, congenital or acquired central nervous system infections, family history of hearing loss, and craniofacial abnormalities
- History of behavioral problems or poor school performance
- Abnormal hearing test

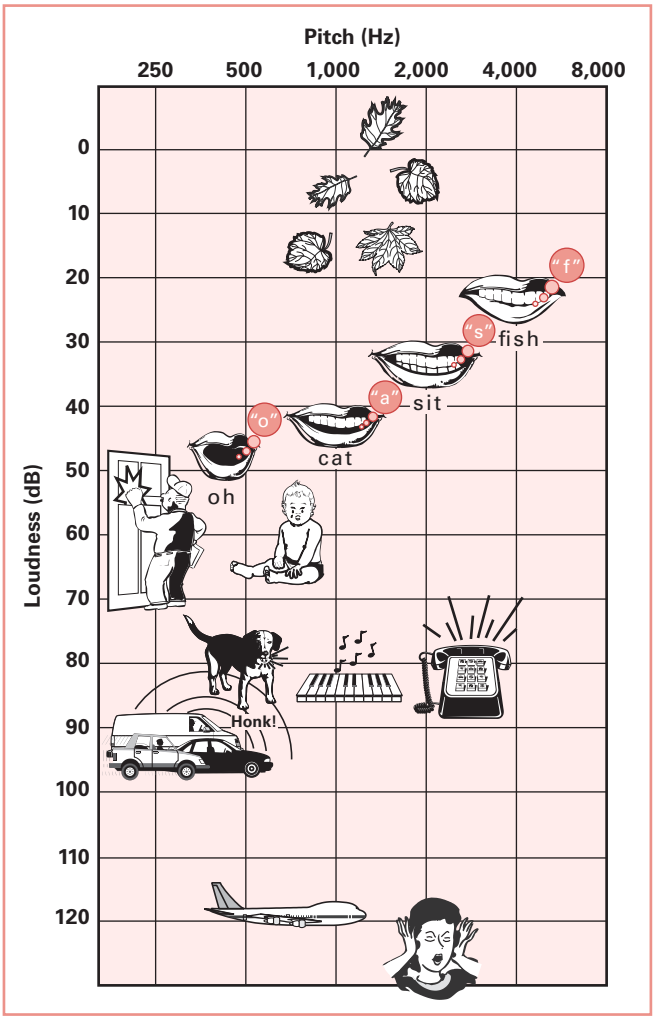

Figure 88.1. **Loudness of everyday sounds.**

Pathophysiology

Mechanism of Hearing

Sounds in the form of pressure waves are carried from the environment through the external auditory canal to the tympanic membrane (TM). These waves are converted to mechanical vibrations by the ossicles, and the mechanical vibrations are then transmitted from the TM to the inner ear, where they are transformed to fluid vibrations. Finally, these fluid vibrations are converted into nerve impulses by nerve endings within the organum spirale located in the cochlea in the inner ear. These impulses are conducted via the auditory nerve to the auditory cortex (Figure 88.2).

Hearing impairments can be classified according to the part of the auditory system affected or by the cause of the hearing loss.

Types of Hearing Loss

A *conductive hearing loss* (CHL) denotes an abnormality from the pinna, external auditory canal, TM, or middle-ear ossicles. Conductive hearing loss can occur in congenital anomalies, such as atresia, impacted cerumen, otitis externa, serous otitis media, otitis media with effusion, TM perforation, ossicular discontinuity, and otosclerosis. An SNHL is an abnormality that affects the cochlea, inner ear, or auditory nerve. Congenital infections, anomalies, genetic disorders, and loud noise result in this type hearing loss. The loss of cochlear function, usually from damage to sensory hair cells in the organum spirale, is the main cause of permanent childhood hearing loss. A *mixed disorder* has characteristics of both conductive and sensorineural losses. In *retrocochlear hearing loss*, the auditory nerve, brain stem, or cortex is affected. This includes ANSD noted in neonates after neonatal intensive care unit stays. In auditory neuropathy, sound enters

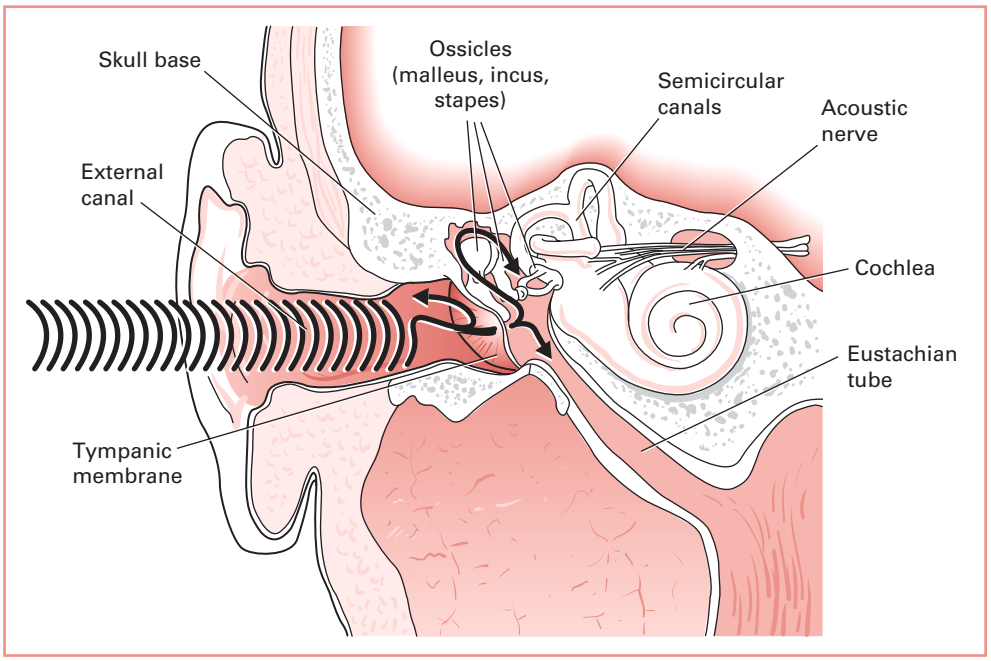

Figure 88.2. **Sound waves (represented by arrows) passing through the external ear into the middle ear.**

the ear normally, but because of damage to the inner ear or the hearing nerve, sound is not organized in a way that the brain can understand.

Etiology of Hearing Impairment

The causes of hearing loss can be broadly divided into genetic and acquired and further divided into congenital and/or progressive (Table 88.1). Of the 1 in 1,000 individuals born with severe to profound hearing loss, the cause is genetic in approximately 50%, nongenetic in approximately 25%, and idiopathic in approximately 25%. Of the 50% with a genetic cause, the hearing loss is syndromic in 30% and nonsyndromic in 70%. More than 500 forms of syndromic hearing loss exist, each with associated clinical features. Most of these syndromes are rare. Waardenburg syndrome is the most common type of autosomal dominant syndrome with SNHL. Usher syndrome and Pendred syndrome with goiter are examples of autosomal recessive syndrome with SNHL. Down (ie, trisomy 21) syndrome and oculoauriculovertebral dysplasia (ie, Goldenhar syndrome) often have associated hearing impairment. Alport syndrome with progressive SNHL and nephritis is also well recognized and is X-linked. Most cases of genetic hearing loss are nonsyndromic, however, and result from a single gene defect encoding connexin 26 protein. This recessive disorder with mutations in the *GJB2* gene accounts for 30% to 50% of all cases of nonsyndromic hearing loss. Genetic malformations of the ear pinnae or ossicles do occur but are the least common cause of hearing loss. Genetic mutations may result in different types of deafness with various presentations and outcomes, that is, hearing loss may be conductive, sensorineural, or mixed and may be static or progressive, with the initial presentation in infancy or later childhood.

Table 88.1. Major Causes of Childhood Deafness

Hearing Loss Type	*Conductive Hearing Loss*	*Sensorineural Hearing Loss*
Congenital	Microtia/atresia Tympanic membrane abnormalities Ossicular malformations	Genetic disorders (eg, syndromic, connexin 26, mitochondrial) In utero infection (eg, cytomegalovirus, measles, mumps, rubella, varicella, syphilis) Anatomic abnormalities of the cochlea or temporal bone Exposure to ototoxic drugs during pregnancy (eg, alcohol, isotretinoin, cisplatin) Hyperbilirubinemia
Acquired	Infection (eg, acute otitis media, otitis externa, ossicular erosion) Otitis media with effusion Foreign body (including cerumen) Cholesteatoma Trauma (eg, ossicular disruption, tympanic membrane perforation)	Infection (eg, bacterial meningitis, measles, mumps, rubella, Lyme disease) Trauma (eg, physical or acoustic) Radiation therapy for head and neck tumors Neurodegenerative or demyelinating disorders (eg, Alport syndrome, Cogan syndrome)

Adapted with permission from Gifford KA, Holmes MG, Bernstein HH. Hearing loss in children. *Pediatr Rev.* 2009;30(6):207–216.

Acquired environmental causes of hearing loss include prenatal, perinatal, or postnatal events and exposures, such as congenital infections, bacterial meningitis, hyperbilirubinemia, complications of prematurity, and exposure to ototoxic drugs. Cytomegalovirus (CMV) likely is the most frequently unrecognized congenital infection causing deafness. Even if an infant is asymptomatic from the CMV infection, a 10% to 15% chance exists that the infant will develop an SNHL. Other congenital infections, such as toxoplasmosis, measles, mumps, rubella, herpes simplex virus, HIV, and syphilis can also cause hearing loss. Hearing loss associated with bacterial meningitis accounts for as many as 20% of cases, with *Streptococcus pneumoniae* as the prevalent responsible organism. The incidence of *S pneumoniae* and *Haemophilus influenza* type b meningitis has decreased tremendously in young children following the advent of conjugate vaccine, and the prevalence of postmeningitic hearing loss has similarly declined. The role of steroids in the management of bacterial meningitis has also contributed to the decrease in SNHL in survivors.

With the recognition and treatment of hyperbilirubinemia in term newborns, hyperbilirubinemia as a cause of hearing loss is now rare in the United States and other developed countries. Preterm birth as a cause of hearing loss is, however, not uncommon. Because of associated complications, preterm newborns have higher rates of severe hearing loss than do term newborns. Some antibiotics (eg, aminoglycosides) and other medications (eg, loop diuretic agents) can be irreversibly ototoxic; other drugs may cause only transient effects.

Any head injury, especially if the injury damages the temporal bone, can cause deafness in children. Fractures through the cochlea and vestibule can result in severe to profound hearing loss, and damage to the TM and/or ossicles can result in a significant CHL. Acoustic trauma (ie, noise-induced hearing loss) from continuous or significant exposure to loud noise can also cause irreversible SNHL. With children's use of personal listening devices, the prevalence of this cause of hearing loss is increasing.

Hearing loss caused by middle ear effusions is the most common cause of childhood hearing loss. It is often not discussed because it is usually considered benign and transient in nature. However, of all ears with resolved otitis media persistent fluid is exhibited in 40% at 1 month, 20% at 2 months, and 10% at 3 months after infection or after the conclusion of treatment. It is important to identify whether this effusion is affecting the child's hearing. Speech development is greatest in the first 3 years after birth and can be affected if a child has chronic effusion that is

causing hearing loss. Any concern for hearing loss warrants objective testing, and consultation with an otolaryngologist should be recommended.

Differential Diagnosis

In addition to hearing loss, communication disorders should be considered in the infant or child with delayed speech and language development. These include problems with speech perception, language comprehension, formulation of language output, and speech production. Unrecognized conditions, such as intellectual disability or autism spectrum disorder, are responsible for some of these disorders. Other etiologies include specific central nervous system deficits as well as impairments of fine motor control of the oropharynx.

Evaluation

Newborn Hearing Screening

The earlier the diagnosis of hearing loss is made, the sooner interventions can be initiated to help the child develop. In 1994, the Joint Committee on Infant Hearing (JCIH), composed of representatives from several professional organizations, endorsed universal newborn hearing screening. The goal was the early identification of hearing loss in newborns and infants before age 3 months and the implementation of intervention services by age 6 months. As a result of these recommendations, states have implemented legislation mandating newborn hearing screening and intervention programs. A subsequent position statement was issued in 2000. The American Academy of Pediatrics endorsed this statement and promoted newborn hearing screening as well as periodic hearing assessment for every child. As a result, hearing screening has been established as an essential newborn evaluation; however, a significant need exists to improve infrastructure to ensure that physicians receive and process screening results. The JCIH policy statement was most recently updated in 2007 and includes more specific guidelines for diagnostic audiologic evaluation, medical evaluation, and surveillance screening in the medical home. Per the policy, all infants and children—regardless of hearing screening results—should undergo ongoing assessment of communication skills beginning at 2 months of age. Any child with evidence of hearing loss in 1 ear or both ears should be offered early intervention. In 2013, a supplement was published to the 2007 JCIH position statement describing principles and guidelines for early intervention after a child is diagnosed with hearing impairment.

History

Because the primary symptom of hearing impairment or deafness is failure to learn to speak at the appropriate age, the most important aspect of the history in the child with possible hearing loss is determining whether speech is developing normally. Even an infant with deafness may begin cooing and babbling in infancy, and these early attempts at verbalization are not useful milestones for assessment of hearing deficits. It helps to ask the parent or guardian whether that individual is at all suspicious or concerned about the child's speech or hearing. Guidelines for assessing language development are found in Table 88.2 (also see Chapter 33). It is also important to assess for risk factors for deafness, such as a positive family history, infection during gestation, history of prematurity, hyperbilirubinemia, neonatal sepsis, and asphyxia (Box 88.3).

Table 88.2. Expected Speech, Language, and Auditory Milestones

Age	*Receptive Skills*	*Expressive Skills*
Birth	Turns to source of sound Shows preference for voices Shows interest in faces	Cries
2–4 months	Turns to source of sound Shows preference for voices Shows interest in faces	Coos Takes turns cooing
6 months	Responds to name	Coos Takes turns cooing
9 months	Understands verbal routines (eg, "wave bye-bye")	Babbles Points Says mama, dada
12 months	Follows a verbal command	Uses jargon Says first words
15 months	Points to body parts by name	Learns words slowly
18–24 months	Understands sentences	Learns words quickly Uses 2-word phrases
24–36 months	Answers questions Follows 2-step commands	Phrases 50% intelligible Builds ≥3-word sentences Asks "what" questions
36–48 months	Understands much of what is said	Asks "why" questions Sentences 75% intelligible Masters the early acquired speech sounds: m, b, y, n, w, d, p, and h
48–60 months	Understands much of what is said, commensurate with cognitive level	Creates well-formed sentences Tells stories 100% intelligible
6 years	Understands much of what is said, commensurate with cognitive level	Pronounces most speech sounds correctly; may have difficulty with sh, th (as in think), s, z, th (as in the, l, r, and s in treasure)
7 years	Understands much of what is said, commensurate with cognitive level	Pronounces speech sounds correctly, including consonant blends, such as sp, tr, bl

Box 88.3. What to Ask

Hearing Impairment

- Does the child seem to respond to sounds?
- Does the child attempt to repeat sounds?
- How does the child indicate his, her, or their desires or needs?
- How are the parent(s)/guardian(s) currently communicating with the child?
- Does evidence exist of a congenital infection, structural anomaly of the head and neck, or syndrome?
- Is there a history of prematurity or other prenatal or perinatal problem?
- Has the child had any serious bacterial infection, such as meningitis?
- Does the child have a history of repeated ear infections or exposure to ototoxic drugs?
- Aside from the hearing problem, is the child developmentally normal?
- Is there a family history of deafness, consanguinity, or multiple miscarriages or stillbirths?

Physical Examination

A complete physical examination should be performed on all children. In particular, any dysmorphic facial features that may be suggestive of a syndrome with an associated hearing deficit should be noted. Other anomalies of the head and neck should be noted as well. Abnormal pigmentary conditions may be important clues. The eyes should be evaluated for heterochromia and hypertelorism findings seen in Waardenburg syndrome, which also includes SNHL. The size and shape of the pinnae and external ear canals should be carefully inspected for abnormalities and patency, respectively. Preauricular pits or tags may be apparent. Additionally, the TMs should be visualized and assessed for the presence of middle ear effusion that may influence subsequent audiologic tests. Insufflation may be helpful in the assessment of middle ear effusion. The oropharynx should be examined for a cleft palate or bifid uvula, which may be associated with a submucosal cleft. The manner in which the child communicates with the parent or guardian should be noted, if possible, and the child should be assessed for response to sound.

Laboratory Tests

Tympanometry does not measure hearing, but it is useful in assessing the presence of middle ear fluid and the mobility of the TM. Tympanometry can be particularly helpful with the uncooperative, crying child in whom assessing the appearance of the TM and insufflation is difficult. Different types of hearing tests for evaluating infants and children for possible hearing deficits are available to the primary care physician (Box 88.4). The 2 tests used for the screening of newborns are otoacoustic emissions and auditory brainstem response (ABR), the latter of which is also referred to as brainstem auditory evoked response. *Otoacoustic emissions* testing measures cochlear function in response to a specific stimulus via a small probe that contains a microphone that is placed in the ear canal. This test can be used for newborn hearing screening in the low-risk newborn. It requires no sedation and is inexpensive and quick; it can be completed in 10 minutes. It has been implemented quite successfully as the hearing screening test in hospitals and primary care physician offices and has the advantage of being useful for all ages. ABR is an electrophysiological measurement of activity in the auditory nerve and brain stem pathways. Electrodes are placed on the head of the newborn, infant, or child to record brain wave activity while a specific auditory stimulus is presented through earphones to 1 ear at a time. Auditory thresholds can be estimated. ABR is used as a screening tool for newborn hearing screening and only takes approximately 10 minutes. As a screening tool, it delivers a preset intensity and frequency. If an infant does not pass the screening test, a full ABR should be done in which different intensities and frequencies are used to help identify the degree of hearing loss and at what frequencies. This evaluation takes approximately 90 minutes. Both otoacoustic emissions and ABR results can be affected by the presence of outer ear or middle ear disease. ABR requires a calm, resting infant. The older infant may require sedation. *Behavioral observation audiometry* measures a child's response to speech and frequency-specific stimuli presented through speakers in a soundproof room. This method of testing assesses hearing in the better ear only and cannot detect unilateral hearing loss. It is used for the child with a developmental age of younger than 6 months. *Conditioned play audiometry*, like *conventional audiometric testing*, measures auditory thresholds in response to frequency-specific stimuli presented through earphones to 1 ear at a time. The patient is instructed to perform a particular task, such as putting a block in a container or raising his or her hand, when the stimulus is heard. The child as young as 3 years can be tested by conditioned play audiometry, and the child age 4 or 5 years can be assessed using conventional audiometric testing. Any abnormal results on these screening tests should be used in conjunction with evaluation by an audiologist and an otolaryngologist. In the case of the high-risk infant, audiologic testing should be repeated at least every 6 months until 3 years of age and at appropriate intervals thereafter, depending on the etiology of the suspected hearing loss and test results.

Box 88.4. Tests for Evaluating Hearing

- Automated auditory brainstem response: used for newborn hearing screening
- Behavioral observation audiometry
- Brainstem auditory evoked response
- Evoked otoacoustic emissions (a newer type of newborn hearing screening)
- Conditioned play audiometry
- Conventional audiometric testing

Diagnostic tests to consider in evaluating the cause of deafness include titers for congenital infections, such as CMV, toxoplasmosis, HIV, and rubella, and fluorescent treponemal antibody absorption tests for syphilis. In the newborn period, a CMV culture may be helpful. Testing for the *GJB2* gene, the mitochondrial A1555G mutation that predisposes an individual to ototoxicity from drugs, and the *SLC26A4* gene for Pendred syndrome, along with CMV testing, would reveal an etiology for 40% of cases of congenital hearing loss and 60% of cases of late-onset hearing loss. Thyroid function tests are necessary if Pendred syndrome is suspected, especially in the school-age child with goiter. Proteinuria and hematuria should also be ruled out by urinalysis, especially in boys with a positive family history of deafness and renal failure, both of which are findings suggestive of Alport syndrome. Electrocardiography is recommended for the detection of conduction defects, such as QT prolongation in Jervell and Lange-Nielsen syndrome.

Imaging Studies

Occasionally, computed tomography or magnetic resonance imaging of the temporal bone may be obtained to view the anatomy of the middle and inner ear, particularly in cases of a suspected cochlear or vestibular malformation or fistula. Necessity for such studies should be determined by an audiologist or otolaryngologist.

Management

According to the 2013 supplement to the JCIH 2007 statement, "Screening and confirmation that a child is deaf or hearing impaired are largely meaningless without appropriate, individualized, targeted and high-quality intervention. For the infant or young child who is deaf or hard of hearing to reach his or her full potential, carefully designed individualized intervention must be implemented promptly, utilizing service providers with optimal knowledge and skill levels and providing services on the basis of research, best practices, and proven models." Studies have shown that the earlier a hearing deficit is detected and remediation begun in an otherwise normal newborn, the greater the likelihood the child will have language development close to that of a hearing child. Initiation of intervention before 6 months of age contributes to infants being able to develop language as well as social and emotional skills appropriate for their age. School performance and communication skills have been shown to be better in those identified at a younger age. It appears as though the critical period for hearing and speech development is from birth to 3 years of age. All newborns, infants, and children identified with a hearing deficit should be referred to an otolaryngologist and audiologist for immediate assessment and recommendation for assistive devices.

If a child is diagnosed with bilateral otitis media with effusion, recent guidelines indicate that a hearing test should be done if the effusion lasts for 3 months or longer. If a hearing loss is identified, tympanostomy tubes should be inserted.

Additional assessment for the child with identified hearing loss includes an ophthalmologic evaluation and referral to a geneticist. After an infant or child is found to have a hearing impairment, careful follow-up is necessary so that any further reduction in hearing is promptly identified. The role of the primary care physician thus becomes even more crucial. Coordination of care with speech and language specialists as well as educators who have experience working with children with deafness is essential. Parents or guardians and other family members may initially be devastated by the diagnosis of a hearing impairment, especially if the deficit is severe to profound. These individuals often have multiple questions about the child's medical prognosis and educational future. The possibility of further speech and language development may also be a foremost concern in their minds. In addition to providing the patient with comprehensive care, all the questions and concerns of the parent or guardian must be addressed and anticipated.

Future Audiologic Evaluations

In the newly diagnosed patient with SNHL, audiology testing should be repeated every 3 months in the first year after birth, every 6 months when the child is in preschool, and at least annually after the child has begun school. Continued monitoring is essential to detect any progression of the hearing deficit.

Assistive Devices

Although hearing aids may not restore normal hearing, all children with CHL as well as SNHL benefit from amplification. Several different types of hearing aids are available for children; these devices should be fitted appropriately and adjusted regularly by a specialist. Additionally, it is also recommended that all patients receive bilateral hearing aids to improve auditory localization and training, particularly in the context of different learning situations.

A frequency modulation system is an additional assistive listening device that can be used in a classroom. A speaker (eg, the teacher) uses a microphone to transmit to a receiver worn by the child to improve reception. Closed-caption television, whether signed or subtitled, is another method of auditory training. Teletype telephone systems are available for children who can read.

Cochlear implants may be surgically placed in the cochlea to improve hearing. Implants were first approved by the US Food and Drug Administration for use in children in 1990. The implant consists of an electrode array placed in the cochlea with a receiver-stimulator under the skin and a processor worn over the ear that transmits by radio waves an impulse that produces an electrical discharge within the cochlea. These electrical pulses effectively stimulate the auditory system. The implant can be used in children 12 months or older with severe to profound SNHL. Its use is now considered to be standard of care for patients with SNHL and is being used in infants as young as 6 months. Speech, language, and special education resources should be provided. Most patients with implants show significant improvement in communication skills. Children with cochlear implants are

at increased risk for meningitis; therefore, pneumococcal and routine *H influenzae* type b vaccines are recommended.

Education and Communication

Much controversy exists concerning the optimal method of communication for children with deafness. Oral communication (ie, lip reading) and sign language each has advantages and disadvantages depending on the child's age, type of deafness, and whether the deficit is congenital or acquired. Whether the child already knows a language is also important to consider. The preferred methods seem to vary from region to region; therefore, schools, other institutions, and resource groups often use the most popular communication method in a particular area. Generally, some authors recommend that children with minimal hearing loss may do better with lip reading than those with greater hearing loss, who will most likely benefit more from sign language. Early intervention and education programs can be home-based or in a group setting, but it is recommended that educators be familiar with working with children with hearing impairment.

Whether to mainstream the child with severe hearing loss in a regular classroom with an interpreter or place the child in a school for children with deafness is another controversial issue. Parent(s)/guardian(s) should be encouraged to explore the possibilities of each option and to make a decision based on the individual needs of the child rather than on current trends. The expertise of an educator who is knowledgeable in this field can be helpful when making this decision.

Outside Resources and Referrals

As previously mentioned, it takes a team to properly evaluate a child with hearing loss. The newly diagnosed child should be evaluated by an otolaryngologist with pediatric expertise, an audiologist, a pediatric ophthalmologist, and a medical geneticist. Any refractory error should be managed and followed closely, because the child with severe hearing difficulty is more dependent on vision. A genetics evaluation is important for diagnostic reasons as well as for providing families with information and counseling about the risk of recurrence.

Speech assessment and therapy are an essential part of long-term management, as are special education resources. Support groups and referrals to national organizations for individuals with hearing impairment can be valuable for parents/guardians and families. Resources for financial support should also be explored. Agencies with multidisciplinary teams are particularly important for newborns, infants, and children with other associated disabilities.

Prognosis

The goals of early recognition and treatment of newborns, infants, and children with hearing deficits are to minimize possible long-term sequelae of persistent speech and language problems and maximize cognitive development. An additional goal is to prevent learning disabilities with subsequent educational failure. The earlier the intervention, the more likely children are to succeed and maximize their potential. With appropriate treatment, the child with hearing impairment should be able to lead a normal life.

CASE RESOLUTION

The child has a history that is classically positive for a hearing deficit. She does not turn to loud noises, she has not developed any specific words, and she indicates her needs nonverbally. Although obvious historical risk factors for hearing loss are lacking, behavioral audiography or brainstem auditory evoked response should be performed by an audiologist. The physician's suspicion should be discussed with the family, and a follow-up visit should be arranged to review hearing test results as soon as possible.

CHAPTER 89

Sore Throat

Casey Buitenhuys, MD, FACEP, and Stanley H. Inkelis, MD, FAAP

CASE STUDY

An 8-year-old girl has had a sore throat and fever for 2 days. She also has pain on swallowing, a headache, and a feeling of general malaise but no stridor, drooling, breathing difficulty, or rash. Other than the current illness, the girl is in good health. Although she has had sore throats in the past, she has never had one this severe. One week previously, her mother and father had sore throat and fever that resolved after 5 days with no medication.

The child has a temperature of 39.0°C (102.2°F). The physical examination is normal except for red tonsils with exudate bilaterally, palatal petechiae, and tender cervical lymphadenopathy.

Questions

1. What are the causes of sore throat in children?
2. What is the appropriate evaluation of the child with sore throat? What laboratory tests are necessary?
3. What is the appropriate management for the child with sore throat?
4. When should otolaryngologic consultation be obtained?

Sore throat, which is among the most common illnesses seen by the primary care physician, is a painful inflammation of the pharynx, tonsils, or surrounding areas. In most cases, children with sore throat have mild symptoms that require little or no treatment. However, sore throat may be the presenting symptom of a severe illness, such as epiglottitis or retropharyngeal abscess. Young children may not able to define their symptoms very well, which makes a careful history from parents or other caregivers and a good physical examination essential for correct diagnosis. Optimal management of sore throat, especially if group A β-hemolytic streptococcus (GABHS; *Streptococcus pyogenes*) is suspected, remains quite controversial.

Epidemiology

In the United States, sore throat accounts for approximately 15 million outpatient physician visits each year, and approximately 5% of all pediatric emergency department visits are for pharyngitis. Sore throat is most common in children between 5 and 15 years of age. It is uncommon in infants younger than 1 year. Like other respiratory infections, sore throat occurs most often in the late fall and winter months. Approximately 11% of all school-age children receive medical care for pharyngitis. Twenty percent to 30% or more of cases of pharyngitis in these children are caused by GABHS. The estimated medical and nonmedical costs for GABHS pharyngitis are $205 per visit or approximately $224 million to $539 million per year, with much of the indirect costs related to parental loss of time from work.

The organisms that cause bacterial and viral pharyngitis are present in saliva and nasal secretions and are almost always transmitted by close contact. Spread between children in school is the common mode of transmission.

Clinical Presentation

The clinical presentation of sore throat is variable and often depends on etiology (Box 89.1; also see Differential Diagnosis). Most children with sore throat present with sudden onset of pain and fever. The height of the fever is variable and is typically higher in younger children. In the older child, especially if the sore throat is associated with a common cold, fever is minimal or absent. The throat or tonsils are red, and the breath may be malodorous. Headache, nausea, vomiting, and abdominal pain may occur, especially if the child is febrile. Appetite may be decreased, and the child may be less active than usual.

In the child with the common cold, rhinorrhea and postnasal discharge are present. A pharyngeal and tonsillar exudate is not typical. Although the cervical lymph nodes may be enlarged, they are usually not very tender. In contrast, the child with streptococcal pharyngitis typically has high fever, pharyngeal and tonsillar exudate, and tender cervical lymph nodes.

Pathophysiology

Various bacteria and viruses produce sore throat symptoms by causing inflammation in the ring of posterior pharyngeal lymphoid tissue that consists of the tonsils, adenoids, and surrounding lymphoid tissue. This ring of tissue, called Waldeyer tonsillar ring, drains the oral and pharyngeal cavity and defends against infection of the mouth and throat. Other host defenses that protect against infection include the sneeze, gag, and cough reflexes; secretory immunoglobulin A; and a rich blood supply.

Viral sore throat may be acquired by inhalation or self-inoculation from the nasal mucosa or conjunctiva. The local respiratory

Box 89.1. Diagnosis of Sore Throat

Viral Etiology

- Pain in throat
- Fever (variable)[a]
- Rhinorrhea (common)
- Cough (common)
- Erythema of pharynx or tonsils
- Follicular, ulcerative, exudative lesions of pharynx or tonsils[a]
- Conjunctivitis
- Non-scarlatiniform rash
- Occipital or posterior cervical adenopathy

Bacterial Etiology

- Pain in throat, usually sudden onset
- Fever
- Marked erythema of pharynx, tonsils, or uvula
- Headache, nausea, vomiting, abdominal pain
- Tonsillar and posterior pharyngeal wall exudate
- Tender, swollen cervical lymphadenopathy
- Scarlatiniform rash
- Absence of rhinorrhea or cough
- Positive rapid antigen test or throat culture result
- Distortion of natural anatomy

[a] Dependent on etiology (see Differential Diagnosis).

epithelium becomes infected with the virus, and inflammation occurs. In some instances, inflammatory mediators may be responsible for the pain of sore throat. Group A β-hemolytic streptococcus and other bacterial organisms directly invade the mucous membranes. Enzymes produced by this organism, streptolysin O and hyaluronidase, aid in the spread of infection.

Differential Diagnosis

Although most children who present with sore throat have common viral or bacterial pharyngitis, other, less common disorders should be considered, such as infectious mononucleosis, acute HIV seroconversion syndrome, epiglottitis, retropharyngeal abscess, and peritonsillar abscess. See Box 89.2 for a list of causes of sore throat.

Viral Infection

Viral infection, the most common cause of sore throat in children, is most often associated with an upper respiratory infection caused by a rhinovirus. Cough and rhinorrhea associated with a sore throat are suggestive of this etiology. Influenza virus infections may present with sudden onset of high fever, headache, cough, sore throat, and myalgia.

Adenovirus often results in exudative pharyngitis, frequently in children younger than 3 years. Pharyngoconjunctival fever, caused by adenovirus 3, is characterized by a high fever (temperature >39.0°C [>102.2°F]) for several days, conjunctivitis, and exudative tonsillitis.

Coxsackievirus and echovirus, both of which are enteroviruses, are the usual cause of herpangina. Vesicles and ulcers are generally apparent on the anterior tonsillar pillars and soft palate. They may also be found on the tonsils, pharynx, or posterior buccal mucosa. The child may have a high fever (temperature >39.0°C [>102.2°F]), be irritable, and refuse to eat or drink; dehydration may result. Coxsackievirus A16, coxsackievirus A6, and enterovirus 71 cause

Box 89.2. Causes of Sore Throat

Viral Infections

- Adenovirus
- Coxsackievirus
- Echovirus (enteroviruses)
- Common cold
- Cytomegalovirus
- Enteroviral infections
- Epstein-Barr virus
- HIV seroconversion syndrome
- Human herpesvirus
- Influenza virus
- Mononucleosis
- Rhinovirus
- Respiratory syncytial virus

Bacterial Infections

- *Arcanobacterium haemolyticum*
- *Chlamydophila pneumoniae*
- *Chlamydia trachomatis*
- *Corynebacterium diphtheriae* (diphtheria)
- *Francisella tularensis* (tularemia)
- *Fusobacterium necrophorum*
- Group A β-hemolytic streptococcus
- Group B, C, and G β-hemolytic streptococci (non-GABHS)
- *Haemophilus influenzae* type B
- *Mycoplasma pneumoniae*
- *Neisseria gonorrhoeae*
- *Staphylococcus aureus*
- *Streptococcus pneumoniae*
- *Treponema pallidum* (syphilis)

Other Causes

- Abscess (peritonsillar or retropharyngeal)
- Allergic rhinitis with postnasal drip
- Burns
- *Candida albicans*
- Caustic material
- Cigarette smoke (including secondhand smoke)
- Croup
- Kawasaki disease
- Marijuana smoke
- Odontogenic infections
- Trauma
- Tumors
- Vaping

hand-foot-and-mouth disease, which is characterized by ulcerative oral lesions on the tongue and buccal mucosa and, less frequently, on the palate and anterior tonsillar pillars. Vesicular and papulovesicular lesions are evident on the hands and feet and occasionally on other parts of the body, most commonly the knees and buttocks. It usually occurs in children younger than 5 years but can occur in older children as well. A more severe form of hand-foot-and-mouth disease is associated with coxsackievirus A6, a virus new to the United States in 2012. Enterovirus 71 is sometimes associated with severe central nervous system disease. Enteroviral infections typically occur in the late spring, summer, and early fall.

Human herpesvirus may lead to pharyngotonsillitis but can be distinguished from most of the enteroviral infections because human herpesvirus almost always involves the anterior portion of the mouth and lips and is associated with gingivitis (ie, herpetic gingivostomatitis). The lesions often appear as whitish-yellow plaques with an erythematous base and are sometimes ulcerative. This illness is characterized by a high fever (temperature >39.0°C [>102.2°F]) for up to 7 to 10 days and frequent refusal to eat or drink because of the painful lesions. Dehydration may occur.

Epstein-Barr virus (EBV) may cause exudative pharyngotonsillitis alone or as part of the infectious mononucleosis syndrome that includes fever, malaise, lymphadenopathy, palatal petechiae, and hepatosplenomegaly. Fatigue, malaise, eyelid edema, organomegaly, and a maculopapular rash without the other characteristics of a scarlet fever rash help distinguish between infectious mononucleosis and GABHS infection.

Cytomegalovirus may cause an infectious mononucleosis syndrome similar to EBV but is less commonly associated with pharyngitis and splenomegaly.

HIV seroconversion syndrome may present with low-grade fever, myalgia, nonexudative pharyngitis, diffuse adenopathy, anorexia, and weight loss. Generally, onset of symptoms is approximately 1 week after exposure but may not appear until 1 month after exposure.

Bacterial Infection

Group A β-hemolytic streptococcus is the most common cause of bacterial sore throat in children older than 3 years. The pharynx is typically very red and sometimes edematous, and the tonsils are red, enlarged, and covered with exudate. Occasionally, the uvula is quite inflamed as well. The child may also have dysphagia, fever, vomiting, headache, malaise, and abdominal pain. Swollen anterior cervical lymphadenopathy and petechiae on the soft palate and uvula are usually apparent. Additionally, the occurrence of a scarlatiniform rash, strawberry tongue, and Pastia lines (ie, petechiae in the flexor skin creases of joints) is indicative of scarlet fever, which is diagnostic of group A streptococcal infection (see Chapter 139). Sore throat from GABHS typically occurs in the winter and early spring. Rheumatic fever and glomerulonephritis are nonsuppurative complications of group A streptococcal infection.

Peritonsillar abscess or cellulitis and cervical lymphadenitis are suppurative complications of GABHS. Children with peritonsillar abscess often experience trismus and drooling and speak with a "hot potato" voice. The abscess in the affected tonsil causes a bulge in the posterior soft palate and pushes the uvula away from the midline to the unaffected side of the pharynx. On palpation, the abscess may feel fluctuant. Peritonsillar cellulitis typically produces a bulge in the soft palate but does not cause deviation of the uvula.

Parapharyngeal and retropharyngeal abscesses that typically occur in children younger than 6 years are additional life-threatening complications of GABHS. Sore throat is associated with these conditions, but dysphagia is usually more evident when the child swallows. The child with a retropharyngeal or parapharyngeal abscess is toxic-appearing, also reports trismus, has a fever, has dysphonia, refuses to swallow, and drools. Additionally, the child may have meningismus and may be short of breath. A fluctuant mass may be palpated deep to the tonsils. The patient may have pain when the trachea is manipulated in a lateral direction. The neck may be stiff, and the patient may resist passive neck movements. Stridor may be present but usually is an ominous sign of impending airway compromise.

Group B, C, and G β-hemolytic streptococci (non-GABHS) have all been isolated from children with pharyngitis. *Streptococcus pneumoniae* and *Arcanobacterium haemolyticum* infrequently cause pharyngitis in children. The latter organism is associated with a scarlatiniform rash in some patients and is most common in adolescents and young adults. In contrast with scarlet fever, palatal petechiae and strawberry tongue are not present with the pharyngitis caused by this bacterium. Although *Corynebacterium diphtheriae* (diphtheria) rarely causes sore throat in immunized children, this organism should be considered in nonimmunized children or children from developing countries with exudative pharyngotonsillitis and a grayish pseudomembrane that bleeds when removal is attempted.

Chlamydia trachomatis may result in pharyngitis and tonsillitis in adolescents and young adults through sexual transmission. The role of *Chlamydophila pneumoniae* as a cause of sore throat in children remains unclear. *Mycoplasma pneumoniae* does not usually produce sore throat in children unless they have lower respiratory tract disease. *Neisseria gonorrhoeae* may cause sore throat in sexually active adolescents. Its occurrence in prepubertal children is often secondary to sexual abuse. The appearance of the throat is not characteristic, and diagnosis is made by cultures when the degree of suspicion is high. Tularemia is a rare cause of exudative pharyngitis in children but should be suspected if contact with wild animals has occurred.

Fusobacterium necrophorum is a gram-negative anaerobe that may cause an exudative pharyngitis, tender adenopathy, and fever. Untreated, it may progress to Lemierre syndrome or septic thrombosis of the internal jugular vein. Direct extension of the bacterial pharyngitis leads to perivenular inflammation and septic thrombosis of the internal jugular vein. The patient may present with fever, severe lateral neck pain, torticollis, and prominent internal and external jugular veins with erythema and induration. The patient may also present with additional signs and symptoms if septic emboli propagate, including acute neurologic signs (eg, central nervous system

retrograde propagation), and shortness of breath as a result of multilobar pneumonia with or without cavitation (ie, pulmonary propagation). Paradoxical septic emboli may cause other symptoms if a right-to-left cardiac shunt is present.

Other Causes

Candida albicans may be responsible for sore throat in the infant or child who is immunocompromised or taking antibiotics. The child with oral candidiasis usually presents with whitish plaques on the labial or buccal mucosa that do not wipe off easily. When the pharynx and tonsils are involved, some discomfort or dysphagia, but usually not significant pain, may occur.

Epiglottitis (ie, supraglottitis) may present as sore throat. Prior to the *Haemophilus influenzae* type B (Hib) conjugate vaccine, epiglottitis typically affected children 2 to 7 years of age who would present with signs of toxicity, stridor, difficulty swallowing, and drooling. In the relatively well-appearing child with sore throat but no stridor, neither epiglottitis nor retropharyngeal abscess is a likely cause of sore throat. Historically, epiglottitis was almost always caused by Hib. With the widespread use of the Hib conjugate vaccine, however, this organism is now rarely the etiology, the prevalence of epiglottitis is diminished, and epiglottitis is rarely the cause of sore throat in children. Although rare in adolescents, epiglottitis may present with severe sore throat out of proportion to clinical findings. Other signs and symptoms include dysphagia, odynophagia, a muffled voice, and pain on palpation of the anterior neck around the hyoid bone. *Streptococcus pneumoniae*, *Staphylococcus aureus*, and group A, B, and C β-hemolytic streptococci are unusual but reported causative agents of epiglottitis.

The child with croup may have sore throat and stridor but does not usually appear toxic and does not have difficulty swallowing. Affected children are usually between 6 months and 3 years of age (see Chapter 71).

Odontogenic infections may cause localized infection, inflammation, and swelling of the submental and submandibular space. Significant infection of this space may present with Ludwig angina, which is characterized by difficulty with secretions, dyspnea, airway compromise, and elevated position of the tongue and "woody" induration and tenderness of the sublingual space.

Trauma from penetrating objects, burns, or exposure to caustic materials may cause sore throat in children. Household cigarette smoking, marijuana smoking, and vaping may also result in pharyngeal irritation. Additionally, allergic rhinitis with postnasal drip may result in sore throat. Tumor rarely causes sore throat in children but should be considered if a mass is present or pharyngeal inflammation persists. Persistent sore throat may also be a symptom of Kawasaki disease.

Evaluation

History

A thorough history often reveals the etiology of the sore throat (Box 89.3). Questions about duration, fever, headache, vomiting, pain on swallowing, rash, oral lesions, abdominal pain, and history of contact with other family members or classmates with similar symptoms suggest the most common causes of sore throat (eg, infections with viruses and GABHS). A history of rapid onset of fever, toxicity, difficulty swallowing, drooling, and respiratory distress is suggestive of epiglottitis and retropharyngeal abscess. Voice changes are suggestive of peritonsillar abscess or tonsillar hypertrophy associated with infectious mononucleosis (ie, EBV). Immunization history or history of immigration from a developing country is helpful in assessing the risk of diphtheria. Oral sexual activity suggests the possibility of a sexually transmitted infection. A history of allergies, trauma, and environmental smoke may help diagnose other causes of sore throat. Red eye or pinkeye with a rash, persistent fever (>5 days), and sore throat are suggestive of Kawasaki disease. A teenager with at-risk behavior and an influenza-like illness may be presenting with HIV seroconversion syndrome.

Box 89.3. What to Ask

Sore Throat

- How long has the child had a sore throat?
- Does the child have fever, headache, or vomiting?
- How rapid was the onset of fever?
- Does the child have pain on swallowing?
- Are there any voice changes?
- Does the child have a rash or oral lesions?
- Does the child have abdominal pain?
- Does the child have any ill contacts?
- Are the child's immunizations current?
- Is the child having any difficulty breathing?
- Does the child have a history of allergies?
- Has the child suffered any trauma to the throat or neck?
- Has the child been exposed to environmental smoke?
- For the sexually active adolescent or child with a history of sexual abuse with nonresponding sore throat, has there been any oral sexual activity? Any other risk-taking behavior?

Physical Examination

A general physical examination should be performed. It is important to note whether the child appears toxic or if respiratory distress is present. A child in the tripod position or with drooling should be kept in a position of comfort, taking care not to agitate or further distress the child. The child with stridor at rest should be examined in a position of comfort. Further agitation, distress, or attempts at examination of the oropharynx in these patients can precipitate airway obstruction. The skin should be examined for a scarlatiniform, sandpaper-like rash; a vesicular rash involving the hands and feet; or a generalized maculopapular rash. The eyes should be evaluated for conjunctivitis and the nose for rhinorrhea (serous or purulent). The mouth, pharynx, and tonsils should be examined for vesicular lesions, ulcers, and gingivitis. The pharynx should be checked for redness, exudate, vesicles, edema, and foreign bodies. The tonsils and uvula should be examined for these same findings as well as

asymmetry, and the neck should be checked for nuchal rigidity. The lymph nodes should be evaluated for enlargement (adenopathy) and tenderness (adenitis). The abdomen should be examined for hepatosplenomegaly.

Laboratory Tests

Although many signs and symptoms may be suggestive of streptococcal pharyngitis, diagnosis can be confirmed only with laboratory tests. The throat culture is the standard for diagnosis. When done correctly, throat culture has a sensitivity of 90% to 95% in detecting pharyngeal GABHS. Specimens should be obtained from the surfaces of both tonsils and posterior pharynx without touching other parts of the pharynx or mouth. The main disadvantage of throat culture is that the results are not available for a day or more after the specimen is obtained. Nevertheless, throat culture is the most reliable means of confirming streptococcal infection.

Rapid antigen detection tests (RADTs) are available for on-the-spot diagnosis. False-positive results are uncommon (specificity ≥ 95%), but false-negative results for most RADTs occur commonly (sensitivity 80%–90%). Because a negative test may not exclude a streptococcal infection, guidelines recommend that a negative result be confirmed by throat culture. Because RADTs are highly specific, it is not necessary to confirm a positive test result with a throat culture.

Newer RADTs using optical immunoassay (OIA) and chemiluminescent DNA probes boast sensitivities of greater than 99%. A recent Cochrane review, however, demonstrates a pooled sensitivity of RADTs of 85% with a specificity of 95%. A throat culture in the setting of a negative RADT is still beneficial given the sensitivity.

Rapid and sensitive OIA RADTs reduce antibiotic prescription rates by 50% in pediatric emergency care visits related to sore throat. An antistreptolysin-O titer and an anti-deoxyribonuclease-B titer are not useful for the acute diagnosis of GABHS infection because these titers do not increase until 1 to 2 weeks after the onset of pharyngitis and peak at 3 to 4 weeks. However, measurement of these titers may help confirm a prior streptococcal infection if the throat culture is negative, particularly in the child for whom exists a high index of suspicion for acute rheumatic fever or acute poststreptococcal glomerulonephritis. Diagnostic studies are typically not necessary for children younger than 3 years because GABHS pharyngitis is uncommon and the risk of developing acute rheumatic fever and suppurative complications is low. The role of antibiotic prophylaxis for household contact of patients with acute GABHS is not recommended. Symptomatic contact should be evaluated with an RADT or throat culture.

Differentiating between viral and bacterial pharyngitis is often difficult, and rapid streptococcal antigen tests and throat cultures should be reserved for the patient with signs and symptoms common for both illnesses. Some children have clinical findings that are not consistent with bacterial pharyngitis. For example, the afebrile child with a sore throat, runny nose, and cough who has slight pharyngeal erythema almost certainly has viral pharyngitis and does not require further workup. However, the child with a constellation of signs and symptoms suggestive of bacterial pharyngitis, such as sudden onset of sore throat, fever, headache, swollen and erythematous tonsils, tonsillar or posterior pharyngeal wall exudate, uvulitis, tender and enlarged cervical lymphadenopathy, absence of runny nose or cough, or exposure to an individual with streptococcal pharyngitis, may warrant further testing with RADT or throat culture to confirm group A streptococcal pharyngitis because an accurate diagnosis cannot be made on clinical grounds alone. Approximately 20% of all children are asymptomatic carriers of GABHS in the pharynx, especially during winter and spring. If tested, these children will be positive for GABHS even though they may have a viral illness and will be unnecessarily treated with antibiotics. Guidelines for clinical prediction have been evaluated and have suggested different approaches to the need for RADT or throat culture and antibiotic management. The Centor criteria were derived and validated in adult patients and overestimate the likelihood of GABHS pharyngitis in children. A modified McIsaac score is more predictive than the Centor criteria in children but is not sufficiently sensitive or specific enough to rely on alone. In a meta-analysis of signs and symptoms predicting GABHS, presence of a tonsillar exudate, pharyngeal exudate, or exposure to strep infection in the previous 2 weeks (positive likelihood ratios of 3.4, 2.1, and 1.9, respectively) and the absence of tender anterior cervical nodes, tonsillar enlargement, or exudate (negative likelihood ratios of 0.6, 0.63, and 0.74, respectively), were most predictive. Guidelines that recommend identifying patients who are likely to have group A streptococcal pharyngitis based on clinical or epidemiologic findings and providing antibiotics for only those confirmed by RADT or throat culture decrease the unnecessary overuse of antibiotics.

Viral throat cultures and acute and convalescent titers to determine viral pharyngitis are rarely indicated unless systemic infection occurs (eg, herpes encephalitis). Epstein-Barr virus infection can be determined by specific serologic antibody assays, but nonspecific tests for heterophile antibody (eg, mononucleosis spot [ie, monospot] test) are most available and are usually the tests of choice for diagnosing infectious mononucleosis. However, it may be negative in children younger than 4 years or early in the course of the infection. Only 75% of infected children between 2 and 4 years of age and less than 30% of children younger than 2 years are identified by this test. The monospot test, a rapid slide test for heterophil antibodies, may remain positive for months after the infection and incorrectly may suggest the diagnosis of infectious mononucleosis in the child who no longer has this disorder. A complete blood cell count with more than 50% to 60% lymphocytes or more than 10% atypical lymphocytes is suggestive of mononucleosis. When these tests are inconclusive, the specific serologic antibody tests for EBV infection are helpful in establishing the diagnosis. Cytomegalovirus-specific antibody tests should be considered in the patient with a mononucleosis syndrome and negative laboratory test results for EBV. Culture or fluorescent antibody evaluation of the pseudomembrane may be used to diagnose diphtheria. Culture or presence of serum agglutinins confirms tularemia. Thayer-Martin culture plates should be used to diagnose suspected gonorrheal sore throat. HIV antibody tests are of little use in the evaluation of acute seroconversion syndrome

because antibody titers take 4 to 6 weeks to become detectable. If acute seroconversion is suspected, quantitative RNA polymerase chain reaction should be ordered for HIV.

Imaging Studies

If epiglottitis or retropharyngeal abscess is suspected but not clinically apparent, a lateral neck radiograph may be obtained. Radiography should be performed with a physician in attendance who is capable of performing endotracheal intubation in case the child has respiratory failure (see Chapter 71). Computed tomography of the neck is indicated in the stable patient with suspected deep parapharyngeal or retropharyngeal infection. Emergency bedside ultrasonography is an effective and sensitive tool for differentiating between peritonsillar cellulitis and a peritonsillar abscess.

Management

Management of sore throat in children is based on the etiology of the condition. The early recognition of potentially serious conditions based on history and physical examination is essential to providing optimal care. Otolaryngologic consultation should be obtained for the child with peritonsillar abscess, retropharyngeal abscess, parapharyngeal abscess, submental abscess, epiglottitis, significant pharyngeal trauma, or pharyngeal tumor. Recurrent tonsillitis, especially in the child who misses school, may be a reason for referral to an otolaryngologist.

Outpatient Treatment

For most children with sore throat, the physician must differentiate between viral and streptococcal pharyngitis. Viral sore throat can be managed symptomatically. Treatment with analgesics, such as acetaminophen or ibuprofen to relieve pain, and to promote hydration are the mainstays of therapy for the young child with viral or bacterial sore throat. Gargling with warm water and sucking on hard candy may provide additional symptomatic relief for the older child. The use of steroids for reducing pain for pharyngitis is controversial. One systematic review demonstrated a relatively small reduction in time to significant pain relief of 4.5 hours and a negligible reduction in pain in 24 hours when a single dose of dexamethasone (0.6 mg/kg, maximum 10 mg) is given. However, an additional study in adult patients found a significant reduction in pain at 48 hours after treatment. The decision to administer steroids should be individualized to the patient.

The pain from lesions of herpetic stomatitis often responds to acetaminophen or ibuprofen. Anesthetics, such as lidocaine, may also decrease the pain. A convenient means of delivering lidocaine is in a mixture (1 part each) of lidocaine, diphenhydramine (eg, Benadryl), and a liquid antacid. This mixture, called "magic mouthwash," may be used in the older child. However, little evidence exists supporting a benefit. If used, it may be inserted into each side of the mouth, gargled, or placed on a gloved finger or cotton swab and applied directly on the oral lesions of the tongue and labial and buccal mucosa. It is best used approximately 30 minutes before feeding or drinking, especially in the child who refuses to drink. Lidocaine should be used cautiously because it can suppress the gag reflex. The dose of lidocaine should never exceed 3 mg/kg. Excess lidocaine may result in seizures or arrhythmias. Magic mouthwash can also be prepared without lidocaine, especially for the younger child. The parent or guardian should be given instruction on how to monitor fluid intake and the signs of dehydration.

In the child without clear-cut evidence of streptococcal pharyngitis, a positive rapid streptococcal antigen test helps direct antibiotic treatment. A negative test in the presence of positive symptoms should be accompanied by a throat culture. The OIA rapid test may preclude the need for culture confirmation, however. The patient can await the results of culture before beginning antibiotic therapy. Antibiotics without confirmation from rapid streptococcal tests or cultures are indicated in the child who appears toxic, who has scarlet fever or peritonsillar cellulitis/abscess, or who has a history of rheumatic fever. Most evidence suggests that early treatment results in more rapid clinical improvement, although this is controversial. Rheumatic fever can be prevented if treatment is started within 9 days of sore throat symptom development. Glomerulonephritis likely is not affected by antibiotic therapy.

Evidence suggests that the child with streptococcal pharyngitis should be treated with antibiotics to relieve symptoms, shorten the course of the illness, and prevent disease dissemination, suppurative complications, and rheumatic fever. Penicillin is the antibiotic of choice. It may be administered orally as penicillin V (ie, phenoxymethyl penicillin) in a dose of 250 mg 2 to 3 times a day for 10 days for children (<27 kg [<60 lb]) and 500 mg 2 to 3 times a day for older children, adolescents, and adults. Most patients will feel better after 2 to 3 days, but it is important to stress to the parent(s)/guardian(s) that the children must complete the full 10-day course. Amoxicillin, given once a day orally (50 mg/kg; maximum, 1,000 mg) for 10 days is as effective as penicillin V given 2 to 3 times a day for 10 days, making compliance more likely. Additionally, amoxicillin is more acceptable to young children because the oral suspension is better tasting. No significant difference in treatment success exists between antibiotics. (See Table 89.1 for dosages.)

If the risk of noncompliance is high or if the risk of complication is great (eg, child with a history of rheumatic fever), penicillin should be administered intramuscularly. Intramuscular penicillin has 2 disadvantages: pain associated with the injection and increased incidence of a potentially more severe allergic reaction. The dose of benzathine penicillin for the child weighing less than 27 kg (<60 lb) is 600,000 U. The dose for larger children and adults is 1.2 million U. Bicillin C-R, which contains 900,000 U of benzathine penicillin and 300,000 U of procaine penicillin, is a satisfactory alternative form of delivering penicillin intramuscularly in children and may be preferable because it causes less pain and less severe local reaction. This preparation has not been determined to be effective in heavier patients (ie, adolescents and adults); therefore, the benzathine preparation noted previously is recommended for this group. The injection of benzathine penicillin is less painful if it is given after it reaches room temperature (Table 89.1). A first-generation oral cephalosporin, such as cephalexin, is recommended for most children with

Table 89.1. Antibiotics Used in the Management of Sore Throat in Children

Cause of Sore Throat	*Drug*	*Dosage*
Streptococcal pharyngitis	Penicillin V	250 mg 2–3 times per day for children (<27 kg [<60 lb]) and 500 mg 2–3 times per day for adolescents orally for 10 days
	Amoxicillin	50 mg/kg once daily orally for 10 days (maximum 1,000 mg)
	Cephalexin	25–50 mg/kg per day every 12 hours orally for 10 days (maximum 500 mg every 12 hours)
	Clindamycin	30 mg/kg per day in 3 divided doses (maximum 900 mg per day) orally for 10 days (for chronic streptococcal carriers or suspected *Fusobacterium necrophorum*)
	Azithromycin	12 mg/kg once daily orally for 5 days (maximum 500 mg)
	Clarithromycin	15 mg/kg per day every 12 hours orally for 10 days
	Benzathine penicillin	600,000 U (<27 kg [<60 lb]); 1.2 million U (≥27 kg [≥60 lb]) as single intramuscular injection
	Bicillin C-R	900,000 U benzathine penicillin and 300,000 U procaine penicillin for children as single intramuscular injection
	Rifampin	10 mg/kg per dose orally every 12 hours for 4 days (given last 4 days of treatment with penicillin V or benzathine penicillin for chronic streptococcal carriers)
Gonococcal pharyngitis	Ceftriaxone plus Azithromycin or Erythromycin or (if ≥ 9 years of age) Doxycycline	125 mg intramuscularly in a single dose if <45 kg (<99 lb), 250 mg intramuscularly in a single dose if ≥45 kg (≥99 lb) 20 mg/kg (maximum 1 g) orally in a single dose 50 mg/kg per day (maximum 2 g per day) orally every 6 hours for 14 days 100 mg orally 2 times per day for 7 days

penicillin allergy but should not be used in the child with an immediate or type 1 hypersensitivity to penicillin. Clindamycin may also be used for the patient with penicillin allergy; however, the liquid preparation is not palatable and compliance may be poor. Azalides and macrolides, such as azithromycin or clarithromycin, may be substituted in the child with penicillin allergy. These agents are preferred to erythromycin because they are associated with fewer gastrointestinal side effects. Azithromycin has the added advantage of once daily dosing and a shortened course of therapy of only 5 days. Additionally, shorter-duration alternatives to penicillin are superior in time to symptom improvement as well as duration of fever. Macrolide resistance, however, is 5% to 8% in most areas of the United States. Tetracyclines; sulfonamides, including trimethoprim-sulfamethoxazole; and fluoroquinolones are not recommended for the management of streptococcal pharyngitis.

If symptoms persist and the child has a persistently positive throat culture after completing a course of therapy, the child may be re-treated with the same antibiotic, given another oral antibiotic (as noted previously and in Table 89.1), or given an intramuscular dose of penicillin, especially if compliance is in question.

As noted previously, approximately 20% of children are asymptomatic carriers of group A streptococci. Typically, these children do well, and eradication of the bacteria is not necessary. Cultures after treatment are generally not recommended, except for the child with recurring or persistent symptoms or with a previous history of rheumatic fever. In selected cases of children whose throat cultures remain positive, eradication of the pharyngeal carriage should be strongly considered. These indications are as follows: an outbreak of acute rheumatic fever or poststreptococcal glomerulonephritis, an outbreak of group A streptococcal pharyngitis in a closed or semi-closed community, a family history of rheumatic fever, or repeated episodes of documented symptomatic group A streptococcal pharyngitis within a family over several weeks despite appropriate therapy. If cultures remain positive, these children may be treated with benzathine penicillin and oral rifampin for 4 days in an attempt to eradicate the organism (Table 89.1). Clindamycin is reportedly more effective in eradication of the organism from symptom-free carriers (Table 89.1).

Mycoplasma pneumoniae pharyngitis usually is associated with a generalized infection. Because it is often a self-limited illness, antibiotic therapy is unnecessary unless symptoms persist. Treatment with any of the macrolide antibiotics may be helpful. However, clarithromycin and azithromycin have fewer side effects and are likely to produce better compliance. Macrolides are also the drugs of choice for children with *A haemolyticum* pharyngitis.

Diphtheria, which occurs almost exclusively in developing countries, is a life-threatening infection that requires prompt diagnosis

and treatment. Penicillin G or erythromycin must be given to kill *C diphtheriae*; additionally, equine antitoxin must be administered to neutralize the exotoxin. Tularemia pharyngitis is unusual, but if suspected, it is treated with gentamicin.

For gonococcal pharyngitis caused by *N gonorrhoeae*, intramuscular ceftriaxone is the drug of choice (Table 89.1). Additional antibiotic coverage for associated *C trachomatis* infection should be administered. Oral azithromycin or doxycycline should also be given to children 9 years or older (Table 89.1). Azithromycin or erythromycin may be used for the younger child. The child should be examined and cultured for sexually transmitted infections in other sites and should undergo a serologic testing for syphilis at the first visit as well as a repeat test 6 to 8 weeks later. The child should also be evaluated for concurrent hepatitis B and HIV infection. Sexual abuse should be considered in all cases of gonococcal pharyngitis, particularly in the prepubertal child (see Chapters 60 and 145).

Children with croup usually respond to steroids. Oral nystatin can be used in the child with oral candidiasis. The adolescent with uncomplicated peritonsillar abscess may be treated on an outpatient basis in selected cases with needle aspiration and oral antibiotics.

Inpatient Treatment

The child with sore throat should be admitted to the hospital in the setting of airway obstruction or a need for intravenous (IV) hydration or antibiotics. The child with retropharyngeal abscess and epiglottitis requires IV antibiotics and should be managed in consultation with an otolaryngologist. The preadolescent child or adolescent with complicated peritonsillar abscess also requires IV antibiotics. Surgical intervention is indicated if the abscess is fluctuant, the child is toxic or has severe trismus or airway compromise, or no resolution occurs within 24 hours. Needle aspiration may be acceptable in selected cases but this is associated with an increased rate of treatment failure. Intravenous hydration is occasionally needed for patients with severe herpetic stomatitis who will not drink because of pain and who become dehydrated.

The patient with Lemierre syndrome should be admitted and started on IV antibiotics covering a polymicrobial infection, including anaerobic organisms. If *F necrophorum* pharyngitis is suspected, antibiotics covering anaerobes are indicated.

Suspected deep space infection of the pharynx other than uncomplicated peritonsillar abscess requires inpatient admission and treatment. Retropharyngeal and parapharyngeal abscesses usually require incision and drainage during or after antibiotic initiation. Ludwig angina requires IV antibiotics for an uncomplicated cellulitis or an incision and drainage procedure in the operating room. Meticulous monitoring of the patient's airway is required if it is not secured preoperatively.

The role of tonsillectomy or adenotonsillectomy for the child with recurrent sore throat remains controversial. However, the American Academy of Otolaryngology-Head and Neck Surgery convened a panel of clinicians from various disciplines to develop evidence-based guidelines to identify children who are most likely to benefit from tonsillectomy. These guidelines, containing content based on previous work done by Paradise et al about children with recurrent sore throat, have been recently published. Most children with sore throat improve on their own, and recommendations are therefore for watchful waiting in the setting of fewer than 7 documented sore throat episodes in the past year, fewer than 5 per year over the past 2 years, and fewer than 3 per year over the past 3 years. Parental or guardian report does not qualify as documentation. If the number of documented sore throats meets or exceeds these numbers and associated findings exist (eg, temperature >38.3°C [>101°F], cervical lymphadenopathy, tonsillar exudate, positive test for GABHS), the physician may recommend tonsillectomy. Consultation with an otolaryngologist and a period of watchful waiting should be considered. If a child with recurrent sore throat does not meet these criteria, the child should be assessed for other factors that may favor tonsillectomy over observation, including, but not limited to, multiple antibiotic allergy or intolerance, PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, and adenitis), or a history of peritonsillar abscess. Although these guidelines are evidence-based and the recommendations are better defined than before, each case should be individualized. As with all clinical decisions, a role exists for shared decision-making with the child's caregiver and primary care physician about the need for tonsillectomy.

Education

Patients and families should receive general education about sore throat. Medication for pain with drugs such as acetaminophen or ibuprofen is useful, especially if the child is having difficulty swallowing. Gargling with warm salt water or sucking on hard candy may soothe the pain of sore throat. For the child with herpetic gingivostomatitis, avoidance of acidic or spicy food products may prevent pain during eating. The child with bacterial pharyngitis may return to school after 24 hours of antibiotic therapy and the disappearance of fever. Children are likely noninfectious 12 hours after a single dose of amoxicillin. It should be recommended that symptomatic family members see a physician. The parent(s)/guardian(s) should call or return to the physician if the child has respiratory or swallowing difficulties, drooling, severe pain, or fever (temperature >38.3°C [>101°F]) for more than 48 hours after the initiation of appropriate antibiotics.

Prognosis

The prognosis for the child with viral sore throat is excellent because of its self-limited nature. The outlook for the child with streptococcal sore throat is also excellent. If the infection is not diagnosed and managed appropriately, however, suppurative (eg, peritonsillar abscess) and nonsuppurative complications (eg, rheumatic fever, acute glomerulonephritis) may occur. With early diagnosis and prompt treatment, the prognosis for unusual, life-threatening causes of sore throat is also very good. The cross-immunogenicity of GABHS presents a unique and challenging case for vaccine development.

CASE RESOLUTION

The child has palatal petechiae and tonsillar exudate, which are signs and symptoms consistent with streptococcal pharyngitis. A streptococcal RADT is performed and is positive. The child is treated with oral penicillin. Neither of her parents has sore throat symptoms.

CHAPTER 90

Nosebleeds

Anna K. Schlechter, MD, Katherine E. Remick, MD, FACEP, FAEMS, FAAP; and Stanley H. Inkelis, MD, FAAP

CASE STUDY

A 3-year-old boy is brought to the office on a winter day. He has had 4 nosebleeds in the past week as well as a cold with rhinorrhea and cough, which began the day before the first nosebleed. The nosebleeds occur at night or during sleep and stop spontaneously or with gentle pressure. Other than the cold and nosebleeds, the boy is in good health. He is active, with bruises over both tibias but none elsewhere. The many cuts and scrapes he has had in the past resulted in minimal bleeding. His family has no history of a bleeding disorder or easy bruising.

The child's physical examination is entirely normal except for a small amount of blood in the left anterior naris.

Questions

1. What are the common causes of nosebleeds in children?
2. What systemic diseases are associated with nosebleeds?
3. How should nosebleeds be evaluated in children?
4. How should minor and severe nosebleeds be managed in children?

Nosebleed, or epistaxis, occurs commonly in children, especially in those between 2 and 10 years of age. In most cases, nosebleeds are secondary to local trauma and can be managed by primary care physicians. In rare instances, however, a nosebleed may be difficult to control or may be a manifestation of a serious systemic illness. Referral to an otolaryngologist or a hematologist/oncologist is usually not required except in these situations, and hospitalization is generally unnecessary. Parents and children often are frightened by nosebleeds and frequently overestimate the amount of blood lost. Providing reassurance and a basic understanding of the most common causes are important in allaying anxiety.

Epidemiology

Thirty percent of children experience 1 nosebleed by 5 years of age. In children between the ages of 6 and 10 years, the frequency increases to 56%. Nosebleeds are rare in infancy, with an estimated 1 nosebleed per 10,000 patients younger than 2 years. Nosebleeds are infrequent after puberty. They occur much more frequently in the late fall and winter months, when upper respiratory infections (URIs) are common, environmental humidity is relatively low, and the use of heating systems may result in dryness. Nosebleeds are also more common in children who live in dry climates, especially in the presence of a concomitant URI or chronic allergic rhinitis.

Clinical Presentation

Most children with nosebleeds have a history of bleeding at home and have minimal or no bleeding at the time of presentation (Box 90.1). However, children with underlying clotting disorders (eg, hemophilia) may have recurrent nosebleeds and a history of prolonged bleeding, easy bruising, or multiple bruises in uncommon locations such as the gingivae or joints. Less commonly, nosebleeds are among the first manifestations of an undiagnosed malignancy or other systemic illness. In unusual situations, children with gastrointestinal or respiratory tract bleeding may present with blood exiting through the nose. Alternatively, some children with nosebleeds may present with hematemesis, hemoptysis, melena, or anemia. In these cases, a nasal source should be considered.

Box 90.1. Diagnosis of Epistaxis

- Blood in anterior nares, nasopharynx, or mouth
- History of any of the following:
  - — Frequent digital manipulation (ie, nose picking)
  - — Upper respiratory infection (recent)
  - — Allergic rhinitis
  - — Dry climate
  - — Foreign body in nose
  - — Trauma to nose
  - — Prolonged or difficult-to-stop bleeding, or easy bruising
- Physical examination consistent with any of the following:
  - — Rhinorrhea
  - — Dry, cracked nasal mucosa
  - — Foreign body in nose
  - — Trauma to nose
  - — Multiple bruises

Nosebleeds are generally categorized by anatomic location as anterior or posterior. Anterior epistaxis is most common, comprising 90% of pediatric nosebleeds, and is almost always self-limited. With

anterior nosebleeds, vessels from the anterior portion of the nose rupture, resulting in readily visible blood loss through the nares. With posterior nosebleeds, most of the blood runs into the nasopharynx and mouth, although some blood may exit through the nose as well. Posterior nosebleeds, though uncommon in children, tend to be heavier and more difficult to control, and children have a propensity to become hemodynamically unstable.

Pathophysiology

More than 90% of nosebleeds in children are anterior and easily controlled. Anterior bleeding originates approximately 0.5 cm from the tip of the nose, known as the Kiesselbach area. This area is a confluence of small vessels supplied by the anterior and posterior ethmoidalarteries, the sphenopalatine artery, and the septal branches of the superior labial artery (Figure 90.1). The mucosa covering the Kiesselbach area is thin and friable, providing little structural support to the small vessels supplying the nasal mucous membrane.

The congestion of vessels located in the Kiesselbach area as the result of URIs or drying of the mucosa secondary to low environmental humidity makes this area susceptible to bleeding. Viral respiratory infections, such as infectious mononucleosis and influenza, may predispose children to nosebleeds because of the local inflammatory effect of such infections. Nosebleeds in children with these infections are more common in areas of low environmental humidity. Even in the absence of URI-like symptoms, however, children may experience nosebleeds in such environments, especially in the winter, when inhaling dry, hot air from heating systems causes desiccation of the nasal mucosa (ie, rhinitis sicca). Nosebleeds also occur more commonly in children who have nasal colonization with *Staphylococcus aureus*. It is postulated that *S aureus* replaces existing flora and results in inflammation and new vessel formation.

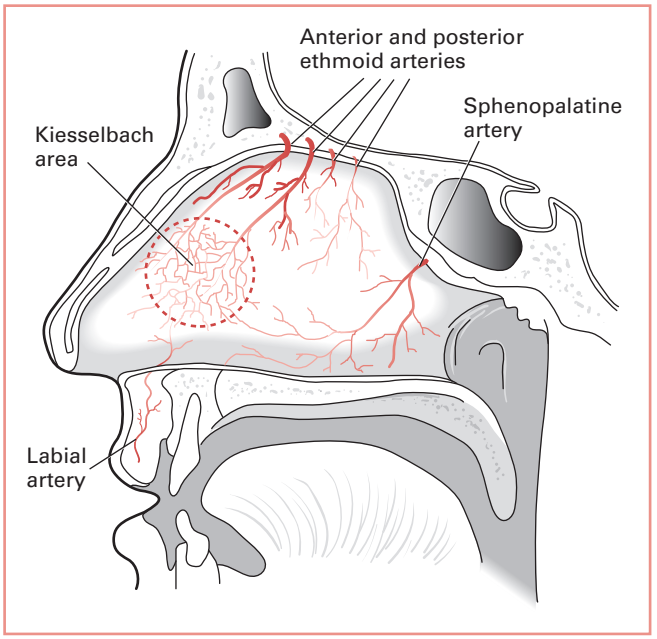

Figure 90.1. Vascular supply of the nasal septum. Note the confluence of vessels that forms the Kiesselbach plexus.

Posterior nosebleeds are unusual in children and are most commonly associated with trauma. If bleeding is vigorous or poorly controlled with anterior nasal packing or involves both nares, a posterior source is likely to be responsible. Posterior nosebleeds generally arise from the turbinate or nasal wall. Significant bleeding, usually from a branch of the sphenopalatine artery, may occur. Because of the posterior location, children often present with symptoms other than frank epistaxis (eg, hematemesis, hemoptysis, melena, anemia).

Differential Diagnosis

Trauma from nose picking and inflammation of the nasal mucosa from a URI are by far the most common causes of nosebleed in children. Repetitive, habitual nose picking (ie, epistaxis digitorum) results in the formation of friable granulation tissue that bleeds when congested blood vessels are traumatized. As the nasal mucosa dries, crust formation and cracking may occur. Bleeding may occur spontaneously or from nose rubbing, but more often it results from forceful nose blowing and sneezing, which increase venous pressure in the more vascularized nasal septum.

Foreign bodies may cause direct trauma or pressure necrosis to the vessels of the nasal mucosa. Toddler-age children may place small toys, beads, pebbles, or food items into the nares. Button batteries are particularly troublesome and should be removed immediately to avoid septal perforation. Children with unilateral epistaxis with purulent or foul-smelling nasal drainage should be evaluated for a foreign body. External trauma secondary to falls or blunt force can cause tears to the nasal mucosa or nasal fractures. If bleeding from mucosal vessels occurs but the mucosa remains intact, a septal hematoma may occur. Thus, it is important to carefully examine the nasal septum. Abscess formation or septal perforation may occur if the septal hematoma is not drained. Non-accidental trauma, specifically asphyxiation, should be considered in any child younger than 2 years with a nosebleed.

Allergic rhinitis with inflammation and subsequent drying also may result in nosebleeds. Airborne environmental pollutants have been associated with increased inflammation of the nasal mucosa. Children with allergic rhinitis who take decongestants or use topical nasal decongestants or topical nasal steroid sprays may have an increased likelihood of experiencing nosebleeds. In addition, the dispenser tip of these sprays may traumatize the already dry and friable mucosa, causing the nose to bleed.

Although nosebleeds are usually benign conditions, they may be among the first signs of serious illness. Persistent or recurrent nosebleeds with no obvious cause should raise the suspicion of bleeding disorders (see Chapter 99). Thrombocytopenia is the most common coagulation defect that results in nosebleeds. Idiopathic thrombocytopenic purpura is the thrombocytopenic disorder most frequently associated with nosebleeds. Leukemia, aplastic anemia, and HIV infection also should be considered and ruled out in children with nosebleeds and thrombocytopenia. Platelet aggregation disorders also may be a cause of recurrent nosebleeds.

The most commonly inherited bleeding disorder associated with nosebleeds is von Willebrand disease, an autosomal-dominant bleeding disorder characterized by varying degrees of factor VIII deficiency and platelet dysfunction (ie, decreased platelet adhesiveness). Hemophilia (factor VIII, IX, or XI deficiency), factor VII deficiency, Glanzmann thrombasthenia, and Bernard-Soulier syndrome are other inherited bleeding disorders that may result in nosebleeds. Hepatic disease, severe vitamin K deficiency, or malabsorption syndrome are associated with acquired coagulopathy, of which nosebleed may be a presenting sign. Administration of valproic acid has been associated with acquired von Willebrand disease and nosebleeds.

Nosebleeds may be a manifestation of hereditary or acquired blood vessel disorders. Hereditary hemorrhagic telangiectasia (ie, Osler-Weber-Rendu disease) is an inherited autosomal-dominant disease with multiple mucosal telangiectasias, especially in the nose. Because telangiectasias are deficient in muscular and connective tissue, they may rupture spontaneously and bleed profusely. An association between migraine headaches and recurrent nosebleeds has also been reported.

Neoplasms, particularly malignancies, are uncommon causes of nosebleeds in children. Although nasal polyps generally are benign, they usually occur in association with cystic fibrosis or allergies. Capillary, cavernous, and mixed hemangiomas may occur in the nose and be a source of bleeding. Juvenile nasopharyngeal angiofibroma occurs almost exclusively in adolescent males who present with nasal obstruction and bleeding. Rhabdomyosarcoma, lymphoma, and squamous cell carcinoma of the nose, sinuses, or nasopharynx are rare causes of nosebleeds in the pediatric population.

Drugs such as aspirin and nonsteroidal anti-inflammatory drugs, which interfere with platelet function, and warfarin and heparin, which inhibit clotting factors, increase the risk for nasal hemorrhage with minor trauma, infection, or inflammation. Unintentional ingestion of these medications should be suspected if they are accessible to the child. Snorting cocaine or heroin may cause nasal septal perforation and nosebleeds. Some complementary and alternative therapies, such as *Ginkgo biloba*, may also be associated with abnormal bleeding.

Hypertension is rarely associated with nosebleeds in children. Wegener granulomatosis and lethal midline granuloma are rare idiopathic inflammatory diseases in children that result in nasal tissue destruction and bleeding. Nosebleeds during menstruation, that is, *vicarious menstruation*, may be secondary to hormonal changes that result in vascular congestion of the nasal mucosa.

Evaluation

History

A thorough history often reveals the etiology of the nosebleed (Box 90.2). Information concerning the side of the nose from which the bleeding occurred, amount of bleeding, measures used to stop the bleeding, and time required to stop the bleeding may be helpful to quickly assess the severity of the nosebleed.

Box 90.2. What to Ask

Nosebleeds

- Does the child pick his or her nose?
- Has the child suffered any trauma recently?
- Is there suspicion of non-accidental trauma?
- Has the child recently had an upper respiratory infection?
- Has the child recently had any systemic viral or bacterial illness?
- Does the child have any allergies?
- Is the child exposed to dry conditions (eg, dry climate, dry heat, dehumidified air)?
- Has the child put or tried to put foreign objects in his or her nose?
- Is there a history of easy bruising or prolonged, difficult-to-stop bleeding in the child or family?
- Does the child or anyone in the family use any aspirin, aspirin-containing medications, nonsteroidal anti-inflammatory drugs, or warfarin?
- Does the child or any family member use cocaine, heroin, inhalants, or any other drugs of abuse?
- Does the child or any family member use complementary and alternative therapies, such as *Ginkgo biloba*?
- Which side of the nose was bleeding? Was it bilateral?
- How extensive was the bleeding?
- Did the child spit out or swallow blood? Was there blood in the mouth?
- What measures were used to stop the bleeding? How long did it take to stop the bleeding?
- Was this the first nosebleed? If nosebleeds are recurrent, how often do they occur and how long do they last?

Physical Examination

A general physical examination should be performed. In children with significant blood loss, particular attention should be directed toward the mental status and vital signs to determine hemodynamic stability. If vital signs are normal, these children should also be evaluated for orthostatic changes. If blood pressure is elevated, it should be reassessed at a time when the anxiety related to the nosebleed has dissipated.

In addition, the skin and mucous membranes should be checked carefully for petechiae, purpura, and ecchymoses, as well as pallor. The conjunctiva may reveal icterus, a sign of liver disease presenting as a coagulopathy. The abdomen should be examined for hepatosplenomegaly and the child should be evaluated for lymphadenopathy, which is suggestive of leukemia. Telangiectasia in the oropharynx or mucous membranes is associated with hereditary hemorrhagic telangiectasia. The oropharynx and nasopharynx should be examined for masses, foreign body, and blood dripping downward from a posterior bleed. Next, the nose should be inspected for the site of bleeding, with particular attention paid to the Kiesselbach area in the anterior septum. In children younger than 2 years with nosebleeds, suspicion of non-accidental trauma should be considered, especially if nosebleeds are recurrent, the event is not witnessed, or the story given by the caregiver changes. In such cases, the patient should be evaluated for burns and other marks that may be indicative of non-accidental trauma.

Diagnostic Studies

Laboratory tests are rarely indicated in most children with nosebleeds. They might be considered for those patients in whom bleeding lasted longer than 30 minutes, patients younger than 2 years, or patients who have experienced more than 2 to 3 episodes of epistaxis each week for several weeks. Hematocrit and hemoglobin tests should be performed if the nosebleeds are severe or recur frequently. For children with signs or symptoms of hypovolemia (ie, increased pulse; cool, clammy skin; increased capillary refill; decreased blood pressure) or a marked drop in hematocrit, blood should be tested for type and crossmatch. If the history or physical examination are suggestive of coagulopathy, a complete blood cell count with platelet count and examination of peripheral smear, prothrombin time, and partial thromboplastin time should be obtained. If these laboratory tests are negative, screening for von Willebrand disease should be considered if the other laboratory tests are negative.

Radiography and other imaging studies are rarely necessary in children with nosebleeds. However, if a mass is visualized, further imaging may be necessary to evaluate it. The most commonly used modalities include magnetic resonance imaging and contrast-enhanced computed tomography. Rarely, pseudoaneurysm of the internal carotid artery has been associated with epistaxis; in these cases, angiography may be required for further evaluation.

Management

Children who present to primary care physicians with a history of 1 or more nosebleeds that have resolved spontaneously or with application of pressure to the nasal alae need no further treatment in the office or emergency department setting, provided that the history and physical examination are consistent with a benign cause. These children or their parents should be instructed to apply a lubricant (eg, petroleum jelly) or an antibiotic ointment, inside the septal portion of the involved naris twice a day for 3 to 5 days with a cotton-tipped swab or little finger. Often the child's little finger is used because it is nonthreatening and it "knows where to go." Further nose picking should be discouraged, and fingernails should be trimmed to minimize trauma. In addition, a bedside humidifier helps moisturize the air, especially in dry climates or during the winter when forced hot-air heat is used. Children whose nares moisten from rhinorrhea and then dry and crack also benefit from humidified air. Buffered saline nasal spray may also be helpful in humidifying the nose. Children who are prone to recurrent nosebleeds and in whom serious causes have been ruled out may benefit from regular use of some of the aforementioned measures when they have URIs or allergic manifestations or are in a dry season or environment. Patients with suspected allergic causes may benefit from the use of an oral antihistamine or topical corticosteroids. In addition, for children with *S aureus* nasal colonization, eradication with a course of mupirocin nasal ointment should be considered.

Children or parents should be given advice about how to care for nosebleeds at home. These instructions can also be given to parents who seek advice over the telephone about how to stop children's nosebleeds. Health professionals should reassure parents and children that most nosebleeds are easily controlled. Children should sit upright and lean forward slightly while direct pressure is applied to the nose. External compression of the nasal alae between the thumb and forefinger for 5 to 10 minutes typically is sufficient. Most nosebleeds originate at the anterior and mid-portion of the nose; thus, application of pressure here is more effective in stopping bleeding than application of pressure at the base of the nose.

Children who are actively bleeding through the nose at the time of evaluation by a primary care physician should be positioned sitting upright and leaning forward slightly, and they should be given a basin and facial tissue. Direct pressure should be applied by a provider or reliable parent to the anterior and mid-portion of the nose while following universal precautions. A cotton dental roll may be placed under the upper lip to compress the labial artery in older children in whom concern about displacement and possible aspiration of the cotton is minimal. If the bleeding continues after external compression, children should be instructed to blow their nose to remove as much clot as possible. Fresh blood should be removed with suction. Cotton pledgets moistened with a few drops of a topical vasoconstrictor, such as 0.05% oxymetazoline (Afrin, OcuClear, Drixine), or topical thrombin should be inserted into the involved side of the nose. Pressure should be applied for an additional 10 minutes. Because phenylephrine has been associated with significant morbidity and mortality when topically applied, it should be avoided in the management of pediatric epistaxis.

If the bleeding persists, cauterization of the bleeding site with a 75% silver nitrate stick is indicated. If not already applied, topical anesthesia with 2% to 4% lidocaine should be applied before cauterization. Continued bleeding is slowed by first cauterizing a small ring around the bleeding point to interrupt flow from surrounding vessels and then rolling the tip of the applicator onto the bleeding site for 5 seconds or less. Cauterization is often difficult in children, and consultation with an otolaryngologist is advised. Cauterization should not be performed in children with a bleeding diathesis. In addition, cauterization should only be done unilaterally. Cauterizing both sides of the nasal septum can result in septal ischemia and possible necrosis and ultimately, septal perforation.

If the bleeding continues, an absorbable nasal sponge made of oxidized cellulose (eg, Merocel, Rhinocell, Surgicel) or gelatin (eg, Gelfoam) may be directly applied to the bleeding site to form an artificial clot. This also may be done to avoid cauterization. Hemostatic seals (eg, Floseal, Avitene) may also be used; these agents are composed of collagen or thrombin derivatives and help support platelet aggregation and clot formation when applied to the bleeding site. Alternatively, nasal tampon, which is made of a dehydrated material that expands when it becomes moist, may be inserted to tamponade the area of bleeding. This method is less well tolerated than an absorbable nasal sponge, however. The application of antibiotic ointment, preferably mupirocin or chlorhexidine-neomycin, to the tampon allows for easier insertion and removal and may prevent *S aureus* colonization

and infection. Another option to stop the bleeding is insertion of an inflatable balloon (eg, Rapid Rhino, Epi-Stat, Epi-max, Post-Stop) coated with a platelet aggregator. Continued uncontrolled bleeding requires anterior nasal packing with gauze strips. Antibiotic-impregnated (preferably with mupirocin), 1-inch petrolatum gauze strips may also be used, although these have not been shown to prevent toxic shock syndrome. The nasal packing should remain in place for approximately 2 to 3 days. Prophylactic antibiotics are not routinely recommended because they have not been shown to prevent toxic shock syndrome. In the patient with evidence of an underlying sinus infection, however, it has been shown that antibiotics that provide coverage for staphylococcal organisms (in particular, methicillin-resistant *S aureus*) and sinusitis should be prescribed. For all patients with packing, an otolaryngologist should be consulted, and the otolaryngologist should be present at the time of packing removal. In general, packing should not be done in patients younger than 1 year because of the risk of aspiration.

Posterior nosebleeds, which are more difficult to control than anterior nosebleeds, should be suspected if the measures described previously are ineffective, bleeding is vigorous and the cause cannot be identified, or most of the bleeding is into the nasopharynx and mouth. A posterior nasal pack can be created using rolled gauze or a nasal tampon. Alternatively, a Foley catheter or an Epi-Stat inflatable nasal balloon catheter may be used to control posterior nosebleeds. Posterior packs should never be used without the presence of a concurrent anterior nasal pack. Thus, a double-balloon catheter (eg, Nasostat, Epi-Stat) can be used, obviating the need for 2 separate packing mechanisms. Posterior packing can result in significant discomfort for the patient, and appropriate analgesia should be provided. However, significant pain with balloon inflation should not occur, and overinflation may result in ischemia if the balloon is not slightly deflated. Posterior packing should be left in place for 2 to 3 days, and antibiotics should be initiated to prevent sinusitis. Additionally, posterior packing can result in hypoventilation and hypoxia. Therefore, all patients with posterior packing should be admitted to the hospital and placed on a cardiorespiratory monitor. This also allows for monitoring of potential complications, such as aspiration caused by unintentional dislodgment of the packing material; septal ischemia secondary to packing; and the development of hypotension, bradycardia, or apnea secondary to a pronounced nasal-vagal response.

The need for consultation with an otolaryngologist is dependent on the experience of the individual physician and availability of consultation. Prompt consultation, if available, should be obtained for children with severe nosebleeds who need volume replacement; with nosebleeds that do not stop or that recur after implementation of the aforementioned measures; who may need anterior or posterior nasal packing; and with recurrent, difficult-to-stop nosebleeds. For patients with suspected nasal fracture, surgical consultation should be sought prior to placement of nasal packing. In some cases, obtaining consultation before cauterization with silver nitrate is advisable, particularly in patients with known bleeding disorders. Children with septal hematoma, tumor, polyp, telangiectasia, and intractable bleeding should be referred to an otolaryngologist for further care and possible surgical intervention. Children with a documented or suspected bleeding disorder should be referred to a hematologist. Selective angiographic embolization (most commonly of the internal maxillary artery) by an interventional radiologist or sphenopalatine artery ligation may be indicated for patients with persistent, intractable nosebleeds. Intranasal laser surgery may be indicated in patients with recurrent nosebleeds resulting from abnormal vascular malformations, such as hereditary hemorrhagic telangiectasia.

In children with severe nosebleeds, an intravenous line should be started early, blood should be sent for type and crossmatch and, depending on the amount of blood loss and physical evidence of hypovolemia, fluid replacement therapy should be initiated. In children who are frightened or in whom certain procedures (eg, cauterization of bleeding site, drainage of septal hematoma) are performed, procedural sedation should be strongly considered. Intravenous pain medication should be used in children who need anterior or posterior packing. If procedures that cause undue pain or discomfort are necessary, general anesthesia in an operating room setting may be indicated.

Children with underlying systemic illness that is causative for nosebleeds may benefit from an individualized approach. For example, platelets should be administered to patients with nonimmune thrombocytopenia, and appropriate factor should be administered to patients with hemophilia. Patients with epistaxis who have von Willebrand disease benefit from packing with cellulose soaked in topical thrombin as well as administration of desmopressin. Replacement therapy with Factor VIII or with recombinant human Factor VIIa depends on the type of von Willebrand disease and their response to local treatment. For patients with immune thrombocytopenia, intravenous immunoglobulin or anti-D immune globulin in conjunction with high-dose steroids has been shown to be effective. Cautery should be avoided in patients with hereditary hemorrhagic telangiectasia; fibrin glue has been shown to be effective in controlling bleeding.

Hospitalization is rarely necessary for children with nosebleeds. However, children who are hemodynamically unstable on presentation usually require inpatient treatment. As mentioned previously, children for whom placement of a posterior nasal pack is required should be admitted to the hospital for close airway observation. Hospitalization may be necessary for children with difficult-to-stop bleeds who need an anterior nasal pack or who have a bleeding disorder or underlying chronic illness, such as leukemia, aplastic anemia, or HIV infection.

Prognosis

The prognosis for nosebleeds in children is excellent. Almost all nosebleeds are easily controlled with a minimal amount of home care or medical management. Surgery is rarely indicated. Complications associated with significant nosebleeds include hypovolemia resulting from blood loss, and sinusitis and toxic shock syndrome resulting from *S aureus* associated with anterior or posterior nasal packing. Recurrent idiopathic epistaxis resolves with time and is uncommon in children older than 14 years. Even for rare causes of nosebleeds, the prognosis is very good with prompt diagnosis and treatment.

CASE RESOLUTION

The boy has experienced several nosebleeds of short duration associated with a URI and winter dryness. His history and physical examination are unremarkable for a bleeding disorder or chronic illness. The small amount of blood in his nose is consistent with an anterior nosebleed originating from the Kiesselbach area, with inflammation and drying of the nasal mucosa. Laboratory tests are not indicated. The parents should be instructed to apply petroleum jelly to the septal portion of the left side of the child's nose twice a day for 3 to 5 days and to humidify the child's bedroom. They should also be reassured that their child has a common condition that he will outgrow.

CHAPTER 91

Strabismus

Teresa O. Rosales, MD

CASE STUDY

The mother of an 8-month-old reports that every time her son looks to either side, his eyes seem crossed. Otherwise, he is growing and developing normally. Symmetric pupillary light reflex, bilateral red reflex, and normal extraocular eye movements in all directions are noted on physical examination of the eyes.

Questions

1. What is strabismus?
2. What conditions make an infant's eyes appear crossed? What is the differential diagnosis?
3. What tests are used in the office evaluation of the child with suspected strabismus?
4. Which infants with crossed eyes require referral for further evaluation and treatment?

The term strabismus refers to any abnormality in ocular alignment, whether the eyes go in or out or 1 eye is higher than the other. It is among the most common eye problems observed in infants and children. The pediatrician plays an important role in the early detection and prompt referral of children with suspected ocular alignment abnormalities.

Epidemiology

Strabismus affects approximately 3% of the population, and the condition occurs most commonly in children younger than 6 years. Approximately 50% of all affected children have a positive family history of strabismus, although the exact genetic mode of inheritance is unclear. Up to 75% of otherwise healthy newborns and infants have transient intermittent strabismus during the first 3 months after birth.

Clinical Presentation

Children with ocular misalignment have an asymmetric corneal light reflex test. Eye movement is noted on cover testing. Children with paralytic strabismus may present with torticollis (ie, head tilt) in an effort to avoid double vision (ie, diplopia; Box 91.1).

Pathophysiology

Normal binocular vision is the result of the fusion of images from both eyes working synchronously across the visual field. Six extraocular muscles control all eye movements. *Orthophoria* is proper alignment of the eyes, and strabismus results from an imbalance in muscle movements.

Strabismus

The classification of strabismus is complex. Based on etiology, it may be considered nonparalytic (comitant) or paralytic (noncomitant). Strabismus may also be classified as congenital or acquired, intermittent or constant, and alternating or unilateral. In *nonparalytic strabismus*, the extraocular muscles and the nerves that control them are normal. The degree of deviation is constant or nearly constant in all directions of gaze. Nonparalytic strabismus is the most common type of strabismus occurring in children, and congenital or infantile esotropia is usually of this type. Ocular or visual defects, such as cataracts or high refractive errors, occasionally cause nonparalytic strabismus.

In *paralytic strabismus*, paralysis or paresis of 1 or more of the extraocular muscles produces a muscle imbalance. The deviation is asymmetric, and characteristically the degree of deviation is worse when gazing in the direction of the affected muscle. Paralytic strabismus may be congenital or acquired. Congenital paralytic strabismus may be the result of birth trauma, muscle anomalies, abnormal development of the cranial nerve nuclei, or congenital infections affecting the eyes. Congenital strabismus may occur in association with neurodevelopmental disorders, such as cerebral palsy. Acquired paralytic strabismus resulting from extraocular muscle palsies usually indicates the presence of a serious underlying condition, such as an intracranial tumor, a demyelinating or neurodegenerative disease, myasthenia gravis, progressive myopathy, or central nervous system (CNS) infection. Children may present with double vision or a compensatory head tilt to avoid double vision.

Intermittent (ie, latent) misalignment of the eyes is referred to as a *phoria*. Under normal conditions, the fusional mechanisms of the CNS maintain eye alignment. Eye deviation is appreciated only under certain conditions, such as illness, fatigue, or stress, or in cases in which fusion is interrupted by occluding 1 eye (eg, during cover testing). Some degree of phoria may be found in almost all individuals and typically, it is asymptomatic. Larger degrees of phoria may give rise to troublesome symptoms such as headaches, transient diplopia, or asthenopia (eg, eyestrain).

Box 91.1. Diagnosis of Strabismus

- Head tilt
- Double vision (ie, diplopia)
- Squint
- Asymmetric corneal light reflex
- Eye movement with cover testing

Constant misalignment of the eyes is referred to as *heterotropia* (ie, strabismus). This condition occurs because normal fusional mechanisms are unable to control eye deviation; children are unable to use both eyes together to fixate on an object. In alternating heterotropia, both eyes appear to deviate equally, and vision generally develops normally in each eye because children have no preference for fixation. If strabismus affects only 1 eye, the other eye is always used for fixation, and a danger exists for the development of amblyopia or vision loss in the deviating eye.

Convergent deviation, which is a turning in or crossing of the eyes, is an esodeviation (eg, esotropia, esophoria). *Divergent deviation*, which is a turning out of the eyes, is an exodeviation. The term *hypertropia* refers to conditions involving upward vertical deviations. Esodeviations are the most common type of ocular misalignment, accounting for 50% to 75% of all cases of strabismus. Vertical deviations represent less than 5% of all cases of strabismus.

Amblyopia

Amblyopia is a potential complication if strabismus is not corrected in a timely manner. *Amblyopia* refers to poor vision in 1 eye or, rarely, both eyes despite correction of any refractive errors. A child with no significant refractive error and with visual acuity of 1 eye that is worse than the other has amblyopia. Diagnosis of amblyopia is based on a difference in visual acuity of at least 2 lines (eg, 20/20 in 1 eye and 20/40 in the other), as measured by reading an eye chart. Amblyopia is the leading cause of preventable visual loss in children.

Amblyopia may be classified into 3 major categories: deprivation amblyopia, refractive amblyopia, or strabismic amblyopia. Generally, *deprivation amblyopia* is the result of obstruction of vision caused by a unilateral lesion or developmental defect in 1 of the structures of the eye or its visual pathways. Causes of deprivation amblyopia include congenital cataract, ptosis, corneal opacity, retinal detachment, retinoblastoma, coloboma, optic nerve defect (eg, optic nerve hypoplasia), and orbital tumor. These conditions cause a lack of formation of a retinal image or a blurred retinal image, usually in 1 eye. *Refractive amblyopia* refers to a blurring of the retinal image resulting from large or asymmetric refractive errors. Amblyopia is usually considered a unilateral abnormality, but it may be bilateral in cases of large refractive errors (usually, astigmatism or hyperopia). In *strabismic amblyopia*, the immature or developing brain suppresses images from the deviating eye to prevent diplopia. Strabismic amblyopia is most commonly associated with strabismus that manifests in children younger than 4 years. If the condition that causes amblyopia is not corrected while the brain's visual pathways are still malleable (eg, before approximately 6–7 years of age), children may experience some degree of permanent visual loss.

Differential Diagnosis

The differential diagnosis of strabismus may be divided into 3 categories: transient neonatal strabismus, congenital or infantile strabismus, and acquired strabismus. It is important to differentiate true strabismus from the illusion of deviation created by facial asymmetry or anatomic variations (ie, pseudostrabismus).

Transient Neonatal Strabismus

Eye alignment in normal newborns and infants during the first 2 to 3 months after birth may vary from normal to intermittent esotropia or exotropia. These deviations are believed to result from CNS immaturity and resolve spontaneously in most infants by 4 months of age. If such deviations are constant or persist beyond this age, the child should be referred to an ophthalmologist for further evaluation.

Congenital or Infantile Strabismus

Congenital or infantile strabismus is deviation that occurs within the first 6 months after birth. Because the deviation may not always be present at birth, the term "infantile" may be more accurate. The differential diagnosis of infantile strabismus is presented in Box 91.2. *Pseudoesotropia* is an illusion or apparent deviation; it is not a true deviation. In many infants, the broad, flat nasal bridge and prominent epicanthal folds may obscure a portion of the sclera near the nose and create the appearance of esotropia (Figure 91.1). This illusion resolves as children mature. Symmetric corneal light reflexes or normal cover tests differentiate pseudoesotropia from true esotropia.

Esotropia is among the more common types of childhood strabismus. The constant deviation of infantile esotropia typically is readily apparent because of the large angle of deviation. Affected children usually have good bilateral vision because of the alternation of fixation from 1 eye to the other. *Cross-fixation*, in which children look to the left with the adducted right eye and to the right with the adducted left eye, may be evident because of the large angle of deviation. Rarely, esotropia may be caused by *abducens palsy* (ie, palsy of the sixth cranial nerve) in isolation or association with other cranial nerve palsies (eg, Möbius syndrome).

Infantile exotropia is less common than esotropia. Like esotropia, exotropia manifests within the first 6 months after birth and is characterized by a large angle of deviation. Causes of infantile exotropia include trochlear palsy (ie, congenital third nerve palsy, a type of paralytic strabismus) and abnormalities of the bones of the orbit (eg, Crouzon syndrome).

Acquired Strabismus

Acquired strabismus may result from a variety of causes (Box 91.2). Accommodative esotropia and intermittent exotropia are the 2 most

common types of acquired strabismus. Accommodative esotropia typically manifests in children between 2 and 4 years of age but may occur as early as 6 months or as late as 8 years. Children with hyperopia use accommodation (ie, attempts to focus) to see clearly. The accommodative reflex is closely linked to convergence; when accommodation occurs, so does convergence. If children have severe hyperopia (ie, farsightedness), the amount of convergence that occurs with accommodation may be severe and may result in the development of esotropia. Such esotropia is usually intermittent initially and only gradually becomes constant. Often, the deviating eye becomes amblyopic.

Intermittent exotropia, which is the most common form of exodeviation in children, manifests between birth and 4 years of age. Although it begins as an intermittent condition in which the eyes appear to deviate outward, especially when a child is tired, ill, or fixating at a distance, the exotropia can become constant with time. A child also may close 1 eye in bright sunlight, presumably in an attempt to prevent diplopia.

Box 91.2. Differential Diagnosis of Strabismus

Congenital or Infantile Strabismus

Esophoria/Esotropia
- Infantile esotropia
- Pseudoesotropia
- Möbius syndrome
- Abducens palsy (ie, congenital sixth nerve palsy)
- Duane syndrome

Exophoria/Exotropia
- Congenital exotropia
- Trochlear palsy (ie, congenital third nerve palsy)
- Abnormalities of the bony orbit (eg, Crouzon syndrome)

Esophoria/Esotropia and Exophoria/Exotropia
- Duane syndrome (esotropia more common than exotropia)

Acquired Strabismus

Esophoria/Esotropia
- Accommodative esotropia
- Abducens palsy (benign sixth nerve palsy)

Exophoria/Exotropia
- Intermittent exotropia
- Overcorrection after surgery for esotropia

Esophoria/Esotropia and Exophoria/Exotropia
- Poor vision
- Orbital trauma causing entrapment of extraocular muscles
- Intracranial tumors or tumors involving the orbit (eg, retinoblastoma)
- Myasthenia gravis
- Central nervous system infection (eg, meningitis)
- Central nervous system tumor
- Orbital cellulitis

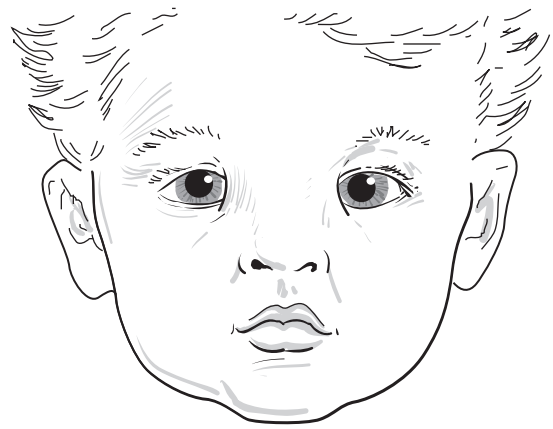

Figure 91.1. Illustration showing a child with pseudoesotropia. Note the wide nasal bridge and prominent epicanthal folds.

Evaluation

History

Evaluation of infants or children with suspected strabismus should begin with a thorough family history, because strabismus often runs in families (Box 91.3). Parental description of the ocular deviation is useful because misalignments, especially intermittent deviations that may manifest only when children are tired, may not always be evident during the office visit. A history of head or orbital trauma may help in the evaluation of acquired strabismus.

Physical Examination

On physical examination, the presence of any dysmorphic features and structural abnormalities of the face or neck (eg, torticollis) is noted. Children with paralytic strabismus (eg, trochlear palsy [ie, fourth nerve palsy], superior oblique palsy) may compensate for their paretic lesion by tilting the head to avoid diplopia. It is important that visual screening of children begin during the neonatal period. Newborn screening should emphasize the presence of a bilateral red reflex. An abnormal red reflex or a white reflex may be indicative of a cataract or retinoblastoma, both of which require immediate referral to an ophthalmologist. Evaluation for ocular alignment should begin at the 4-month health maintenance visit. Intermittent misalignment of the eyes is often seen in otherwise healthy infants younger than 4 months. Constant misalignment at any age, however, requires immediate attention.

Box 91.3. What to Ask

Suspected Strabismus
- Does the infant or child have a family history of strabismus?
- Does the infant or child constantly tilt the head toward one side?
- Does the infant or child squint?
- Has the infant or child reported blurred or double vision?
- Does the infant or child close 1 eye in bright sunlight?
- Has the infant or child incurred any recent trauma to the eyes or head?

Vision Testing

Testing visual acuity is essential in the evaluation of children with suspected strabismus. Such testing may be performed as early as 3 years of age if children are cooperative. Charts with symbols, figures, or letters can be used. The traditional Snellen chart with letters can generally be used in children as young as 4 years of age. Decreased vision in 1 eye may be indicative of ocular abnormalities, including ocular deviations.

The 2 basic tests for strabismus that can be easily performed in the office are the corneal light reflex test (ie, Hirschberg method) and the cover test. The pediatrician should be comfortable performing both tests.

The simplest and quickest test for the evaluation of strabismus is the *corneal light reflex test*, in which a penlight is projected simultaneously onto the corneas of both eyes as the child looks straight ahead. The examiner compares the placement of the corneal light reflex in each eye with respect to the center of the pupil. If the eyes are straight, the reflection appears symmetrically in the center of both pupils or on the same point on each cornea. If the light reflex appears off center in 1 eye compared with the other, the test is positive for ocular deviation or heterotropia. Nasal deviation of the light reflex on the cornea indicates exotropia on that side, temporal deviation signifies esotropia, and inferior deviation indicates hypertropia.

Unlike the corneal light reflex test, which may be performed even in uncooperative children, cover tests require a child's cooperation and ability to fixate on a specified object. These tests are used to detect heterophoria. Two types of cover test are used: the alternate cover test and the cover-uncover test. Only the alternate cover test detects both heterophoria and heterotropia. This test may be preferred by the primary care physician as a screening tool. The cover-uncover test detects only manifest deviation or heterotropia. In the *alternate cover test*, first 1 eye and then the other is covered as the child fixates on an object at a distance. If neither eye moves as the cover is moved rapidly between the eyes, the eyes are in alignment (ie, orthophoric). With heterotropia, the deviating eye moves when the fixating eye is occluded; in heterophoria, the deviating eye moves when it is uncovered (Figure 91.2).

The alternate cover test may be illustrated with the following example. A child presents with constant esotropia of the left eye. When the right or fixating eye is occluded, the left eye is forced to fixate so that the child can see, and the left eye moves outward as the right eye is occluded. In the case of a child with an esophoria or latent deviation of the left eye, the eye deviates inward when it is occluded because it is not being forced to fixate. As the cover is moved from the left eye to the right, the left eye moves outward and returns to a position of fixation.

The alternate cover test may be more difficult to interpret in children with bilateral or alternating strabismus who use both eyes in turn for fixation. It is not necessary for the pediatrician to identify exactly what type of strabismus is present. Rather, it is sufficient to note abnormal movement and refer the child for further evaluation. An ophthalmologist can perform a more detailed examination.

Management

The goals of management are the attainment of the best possible vision in each eye, straight eyes cosmetically, and fusion. The sooner deviations are corrected, the better the child's chances for equal

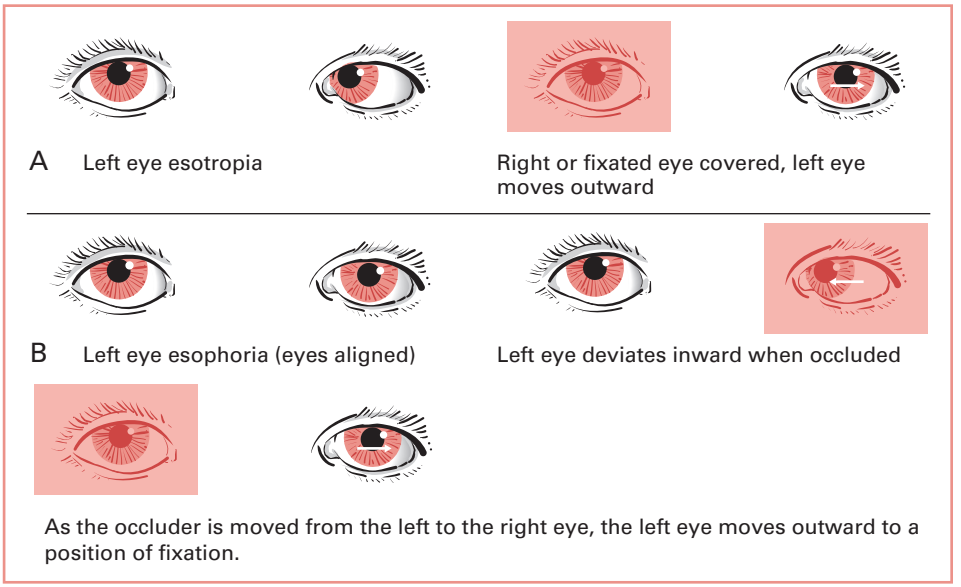

Figure 91.2. Alternate cover test in the detection of strabismus. Normally, both eyes appear to be aligned and centrally fixed. A, Detection of esotropia. The right eye is fixating, and a left esotropia is present. When the right or fixating eye is covered, the left eye moves outward (away from the nose). B, Detection of esophoria. The eyes are aligned with a left esophoria. When the left eye is covered, it deviates inward. As the cover is moved from the left eye to the right eye, the left eye moves outward to a position of fixation.

bilateral vision. Treatment includes correction of any underlying refractive error with corrective lenses. Such lenses, which remedy the refractive error and minimize the need for accommodation, are used in the management of accommodative esotropia. Glasses are also used in cases of anisometropic amblyopia in which the refractive error in 1 eye is significantly different from that in the other eye.

Children who do not see equally well from both eyes may be at risk for amblyopia if they preferentially fixate with only 1 eye. If detected, amblyopia should be corrected with occlusion therapy of the fixating "good" eye. Occlusion therapy forces children to use the amblyopic eye. This treatment is best accomplished by constantly patching the eye with better vision during waking hours or penalization with dilating drops in the better-seeing eye. Children require repeat evaluations and close monitoring during this therapy.

If eye alignment is not achieved nonsurgically, surgical correction may be necessary. Surgery may be used to achieve the best possible ocular alignment and is usually required for the management of infantile esotropia. It is generally performed in infants between 6 months and 1 year of age, while the visual system is still pliable enough to allow for the development of postoperative binocular vision. Surgery also may be needed in children with intermittent exotropia in whom the frequency of deviation is increasing.

Prognosis

Certain conditions, such as pseudoesotropia or infrequent intermittent exotropia, may resolve as children mature. Others, such as infantile esotropia, require early detection and management to achieve the best binocular vision. Amblyopia and permanent vision loss may result if correction of strabismus is delayed.

CASE RESOLUTION

The infant has pseudoesotropia. Although the boy's eyes appear to deviate, the corneal light reflex and cover tests are normal. Physical examination reveals prominent epicanthal folds and a broad, flat nasal bridge.

CHAPTER 92

Infections of the Eye

Teresa O. Rosales, MD

CASE STUDY

A 10-day-old neonate has a 1-day history of red, watery eyes and nonproductive cough with no fever. She is breastfed and continues to eat well. She was the 3,232-g (7-lb, 2-oz) product of a term gestation, born via normal spontaneous vaginal delivery without complications to a 26-year-old woman. The pregnancy was also uncomplicated. No one at home is ill.

On examination, the infant is afebrile with normal vital signs. Examination of the eyes reveals bilateral conjunctival injection with only a mild amount of purulent discharge. Bilateral red reflexes are present. The remainder of the physical examination is within normal limits.

Questions

1. What is the differential diagnosis of conjunctivitis during and after the neonatal period?
2. What laboratory tests, if any, should be performed in neonates with conjunctivitis?
3. When is chest radiography indicated in the evaluation of the neonate with conjunctivitis?
4. What are management strategies for eye infection in older infants and children?

Infections of the eye and surrounding structures are commonly seen by pediatricians. Such infections range in severity from common problems, such as blepharitis and conjunctivitis, which lack serious sequelae, to severe and less common infections, such as periorbital and orbital cellulitis. The presenting concern in many children with eye infection is a red-appearing eye. Familiarity with the common causes of a red eye makes prompt diagnosis and treatment possible.

Epidemiology

Conjunctivitis, which affects children of all ages, is perhaps the most common eye infection of childhood. The rate of conjunctivitis in the newborn period is estimated to range from 1.6% to 12%. The prevalence of chlamydial conjunctivitis is approximately 8 in 1,000 live births. Approximately two-thirds of acute childhood conjunctivitis has a bacterial etiology, and one-third is viral. *Haemophilus influenzae* and *Streptococcus pneumoniae* are the most common bacterial agents and account for approximately 40% and 10% of culture-proven cases, respectively. The incidence of *H influenzae* is decreasing with the advent of the *H influenzae* type b vaccine. The incidence of community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) is increasing. *Staphylococcus aureus* is isolated from the conjunctivas of children with acute conjunctivitis, but it is found with approximately the same frequency in the eyes of children without conjunctivitis. Adenovirus is the most common viral isolate. Most cases of acute conjunctivitis in young adults have a viral etiology. Serious eye infections, such as periorbital and orbital cellulitis, occur far less often.

Clinical Presentation

Red eyes and discharge are the common presenting signs of infection of the eyelids and conjunctivas. Eyelid edema and erythema surrounding the eye characterize periorbital and orbital cellulitis. Proptosis, abnormal extraocular movement, or loss of visual acuity may signal spread of the infection beyond the orbital septum, as in orbital cellulitis (Box 92.1).

Pathophysiology

Eye infections may be divided into 2 types: those affecting the structures surrounding the orbit and those involving the orbital contents themselves (Figure 92.1). Although all structures surrounding the eye may potentially become inflamed or infected, the eyelids; nasolacrimal drainage system, as in dacryocystitis (see Chapter 93); conjunctiva; and cornea are most commonly involved. *Orbital cellulitis* is defined as an infection of the orbital structures posterior to the orbital septum. The orbital septum, an extension of the periosteum of the bones of the orbit, extends to the margins of the upper and lower eyelids and provides an anatomic barrier to the spread of most infectious and inflammatory processes. Preseptal or periorbital cellulitis is localized to structures superficial to the orbital septum, whereas postseptal or orbital cellulitis implies that the disease process involves orbital structures extending beyond the septum.

Differential Diagnosis

Infections of the eye are included in the differential diagnosis of conditions presenting with red eye (Box 92.2). Also included in the differential diagnosis are congenital, inflammatory, traumatic, and

Box 92.1. Diagnosis of Eye Infection

Eyelid Infections
- Redness
- Itching (blepharitis)
- Burning (blepharitis)
- Scales at the base of the lashes (seborrheic blepharitis)
- Swelling (hordeolum or chalazion)
- Pain (hordeolum)

Conjunctivitis
- Conjunctival injection and edema
- Excessive tearing
- Discharge or crusting
- Itching (allergic conjunctivitis)

Uveitis
- Conjunctival injection
- Pain
- Blurred vision
- Photophobia
- Headache

Periorbital Cellulitis
- Unilateral eyelid edema
- Erythema surrounding the eye
- Pain
- Fever

Orbital Cellulitis
- Eyelid edema
- Proptosis
- Decreased extraocular movements
- Loss of visual acuity
- Fever
- Ill appearance
- Associated sinusitis

Box 92.2. Differential Diagnosis of Red Eye

Congenital Anomalies
- Nasolacrimal duct obstruction
- Congenital glaucoma

Infection
- Keratitis
- Conjunctivitis
- Dacryocystitis
- Corneal ulcer
- Periorbital and orbital cellulitis

Inflammation
- Blepharitis
- Hordeolum
- Chalazion

Trauma
- Corneal abrasion
- Foreign body
- Blunt trauma: hyphema
- Perforating injuries
- Exposure to chemicals or other noxious substances

Systemic Illnesses
- Kawasaki disease
- Varicella
- Measles
- Lyme disease
- Stevens-Johnson syndrome
- Ataxia-telangiectasia
- Juvenile rheumatoid arthritis

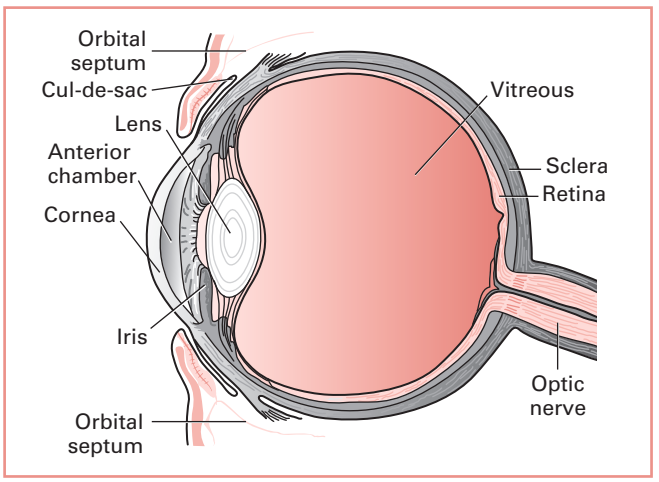

Figure 92.1. The eye and surrounding structures.

systemic processes. Although infection and irritation are by far the most common causes of an acute onset of red eye, other possibilities, including trauma, glaucoma, or underlying systemic disease, must be considered.

Eyelid Infections

Common conditions affecting the eyelid and its related structures are blepharitis, hordeolum, and chalazion.

Blepharitis is an inflammation of the lid margins. This condition, which is often bilateral, may be chronic or recurrent. The 2 most common causes of blepharitis are staphylococcal infection and seborrheic dermatitis. The child with staphylococcal blepharitis often presents with scales at the base of the lashes, ulceration of the lid margin, and loss of lashes. The infection may spread to the conjunctiva or cornea, producing conjunctivitis or keratitis. In contrast, seborrheic blepharitis is characterized by greasy, yellow scales attached to the base of the lashes. Additionally, associated seborrhea of the scalp or eyebrows may be present. Mixed staphylococcal-seborrheic infections, which occur as staphylococcal superinfection, may complicate seborrheic blepharitis. Less commonly seen forms

of blepharitis are parasitic blepharitis, which results from infestation of the lids by the head louse, *Pediculus humanus capitis,* or crab louse, *Phthirus pubis,* and primary or recurrent human herpesvirus 1 infections that may manifest as clusters of vesicles on the eyelids. Rosacea may rarely occur in childhood and can present very similarly to chronic blepharitis.

The glands of the eyelid can also be infected. *Staphylococcus aureus* is the most common organism. A *hordeolum*, or common *stye*, results from an infection of the meibomian glands located along the lid margins. The glands become obstructed and an abscess can form. The affected child presents with a well-circumscribed, painful swelling that may be at the lid margin or deeper in the lid tissue. These generally rupture or resolve without complications when managed aggressively with hot compresses.

A *chalazion* is a hordeolum that has not resolved over weeks to months. It is no longer an infectious process but has become a chronic granulomatous inflammation of the meibomian glands. The resulting firm, nontender, slow-growing mass within the upper or lower eyelid may be painful if secondary infection is present.

Infections of the Conjunctiva

Conjunctivitis refers to any inflammation of the conjunctiva. The condition may be allergic, chemical, viral, or bacterial in etiology. Additionally, it may be a sign of systemic disease, such as Kawasaki disease or Stevens-Johnson syndrome.

Acute conjunctivitis, or pinkeye, is common during childhood and can be extremely contagious. The usual signs are conjunctival injection, tearing, discharge, crusting of the lashes, and conjunctival edema (ie, chemosis). Pain and decreased vision are uncommon symptoms and may signal corneal involvement.

Generally, it is difficult to distinguish bacterial conjunctivitis from viral conjunctivitis on clinical features alone. Certain clinical characteristics may guide the diagnosis. The average age of children affected with bacterial conjunctivitis tends to be younger than the age of those with viral conjunctivitis, which occurs more frequently in adolescents; however, considerable overlap occurs. The child with bacterial conjunctivitis typically presents with an acute onset of unilateral or bilateral injection and edema of the palpebral and bulbar conjunctiva, minimal to copious purulent discharge, and crusting of the eyelashes. The child may have difficulty opening the eyes on awaking in the morning because of the exudate. An association between conjunctivitis and concomitant otitis media has been well described. *Haemophilus influenzae,* which is often resistant to ampicillin, is the pathogen most commonly isolated from affected children.

The diagnosis of viral conjunctivitis is considered if signs of viral upper respiratory infection (eg, low-grade fever, cough, rhinorrhea) are evident. Viral infection is associated with conjunctival injection, watery or thin mucoid discharge, and only mild lid edema and erythema. Adenoviral infection is usually bilateral, with significant conjunctival injection and chemosis of the conjunctiva, and is often accompanied by a tender preauricular lymph node. Epidemic keratoconjunctivitis is a highly contagious form of adenoviral conjunctivitis. Affected children often report foreign body sensation beneath the lids or photophobia resulting from corneal involvement. Pharyngeal conjunctival fever, another presentation of adenoviral conjunctivitis, usually manifests as conjunctivitis in association with pharyngitis and fever.

The infant with chronic or recurrent conjunctival discharge may have an obstruction of the nasolacrimal duct, whereas the older child with chronic conjunctivitis may have allergic disease, recurrent blepharitis, or chlamydial infection. Blepharitis is the most common cause of chronic conjunctivitis in older children. *Staphylococcus aureus* is frequently implicated in these infections.

Itching, tearing, and conjunctival edema are the hallmarks of *allergic conjunctivitis*, a noninfectious form of conjunctival inflammation often occurring in children with other allergic disorders, such as asthma or hay fever. Conjunctival injection tends to be mild, bilateral, and seasonal. The etiology is most often a hypersensitivity to pollens, dust, or animal dander. Vernal conjunctivitis is a bilateral, severe form of allergic conjunctivitis seen primarily during childhood. Most cases occur during the spring and summer. Severe itching and tearing are the most frequent complaints. The palpebral conjunctiva may have a cobblestone appearance resulting from the accumulation of inflammatory cells, or there may be small, elevated lesions of the bulbar conjunctiva at the corneal limbus. The pathogenesis is unclear, but atopy seems to play a role.

Chlamydial conjunctivitis frequently affects neonates and adolescents. Inclusion conjunctivitis is an acute infection of the eyes caused by sexually transmitted *Chlamydia trachomatis* (usually serotypes D–K). This condition may be seen in the neonate or sexually active adolescent. Trachoma, the most common cause of impaired vision and preventable blindness worldwide, is a chronic conjunctivitis usually caused by *C trachomatis* serotypes A, B, and C. Although this disease is rarely seen in North America, it is endemic among certain populations, especially Native Americans. Inclusion conjunctivitis and endemic trachoma are characterized initially by conjunctivitis with small lymphoid follicles in the conjunctiva.

Neonatal conjunctivitis, or ophthalmia neonatorum, occurs during the first month after birth. In decreasing order of frequency, the major causes of neonatal conjunctivitis are chemical, chlamydial, and bacterial. Ophthalmia neonatorum may be produced by the same bacteria that cause childhood conjunctivitis but also results from organisms such as *C trachomatis* and *Neisseria gonorrhoeae.* The newborn may acquire these latter pathogens following premature rupture of membranes or passage through an infected or colonized birth canal. *Chlamydia trachomatis* is the organism most commonly identified. It has been isolated from 17% to 40% of neonates with conjunctivitis. The neonate born to a mother with active cervical chlamydial infection has a 20% to 50% chance of developing chlamydial conjunctivitis. Viruses are uncommon causes of neonatal ocular infections. Human herpesvirus is the primary viral agent involved in neonatal conjunctivitis. The presence of characteristic vesicular skin lesions or corneal dendritic lesions helps in the diagnosis.

Time of onset of symptoms is related to the etiologic agent. Inflammation secondary to the silver nitrate drops instilled at birth to prevent gonococcal infection presents as mild conjunctivitis 12 to 24 hours after birth in 10% to 100% of treated newborns. This condition usually resolves spontaneously in 24 to 48 hours. This is more of historic interest because erythromycin ointment 0.5% has replaced silver nitrate in most hospitals. (Silver nitrate was ineffective against *C trachomatis.*) Conjunctivitis resulting from *N gonorrhoeae* appears 2 to 5 days after birth and is associated with copious purulent discharge. Conjunctivitis caused by *C trachomatis* occurs at 5 to 14 days, a result of a longer incubation period. Time of onset and severity of symptoms of these 2 conditions may overlap, however. The presentation of gonococcal infection may be delayed for 5 days or more because of the partial suppression of the infection by the prophylactic drops instilled at birth. Chlamydial infection can vary in severity from mild erythema of the eyelids to severe inflammation and copious purulent discharge. Chlamydial infection is primarily localized to the palpebral conjunctiva and only rarely affects the cornea. Gonococcal conjunctivitis is considered a medical emergency because the gonococcus can penetrate the cornea, resulting in corneal ulceration and perforation of the globe within 24 hours if untreated.

Concomitant nasopharyngeal chlamydial infection is common. Spread of the organism from the nasopharynx to the lungs is a sequela of colonization. Ten percent to 20% of newborns and infants with conjunctivitis have chlamydial pneumonia. It may occur simultaneously with the conjunctivitis or up to 4 to 6 weeks later. The affected newborn or infant usually is afebrile and presents with symptoms of increasing tachypnea and cough.

Anterior uveitis may be confused with conjunctivitis. The uvea consists of the iris, ciliary body, retina, and choroid. Inflammation of the iris or ciliary body may produce conjunctival injection, which may be associated with decreased visual acuity, pain, headache, and photophobia. Systemic conditions associated with uveitis include Kawasaki disease, juvenile idiopathic arthritis, Lyme disease, tuberculosis, sarcoidosis, *Toxocara* infection, toxoplasmosis, and spondyloarthropathies.

Infections of the Eye and Surrounding Tissues

Preseptal cellulitis and orbital cellulitis are 2 serious infections of the eyelids and surrounding structures. Although these infections are not as frequent as those that are limited to the eye, they have serious sequelae. The preseptal space is defined by the skin of the eyelid on one side and the orbital septum on the other. The child with preseptal cellulitis, or periorbital cellulitis, usually presents with acute onset, unilateral upper and lower eyelid edema, erythema, and pain. The condition is often associated with systemic signs and symptoms, such as ill appearance, fever, and leukocytosis. The eye itself usually appears normal. Infection may follow hematogenous seeding of the preseptal space, most often with *H influenzae* type b or *S pneumoniae,* or after traumatic breaks in the skin that usually result in *S aureus* infection.

Orbital cellulitis is an infection of the contents of the orbit posterior to the orbital septum. Usually an insidious onset of eyelid edema, proptosis, decreased extraocular movements, and loss of visual acuity occur. As with periorbital cellulitis, the affected child is often febrile and ill-appearing. Contiguous spread of infection from adjacent sinusitis (most often ethmoid) is the most common cause. The organisms most often involved are the same as those in acute sinusitis (ie, *S aureus, S pneumoniae,* non-typeable *H influenzae*). Untreated, the infection may progress to orbital abscess formation or progress posteriorly in the orbit to the cavernous sinus and brain.

Primary human herpesvirus infection can affect the skin surrounding the eyes as well as the eye itself. Most of these infections are caused by human herpesvirus 1, although human herpesvirus 2 infections may occur in the newborn. The child with herpetic infection of the eye usually presents with unilateral skin vesicles and a mild conjunctivitis or keratitis. Herpetic keratoconjunctivitis can recur after fever, exposure to sunlight, or mild trauma. The characteristic corneal lesion of herpetic keratitis is the dendritic corneal ulcer, which appears as a tree branch pattern on fluorescein staining of the cornea. Although this lesion may occur with primary infection, it is more common in recurrent infections. Skin vesicles may not appear with a recurrence, which makes it difficult to distinguish herpetic infection from other causes of conjunctivitis. Steroids may cause progression of the herpetic infection and permanent corneal scarring as well as cataracts and glaucoma. Empiric topical steroid treatment for presumed viral conjunctivitis should be avoided for this reason. Neonatal herpetic infections of the eye primarily result from human herpesvirus 2. Infections may be isolated to the eye, or the eye may be infected secondarily resulting from central nervous system or disseminated disease. Proper diagnosis is important because disseminated herpetic disease has a mortality rate of approximately 85%, and central nervous system disease has a mortality rate of 50%. Isolated herpetic eye disease is quite rare in neonates.

Evaluation

History

A careful history taken from the parent or primary caregiver as well as the child can guide the diagnosis (Box 92.3). It is important to exclude the possibility of ocular trauma or exposure to noxious chemicals when evaluating the child with red, irritated eyes.

Physical Examination

A thorough examination of the eyes should be performed. The eyelids, conjunctiva, and cornea should be inspected for evidence of inflammation or foreign bodies. The presence of any discharge or crusting of the eyelids as well as light sensitivity or pain should be noted. Extraocular movements should be checked, and their symmetry should be noted. Visual acuity should be determined, and an ophthalmoscopic examination of the retina should be performed whenever possible. A slit-lamp examination of the eye is indicated if uveitis is suspected. Additionally, it is important to perform a thorough head and neck examination, noting the

Box 92.3. What to Ask

Eye Infections

- How long has the child had symptoms?
- Is the child having any difficulty seeing clearly?
- Is the child reporting light sensitivity?
- Has the child had fever, cold symptoms, or purulent nasal discharge (eg, green, yellow)?
- Are the eyes pruritic (ie, itchy) or painful?
- Does the child have difficulty opening the affected eye on awaking in the morning or after naps?
- Has the parent or guardian noticed any discharge from the eyes or crusting around the eyelids?
- Is the child reporting earache or sore throat?
- Does the child have allergies, asthma, or hay fever?
- Has any trauma or bug bites occurred?

presence of associated sinusitis, otitis media, pharyngitis, or preauricular nodes.

Laboratory Tests

Laboratory assessment is guided by the history and physical examination. Although clinical differentiation between a bacterial and viral etiology is difficult, cultures usually are not required because acute conjunctivitis in children is a self-limited disease. In neonatal conjunctivitis, however, the time of onset of illness and clinical findings overlap, and Gram stain and cultures are essential. Gonococcal infection is assessed by Gram stain and culture. Treatment may be initiated on the basis of Gram stain alone because of the serious potential for corneal involvement and subsequent loss of visual acuity.

If human herpesvirus is suspected, viral cultures should be obtained. If chlamydial infection is suspected, a nasopharyngeal culture should be sent in addition to conjunctival scraping. Purulent material may be examined for gonococci, but conjunctival scrapings are required for chlamydia because chlamydia is an obligate intracellular organism. Laboratory assessment of periorbital cellulitis includes a complete blood cell count, blood culture, and a lumbar puncture in the young infant or child with signs of meningeal irritation. The reported prevalence of meningitis is 1% in children with periorbital cellulitis and 10% in children with bacteremia and periorbital cellulitis. As with periorbital cellulitis, laboratory assessment of orbital cellulitis includes a complete blood cell count and blood culture.

Imaging Studies

Imaging studies are required infrequently in the assessment of eye infections. Chest radiography to detect pneumonia should be obtained if the infant with neonatal conjunctivitis has respiratory symptoms. Characteristic features on chest radiography include hyperinflation and diffuse or patchy interstitial infiltrates. In orbital cellulitis, computed tomography of the orbit and sinuses may be useful for assessing the degree of involvement.

Management

Most common eye infections resolve spontaneously or respond readily to hygiene and topical antibiotics. Treatment of staphylococcal and seborrheic blepharitis consists of daily lid hygiene (usually at bedtime), including application of a warm compress and removal of the scales and crusts with a moistened, warm washcloth. The eyelashes and lid margins may also be scrubbed with a washcloth soaked in a 50:50 mixture of baby shampoo and water. When staphylococcal blepharitis is present, an ointment containing an anti-staphylococcal antibiotic agent, such as erythromycin, may be applied to the eyelids after cleansing. Treatment of parasitic blepharitis consists of application of petrolatum ophthalmic ointment (to smother the nits) several times a day for 1 week, followed by removal of the remaining parasites and their ova with tweezers or forceps.

Treatment for hordeola consists of application of hot compresses several times a day. This usually causes the abscess to come to a point and drain. Occasionally, surgical excision and drainage may be required if the abscess does not resolve. Unlike the hordeolum, a chalazion generally requires surgical excision because spontaneous resolution is uncommon.

Most cases of acute childhood conjunctivitis can be managed successfully by the primary care physician. Acute conjunctivitis in childhood is generally a self-limited disease. However, antibiotic treatment of bacterial conjunctivitis hastens recovery and may help prevent secondary cases by eradicating the bacterial pathogen. It is helpful to determine clinically whether the infection is bacterial and initiate empiric treatment with topical antibiotic preparations. Trimethoprim and polymyxin B sulfate (eg, Polytrim), sodium sulfacetamide (eg, Bleph-10, Sodium Sulamyd), gentamicin (eg, Garamycin, Gentak), tobramycin (eg, Tobrex), and moxifloxacin (eg, Vigamox) are some of the commonly prescribed antibiotics. Trimethoprim and polymyxin B sulfate as well as gentamicin remain highly effective against MRSA. Neomycin-containing products should be avoided, because sensitivity to neomycin occurs frequently. Antibiotic ointments may be easier to instill in the infant or young child. Antibiotic drops should be used in the older child during the day because the ointments can blur the vision; ointments may be used at bedtime. Systemic therapy can be considered for concomitant conjunctivitis and otitis media. Good hygiene with special attention to handwashing is important to prevent the spread of the infection to the other eye as well as family and friends. Even if the child is on antibiotic drops, the child should not go to school until the discharge and drainage have resolved. If symptoms persist for more than 7 to 10 days or if the diagnosis is in question, appropriate cultures should be taken. Immediate referral to an ophthalmologist is required for complicated cases, such as suspected herpetic, gonococcal, or MRSA infection; foreign bodies that cannot be removed easily; loss of visual acuity; presence of significant pain; those involving a history of recent penetrating ocular trauma or surgery; and those involving contact lens use. Contact lens wearers with red eyes are at high risk for corneal ulcers. They should be instructed to leave their lenses out until seen by the ophthalmologist.

Allergic conjunctivitis can be managed with cool compresses. Topical decongestant or antihistamine drops drops may provide symptomatic relief if treatment is indicated. Vernal conjunctivitis may be managed with topical cromolyn sodium drops or medications designed to relieve redness and itching and stabilize mast cells, such as olopatadine hydrochloride (eg, Patanol, Pataday) or ketorolac tromethamine (eg, Toradol, Acular). Caution should be used when prescribing corticosteroid preparations for the eye because they may cause progression of an undiagnosed herpetic eye infection. Chronic use of topical steroids can cause cataracts and glaucoma.

Management of neonatal conjunctivitis depends on the diagnosis. If gonococcal infection is suspected and Gram stain result is positive for gram-negative diplococci, immediate parenteral therapy with ceftriaxone should be initiated. Chlamydial conjunctivitis should be managed with systemic rather than topical treatment to prevent systemic disease. Oral erythromycin is the drug of choice. Although oral treatment provides adequate local antibiotic levels, topical erythromycin ointment may be used in conjunction with systemic therapy to provide more prompt relief of ophthalmic symptoms. The parent(s) or guardian(s) should also be treated.

Empiric parenteral antibiotic therapy (eg, cefuroxime) should be initiated for periorbital cellulitis. Repeat evaluations for signs of progression should be performed frequently during the initial 24 to 48 hours. If orbital cellulitis is suspected, an ophthalmologist should be consulted, and hospitalization and systemic antibiotics should be instituted. Surgical drainage of the sinuses or an orbital abscess is sometimes necessary.

The child with suspected herpetic infection should be referred to an ophthalmologist. Intravenous acyclovir is often recommended for the management of isolated herpetic eye infections in the neonate.

Prognosis

Most common eye infections, such as blepharitis, hordeolum, and acute childhood conjunctivitis, resolve without sequelae. Recurrence is common for hordeola, and periorbital cellulitis may be a potential complication in rare or untreated cases. Unlike acute conjunctivitis, chronic conjunctivitis may not be self-limited. Appropriate diagnosis and management are extremely important to prevent serious sequelae in some children. For example, endemic trachoma may progress to produce conjunctival scarring, pannus formation, and even blindness if not appropriately managed with systemic erythromycin or tetracycline. (Generally, systemic tetracycline should not be used in the child younger than 8 years to avoid discoloration of the teeth.)

Periorbital cellulitis generally resolves without sequelae if treated promptly with systemic antibiotics. Orbital cellulitis should be considered a true ophthalmologic emergency because the potential for complications is high. The optic nerve may become involved, resulting in loss of vision or spread of the infection into the cranial cavity. This spreading may result in meningitis, cavernous sinus thrombosis, or brain abscess.

CASE RESOLUTION

The newborn has neonatal conjunctivitis. A Gram stain of the purulent discharge should be examined, and cultures should be taken from the eye and nasopharynx. If the Gram stain result is negative for gonococci, empiric treatment for chlamydia may begin with oral erythromycin.

CHAPTER 93

Excessive Tearing

Teresa O. Rosales, MD

CASE STUDY

A 4-week-old girl has had a persistent watery discharge from both eyes since birth. Her mother has noticed white, crusty material on her daughter's eyelids for the past few days. The infant's birth and medical history are unremarkable. Examination of the eyes, including bilateral red reflexes and symmetric extraocular movements, is normal, except that the left eye appears "wetter" than the right.

Questions

1. What is the differential diagnosis of excessive tearing in infancy?
2. How do physical findings such as corneal enlargement and haziness influence the differential diagnosis?
3. How should excessive tearing in infants be managed?
4. When should a child with excessive tearing be referred to an ophthalmologist?

Excessive tearing or epiphora in 1 or both eyes in infants or young children is a common pediatric ophthalmologic concern. The pediatrician must be capable of differentiating benign causes of this common childhood condition from more serious illnesses (eg, glaucoma) that have the potential to threaten vision.

Obstruction of the Nasolacrimal Duct

Epidemiology

Dacryostenosis, that is, congenital obstruction of the nasolacrimal duct (NLD), occurs in 1% to 6% of newborns and infants and is the most common cause of excessive tearing in infancy. Eighty percent of cases of dacryostenosis resolve spontaneously by 6 months of age.

Clinical Presentation

Infants with dacryostenosis typically present with a history of a mucoid discharge and crusting along the eyelid margins. The affected eye appears "wetter" than the normal eye, and a small pool of tears may be noted along the lower eyelid. Frequent tearing is reported. Commonly, the patient has repeated episodes of infection with purulent discharge (Box 93.1).

Pathophysiology

The lacrimal system produces and drains tears away from the eyes and into the nose (Figure 93.1). Typically, reflex tearing is present shortly after birth; however, it may be delayed for several weeks to months until the lacrimal gland begins to function. Tears drain away from the eyes through the superior and inferior puncta into the superior and inferior canaliculi and finally into the NLD, which drains beneath the inferior turbinate into the nose.

Outflow obstruction, which typically results from dacryostenosis, is the most common cause of excessive tearing in infancy. The obstruction is usually bilateral and occurs during fetal development. Most commonly, a persistent, thin membrane (Hasner membrane) obstructs the opening of the sac in the nose. Typically, the membrane is located in the distal or nasal segment of the duct rather than the proximal portion. The term *dacryocystitis* is used in cases in which acute infection or inflammation is associated with the obstruction. If the canaliculi and NLD are obstructed, a dacryocystocele involving the nasolacrimal sac may be noted at birth. This sac appears as a bluish, firm mass located over the lacrimal sac. Atresia of some portion of the drainage system is an extremely rare occurrence. Infants with dacryocystocele, who have large intranasal cysts, may present with respiratory symptoms because infants are obligate nasal breathers. Symptoms range from difficulty during feeding (caused by obstruction of the mouth) to respiratory distress.

Differential Diagnosis

Box 93.2 outlines the differential diagnosis of excessive tearing in infancy. Although obstruction of the NLD is the most common cause of excessive tearing in newborns and infants, it is important to consider and rule out glaucoma when evaluating neonates and infants with excessive tearing. Infantile glaucoma may be unilateral or bilateral.

Acute onset of excessive tearing in older children is usually the result of ocular irritation. Any irritation of the conjunctiva, cornea, or eyelids may produce tearing. Conjunctivitis and corneal abrasion (secondary to a foreign body in the eye or human herpesvirus keratoconjunctivitis) are the 2 most common causes. Eye infections are discussed in Chapter 92.

Evaluation

History

Evaluation of excessive tearing begins with a thorough patient history. The nature of any discharge (eg, watery, mucoid, purulent) is noted.

Box 93.1. Diagnosis of Excessive Tearing

- Conjunctival edema or injection
- Crusting of the eyelids
- Rhinorrhea
- Photophobia
- Corneal haziness
- Reflux of tears with gentle pressure on the medial canthus
- Wetness of the eye

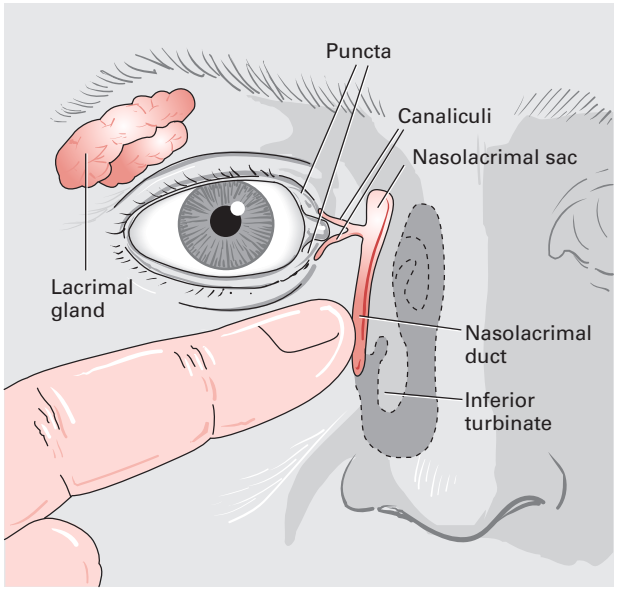

Figure 93.1. The lacrimal system, showing massage of the lacrimal sac (ie, Crigler massage).

Box 93.2. Differential Diagnosis of Excessive Tearing in Newborns and Infants

Increased Production

- Infantile glaucoma
- Allergy
- Conjunctivitis
- Corneal abrasion
- Foreign body under the eyelid

Outflow Obstruction

- Obstruction of the nasolacrimal duct (ie, dacryostenosis)
- Anomalies of the lacrimal drainage system
- Mucocele of the lacrimal sac
- Atresia of the lacrimal punctum or canaliculus
- Nasal congestion
- Craniofacial anomalies involving the midface

Parents or other caregivers should be questioned about the appearance of the infant's eyes (Box 93.3). The excessive mucoid discharge in the medial canthal region and on the eyelashes is noticeable to the family, as is the increased tearing. Crusting along the eyelashes caused by drying of the mucoid material is usually noted when infants awake in the morning or after a nap. Mucopurulent discharge may be noted if an associated acute infection is present (eg, dacryocystitis).

Physical Examination

A careful examination of the eyes in infants includes inspection, evaluation of extraocular movements, and funduscopic examination. While funduscopic examination may be difficult in this age group, it is easy to elicit bilateral red reflexes. Signs of dacryostenosis, which usually appear days to weeks after birth, include tearing, mucoid discharge, and crusting of the eyelids. Tearing may be as mild as an increased wetness of the affected eye; this is best evaluated prior to disturbing the infant. Visible overflow of tears from the affected eye is not unusual and is typically seen when the eye is irritated (eg, from cold or wind). Infants with dacryostenosis may present with associated erythema and edema of the eyelids as well. Dacryocystitis may also spread to the surrounding tissues, producing a periorbital cellulitis; systemic signs of infection, such as fever, may be noted. Gentle pressure along the medial canthal region over the lacrimal sac may produce a reflux of tears or mucoid discharge onto the surface of the eye, thus confirming the diagnosis of obstruction.

Laboratory Tests

Typically, routine laboratory assessment is not necessary.

Management

Early treatment of dacryocystoceles before 13 months of age is advised to prevent complications related to infection or respiratory distress. Digital massage may be attempted to decompress the dacryocystocele; occasionally, the condition resolves without surgery. Dacryocystoceles associated with acute respiratory distress require immediate surgical intervention.

Nasolacrimal duct probing alone may be curative; however, in approximately 25% of patients the condition persists after probing.

Box 93.3. What to Ask

Excessive Tearing

- How old was the infant when the excessive tearing began?
- Does the condition affect 1 eye or both eyes?
- How does the eye appear? How has its appearance changed?
- Is there a family history of infantile glaucoma?
- Does the infant have photophobia or light sensitivity (eg, closes eyes in bright sunlight)?
- Has the infant had any persistent, watery discharge?
- Does the infant have difficulty opening the affected eye on awaking in the morning or after a nap?

Nasolacrimal duct probing in conjunction with nasal endoscopy and intranasal cyst removal is effective in more than 95% of infants.

Spontaneous resolution of dacryostenosis is common by 6 to 8 months of age. The primary medical treatment of uncomplicated NLD obstruction consists of local massage and cleansing, beginning when symptoms are noted. Parents are instructed to massage the NLD several times a day by applying firm, downward pressure over the medial canthal region with a finger and sliding the finger down toward the mouth (ie, *Crigler massage*; Figure 93.1). This maneuver is done in an attempt to move fluid trapped within the nasolacrimal sac down through the duct to break the obstruction with hydrostatic pressure. Parents may be asked to cleanse the eyes with warm water before performing this maneuver. Antibiotic ointments and drops should be prescribed only if the discharge is purulent or associated conjunctivitis is evident.

Controversy exists about when probing of the NLD should be performed. Some ophthalmologists prefer probing the duct before infants are 6 months of age, because before this age the procedure may be performed in the office without general anesthesia. Other ophthalmologists state that more than 80% of obstructions resolve with conservative medical management by 6 months of age and prefer to delay probing until 9 to 12 months of age. At this age, however, the procedure must be performed under general anesthesia. Deciding when to proceed with probing depends on the standard of practice within the community, severity of symptoms, response to medical management, and level of parental concern.

Ophthalmologic referral is necessary for affected infants by 6 months of age if the obstruction has not resolved. Referral should be made sooner if symptoms are severe or infections recur.

Prognosis

Most cases of dacryostenosis resolve spontaneously by age 1 year without further sequelae. Tear duct probing, should it be necessary, is 90% to 95% successful if performed before 13 months of age. The success rate drops to 70% between 13 and 15 months of age and to 50% in those older than 18 months.

Congenital Glaucoma

Epidemiology

Congenital or infantile glaucoma, which is a serious cause of excessive tearing, is rare, with a prevalence of approximately 1 in 10,000 live births. Although glaucoma may be present at birth, onset during the first few weeks to months after birth is more common. Approximately 25% of cases are diagnosed at birth, and 80% of cases are diagnosed by 1 year of age. The severity of the disease is worse with earlier onset. Most affected infants are male; the male to female ratio in older infants is 2:1. Infantile glaucoma seems to have a multifactorial inheritance pattern, but most cases are sporadic. In families with 1 affected infant or a parental history of infantile glaucoma, the chance of having an infant with glaucoma is approximately 5%. Although glaucoma may be unilateral or bilateral, 75% to 90% of infants who present before 3 months of age have bilateral glaucoma.

Clinical Presentation

In addition to excessive tearing, other clinical signs of infantile glaucoma include *blepharospasm* (ie, spasmodic blinking of the eyelids), photophobia, corneal enlargement and corneal haziness resulting from corneal edema, progressive enlargement of the eye (ie, *buphthalmos*), and cupping and atrophy of the optic nerve (Box 93.1).

Pathophysiology

Glaucoma is the most serious and potentially sight-threatening etiology for excessive production of tears. *Glaucoma* refers to an increase in intraocular pressure that is severe enough to damage the eye and alter vision. In infants and children, glaucoma usually is a result of a developmental abnormality of the iridocorneal angle, which interferes with drainage of aqueous humor from the anterior chamber. Young infants differ from adults in that the globe in infants' eyes is distensible; the increased intraocular pressure not only produces corneal enlargement and edema but also expands the globe itself. Breakdown of the corneal epithelium and resultant irritation of the eyes produce reflex tearing and photophobia. Untreated glaucoma may result in optic nerve damage with resultant loss of visual acuity, decreased visual field, and even blindness. Glaucoma in children younger than 3 years of age is referred to broadly as *infantile glaucoma*, and glaucoma that occurs in children between 3 and 20 years of age is called *juvenile glaucoma*. Infantile glaucoma is further classified as primary or secondary. *Primary glaucoma* refers to isolated abnormalities of the iridocorneal angle, whereas *secondary glaucoma* may be associated with other ocular or systemic diseases. Juvenile glaucoma is a form of open-angle glaucoma.

Differential Diagnosis

Excessive tearing may be caused by increased production or outflow obstruction (see Box 93.2). Infants with increased production of tears demonstrate rhinorrhea in association with epiphora, a finding that distinguishes glaucoma from dacryostenosis. Rhinorrhea is not associated with dacryostenosis because the NLD is obstructed and no tears drain out the nose. Ocular irritation, which occurs with conjunctivitis, corneal abrasion, or a foreign body under the eyelid, also can produce excessive tearing, especially in older children. In addition, allergies are associated with excessive tearing resulting from overproduction.

Disorders associated with outflow obstruction include dacryostenosis, anomalies of the lacrimal drainage system (eg, dacryocystocele of the lacrimal sac, atresia of the lacrimal punctum or canaliculus), nasal congestion, and craniofacial anomalies involving the midface.

Evaluation

A corneal diameter greater than 12 mm in infants is suggestive of infantile glaucoma. Corneal edema is more common in newborns and in infants younger than 3 months and may cause the red reflex to appear dull in the affected eye. The optic cup may be enlarged. A cup to disk ratio greater than 0.3 or an asymmetry of the ratio between the eyes may be indicative of glaucoma.

As in adults, loss of visual fields occurs in children with glaucoma. Visual fields are difficult to evaluate in infants and young children because of their inability to cooperate with the examination.

Management

Suspected cases of glaucoma should be referred to an ophthalmologist immediately for further evaluation, including measurement of intraocular pressure. Pressures greater than 20 mm Hg are suggestive of glaucoma. (In persons of any age, normal intraocular pressure is 10 to 20 mm Hg.)

Surgery is the primary treatment for glaucoma. The goal is to normalize intraocular pressure and minimize irreversible damage to the cornea and optic nerve.

Prognosis

Left untreated, infantile glaucoma may progress to blindness. The visual prognosis depends on several factors, including age at onset, with the earlier the onset, the worse the prognosis; the amount of optic nerve damage; and the degree of myopia caused by the enlargement of the eye. In addition, amblyopia secondary to deprivation resulting from corneal opacities or unequal refractive errors is often seen (see Chapter 91).

CASE RESOLUTION

The infant has dacryostenosis. At this stage, it can be managed with medical treatment, such as local massage and cleansing. If her symptoms persist beyond age 6 months, consultation with an ophthalmologist is recommended.

CHAPTER 94

Neck Masses

Casey Buitenhuys, MD, FACEP, and Stanley H. Inkelis, MD, FAAP

CASE STUDY

A 2-year-old boy is brought to the office with a 1-day history of an enlarging red, tender "bump" beneath his right mandible. He has a fever (temperature 38.7°C [101.6°F]) and sores around his nose, upper lip, and cheek. These sores have been present for 3 days and have not responded to an over-the-counter antibiotic ointment. He had an upper respiratory tract infection 1 week previously, which has almost entirely resolved. He is otherwise in good health. The family has no history of tuberculosis or recent travel, and the child has not been playing with cats or other animals.

The physical examination is completely normal except for fever, mild rhinorrhea, honey-crusted lesions on the nares and upper lip, and a 4- × 5-cm, right submandibular neck mass that is erythematous, warm, and tender to palpation.

Questions

1. What are the common causes of neck masses in children?
2. What steps are involved in the evaluation of the child with a neck mass?
3. What clinical findings suggest that neck masses are neoplasms? When should neck masses be biopsied or removed?
4. What is involved in the treatment of the different types of neck masses in children?
5. When should the child with a neck mass be referred for further consultation?

A *neck mass* is any swelling or enlargement of the structures in the area between the inferior mandible and the clavicle. Normal variants, such as the angle of the mandible or tip of the mastoid bone, may occasionally appear as swellings, and the parent or guardian sometimes confuses these with neck masses. If the swelling is not a normal structure, a well-directed history and physical examination usually determine the etiology.

Lymphadenopathy from viral or bacterial throat infections is the most common cause of neck masses in children. Therefore, neck masses are common because children frequently have sore throats. Most parents and guardians know about swollen lymph glands, and they usually do not seek medical advice unless the glands become quite large or do not recede in a few days. Neck masses in children may have many other causes besides lymphadenopathy. Most of these masses may be categorized as inflammatory, neoplastic, traumatic, or congenital in origin. A well-described mnemonic in the adult literature, KITTENS (congenital/developmental anomalies, infectious/inflammatory, trauma, toxic, endocrine, neoplasms, systemic disease), can summate many of the causes of neck masses in children as well (Box 94.1).

Epidemiology

Most neck masses are benign. Almost 50% of all children 2 years of age and up to 90% of children between 4 and 8 years of age have palpable cervical lymph nodes. Although more than 25% of malignant tumors in children are found in the head and neck region (this is the primary site in only 5%), less than 2% of suspicious head and neck masses are malignant.

The epidemiology of neck masses of infectious origin depends on the infectious agent itself, geographic location of the child, and the child's immediate environment. Neck masses of viral origin may be related to focal infection of the oropharynx or respiratory tract but often are associated with generalized adenopathy. Neck masses of bacterial origin typically occur from normal bacterial flora of the nose, mouth, pharynx, and skin that secondarily spreads to lymph nodes. These organisms are not usually transmitted from person to person. Pathologic flora, such as group A streptococcus and *Mycobacterium tuberculosis*, that result in neck masses can spread by human-to-human contact, however. Additionally, cat-scratch disease is caused by *Bartonella henselae,* a vector-borne pathogen.

Clinical Presentation

Children with neck masses present in a variety of ways depending on the etiology of the mass. Typically, a swelling or enlargement in the neck, which a parent or guardian often notices more than the child, is evident. Associated signs and symptoms include fever, upper respiratory tract infection, sore throat, ear pain, pain or tenderness over the mass, changes in skin color over the mass, skin lesions of the head or neck, and dental caries or infections (Box 94.2). Malignant tumors are usually slow-growing, firm, fixed, nontender masses. Congenital neck masses and benign tumors, which have frequently been present since birth or early infancy, are soft, smooth, and cyst-like and may be recurrent. Neck masses associated with trauma are often rapidly evolving and may result in airway obstruction. Temporal development of neck masses is a helpful predictor

Box 94.2. Diagnosis of Neck Masses in the Pediatric Patient

Inflammatory/Infectious

- Swelling or enlargement in the neck
- Fever
- Sore throat, dental infection, skin infection of head or neck
- Pain or tenderness over the mass (usually)

Neoplastic

- Slowly enlarging mass
- Unilateral, discrete
- Firm or rubbery
- Fixed to tissue
- Deep within the fascia
- Nontender (usually)

Traumatic

- Rapidly enlarging mass
- Hematoma
- Acute airway obstruction

Congenital

- Enlargement in neck (usually present since birth or soon after)
- Soft, smooth, cyst-like
- Nontender (unless infected)
- Recurrent

Table 94.1. Rule of 7 for the Differential Diagnosis of Neck Masses

Mass Duration	*Likely Mass Etiology*
7 minutes	Trauma
7 days	Inflammation/infection
7 months	Neoplastic
7 years	Congenital

Adapted with permission from Skandalakis JE. Neck. In: Skandalakis LJ, Skandalakis JE, Skandalakis PN, eds. *Surgical Anatomy and Technique: A Pocket Manual*. 3rd ed. New York, NY: Springer; 2009:17–91.

of mass etiology. The "rule of 7" proposed by Skandalakis may be applied and adapted to pediatric neck masses (Table 94.1).

Pathophysiology

The pathophysiology of neck masses in children is dependent on etiology. Most neck masses are related to inflammation or infection of lymph nodes. Enlargement of lymph nodes usually results from proliferation of intrinsic lymphocytes or macrophages already present in the lymph node (eg, lymphadenopathy caused by a viral infection) or from infiltration of extrinsic cells (eg, lymphadenitis, metastatic tumor). Neck masses from trauma occur from leakage of fluid into the neck, and congenital anatomic abnormalities become apparent because of fluid collection or infection of the defect. The parotid gland may be enlarged from inflammation (eg, blocked salivary gland duct), infection (eg, mumps), or tumor (eg, pleomorphic adenoma), but the swelling primarily involves the face rather than the neck and obscures the angle of the jaw. Other salivary glands may be infected or obstructed and may cause submandibular swelling, erythema, and tenderness.

Differential Diagnosis

Neck masses in children are usually the result of inflammation or infection of lymph nodes, tumors of lymph nodes and other neck structures, trauma, and congenital lesions. The location of the mass is often a clue to its etiology (Figure 94.1).

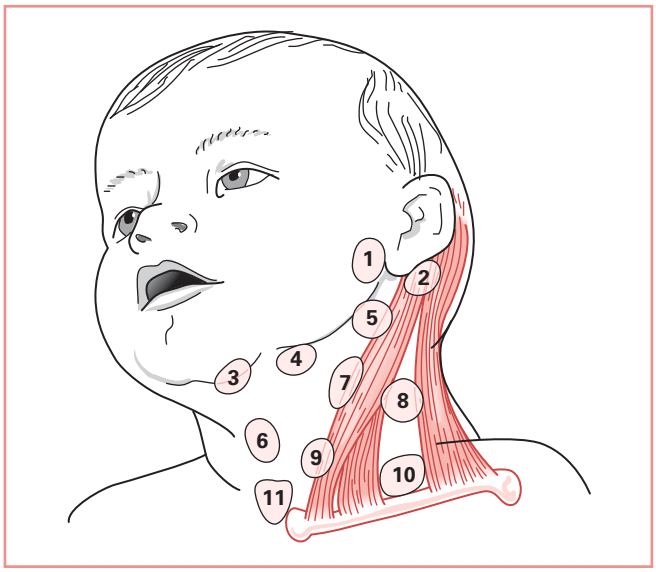

Figure 94.1. Differential diagnosis of neck mass by location. 1, Parotid—cystic hygroma, hemangioma, lymphadenitis, parotitis, Sjögren syndrome, infantile cortical hyperostosis (Caffey-Silverman syndrome), lymphoma. 2, Postauricular—lymphadenitis, branchial cleft cyst (first), squamous epithelial cyst. 3, Submental—lymphadenitis, cystic hygroma, thyroglossal duct cyst, dermoid, sialadenitis. 4, Submandibular—lymphadenitis, cystic hygroma, sialadenitis, tumor, cystic fibrosis. 5, Jugulodigastric—lymphadenitis, squamous epithelial cyst, branchial cleft cyst (first), parotid tumor, normal-transverse process C2, styloid process. 6, Midline neck—lymphadenitis, thyroglossal duct cyst, dermoid, laryngocele, normal hyoid, thyroid. 7, Sternomastoid (anterior)—lymphadenitis, branchial cleft cyst (second, third) pilomatricoma, rare tumors. 8, Spinal accessory—lymphadenitis, lymphoma, metastasis from nasopharynx. 9, Paratracheal—thyroid, parathyroid, esophageal diverticulum. 10, Supraclavicular—cystic hygroma, lipoma, lymphoma, metastasis, normal fat pad, pneumatocele of upper lobe. 11, Suprasternal—thyroid, lipoma, dermoid, thymus, mediastinal mass. Adapted with permission from May M. Neck masses in children: diagnosis and treatment. *Pediatr Ann.* 1976;5[8]:517–535, with permission from SLACK Inc.

Lymphadenopathy/Lymphadenitis

Lymphadenopathy is lymph node enlargement or hyperplasia secondary to localized infection or antigenic stimulation proximal to the involved node or nodes. Because lymphoid tissue steadily increases until puberty, palpable lymph nodes, including those in the cervical area, are a common, normal finding in children. Palpable cervical lymph nodes are present in up to 90% of children between 4 and 8 years of age. Any lymph node in the neck larger than 10 mm qualifies as cervical lymphadenopathy.

The most common cause of bilateral cervical lymphadenopathy is a viral infection of the upper respiratory tract. Lymphadenopathy usually begins and resolves with the acute infection. Occasionally, the swelling remains for several days or months, however, and a child presents because of parental or guardian concern. Bacterial pharyngitis, usually from infection with group A β-hemolytic streptococcus, is often associated with cervical lymphadenopathy. Cervical as well as generalized lymphadenopathy may occur in the child with systemic illness (eg, Kawasaki disease, sarcoid, HIV, mononucleosis). Cat-scratch disease, toxoplasmosis, fungal infection, and mycobacterial and atypical mycobacterial infections may be associated with lymphadenopathy that may later progress to lymphadenitis. Viral illnesses, including Epstein-Barr virus (ie, mononucleosis); adenovirus; enterovirus; human herpesvirus, 1, 2, and 6; and cytomegalovirus commonly cause lymphadenopathy and lymphadenitis.

Lymphadenitis is infection or inflammation of the lymph node that occurs when microorganisms and neutrophils infiltrate the node, resulting in necrosis and abscess formation. This condition usually is associated with proximal bacterial infection that drains to the affected nodes by connecting afferent lymphatic channels. Lymphadenitis often is a progression of disease, resulting in enlarged nodes that measure 2 to 6 cm. These nodes, which are typical of bacterial disease, are often termed "hot nodes," and they are erythematous, warm, tender, and sometimes fluctuant. Subacute or chronic inflammation of lymph nodes typical in illnesses such as cat-scratch disease, mycobacterial infection, or toxoplasmosis are not warm to the touch and are usually not as tender. They are typically not suppurative and may be difficult to distinguish from nodes that are simply enlarged (Figure 94.2).

Staphylococcus aureus and group A β-hemolytic streptococcus are responsible for 50% to 90% of cases of acute unilateral cervical lymphadenitis. These organisms spread from a primary site to the lymph nodes, draining those sites. Common primary sites of infection are the throat, teeth and gums, and skin (lesions), particularly on the scalp or ears. Infections at these sites may result from trauma, such as scratches or scabs, or from primary infection, such as impetigo. Anaerobic oral flora constitute a small portion of causes for bacterial cervical adenitis, especially in older children with poor dentition. *Staphylococcus aureus* or group B streptococcus usually causes cervical lymphadenitis in neonates or very young infants. Such staphylococcal infections, which often are nosocomially spread from contact in the newborn nursery, present as discrete masses. Group B streptococcus causes the "cellulitis-adenitis" syndrome, which presents as cervical adenitis associated with a facial cellulitis. *Pseudomonas aeruginosa* is an unusual cause of cervical adenitis in newborns.

Mycobacterial disease must always be considered in children of all ages who present with cervical adenitis particularly involving posterior cervical nodes. The child with *M tuberculosis* cervical adenitis often has multiple nodes, sometimes bilateral, usually nontender, and usually not erythematous or warm. These children are typically older, commonly reside in an urban setting, have a history of tuberculosis exposure, and often have an abnormal finding or findings on chest radiography. Intradermal placement of a purified protein derivative (PPD) often produces more than 15 mm of induration in most children with typical mycobacterial infection. A reaction of 5 to 14 mm may be caused by tuberculous or nontuberculous mycobacterial infection. Atypical mycobacterial infection usually occurs in children between 1 and 6 years of age with unilateral rather than bilateral lymph node enlargement and normal findings on chest radiography.

Cat-scratch disease should be considered in children who have cats or kittens or who play with them. The infection may result

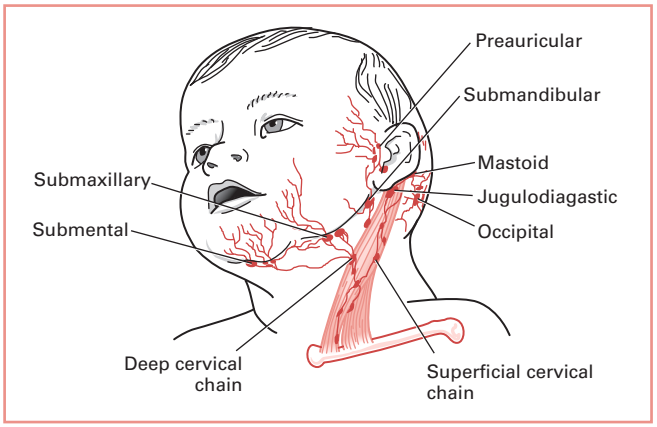

Figure 94.2. The lymphatic drainage and lymph nodes involved in infants and children with cervical lymphadenitis.
Adapted with permission from Feigin RD, Cherry JD, eds. *Textbook of Pediatric Infectious Diseases.* 5th ed. Philadelphia, PA: Saunders; 2004:186.

from a cat scratch or from a cat licking a child's broken skin. If the inoculum is near the head and neck area, cervical adenitis manifests. Contact with the hand may result in axillary lymphadenitis. Occasionally, generalized lymphadenopathy is present. An associated nonpainful papule or papules where the cat scratch or lick occurred may be apparent. *Bartonella henselae* has been identified as the organism causing cat-scratch disease.

Toxoplasmosis may be accompanied by adenitis, usually in the posterior cervical area. Nodes are painless and may fluctuate in size, and children often are asymptomatic. Multiple lymph nodes are involved in approximately one-third to one-half of cases.

The child who presents with recurrent cervical adenitis and recurrent fever may have PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis). This entity usually occurs in children younger than 5 years and can be aborted with steroids.

Kikuchi disease, or histiocytic necrotizing lymphadenitis, has an Asian and female predilection and is characterized by fever, leukopenia, and cervical lymphadenopathy. The illness is self-limited, and follow-up is recommended because of a possible association with systemic lupus erythematosus.

Less common bacterial, viral, and fungal causes of cervical adenitis are listed in Box 94.3.

Tumors

Compared with other neck masses, malignant neck tumors occur rarely; nevertheless, they should be considered in any child with an enlarging or persistent neck mass. Hodgkin disease and non-Hodgkin lymphoma are the most frequent cause of head and neck malignancies in children, accounting for almost 60% of cases. Rhabdomyosarcoma is the next most frequent head and neck malignancy, followed by thyroid tumor, neuroblastoma, and nasopharyngeal carcinoma. Age is an important factor in determining the likelihood of specific tumors. Neuroblastoma, leukemia, and rhabdomyosarcoma are the most common tumor types in children younger than 6 years. Non-Hodgkin lymphoma typically occurs in preadolescence, and Hodgkin disease and thyroid carcinoma are the most common malignancies in adolescents.

Benign neck tumors, with the exception of those mentioned later in the discussion of congenital lesions, are uncommon. They include epidermoid inclusion cysts, lipomas, fibromas, neurofibromas, pilomatricomas (ie, benign skin neoplasms of hair follicle origin), keloids, goiters, and ranulas (ie, intraoral mucocele) and plunging ranula (ie, an extension of the oral ranula into the neck).

Trauma

Trauma to the neck may be associated with bleeding and edema. Large hematomas that affect vital structures are potentially life-threatening. Significant trauma and structural injury usually accompany expanding neck hematomas. Neurologic deficits and stroke after neck trauma should alert the physician to consider cervical arterial dissection. In the child with mild injury and neck hematoma, bleeding disorders are a possible cause of the hematoma. Twisting injury to the neck may result in muscle spasm of the sternocleidomastoid muscle (ie, torticollis) and an apparent mass that is the contracted muscle. Additionally, intramuscular hematoma or bleeding from vaginal delivery may cause torticollis in the neonatal period. The neck is bent toward the side of the affected sternocleidomastoid muscle. Child abuse should also be considered in children who have neck injuries that are not consistent with their histories.

Atlantoaxial rotary subluxation may result in a torticollis-like syndrome in the patient with minimal to no trauma. Because of the relatively flat nature of the facets, rotation and subluxation of C1 on C2 can occur. The patient generally presents with unilateral neck pain and inability to turn the head. The head is tilted to 1 side with the chin rotated the opposite direction from the subluxation.

A foreign body in the neck may present as a mass because of the foreign body itself (eg, piece of glass or metal, bullet) or surrounding inflammation. A crepitant neck mass following trauma to the neck or chest is suggestive of subcutaneous emphysema from tracheal injury or a pneumomediastinum. Crepitant neck masses may also occur secondary to pneumomediastinum in the child with obstructive lung disease, such as asthma or cystic fibrosis.

Congenital Lesions

The child with a congenital neck lesion can present with a neck mass in early infancy or later in childhood. Some congenital lesions are not discovered until adulthood. The most common of these benign lesions are thyroglossal duct cysts, branchial cleft cysts, lymphatic malformations (ie, cystic hygromas/lymphangiomas), and hemangiomas (Figure 94.3).

Thyroglossal duct cysts are almost always midline in the neck and inferior to the hyoid bone. They usually move upward with tongue protrusion or swallowing. Most branchial cleft cysts occur anterior to the middle third of the sternocleidomastoid muscle. Less commonly, branchial cleft cysts may appear in the posterior triangle of the neck and the preauricular area. Branchial cleft sinus tracts appear as slit-like openings anterior to the

Bacterial Origin

- *Staphylococcus aureus* (methicillin sensitive)
- *Staphylococcus aureus* (methicillin resistant)
- Group A β-hemolytic streptococcus
- *Mycobacterium tuberculosis*
- Atypical mycobacteria
- Cat-scratch disease (*Bartonella henselae*)
- Anaerobes
- Gram-negative enteric bacteria
- *Haemophilus influenzae*
- Plague
- Actinomycosis
- Diphtheria
- Tularemia
- Brucellosis
- Syphilis
- Group B streptococcus (neonates)

Viral Origin

- Epstein-Barr virus (infectious mononucleosis)
- Adenovirus
- Cytomegalovirus
- Human herpesvirus types 1 and 2
- Enterovirus
- HIV
- Measles
- Rubella
- Human herpesvirus 6
- Influenza virus

Fungal Origin

- Histoplasmosis
- Coccidioidomycosis
- Aspergillosis
- Candidiasis
- Sporotrichosis
- Cryptococcosis

Parasitic Origin

- Toxoplasmosis
- Leishmaniasis

Tumor

Malignant

- Hodgkin disease
- Non-Hodgkin lymphoma
- Lymphosarcoma
- Rhabdomyosarcoma
- Neuroblastoma
- Leukemia
- Langerhans cell histiocytosis
- Thyroid tumors
- Nasopharyngeal squamous cell carcinoma
- Salivary gland carcinoma

Benign

- Epidermoid cyst
- Lipoma
- Fibroma
- Neurofibroma
- Pilomatricoma
- Keloid
- Goiter
- Osteochondroma
- Teratoma (may be malignant)
- Ranula

Congenital Disorders

Hemangioma

- Cystic hygroma (lymphangioma)
- Branchial cleft cyst
- Thyroglossal duct cyst
- Laryngocele
- Dermoid cyst
- Cervical rib
- Sternocleidomastoid tumor

Trauma

- Hematoma (acute or organized)
- Subcutaneous emphysema
- Foreign body
- Arteriovenous malformation

Immunologic Disorders

- Local hypersensitivity reaction (sting or bite)
- Pseudolymphoma (from phenytoin)
- Serum sickness
- Sarcoidosis
- Infantile cortical hyperostosis (Caffey-Silverman syndrome)
- Kawasaki disease
- Systemic lupus erythematosus
- Juvenile rheumatoid arthritis
- Kikuchi disease (necrotizing lymphadenitis)
- Kimura disease

Miscellaneous

- Sialadenitis
- Parotitis
- Storage disorders
- Niemann-Pick disease
- Gaucher disease
- Obstructive airway disease (asthma, cystic fibrosis)

lower third of the sternocleidomastoid muscle and may present as neck masses if they become infected. Thyroglossal duct cysts and branchial cleft cysts may also present for the first time as infected neck masses.

Cystic hygromas are usually large, soft, easily compressible masses found in the posterior triangle behind the sternocleidomastoid muscle in the supraclavicular fossa. They transilluminate well. Two-thirds of cystic hygromas are present at birth, and 80% to 90% are identified before 3 years of age. They are more common on the left side of the neck. Cystic hygromas occasionally become secondarily infected, with findings of erythema, warmth, and tenderness.

Hemangiomas are usually not present at birth but appear in early infancy and may enlarge rapidly. In most cases, they recede spontaneously by 9 years of age. They are usually much smaller than cystic hygromas, do not transilluminate, and may be recognized by their reddish color (eg, capillary or strawberry hemangioma) or by a bluish hue of the overlying skin (eg, cavernous hemangioma).

The small infant who presents with torticollis should be examined for a sternocleidomastoid mass ("tumor"), which represents fibrosis and contracture of that sternocleidomastoid muscle so that the head tilts toward the affected side with the chin rotating to the opposite side. Contusion of the sternocleidomastoid muscle from traumatic extraction of the head during delivery with subsequent hemorrhage and healing has been implicated as the cause of the fibrotic mass. It is more likely, however, that this mass occurs before birth, because it contains mature fibrous tissue. Additionally, the mass may be present following cesarean section and is associated with hip dysplasia and other congenital lesions, which suggests that the condition is related to abnormal positioning in utero. Venous occlusion of the sternocleidomastoid muscle in utero or at the time of delivery has also been proposed as a cause.

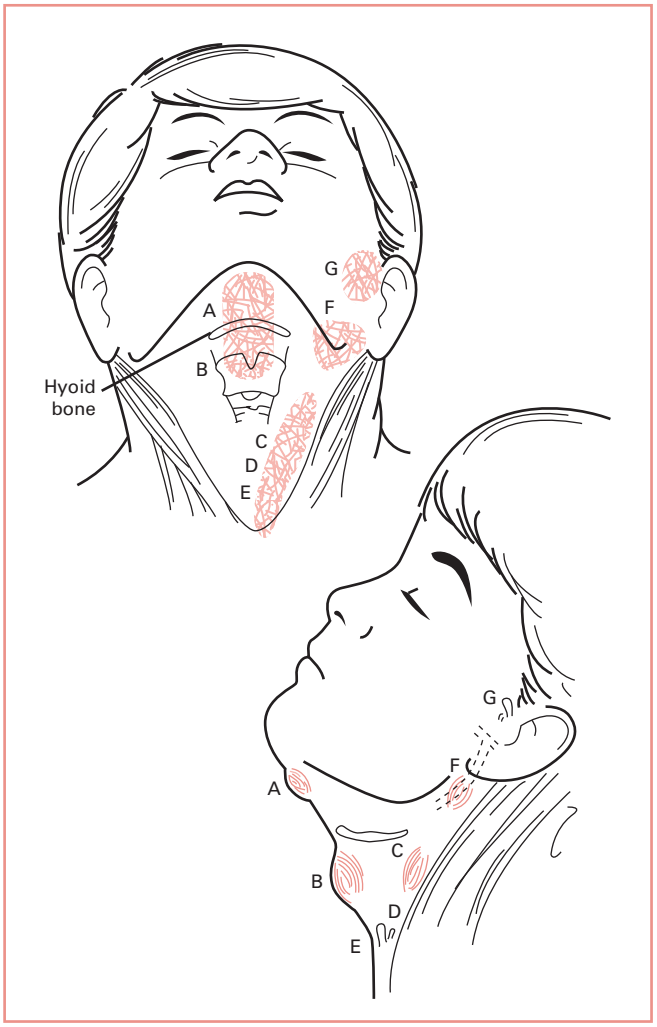

Figure 94.3. Frontal (upper left) and lateral (lower right) views of head and neck congenital lesions that occur in children. The shaded areas denote the distribution in which a given lesion may be found. A, Dermoid cyst. B, Thyroglossal duct cyst. C, Second branchial cleft appendage. D, Second branchial cleft sinus. E, Second branchial cleft cyst. F, First branchial pouch defect. G, Preauricular sinus or appendage.

Evaluation

History

A thorough history is important in establishing the etiology of the neck mass (Box 94.4).

Physical Examination

A general physical examination should be performed. The neck mass should be examined for anatomic location, color, size, shape, consistency, tenderness, fluctuation, and mobility. The mass should also be measured. A mass that has an audible bruit or palpable thrill is suggestive of a vascular malformation or traumatic injury. The airway should be assessed for patency, including presence of stridor, trismus, drooling, or other signs of airway compromise. The head, neck, and face should be examined for lesions, most often infections that drain into neck lymph nodes. Lesions can frequently be found on the scalp, neck, face, ears, mouth, teeth, tongue, gums, and throat. Hairstyles, such as tight braids, can sometimes provide ports of entry for bacteria. Occasionally, sinus tracts or fistulas may be the entry point of infection. Additionally, other lymph node groups should be examined to determine if the lymphadenopathy is local or generalized. Particular attention should be paid to the supraclavicular area because enlarged supraclavicular nodes are more frequently associated with malignant pathology, such as Hodgkin disease. The chest should be examined for use of accessory muscles, equality of breath sounds, and wheezing. The abdomen should be examined for hepatosplenomegaly.

Laboratory Tests

Laboratory tests are rarely indicated in the child with cervical lymphadenopathy or lymphadenitis of acute onset. Although a rapid antigen detection test or throat culture for group A streptococci is helpful in the child with suspected streptococcal sore throat, it may be unnecessary if antibiotic therapy is empirically prescribed for lymphadenitis. If the adenitis is fluctuant, aspiration and culture may be helpful in determining the specific bacteriologic diagnosis.

Box 94.4. What to Ask

Neck Masses

- How old is the child?
- How long has the neck mass been present?
- What signs and symptoms are associated with the neck mass?
- Has the child been exposed to tuberculosis?
- Has the child consumed any unpasteurized cow's milk?
- Has the child been in contact with any cats or kittens? Rabbits? Other animals?
- Has the child traveled to areas where endemic diseases, such as histoplasmosis or coccidioidomycosis, are prevalent?
- Has the child suffered any trauma recently?
- Does the child have any allergies?
- Does the child have any risk factors for HIV?

Fine-needle aspiration cytology and polymerase chain reaction assays may help differentiate between tuberculous and nontuberculous mycobacterial disease. Superficial cervical nodes or axillary nodes, if enlarged, are appropriate first-line aspiration sites because of their superficial nature. A PPD test should be applied to all children who present with lymphadenitis.

If the adenitis does not resolve or improve after 2 to 3 days of observation or therapy, laboratory tests directed by the history and physical examination should be considered. A complete blood cell count with differential and a monospot test or serologic antibody tests for Epstein-Barr virus may be helpful in the diagnosis of infectious mononucleosis. If the neck mass is a hematoma and a bleeding disorder is suspected, a complete blood count with platelet count, prothrombin time, and partial thromboplastin time should be obtained. Possible additional tests include an erythrocyte sedimentation rate and C-reactive protein. If indicated, serologic tests for toxoplasmosis, cytomegalovirus, human herpesvirus 6, coccidioidomycosis, histoplasmosis, tularemia, *B henselae,* and syphilis should be performed. Skin tests for fungi should be considered in those patients coming from endemic areas. These tests should be placed after serologic tests are performed to avoid false-positive results on serologic testing.

Similar laboratory tests should be considered for the child who presents for the first time with enlarged or enlarging lymph nodes of long duration or who does not respond after 2 weeks of antibiotic therapy. The physician may choose to do more of these laboratory tests at the initial evaluation or after a therapeutic trial because the likelihood of viral lymphadenopathy decreases and the possibility of a more unusual etiology increases. HIV testing should also be considered.

Thyroid function testing should be considered in the child with a thyroid mass or suspected thyroglossal duct cyst. Ultrasonography or thyroid scan should be considered for the child with a thyroid mass.

Unless cat-scratch disease is very likely, urgent lymph node biopsy is indicated for enlarged supraclavicular nodes or lymph nodes in the lower half of the neck, rapidly progressive and enlarging nodes, fixed nodes, nodes deep within the fascia, or firm or hard nodes. The child with a persistent fever or weight loss should undergo a biopsy at 1 week if a diagnosis has not been established. The asymptomatic child without an established diagnosis should undergo a biopsy at 2 weeks if the node increases in size, at 4 to 6 weeks if the node is not increased in size but is persistent, and at 8 to 12 weeks if the node has not regressed to a normal size. In some cases, the initial biopsy is nondiagnostic, but on subsequent biopsy, a specific diagnosis may be made. Consequently, the child with persistent adenopathy should be followed closely and undergo biopsy again if indicated. Fine-needle aspiration biopsy in children is controversial but has some demonstrated benefits. It is increasingly being used to differentiate between benign and malignant disease and to potentially decrease the need for open biopsy. If malignancy is a consideration, however, consultation with an oncologist is advisable to determine the biopsy method of choice.

Imaging Studies

A chest radiograph should be obtained in all children with suspected tuberculosis or tumor (eg, enlarged supraclavicular nodes) as well as in children with crepitant neck masses or in whom the diagnosis of the adenitis remains uncertain. If a foreign body in the neck is suspected, anteroposterior and lateral neck radiographs should be obtained.

Almost all neck masses can be evaluated by ultrasonography, computed tomography (CT), or magnetic resonance (MR) imaging. Because there is no ionizing radiation associated with ultrasonography and because it is quickly available, is noninvasive, and does not need sedation, it is the initial imaging study of choice, particularly for thyroid masses, thyroglossal duct cysts, branchial cleft cysts, and parotid masses. Ultrasonography is a reasonable screening tool for all superficial neck masses. If malignancy is suspected or the mass cannot be delineated in the field of view, MR imaging or CT may be more definitive studies. Color Doppler ultrasonography is helpful in differentiating cystic from solid masses and determining if the mass is vascular. Additionally, demonstration of a normal thyroid gland by ultrasonography in the patient with a thyroglossal duct cyst confirms a source of thyroid hormone. Consequently, a thyroid scan is not necessary.

Computed tomography and MR imaging provide better definition and extent of the mass than ultrasonography. Computed tomography with contrast is the preferred method of imaging for deep neck abscesses that present with a neck mass and for enlarged salivary glands. Computed tomography or MR imaging is superior to plain radiography for diagnosing rotary subluxation. Magnetic resonance imaging provides the best anatomic detail, and it is the preferred imaging study for children with vascular and lymphatic malformations and neoplasms; however, it is not as available as CT and often requires a greater degree of sedation.

Management

Neck masses are rarely acutely life-threatening. If a neck mass impinges on the airway, the affected child may experience stridor, hoarseness, drooling, increased effort of breathing, unequal breath sounds, or evidence of shock. Resuscitation and stabilization should be initiated immediately. There should be a low threshold to establish a secure airway in a child with an expanding traumatic neck mass. The algorithm in Figure 94.4 outlines the management of cervical lymphadenitis.

The child with lymphadenitis who does not appear toxic and has no evidence of sepsis may be treated empirically with oral antibiotics that cover *S aureus,* particularly methicillin-resistant *S aureus* (MRSA), and group A β-hemolytic streptococcus. Clindamycin or a combination of cephalexin (administered until the culture from the lymph node, if available, for group A streptococcus is negative) and trimethoprim-sulfamethoxazole may be used to provide coverage for these organisms. If methicillin-susceptible *S aureus* is cultured and sensitivities are determined, a first-generation cephalosporin, such as cephalexin (50 mg/kg per day), dicloxacillin (50 mg/kg per day), or amoxicillin-clavulanate potassium (40 mg/kg per day based on the amoxicillin component)

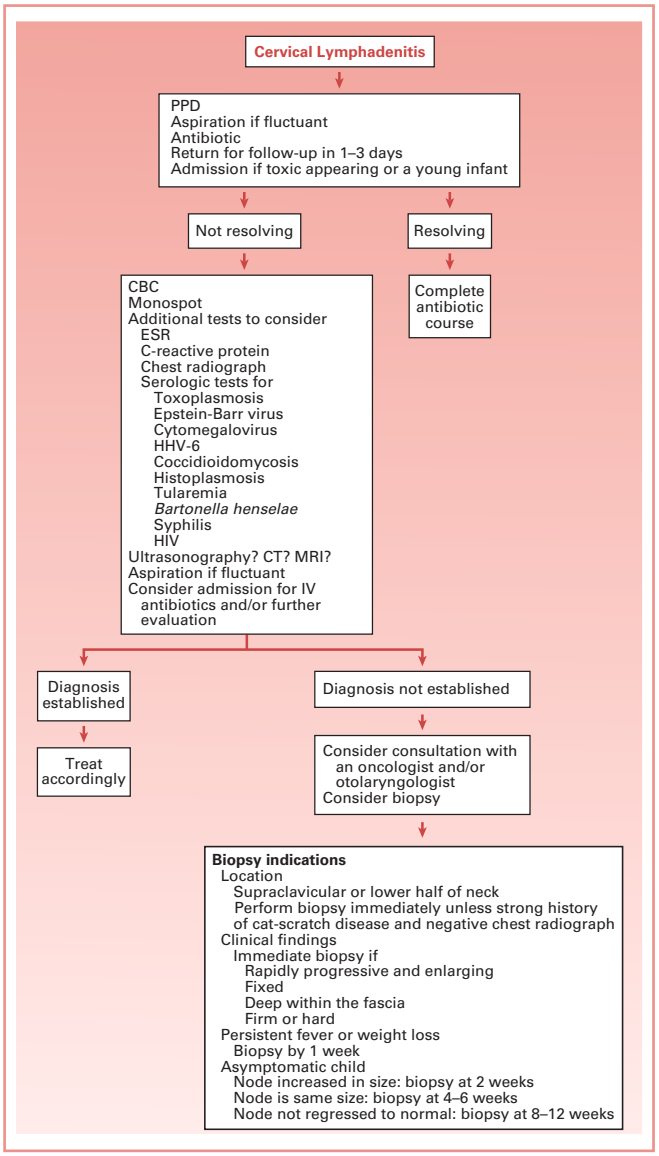

Figure 94.4. Management of cervical lymphadenitis.

may provide satisfactory coverage. Treatment should be continued for at least 10 days but for no less than 5 days after resolution of acute signs and symptoms. Lack of clinical improvement after 36 to 48 hours suggests that the diagnosis and proposed therapy need to be reevaluated.

Infants and younger children, as well as those older children who do not respond to oral antibiotic therapy, may require admission for intravenous antibiotics, such as clindamycin or vancomycin (especially for a potentially life-threatening infection) until culture and sensitivity results are available. If methicillin-susceptible *S aureus* is cultured and sensitivities are determined, oxacillin or a cephalosporin may be satisfactory alternatives. Incision and drainage of large, fluctuant nodes that are clearly from bacterial disease should be done in consultation with an otolaryngologist or surgeon to promote resolution of the lymphadenitis. Alternatively, treatment by needle aspiration instead of incision and drainage has been advocated by some physicians. If *M tuberculosis,* atypical mycobacterial infection, or infection with *B henselae* is suspected, incision and drainage should not be done because persistent sinus tracts may result.

Atypical mycobacterial infection is generally unresponsive to treatment with antituberculous medications. Surgical excision of all visibly affected nodes, deep as well as superficial, is recommended. In cases in which surgery is refused or is incomplete or disease is recurrent, however, macrolide or azalide monotherapy (clarithromycin or azithromycin) or a macrolide in combination with ethambutol hydrochloride, rifampin, or rifabutin has been helpful in managing nontuberculous adenitis. Tuberculous mycobacterial adenitis usually responds to short-course medical therapy. Antituberculous medication for 6 to 9 months is recommended.

Lymphadenitis from cat-scratch disease usually resolves spontaneously in 2 to 4 months. Azithromycin may shorten the course and is recommended by some experts. Antibiotic therapy is indicated if a child is severely ill or appears toxic with systemic cat-scratch disease, has hepatic or splenic involvement, is immunocompromised, develops meningoencephalitis, or is admitted for a suppurative adenitis. Treatment with oral antibiotics, such as azithromycin, rifampin, trimethoprim-sulfamethoxazole, or ciprofloxacin, may be beneficial. If no improvement occurs, the addition of parenteral gentamicin to the regimen may be considered. Aspiration is indicated to relieve symptoms in the patient with fluctuant or painful suppurative nodes. Incision and drainage should not be done. Total removal of the node is sometimes necessary to effect a cure.

No specific therapy exists for lymphadenitis caused by *Toxoplasma gondii*. Excision of the affected node may be indicated if the diagnosis is questionable.

If a tumor is suspected, consultation with a pediatric oncologist is recommended. The mass should be biopsied for a definitive diagnosis. If it is malignant, a treatment plan should be generated with the appropriate consultants.

Congenital torticollis from fibrosis of the sternocleidomastoid muscle is best managed nonsurgically. Repetitive passive range-of-motion exercises over several weeks usually result in loosening the tight muscle and increasing the range of motion. Rotary subluxation is generally treated conservatively with immobilization because most cases resolve. More severe cases are treated in traction by a neurosurgeon.

Fifty percent of hemangiomas will usually resolve by the time children are 5 years of age, 70% by age 7, and 90% by age 9. Propranolol may expedite evolution of hemangioma. Surgical intervention is rarely indicated. Recent literature has demonstrated a profound benefit with oral propranolol therapy in the management of hemangioma. Oral propranolol therapy demonstrates a considerable flattening and effacement of cutaneous and mucous membrane hemangiomas within 24 hours and marked improvement after weeks of propranolol therapy. Multiple studies suggest

excellent efficacy with oral propranolol for the management of life-threatening, vital-organ–impairing (eg, vision loss), refractory, or disfiguring hemangioma. Dosing is titrated up to 3 mg/kg per day and continued for up to 6 months until resolution of the hemangioma. The patient should be closely monitored for hypoglycemia, bradycardia, hypotension, and congestive heart failure during institution of therapy. Propranolol initiation is increasingly performed in the outpatient setting, and evidence exists indicating that initiation can be safely performed in the healthy child. Atenolol appears to work just as well as propranolol, but most studies are performed with propranolol. Corticosteroids, previously the mainline treatment modality for hemangiomas, are now considered an adjunctive treatment with propranolol. Additional therapies include interferon-α-2a and various cytotoxic medications. Interferon-α-2a has been associated with transient or permanent neurologic disabilities, so it is important to balance the benefits and risks of this medication. High-potency topical corticosteroids (eg, clobetasol propionate) or topical beta blockers (eg, timolol) may be used in selected cases.

Surgical excision is usually indicated for cystic hygroma (ie, lymphangioma), branchial cleft cyst, and thyroglossal duct cyst. Thyroid ultrasonography should be performed before removal of a thyroglossal duct cyst to determine the presence of ectopic thyroid tissue. Endocrinologic consultation is recommended in these cases. Thyroid nodules in children may be cancerous, especially in children who have undergone irradiation to the head and neck region. Consultation with an endocrinologist and surgeon should be obtained. Goiters in children should be evaluated by an endocrinologist.

Prognosis

The prognosis for children with neck masses is generally excellent but differs depending on the cause. Children with an infectious etiology do quite well if diagnosed and treated with appropriate antimicrobial agents. Mycobacterial lymphadenitis may result in sinus tract formation or disseminated disease. Surgical excision usually cures atypical mycobacterial infection. Cat-scratch disease is usually benign and self-limited. Encephalopathy is a rare complication of this disorder.

The prognosis for benign tumors of the neck is excellent. The outlook for the child with a malignant neck tumor depends on etiology of the tumor and spread of the malignancy to other organs. Early diagnosis and treatment are important in improving outcome.

The child with a neck mass resulting from trauma usually has sustained significant injury. The outcome often depends on establishment of an airway, provision of ventilatory support, and management of hemodynamic instability. Availability of surgical support is often essential to a good outcome.

The child with a congenital lesion of the neck usually has an excellent prognosis. Some lesions resolve spontaneously, whereas others require simple surgical excision. Cystic hygromas may require multiple operations for complete removal because of their diffuse nature.

CASE RESOLUTION

The boy has signs and symptoms consistent with submandibular bacterial cervical lymphadenitis. The location of the neck mass in relation to the honey-crusted lesions (nonbullous impetigo) implicates spread of bacteria from the primary site of infection to the lymph nodes. Laboratory tests are unnecessary because the child does not appear septic. Culture of the impetigo may be helpful in determining if the organism causing the infection is MRSA. If the affected lymph node is fluctuant, aspiration of fluid for culture is indicated and incision and drainage should be considered. The child should be treated as an outpatient with an oral antibiotic directed against MRSA and group A β-hemolytic streptococcus, such as clindamycin or a combination of cephalexin and trimethoprim-sulfamethoxazole, as well as an analgesic for pain as necessary. If methicillin-susceptible *S aureus* is cultured and sensitivities are determined, cephalexin, amoxicillin-clavulanic acid, or dicloxacillin may be administered. If the child appears toxic or if marked lymph node enlargement is present, the child should be admitted for intravenous antibiotics. A PPD skin test should be placed for tuberculosis. The child should be followed up in 1 to 3 days for clinical improvement depending on the severity of the infection.

CHAPTER 95

Allergic Disease

Nasser Redjal, MD, and Niloufar Tehrani, MD

CASE STUDY

A 3-year-old girl is rushed to an urgent care center by her mother after the girl developed a pruritic rash, facial swelling, and hoarseness shortly after eating a peanut butter sandwich. She had eaten peanut butter once before, and her parents noticed a few small hives on her cheek that self-resolved. Previously, the girl has been well except for recurrent nasal congestion every spring that has responded to antihistamines. She has also had an intermittent skin rash that has been managed with topical steroid creams. She has never before had an acute reaction and has no history of asthma. Her father had asthma as a child.

Physical examination reveals a well-developed, 3-year-old girl with marked facial swelling and a generalized rash who is in mild respiratory distress. Vital signs, including blood pressure, are normal. The girl has a diffuse, blotchy, erythematous rash with central wheals; a hoarse voice; and a mild expiratory wheeze on auscultation of her chest. The remainder of the examination is normal.

Questions

1. What are the various symptoms of allergic disease?
2. What is the appropriate evaluation of a child with manifestations of allergic disease?
3. What allergens are common triggers for allergic symptoms?
4. What treatment is helpful for the child with manifestations of allergic disease?
5. Can allergic disease be prevented?

Allergic disease occurs frequently in the general population and manifests in many ways. Types of allergic disease include asthma, atopic dermatitis, allergic rhinitis, allergic conjunctivitis, urticaria, angioedema, anaphylaxis, and food, insect, and drug allergies. Allergic symptoms result from the production of specific immunoglobulin (Ig) E antibody after exposure to a foreign antigen. The process has 2 steps. The first step is the sensitization or antibody induction stage. The individual develops IgE antibody against an inhaled, ingested, or injected substance. The process usually takes from several days to weeks for medications and foods to months to years for inhalant allergens, such as pollens. Newly formed antigen-specific IgE antibody adheres to IgE receptors on circulating blood basophils or to tissue mast cells. On reexposure, the allergen binds to several specific IgE antibodies on the surface of these cells and triggers degranulation of preformed and rapidly formed mediators, such as histamine and leukotrienes, resulting in the early phase of the reaction. Clinically, this is manifested by sneezing, rhinorrhea, and pruritus in allergic rhinitis; wheal and/or flare in urticaria or angioedema; and shock in anaphylaxis. Mast cell degranulation also releases peptides that attract inflammatory peptides, such as interleukin-4 and interleukin-5, which release mediators that result in chronic inflammation. This late phase of inflammation is responsible for congestion and hyperreactive mucosa in allergic rhinitis and delayed reactions in anaphylaxis. The remaining manifestations of allergies, including allergic rhinitis, conjunctivitis, food allergies, and anaphylaxis are the focus of this chapter.

Epidemiology

Allergic disease or some form of allergic symptoms occur in 12% to 20% of the general population in the United States. The prevalence of symptoms varies depending on the population being investigated. Factors such as age, genetic background, and place of residence are significant. Allergic rhinitis occurs in 10% of children, as does asthma. Up to 6% of children younger than 3 years develop food allergies. Urticaria occurs at some time in approximately 10% to 20% of the population.

It is generally accepted that if neither parent is atopic (ie, has the allergic tendency to manufacture IgE on antigen exposure), the chance that a child of theirs will develop allergic symptoms is less than 1 in 5. If 1 parent is atopic, however, the risk doubles. If both parents are atopic, the chance of their child developing allergic symptoms is better than 3 in 5.

Clinical Presentation

Children with allergic disease frequently present with persistent, clear rhinorrhea; sneezing; postnasal drip; or injected pruritic conjunctivitis. Skin manifestations include dry, scaling, erythematous rashes; wheals; and subcutaneous swelling (Box 95.1). A recurrent cough or wheezing on chest examination is further evidence of allergic disease.

Pathophysiology

Allergic rhinitis, like all allergic manifestations, is caused primarily by an antigen-antibody reaction involving IgE. Antigen-specific

Box 95.1. Diagnosis of Allergic Disease in the Pediatric Patient

- Chronic, clear rhinorrhea
- Nasal congestion
- Conjunctival tearing and pruritus
- Conjunctival injection
- Wheezing
- Chronic cough
- Postnasal drip
- Mouth breathing
- Snoring
- Skin findings of atopic dermatitis or urticaria
- Seasonal variability of symptoms
- Occurrence of symptoms after exposure to an antigen
- Family history of allergic disease
- Acute onset of symptoms following exposure to possible allergen

IgE is produced by the B lymphocytes of allergic patients on exposure to a particular antigen, which attaches to immune cell receptors located on basophils in the circulation and mast cells in the tissue. On reexposure, the antigen reacts with this specific IgE on the mast cells, releasing vasoactive mediators, including histamine, leukotrienes, kinins, and prostaglandins. These mediators produce vasodilation and edema, and they also stimulate neural reflexes to produce mucous hypersecretion and sneezing. Eosinophils, basophils, and other inflammatory cells induced by chemotactic factors enter the affected organ, releasing mediators and thereby worsening the inflammation and damaging tissues. Secretions and released tissue proteins exacerbate existing edema. Other immunologic mechanisms can also be involved.

Children with allergic rhinitis often present with rhinorrhea, sneezing, nasal pruritus, and congestion. Allergic eye symptoms (ie, allergic rhinitis, conjunctivitis) may accompany nasal rhinitis with ocular pruritus, injection of the conjunctiva, and clear tearing. Younger children may present with repeated sniffing, snorting, coughing, or scratching an itchy palate with their tongue (ie, palatal clicking) because they usually cannot blow their nose.

Urticaria, the clinical rash produced by capillary leak vasodilation and edema of the skin, occurs when histamine and other vasoactive peptides, such as prostaglandins and leukotrienes, are released from the epidermal mast cells. Basophils have been identified in biopsies of these lesions. Mast cell degranulation occurs commonly in sensitized patients on reexposure to antigens found in food, medications, supplements, and insect venom when antigen-specific IgE found on mast cells is triggered by these allergens. The mast cell, however, can also be activated and release mediators by a wide number of stimuli independent of IgE mechanisms, including viral, bacterial, parasitic, and fungal infections; collagen vascular disease; malignancy; and endocrine disease. Some patients also experience urticaria to physical factors, such as heat, cold, pressure, sun, and vibration.

An urticarial rash appears as erythematous lesions of various sizes with pale, papular centers that typically are not painful unless traumatized by scratching. Lesions may coalesce, the rash blanches on pressure, and the skin is intact. Usually, individual lesions last less than 24 hours at a single location, although they often recur in the same area.

Angioedema is the extension of the urticarial process deeper into the dermis of the skin, producing swelling. The mucous membranes may be affected. Pathophysiology is similar to that of urticaria. A hereditary type of angioedema, which is not allergy related, is caused by an inherited deficiency of the C1 esterase inhibitor, resulting in unopposed production of the potent vasoactive amine bradykinin. Unlike urticaria, no distinct rash exists and the skin is not pruritic. Capillary leak and edema of the dermis results in tissue swelling, a sense of tightness, and sometimes pain. Involvement of the abdominal viscera may result in colicky abdominal pain.

Chronic urticaria and angioedema is that which persists beyond 6 weeks. More than 90% of chronic urticaria and angioedema in an otherwise healthy patient is idiopathic and is termed *chronic idiopathic urticaria*. Up to one-half of patients with chronic idiopathic urticaria have the circulating mast cell anti-IgE receptor antibody IgG, which repeatedly causes degranulation of cutaneous mast cells in these patients.

Anaphylaxis is an acute, systemic allergic reaction resulting from antigen-specific IgE on mast cells and basophils. Pathophysiology is similar to that of allergic rhinitis, but the reaction occurs in mast cells in many locations simultaneously, and prior sensitization to an allergen is essential. Anaphylactic reactions may be life-threatening. Massive vasoactive mediator release results in large reductions in peripheral resistance caused by capillary leak and vasodilation. This eventually overwhelms compensatory increases in cardiac output (blood pressure = cardiac output × total peripheral resistance), resulting in hypotension and shock. Pooling of blood in the periphery also reduces venous return, resulting in diminished preload and cardiac output. Reactions can occur in seconds or as late as 1 hour after exposure. Up to 20% of adults and 15% of children may experience a late or biphasic phase (ie, a recurrence of symptoms after resolution of anaphylaxis without trigger reexposure) hours after the first reaction because of late recruitment and activation of basophils and other inflammatory cells. Children with anaphylaxis have a reduced risk for late phase reaction, likely of approximately 3% to 5%. Common causes of anaphylaxis include food, medications and biologic agents, and stinging insect venom. The drug most frequently implicated in anaphylaxis is penicillin. Patients initially experience tightness and intense itching of the skin. Nausea, vomiting, and abdominal pain may ensue, followed by the full spectrum of anaphylaxis. Certain agents, such as radiocontrast media and blood products, may cause massive mast cell degranulation via an IgE-independent mechanism, resulting in clinical symptoms that are indistinguishable from anaphylaxis; these reactions, termed *anaphylactoid reactions*, are generally less severe than anaphylaxis.

Confusion exists among less experienced clinicians as to what combination of symptoms constitutes anaphylaxis, which may result

in either overdiagnosis or underdiagnosis. Generally, anaphylaxis is highly likely in the setting of cutaneous findings plus respiratory or hemodynamic compromise; involvement of 2 or more of the following systems: skin, respiratory, and gastrointestinal (GI) organ; and hemodynamic compromise (Box 95.2).

A *food allergy* may produce IgE-mediated reactions and diseases, including acute urticaria or angioedema, anaphylaxis, acute rhinitis, and atopic dermatitis. The localization of IgE-sensitized mast cells to that specific antigen determines the symptoms produced by an allergy. The antigen enters through the GI mucosal barrier. Intact food proteins may enter the circulation, stimulating the production of antigen-specific IgE. Additionally, food allergens may result in some non–IgE-mediated diseases, including eosinophilic esophagitis, food protein-induced enterocolitis syndrome (FPIES), allergic proctocolitis, and Heiner syndrome, a rare reaction to cow's milk protein. Finally, many patients have a nonimmune-mediated reaction to foods termed *food intolerance* (eg, lactose intolerance).

In young children, the most common food allergens are milk, egg, soy, wheat, peanuts, and tree nuts, whereas adults and older children are allergic to peanuts, shellfish, and fish. Adults and older children with atopic predisposition and allergic rhinitis or asthma often become sensitized to tree and weed pollens via the respiratory tract. They exhibit cross-reactivity between common elements of these inhalant tree or weed pollen peptides and similar peptides found in fruits and vegetables, resulting in local (ie, oral) IgE symptoms of tingling and mild swelling when ingesting these foods. These mild reactions are called *pollen-food allergy syndrome*.

Patients with IgE-mediated food allergy may experience urticaria or angioedema, eczematoid dermatitis, vomiting, wheezing, and, in severe cases, anaphylaxis. Eosinophilic esophagitis presents with nonspecific symptoms, including vomiting, reflux, dyspepsia, poor appetite, and failure to thrive. Infants with FPIES present with severe vomiting and bloody stool, generalized edema, and, in some cases, shock on initial ingestion of cow's milk, although soy and other foods have, in rare cases, been implicated. Allergic proctocolitis presents in infants on first exposure to cow's milk protein, including via human milk, but symptoms are mild and involve only blood-streaked stool. *Heiner syndrome* is a rare IgG-mediated reaction to cow's milk protein that results in anemia, wheezing, hemoptysis, melena, and pulmonary infiltrates. Older patients with pollen-food allergy syndrome to fruits and vegetables experience lip, oral mucosa, and tongue tingling as well as minimal swelling. These reactions are local and mild and rarely progress to anaphylaxis.

Box 95.2. Practical Definition of Anaphylaxis

One of the following criteria is fulfilled:

1. Acute onset of mucosa or cutaneous findings, such as hives, pruritus, lip swelling, AND 1 of the following:
   - Respiratory compromise
   - Cardiovascular compromise (eg, hypotension) or end-organ dysfunction (eg, syncope)
2. TWO of the following after likely exposure to allergen:
   - Respiratory compromise
   - Mucocutaneous symptoms
   - Hypotension
   - Persistent gastrointestinal symptoms
3. Reduced blood pressure appropriate for age

Second symposium on the definition and management of anaphylaxis: summary report—second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network symposium. *Ann Emerg Med.* 2006;47(4):373–380, with permission.

Differential Diagnosis

Most patients with allergic rhinitis have clearly identifiable signs and symptoms consistent with a history of exposure; other etiologies should be considered, however, especially with poor response to treatment. Children experience many upper viral respiratory infections each year that can mimic allergic rhinitis. Many types of nonallergic rhinitis exist and the mechanisms responsible are unclear, although cholinergic pathways are likely involved. Vasomotor and cholinergic rhinitis often result in copious amounts of clear rhinorrhea in response to cholinergic stimuli, such as cold air (ie, skier nose) or spicy foods (ie, gustatory rhinitis). Medications such as angiotensin-converting enzyme inhibitors and nonsteroidal anti-inflammatory drugs may cause rhinitis, but this usually occurs in adults and older children. Similarly, hormone surges, such as during ovulation, may result in nasal symptoms. Overuse of topical decongestants containing α-agonists results in rebound rhinitis (ie, rhinitis medicamentosa). In children, foreign bodies produce unilateral nasal obstruction and often malodorous purulent discharge. Patients with a history of basilar skull fracture with cerebrospinal fluid leak may present with clear rhinorrhea.

Urticaria and angioedema have a distinct clinical presentation that is usually easy to distinguish from other skin conditions. As mentioned previously, numerous possible etiologies of urticaria and angioedema exist, and determining the cause of a given instance is challenging. Urticaria and angioedema may last for weeks; however, individual lesions should persist for less than 24 hours, although they can recur at 1 area. *Urticarial vasculitis* is a distinct form of urticaria that results from the persistence of antigens arising from collagen vascular disease, serum sickness, and neoplasia. The rash from urticarial vasculitis lasts for more than 24 hours, has a burning sensation, causes less pruritus than other forms of urticaria, and leaves an area of hyperpigmentation on resolution. Other rashes that mimic urticaria include insect bites, erythema multiforme, mastocytosis, and contact dermatitis. Anaphylaxis is usually associated with cutaneous, respiratory, cardiovascular, and systemic symptoms, such as skin rash, edema, wheezing, arrhythmia, occasionally fever, and shock. A history of an acute exposure to a potential allergen is more likely to be seen with anaphylaxis than with urticaria.

Signs and symptoms of food allergies vary. It is important to determine whether actual immune-mediated disease exists or if the patient has food intolerance. Food may contain toxic peptides, such as in *scombroid fish poisoning*, in which bacteria in unrefrigerated

fish convert amino acids into histamine, which results in allergy-like symptoms when ingested. Patients with enzyme deficiencies, such as lactose intolerance, experience GI symptoms when eating dairy products. Alternatively, food may have pharmacologic properties, such as those found in caffeinated drinks.

Non–IgE-mediated food allergies may produce signs and symptoms similar to other disorders that can be life-threatening, such as FPIES, which often is indistinguishable from sepsis; Heiner syndrome, which shares similarities with serious diseases (eg, pulmonary hemosiderosis); and Wegener granulomatosis. These conditions must be ruled out during the evaluation of these forms of food allergies.

Most patients with symptoms associated with foods do not have an immune-mediated reaction but have food intolerances. Some manifestations have well-defined mechanisms, such as in lactase deficiency or galactosemia, whereas others, such as gustatory rhinitis, are less clear.

Evaluation

History and Physical Examination

Allergic Rhinitis and Conjunctivitis

The child with possible allergic rhinitis has a history of sneezing, itching, nasal discharge, and nasal blockage. The eyes, ears, palate, and throat may itch. The child may also have a history of mouth breathing and snoring at night, sleep disturbances, and daytime fatigue from nasal obstruction. Other signs include sinusitis, postnasal drip, halitosis, cough, and morning sore throat. Symptoms may be seasonal or associated with a specific stimulus. Additionally, systemic symptoms of fatigue, headache, anorexia, and irritability may be present.

The history should also include a search for other manifestations of allergies (eg, wheezing, atopic dermatitis). Approximately 40% of children who present with allergic symptoms also have asthma, 50% have atopic dermatitis, and about 30% have allergic rhinitis. It is also important to obtain an environmental history of allergen exposure, including pets and tobacco smoke, as well as a family history of atopy.

The physical examination should be thorough. The skin should be inspected for atopic dermatitis and the lungs for evidence of asthma. The nasal mucosa should be examined with an otoscope. In the child with allergic rhinitis, the nasal mucosa is swollen, pale, and sometimes cyanotic with copious clear discharge. Nasal polyps, if present, should be noted. Although polyps are most often present on an allergic basis, they may occur with cystic fibrosis. A transverse crease across the nose (ie, allergic crease) can occur from repeatedly using the palm of the hand in an upward thrust on the nares to relieve itching and open the nasal airway (ie, allergic salute). Dark circles under the eyes (ie, allergic shiners) may be present from chronic periorbital edema and venous stasis. Morgan fold (ie, Dennie-Morgan fold), a wrinkle just beneath the lower eyelids, is present from early infancy and is associated with atopic dermatitis and allergic rhinitis. Adenoid facies (ie, allergic gape) is secondary to chronic mouth breathing during the first several years of age and results in a characteristic pattern of maldevelopment of facial bones, causing a high-arched palate, flat maxilla, and angulated mandible with a recessed chin and dental malocclusion (Figure 95.1). If affected, the conjunctivae are erythematous with a clear discharge and may have a follicular appearance. The mouth may reveal a high-arched palate from chronic mouth breathing, and hypertrophic lymphoid follicles in the oropharynx often are seen.

Classification of allergic rhinitis, although not as stringent as that of asthma, is important because it guides the choice of optimal therapy. According to the World Health Organization Allergic Rhinitis and its Impact on Asthma guidelines, allergic rhinitis is considered to be intermittent if symptoms occur fewer than 4 days a week or fewer than 4 weeks in duration, whereas persistent rhinitis is defined as symptoms occurring 4 or more days a week or 4 or more weeks

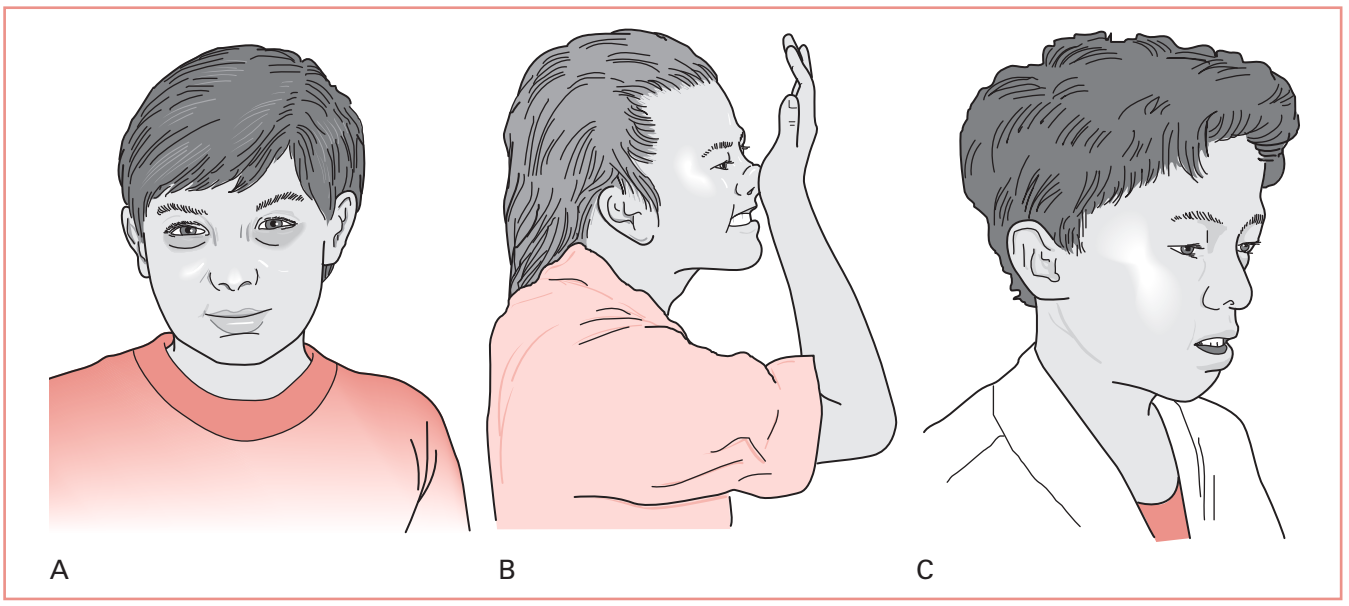

Figure 95.1. Characteristic facial features in children with allergic diseases. A, Allergic shiner. B, Allergic salute. C, Adenoid facies.

in duration. Further, mild allergic rhinitis is defined as having no sleep disturbances; normal activities, sports, and leisure; normal school or work; and no troublesome symptoms. One or more of these symptoms results in classification of moderate/severe persistent allergic rhinitis (Table 95.1). Thus, allergic rhinitis may be classified as mild intermittent, moderate/severe intermittent, mild persistent, and moderate/severe persistent.

Complications of chronic allergic rhinitis may be evident on physical examination, including chronic serous otitis, recurrent otitis media, hearing loss secondary to otitis, sinusitis, nasal polyps, sleep apnea, or dental malocclusion.

Urticaria and Angioedema

Because the most common causes of urticaria and angioedema in children are foods, medications, supplements, and viral infections, questions should focus on recent exposures to drugs, dietary changes, new soaps or detergents, environmental agents, and recent viral illnesses. Consideration should also be given to other serious conditions, such as collagen vascular disease and neoplasm. Laboratory tests usually are not required unless the history and physical examination are suggestive of a potential etiology; for example, a patient with urticaria, joint swelling, pallor, and fatigue requires testing for evidence of systemic lupus erythematosus and malignancy.

Anaphylaxis

In the patient with anaphylaxis, the history is focused on identifying an acute exposure to a foreign antigen (eg, medication, food, venom). Although most patients react within minutes to hours after exposure to the causative agent, anaphylactic reactions occurring many hours to days after exposure have been reported. Therefore, the history must be inclusive of this time frame.

Hemodynamically, patients have reduced peripheral resistance resulting from vasodilation and capillary leak. This results in warm skin and flushing. Compensatory increases in cardiac output result in tachycardia and bounding pulses. Patients often feel a sense of doom. Hypotension ensues if shock is untreated. Respiratory symptoms include airway edema with upper airway obstruction and stridor, and smooth muscle constriction results in wheezing and respiratory distress. Some patients have GI symptoms, including vomiting, abdominal discomfort or pain, and diarrhea. Most patients with anaphylaxis have skin manifestations (typically urticaria).

The most common cause of death from anaphylaxis is respiratory compromise followed by hemodynamic collapse.

Food Allergies

Diagnosing food allergy is not difficult if a reaction is clearly associated with ingestion of a specific food. Timing of the reaction is usually minutes to a few hours after ingestion. Diagnosis is less clear after a meal with multiple ingredients. Maintaining an accurate diet diary helps narrow the list of potential reactive foods. Negative food allergy test results via skin or in vitro serum IgE are reliable in ruling out a food; however, positive test results have limited predictive value unless values are high (Table 95.2). Therefore, a positive test result is suggestive of a food being responsible for a reaction, and confirmation should be pursued via an elimination period followed by food challenge. The double-blind, placebo-controlled food challenge is the diagnostic standard; however, it is impractical in most community clinical settings. National food allergy guidelines recommend using open food challenges to confirm a diagnosis. An absolute exception is in the patient with a serious systemic reaction (eg, anaphylaxis), in which case a strong history and a positive skin or serum test result is sufficient for diagnosis.

Table 95.1. Classification of Allergic Rhinitis

Frequency	Severity	
Not applicable	Mild: No sleep disturbances No impairment of activities, sports, leisure Normal school and work No troublesome symptoms	Moderate/severe (≥1 of the following): Sleep disturbance Impairment of activities, sports, leisure Abnormal school and work Troublesome symptoms
Intermittent (<4 days/week or <4 weeks' duration)	Mild intermittent: same symptoms as above	Moderate/severe intermittent: same symptoms as above
Persistent (≥4 days/week and ≥4 weeks' duration)	Mild persistent: same symptoms as above	Moderate/severe persistent: same symptoms as above

Laboratory Tests

The diagnosis of an allergic disease can be made with a thorough history and physical examination when there is resolution of symptoms with empiric therapy. Additional tests are performed when the diagnosis is in question, to provide optimal avoidance strategies, and if allergen immunotherapy is needed. Testing may be necessary for the diagnosis of food allergy and further evaluation of urticaria and angioedema.

History of exposure followed by symptoms can be suggestive of causative agents; however, the combination of allergy testing with history improves the positive predictive value of a specific antigen causing the symptoms. For example, a patient with year-round indoor symptoms of rhinorrhea and nasal pruritus may be allergic to dust mites, cats, dogs, cockroaches, or mold. Subsequent allergen testing will elucidate which single allergen or combination of allergens is responsible for the symptoms. This results in a more focused and effective approach to environmental control. Allergen testing is also necessary if allergen immunotherapy is being considered.

Allergy testing may be achieved with in vivo skin-prick testing or in vitro specific IgE testing. Skin tests are sensitive and accurate. A positive test result indicates the presence of an antigen-specific IgE. Although skin testing may be less reliable in infants because their skin is less reactive than that of older individuals, these tests have been performed in infants as young as 4 months. Typically, fewer allergens are tested in children younger than 2 years compared with older individuals because those younger than 2 years of age have not been sensitized to a wide range of antigens. Currently, skin-prick testing is the recommended method for skin tests. Intradermal testing involving injection of allergen under the skin is used for testing of stinging insect allergy and various medication hypersensitivity and rarely is necessary for the diagnosis of inhalant or food allergen sensitization. When evaluating food allergy, intradermal testing should not be performed because of the risk of precipitating a systemic reaction.

In vitro allergen-specific IgE concentrations (ImmunoCAP, radioallergosorbent tests) in sera, which are also available for the laboratory assessment of allergies, provide a measure of the amount of IgE specific for individual allergens. Generally, in vitro tests have similar sensitivity and specificity as skin testing but are more expensive. In vitro tests have an advantage in that they can be performed on patients who are using medications that affect skin-testing reactivity, such as antihistamines and tricyclic antidepressants. Additionally, they are the preferred test in patients with poor skin reactivity, such as the very young and very old; those who do not have skin findings, such as atopic dermatitis and dermographism; and those who may have anaphylaxis to the allergens being tested.

For inhalant allergens, in vivo and in vitro tests have good negative and positive predictive values. Both tests have good negative predictive value for food allergy but positive predictive value of approximately 50%. For certain foods, very high levels of specific IgE have good positive predictive values (Table 95.2).

Other screening tests may include a nasal smear for eosinophil counts. More than 10% eosinophils is consistent with allergic rhinitis. Although serum IgE levels are elevated in 60% of patients with allergic rhinitis and asthma, they are not sensitive or specific and have limited value. Rhinoscopy in adults and older children provides a painless method to detect pathology not visible by anterior inspection via the nares. Such pathology includes identification of nasal polyps, deviated nasal septum, adenoidal hypertrophy extending into the nares, sinusitis, vocal cord edema, and polyps and potential masses. Computed tomography is clinically quite useful because it reveals structural abnormalities and mucosal disease, including findings within sinus cavities. The need for such information must be weighed against the high doses of radiation associated with computed tomography. Plain radiography of the sinuses is rarely indicated because of the limited ability to detail nasal anatomy and the high rates of false-negative results for sinusitis along with exposure to radiation.

Management

General Principles

Avoidance of allergen triggers is a natural means of controlling allergy symptoms without medication and should be encouraged in all patients with allergic disease. Currently, avoidance of allergen triggers is the only option available to patients with food allergy and anaphylaxis.

For patients with allergic rhinitis, conjunctivitis, and asthma, allergic triggers consist of perennial and seasonal allergens. Perennial allergens usually include house dust mites, warm-blooded animals with fur (eg, cats, dogs, rodents), cockroaches, and indoor pollens (usually molds). Seasonal allergens include outdoor molds as well as pollen from trees, grasses, and weeds. Effective environmental controls for these are outlined in Box 95.3. In addition to allergic triggers, nonallergic irritant triggers, such as tobacco smoke, automobile exhaust, smog, and perfumes, should be avoided.

Although environmental controls are safe and effective, they may be labor intensive, expensive, and, in rare cases, psychologically detrimental. For instance, removal of carpeting is difficult and expensive, especially in rented housing. Dust mite-proof coverings are expensive and cumbersome to wash in hot water weekly. Removal of family pets may result in psychological issues if children have become attached. Patients are more likely to institute environmental controls if evidence exists of allergic sensitization via skin-prick or blood tests.

Currently, no therapy is available to treat patients with food allergies except avoidance of the triggering food. Food avoidance should be undertaken only after a careful history, allergy testing, and a trial of food elimination and challenge to correctly identify the trigger. A poor history and false-positive testing can result in the implication of many foods, a draconian elimination diet, and undernutrition. The patient who is truly allergic to multiple foods will benefit from consultation with a registered nutritionist or dietitian. Additionally, such patients should be taught to read food labels to avoid offending foods.

Children generally lose sensitivity to milk, soy, egg, and wheat by school age. For instance, a large study noted that 85% of milk-allergic and 66% of egg-allergic children lost their sensitivity by 5 years of age. Only approximately 20% of patients with peanut allergy lose their sensitivity, and even fewer become tolerant of fish

Box 95.3. Environmental Control Strategies for Perennial and Seasonal Allergens

Dust Mites

- Cover mite reservoirs with mite-proof covers (eg, mattress, pillows, box springs, comforter).
- Wash linen in hot water once a week.
- Remove mite reservoirs, such as carpets, and if possible, stuffed toys.
- Use HEPA filter in conjunction with mite reduction strategies.
- Use vacuum cleaner that has HEPA filtration.

Pets (eg, dogs, cats)

- Do not get a warm-blooded furry pet (even if initially not allergic to cats or dogs), because children may sensitize to the pet later, at which time it will be difficult to remove the pet from the home.
- Bathing the pet once a week reduces the allergen load.
- Keep the child's room pet free or, if possible, have an outside cat or dog.
- Use of HEPA filter may help.
- Re-home the pet, if possible. (Note: Cat dander may linger for many months, and continuous house cleaning is required even after removal of the pet.)

Cockroaches/Rodents

- Use of boric acid for cockroach control is a pesticide-free strategy.
- Cockroaches and rodents often require professional extermination.

Mold

- Repair water damage.
- Reduce humidity.

Pollens

- Use HEPA filter.
- Close windows at night (plants usually pollinate in early morning).

Abbreviation: HEPA, high-efficiency particulate air.

and shellfish. Understanding the natural history of food allergies allows the clinician to liberalize the diet if retesting shows negative or reduced reactivity and a supervised food challenge is negative. The decision to challenge depends on the nutritional and social importance of a particular food.

Many patients with FPIES, allergic proctocolitis, and Heiner syndrome also outgrow their food hypersensitivities. The natural history of eosinophilic esophagitis is less clear. Rechallenge to more severe diseases, such as FPIES, must be performed in a monitored setting with staff who are competent in resuscitation.

Anaphylaxis is a medical emergency. Rapid reversal of cardiovascular or respiratory compromise is essential. Epinephrine is the first agent given to increase systemic vascular resistance, reverse bronchospasm, and reduce airway edema. A 0.01 mL/kg per dose of 1:1,000 aqueous solution is given intramuscularly in the lateral thigh. This route achieves high serum concentrations in the shortest time compared with other routes. Subcutaneous injection is no longer recommended. If symptoms progress or do not improve, epinephrine may be repeated in 5 to 10 minutes. Refractory symptoms have been managed with intravenous (IV) epinephrine diluted to 1:10,000. Because of the significant cardiac effects of IV epinephrine, however, cardiac monitoring must be instituted. Because vasoactive mediators result in capillary leak of fluids into the peripheral tissue, rapid volume expansion with normal saline or similar colloids should be instituted early, especially if response to epinephrine is poor. Administration of epinephrine must not be delayed; most deaths from anaphylaxis have been associated with delayed epinephrine administration.

Oxygen therapy should be instituted and bronchodilator drugs (eg, albuterol) given for bronchospasm and wheezing. H_1 and H_2 receptor antagonists, such as diphenhydramine and ranitidine, respectively, usually are given as well as systemic corticosteroids, such as methylprednisolone. Intravenous administration of these drugs ensures systemic delivery, especially if the patient is vomiting. However, antihistamines and corticosteroids are rapidly absorbed orally, and absorption of diphenhydramine is also good intramuscularly. These routes should be considered if IV access cannot be established in a timely fashion.

Because of the risk of a late-phase reaction or a biphasic reaction, the patient with anaphylaxis must be observed for a period of time, usually 4 to 8 hours. Administration of systemic corticosteroids and antihistamines does not adequately reduce the risk of late-phase reactions. The patient must be discharged with an epinephrine auto-injector and taught how to use it (0.15 mg for patients weighing <29.9 kg [<66 lb]; 0.3 mg for patients weighing ≥29.9 kg [≥66 lb]). Inpatient observation is appropriate for patients experiencing severe reactions or who need prolonged resuscitation, when triggers are unclear, if it is difficult to obtain an epinephrine auto-injector, and if the parents are not capable of recognizing anaphylactic symptoms or administering treatment. Medical alert bracelets should be issued if the offending agent is known.

Management of urticaria and angioedema should begin with the identification and elimination of the causal agent. Offending foods or medications should be avoided, underlying infections should be managed, and more serious etiologies, such as collagen vascular disease and malignancy, should be worked up and managed. Medications are required to manage bothersome symptoms and include H_1 and H_2 receptor antagonists and, in severe or persistent cases, corticosteroids. Tricyclic antidepressants are also used in adults and older children because of the potent antihistamine effects of these agents.

Medications

Avoidance of allergens and other triggers is sufficient in mild disease, but often, addition of medications is necessary when symptoms persist or are more severe.

Antihistamines or H_1 receptor antagonists have been used extensively in the management of allergic diseases and are effective in reducing symptoms of pruritus, rhinorrhea, and sneezing. They are less effective in relieving nasal congestion, although many patients report that their nasal congestion improves with these agents. These agents are also effective in reducing hives, swelling, and pruritus in urticaria and angioedema. First-generation antihistamines include

diphenhydramine, chlorpheniramine, and brompheniramine; although these agents are effective, they have significant sedating side effects. Even when administered at bedtime, patients show diminished concentration and attention the next day; sedating antihistamines can impair learning in schoolchildren. Newer H_1 receptor antagonists, such as loratadine, cetirizine hydrochloride, and fexofenadine hydrochloride, are less sedating and should be used as first-line agents in children. Some patients report decreased efficacy of these less-sedating antihistamines compared with older ones. Newer intranasal antihistamines, such as desmethylazelastine, have a rapid onset of action, are effective, and are quite safe but also are sedating.

Anti-inflammatory agents include intranasal corticosteroids, intranasal cromolyn sodium, and systemic corticosteroids. Intranasal corticosteroids have become the mainstay in the management of allergic rhinitis because of their powerful, broad anti-inflammatory properties and excellent safety profile. They are effective in reducing pruritus, rhinorrhea, sneezing, and congestion when used on a chronic preventive basis. Topical intranasal therapy has minimal to no effects on the hypothalamic-pituitary-adrenal axis when newer corticosteroids, such as fluticasone propionate and mometasone furoate, are used. Older agents, such as beclomethasone dipropionate, have more bioavailability, and children may experience small but significant growth delays. Cromolyn sodium is a mast cell stabilizer and has almost no side effects. Clinical efficacy is poor, however, and it is now used infrequently. Although most patients with allergic rhinitis do not require systemic corticosteroids, some patients who are refractory to treatment may benefit from a short course of oral corticosteroids, such as prednisone. Systemic steroids are usually used to control urticaria and angioedema and are mandatory in the management of anaphylaxis.

Alpha-adrenergic agents are used systemically as well as topically in the management of rhinitis. Oral agents, such as pseudoephedrine and phenylephrine, are effective but cause α-adrenergic side effects, such as tachycardia and jitteriness. Topical agents, such as oxymetazoline hydrochloride, are potent vasoconstrictors and can dramatically improve nasal obstruction; however, routine use for more than 3 to 5 days results in rebound congestion with persistent and worse symptoms (ie, rhinitis medicamentosa).

Leukotrienes have biologic effects similar to those of histamine and also recruit inflammatory cells into tissue. Therefore, the leukotriene receptor antagonist montelukast sodium can be used as monotherapy for the management of allergic rhinitis. Intranasal corticosteroids have better efficacy than montelukast sodium, but the latter is an oral agent that promotes better compliance. Additionally, allergic rhinitis is often comorbid with asthma, and montelukast sodium has the advantage of treating both conditions.

Normal saline washes provide a medication-free adjunctive treatment for allergic rhinitis, and their use has increased in popularity among patients.

Immunotherapy is quite effective for the long-term management of allergic rhinitis, allergic conjunctivitis, and stinging insect venom hypersensitivity and is also recommended for allergic asthma and atopic dermatitis when symptoms are not controlled using avoidance strategies and medications. This treatment is effective for symptoms caused by dust mites, pollens, animal dander, molds, and insect venom. Immunotherapy involves a series of injections with extracts of allergens specific for individual patients, producing tolerance to particular antigens. The mechanism of action of immunotherapy is related to the development of allergen-specific blocking antibody (ie, IgG), increased allergen-specific T regulatory cells, decreased lymphocyte cytokine response to an allergen, and decreased basophil histamine release in response to an allergen. The results of skin testing dictate which allergens to use. Initially, injections are given weekly with increasing doses until maintenance concentrations are achieved, at which point the injections are given once every 4 weeks. Immunotherapy is given in a supervised setting with an observation period of approximately 20 minutes, because of the small possibility for anaphylaxis.

In Europe, immunotherapy using sublingual delivery of antigens has been used effectively for many years without the need for injections. In the United States food allergen-specific therapies currently under investigation include oral immunotherapy (OIT), sublingual immunotherapy (SLIT), and subcutaneous immunotherapy (SCIT). Early clinical trials for SCIT have shown efficacy in inducing oral tolerance to peanut allergy; however, most therapies have not been studied in humans. Oral immunotherapy and SLIT have been shown to have lower rates of systemic reactions than SCIT. Moreover, although most studies have reported that OIT has a higher efficacy for desensitization than SLIT, OIT has been found to have a higher incidence of side effects.

Additionally, epicutaneous immunotherapy, which solubilizes the allergen and enters via the stratum corneum, has been shown to be effective for cow's milk protein and peanut allergy and is in preclinical studies for egg allergy. Studies suggest that the risk for systemic reactions may be lower with epicutaneous immunotherapy than with SCIT, OIT, or SLIT.

Caveats About Treatment

Because patients with allergic rhinitis are repeatedly exposed to allergens, they may require use of anti-inflammatory agents, such as intranasal corticosteroids, as first-line therapy. Current guidelines for the United States recommend anti-inflammatory agents as first-line therapy for moderate/severe persistent disease and can be considered for mild persistent and moderate/severe intermittent disease. A patient may require long-term use of anti-inflammatory agents in combination with antihistamines (Figure 95.2).

Allergic conjunctivitis often coexists with allergic rhinitis. Control of nasal symptoms may result in improvement of eye symptoms, but ocular medications may also be required. Available medications include antihistamines, mast cell stabilizers, vasoconstrictors, and combination agents. The sight-threatening allergic ocular conditions of vernal conjunctivitis and atopic keratoconjunctivitis (both of which may cause corneal ulcerations) require prompt referral to an ophthalmologist.

In mild and sporadic cases of urticaria and angioedema, use of antihistamines is sufficient. With frequent and persistent eruptions,

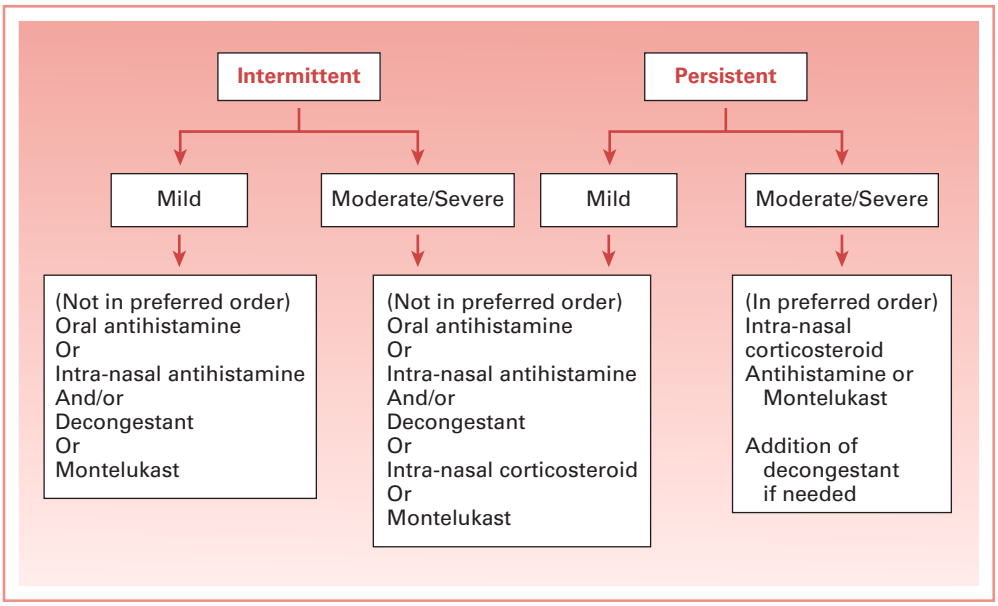

Figure 95.2. Allergic rhinitis treatment algorithm.
Adapted from Bousquet J, Schünemann HJ, Samolinski B, et al; World Health Organization Collaborating Center for Asthma and Rhinitis. Allergic Rhinitis and its Impact on Asthma [ARIA]: achievements in 10 years and future needs. *J Allergy Clin Immunol.* 2012;130[5]: 1049–1062, with permission.

however, the routine use of H_1 blockers with the addition of H_2 blockers may be required. In more severe and refractory cases, older first-generation antihistamines are necessary, with maximal dosages. In adults and older children, tricyclic antidepressants, such as doxepin hydrochloride, can be added when high doses of H_1 and H_2 receptor antagonists do not provide relief. Systemic steroids are effective in controlling symptoms of urticaria and angioedema; symptoms may recur after stopping, however, and patients may become dependent on them for relief.

Chronic urticaria and angioedema may last months to years, some in waxing and waning fashion. The patient with chronic idiopathic urticaria and angioedema must be counseled that the disease is not caused by an external agent. The aforementioned medications must be used long term to allow these patients to lead symptom-free lives until the pathology self-extinguishes.

Prevention

The cost of medical care, lost school days and workdays, disability from complications, and lives lost from allergic disease take a great toll on the population. Prevention significantly reduces the health burden.

Currently, evidence suggests that sensitization to foods can occur in the first 6 to 12 months after birth and even in utero. Strategies to avoid allergic foods during the third trimester and first year after birth have not diminished the prevalence of food allergies. Although breastfeeding is still recommended as the optimal form of nutrition for infants in the first 6 months after birth and studies have suggested mother's milk to have positive immune effects, data are insufficient to support strong associations between exclusive feeding of mother's milk and decreased development of specific allergic diseases (eg, eczema, allergic rhinitis).

In 2000, the American Academy of Pediatrics recommended delaying the introduction of certain highly allergenic foods in high-risk children based on early studies suggesting that delay may help prevent certain allergic diseases, specifically atopic dermatitis. Recent studies have suggested, however, that delayed introduction of solid foods may not only increase the risk of allergy, but that early introduction of certain foods (eg, egg, peanut) between 4 and 6 months of age may decrease the risk of allergy to that food. An interim guideline on the early introduction of peanut for infants at various risk levels was published in 2017 based on the Learning Early About Peanut allergy (LEAP) trial and other studies (Table 95.3); formal guidelines have yet to be developed, however.

Strategies to prevent development of inhalant allergies have not been universally effective. For the patient at risk for the development of allergic rhinitis and asthma, early avoidance of allergens is reasonable; however, this may merely delay sensitization until the patient is older. Strategies include removal of dust mite reservoirs (eg, carpets), covering of mattresses and pillows with mite-proof covers, not having a warm-blooded furry pet, and repair of water damage to reduce mold growth. Prevention of tobacco smoke exposure is essential.

Recently, the hygiene hypothesis has received attention. In this paradigm, exposure to bacterial components, such as endotoxin, results in a natural shift of lymphocytes from IgE-facilitating T helper type 2 cells and T helper type 1 cells. Global shifts away from endotoxin-exposing agrarian societies to more sterile urban societies reduces this shift and may result in the increase in atopy worldwide. A common misconception is that the child exposed to a dirty environment with multiple pets, respiratory infections, and dirt will be protected against atopy. The endotoxin-facilitated shift of T helper type 2 cells and T helper type 1 cells is likely to occur

Table 95.3. Recommendations for the Introduction of Peanuts in Allergic and Non-Allergic Infants

Extent of allergic symptoms	*Recommendation*	*Earliest age of peanut introduction*
Severe eczema, egg allergy, or both	Strongly consider evaluation by serum (peanut-specific IgE) and/or skin prick test and if necessary an oral food challenge. Introduce peanut based on results.	4-6 months
Mild to moderate eczema	Introduce peanut-containing foods	Around 6 months
No eczema or no food allergy	Introduce peanut-containing foods	Age-appropriate and in accordance with family preferences and cultural practices

Derived from DuToit G, Roberts G, Sayre PH, et al. Randomized trial of peanut consumption in infants at risk for peanut allergy. *N Engl J Med*. 2015;372:803-813.

in a narrow window in utero and during the first year after birth, however. Thus, exposure of older children to a dirty environment is unlikely to protect against atopy, and exposure of children with allergic disease exacerbates symptoms.

The method for preventing progression of allergic disease, sometimes referred to as allergic march, is immunotherapy. Immunotherapy against inhalant allergens in the child with allergic rhinitis significantly decreases the risk of asthma. The need for weekly, then monthly injections reduces the acceptance of this method, but the approval of SLIT may improve patient compliance.

Prognosis

Prognosis for the child with allergic disease is good. Some patients lose their allergy naturally or following immunotherapy. For others, allergic rhinitis, urticaria, and anaphylactic reactions persist throughout life on exposure to antigens. With appropriate management, however, the child can thrive and live a normal life. Methods to prevent development of inhalant and food allergies are less well understood; however, current research is focusing on strategies to prevent the development of inhalant and food allergies.

CASE RESOLUTION

The symptoms of rash, swelling, and wheezing after exposure to an antigen are suggestive of an anaphylactic reaction. Treatment with epinephrine, antihistamines, and systemic corticosteroids is clearly indicated. The girl should be observed for the occurrence of late-onset reactions. The child and family should be counseled to avoid any foods that contain peanuts. The parents should read all food labels and carry an epinephrine auto-injector (eg, EpiPen) at all times for emergency use. A medical alert bracelet indicating peanut allergy should be ordered and the patient and parents advised that she should always wear it. The patient should be referred to her primary care physician, who should consider referral to an allergist for further evaluation.

CHAPTER 96

Wheezing and Asthma

Kenny Y.C. Kwong, MD, and Nasser Redjal, MD

CASE STUDY

A 7-year-old boy is referred to the office after being seen in the emergency department for wheezing. He has been treated in the emergency department for wheezing 4 times in the past month and was once hospitalized for 3 days. The boy's father and paternal grandmother both have asthma.

The child's physical examination is remarkable for end-expiratory wheezing on forced expiration.

Questions

1. What are the most common causes of wheezing in infants and children?
2. What are the causes of reversible bronchospasm?
3. What is the pathophysiology of reversible bronchospasm?
4. How should the child with asthma be treated?

Recurrent wheezing is a frequent symptom of obstructive airway disease in children that may be caused by intrinsic or extrinsic compression of the airway, bronchospasm, inflammation, or defective clearance of secretions. Ten percent to 15% of infants wheeze during the first year after birth, and as many as 25% of children younger than 5 years present to their physician with wheezing during a respiratory illness. Most infants and young children with recurrent wheezing have asthma; however, a wide variety of congenital and acquired conditions can cause narrowing of the extrathoracic or intrathoracic airways and may present with wheezing. Reactive airway disease is the most common cause of wheezing in childhood. Childhood asthma typically falls into 1 of 3 categories: transient wheezing, late transient wheezing, and atopic wheezing.

Transient wheezing occurs in infants who are born with smaller caliber airways and who wheeze with viral lower respiratory tract infections and bronchiolitis. These infants do not have atopy and usually have no more wheezing by 3 years of age. Most patients with no atopic predisposition who wheeze in the early years after birth fall into this category. Late transient wheezing occurs in children who usually have a history of serious lung insult, such as severe respiratory syncytial virus (RSV) infections, and persistent wheezing beyond 3 years of age. These children also have no atopy, and symptoms usually slowly resolve over time. Atopic wheezing occurs in children with a strong atopic predisposition. Such children are most likely to develop asthma that persists throughout the school-age years.

Wheezes can originate from airways of any size, from the large extrathoracic upper airway to the intrathoracic small airways. In addition to narrowing or compression of the airway, wheezing requires sufficient airflow to generate airway oscillation and produce sound. Thus, the absence of wheezing in a patient who presents with acute asthma may be an ominous finding suggestive of impending respiratory failure. The audible musical or squeaking sounds noted with obstruction are caused by turbulence of the air as it is forced through a narrowed airway. Infants and young children are more prone to wheezing when they have airway obstruction because air forced through smaller airways is more turbulent than air forced through the larger airways of older children and adults. Infection-induced wheezing in children younger than 2 years is associated with RSV, especially in infants with passive exposure to smoke, and with rhinovirus in children older than 2 years. The most common causes of wheezing in infants and children are asthma, bronchiolitis, and pneumonia. Less common causes include congenital structural anomalies, gastroesophageal reflux and aspiration, cardiac failure, cystic fibrosis, foreign bodies, and vocal cord dysfunction (Box 96.1).

The modified Asthma Predictive Index (mAPI) is a clinical instrument used to predict persistence of asthma. Predictive factors include wheezing before 3 years of age and the presence of either 1 major risk factor (ie, parental history of asthma, personal history of atopic dermatitis, or patient sensitized to aeroallergen) or 2 of 3 minor risk factors (ie, patient sensitized to food, wheezing apart from colds, or eosinophilia). The mAPI has a positive predictive value of 76% and a negative predictive value of 95%. More than 80% of infants with a history of wheezing in the first postnatal years do not wheeze after 3 years of age.

Asthma is a common chronic disorder of the airways characterized by variable and recurring symptoms, airflow obstruction, bronchial hyperreactivity, and underlying inflammation. Bronchospasm is reversible spontaneously or with treatment. In some patients, permanent alterations in the airway structure, referred to as *airway remodeling*, occur and are not prevented by or fully responsive to currently available treatment. Clinically, asthma is characterized by recurrent episodes of cough, chest tightness, dyspnea, prolonged expiration, wheezing, hyperinflation of the chest (ie, air trappings), use of accessory chest muscles (ie, retractions), and, in severe cases, cyanosis.

Box 96.1. Causes of Wheezing

Infection
- Bronchiolitis
- Pneumonia
- Bronchitis
- Laryngotracheobronchitis
- Bacterial tracheitis
- Toxocariasis
- Ascariasis

Reactive Airway Disease
- Asthma
- Exercise-induced asthma
- Anaphylaxis
- Nighttime cough asthma
- Toxic exposure (eg, smoke, organophosphate poisoning)
- Allergic aspergillosis

Laryngeal Dysfunction
Congenital Structural Anomalies
- Vascular rings
- Bronchiectasis
- Lung cysts
- Laryngotracheoesophageal cleft
- Tracheobronchomalacia

Defective Secretion Clearance
- Cystic fibrosis
- Immotile cilia syndrome

Tumor (Mediastinal)
- Lymphoma
- Teratoma
- Neuroblastoma
- Thymoma

Chronic Aspiration
- Gastroesophageal reflux
- Bulbar palsy
- Tracheoesophageal fistula

Other Causes
- Bronchopulmonary dysplasia
- α_1-Antitrypsin deficiency
- Pulmonary hemosiderosis
- Sarcoidosis

Foreign Body
Cardiac Disease
Immunodeficiency

Epidemiology

Asthma is the most common chronic childhood illness. In 2017, the National Health Interview Survey noted that 9.5 million children had asthma. Asthma is the leading cause of emergency department (ED) visits, hospital admissions, and school absenteeism. Over the past several decades, the prevalence of asthma has increased worldwide, an increase that varies from 40% in some areas of the United Kingdom and Australia to 3% in Indonesia, China, and India. Asthma prevalence, mortality, and hospitalization rates are higher in blacks than in whites. One-third of patients initially experience symptoms in the first year after birth, and 80% are diagnosed by the time they reach school age. In the United States, asthma is a leading diagnosis for children admitted to children's hospitals. Hospitalization rates have remained relatively stable, with lower rates in some age groups but higher rates in children 0 to 4 years of age. Additionally, asthma is a major cause of school absence; 23% of school days missed can be attributed to asthma. The male-to-female ratio is 2:1 until age 10 years and is equal from ages 10 to 14 years; after puberty, asthma incidence is greater in girls and women.

In recent years, the incidence of more serious disease in younger children and adolescents has increased. Low socioeconomic status is associated with an increase in asthma prevalence, morbidity, and mortality. Inner-city blacks are most at risk, but studies suggest that socioeconomic class and health care disparities only partially account for these differences.

Clinical Presentation

The child with asthma may present with acute symptoms of cough, shortness of breath, prolonged expiration, use of accessory muscles of respiration, wheezing, reports of chest tightness or congestion, hyperinflation of the chest, cyanosis, exercise intolerance, tachycardia, and abdominal pain.

Wheezing may be audible and detected by the parent or guardian or may not be appreciated until the child is examined by a physician. The child with severe bronchoconstriction may have no wheezing because the flow of air is impeded; however, wheezing may occur after bronchodilator treatment resulting from partial opening of the airway.

Some children have cough, which may be nocturnal or recurrent as a predominant symptom. Some pediatric patients have symptoms, such as cough or wheezing, that are precipitated or exacerbated by exercise (Box 96.2).

Abdominal pain and vomiting also are common in younger children and may be followed by temporary relief of respiratory symptoms. During an acute asthma attack, a low-grade fever, profuse sweating, and fatigue from the hard work of breathing may be apparent.

Pathophysiology

Asthma is a chronic inflammatory disorder of the airways. The immunohistopathologic features of asthma include alteration and denudation of the airway epithelium, thickening of the basement membrane, fibrotic changes in the subbasement membrane, bronchial smooth muscle hypertrophy, edema and angiogenesis, mast cell activation, and inflammatory cell infiltration (ie, neutrophils, lymphocytes, eosinophils), which release mediators such as histamine, prostaglandin, leukotriene, and major basic proteins. These

Box 96.2. Diagnosis of Asthma in the Pediatric Patient

- Recurrent wheezing
- Shortness of breath
- Exercise intolerance
- History of allergies
- History of atopic dermatitis
- Nasal polyps
- History of nighttime cough

changes result in airway hyperreactivity, airflow limitation, respiratory symptoms, and disease chronicity. The limitation to the flow of air results from acute bronchoconstriction, airway edema, mucus plug formation, and airway wall remodeling. The unique anatomy and physiology of the lung in infants compared with adults predisposes infants to obstructive airway disease. These anatomic differences include reduced number and size of the alveolar pores and canals of Lambert, causing deficient collateral ventilation and a predisposition to atelectasis distal to the obstructed airway. Mucous gland hyperplasia favors increased intraluminal mucus production. Decreased smooth muscle in the peripheral airway results in less support and narrower airways. Decreased number of fatigue-resistant skeletal muscle fibers in the diaphragm, its horizontal insertion to the rib cage (versus oblique in adult), and a highly compliant rib cage increase the work of breathing in children. Decreased static elastic recoil predisposes to early airway closure during tidal breathing, resulting in ventilation-perfusion mismatch and hypoxemia.

Atopy, the genetic predisposition to the development of immunoglobulin (Ig) E–mediated response to common aeroallergens, is a predisposing factor for developing asthma. At least 50 genes influence susceptibility to asthma and its clinical expression. Sites located on chromosomes 6p, 12q, 5q, 11q, and 16p are known to be associated with allergic diseases and encoding for major histocompatibility complex, IgE, interferon, and cytokine.

Environmental changes, such as wind, temperature fluctuations, and increased exposure to allergens or air pollutants (eg, tobacco smoke, ozone, sulfur dioxide, nitrogen dioxide), and particulate matter (eg, diesel exhaust, biologic residues [eg, endotoxin]), may precipitate clinical attacks. Inhalant allergens, particularly indoors, play an important role. The most important allergens are house dust mite feces (Der p1 and Der p2), cat allergen (Fel d1), and cockroach saliva (Bla g2, Bla g4, and Bla g5). Other inhalant allergens, such as dog dander, outdoor fungus (ie, *Alternaria*), and some pollens, also play a role. Infections, particularly respiratory ones, are implicated, influencing not only the exacerbation of asthma but also its inception and persistence. Viral infections, such as RSV, parainfluenza, and rhinovirus, are the most frequent precipitants of asthma exacerbations in infancy. The frequency of lower tract respiratory infection during early childhood with these viruses is a strong independent factor in development of asthma. *Mycoplasma* and *Chlamydia* infections can cause wheezing and persistence of asthma. Emotional stress may also play a role in the exacerbation of asthma.

The physiological changes involved in asthma occur in 2 phases: early and late. An immediate response (early phase) to the offending agent causes edema and bronchial smooth muscle constriction that result in narrowing of the airway and plugging with secretions. Air is trapped behind the narrowed airways, resulting in altered gas exchange, increased respiratory rate, decreased tidal volume, and increased work of breathing. The late response, which occurs 4 to 12 hours after the initial symptoms, primarily involves infiltration of the airways with inflammatory cells. The end pathway in the disease process is obstruction to airflow. The pathophysiology of asthma is reviewed in Figure 96.1.

Differential Diagnosis

An extensive differential diagnosis of asthma is listed in Box 96.1. Most conditions are differentiated from asthma by the presence of associated symptoms or the child's response to bronchodilators.

Evaluation

History

A thorough history, including how the child and family are coping with the asthma, should be obtained (Box 96.3). If acute respiratory distress is present, an abbreviated history focusing on potential precipitating factors and medication use should be obtained first, saving the more detailed history for a later time.

Physical Examination

Vital signs, including pulse oximetry, should be obtained. Objective determination of pulmonary function involves measuring the peak expiratory effort. *Paradoxical pulse*, the difference between systolic arterial blood pressure during inspiration and expiration, is usually under 10 mm Hg. This difference may be increased during an acute asthma exacerbation, but the measurement is difficult in young children. Breath sounds, work of breathing, the inspiratory-expiratory ratio, use of accessory muscles, presence of retractions, quality of breath sounds (whether decreased), presence of prolonged expiration, and quality of wheezing should be carefully assessed (Table 96.1). *Polyphonic wheezing* (ie, many different pitches, starting and stopping at varying points in the respiratory cycle) and cough are strongly suggestive of asthma. *Monophonic wheezing* (ie, a single, distinct noise of 1 pitch and starting and stopping at 1 discrete time) and cough should always raise suspicion for large airway obstruction caused by foreign body aspiration, vascular ring, or tracheomalacia. The nose and associated nasal passages should be examined for secretions, edema, pallor, and polyps. The skin should be assessed for eczema and other rashes. The chest should be carefully checked for increased anteroposterior diameter of the chest wall, a sign of air trapping. Fingers should be examined for signs of digital clubbing, which is suggestive of a diagnosis other than asthma.

Laboratory Tests

Laboratory assessment of wheezing children is indicated if the diagnosis is unclear or to eliminate disorders that mimic asthma. Pulmonary function tests are noninvasive, objective, and cost-effective in the diagnosis and follow-up of patients with asthma. These tests can be performed in children older than 5 years with appropriate coaching. After the administration of an aerosolized bronchodilator, dynamic tests of airflow increase or return to normal. An improvement in forced expiratory volume in 1 second (FEV_1) greater than 12% is nearly diagnostic, but lack of improvement in FEV_1 does not preclude asthma. Exercise tolerance tests using a treadmill or free running followed by pulmonary function tests can be performed; a decrease greater than 12% in FEV_1 or 30% in forced expiratory flow is diagnostic for exercise-induced asthma. Peak flow meters, which measure forced peak expiratory flow, are useful in the office and at home to monitor expiratory flow rate. A decrease in peak expiratory flow may predict the onset of an exacerbation and suggests the need for early intervention, using additional drug therapy. A complete blood cell count with a differential count may be suggestive of infection or allergies. Peripheral eosinophil counts may be elevated in asthma. Pulse oximetry assesses the degree of oxygen saturation. Although not used as a parameter in North American asthma

Box 96.3. What to Ask

Asthma

- What symptoms (eg, wheezing, exercise intolerance) does the child experience?
- Does the child experience any nocturnal awaking or cough?
- What time of day and year do the symptoms occur?
- When did the symptoms begin? How old was the child?
- Are the symptoms associated with any particular activity? Does anything seem to trigger the symptoms?
- Are the child's activities limited in any way?
- How often do asthma attacks occur?
- What is the child's living situation? Are there pets in the home?
- Does anyone smoke in the home?
- Do asthma attacks cause the child to be absent from school?
- Does the child manage the condition at home with any particular treatments or medications?
- Has the child visited any urgent care facility or emergency department for treatment for asthma or related episodes in the past? Has the child had any hospitalizations?
- Does the child have a history of allergies?

guidelines for classification or assessment of asthma control, fractional exhaled nitric oxide (FeNO) has been shown to help differentiate diagnosis of asthma from other conditions that may mimic asthma, such as upper airway disease and reflux (ie, chronic cough). Additionally, some specialists use serial FeNO measurements to help wean patients off anti-inflammatory medications.

Sputum smear, stained with eosin-methylene blue agar, may show numerous eosinophils and granules from disrupted white blood cells, eosinophils, and epithelial cells. The presence of more than 5% to 10% eosinophils is suggestive of allergic inflammatory disease. Other findings in the sputum include Curschmann spirals, which are threads of glycoprotein; Creola bodies, which are clusters of epithelial cells; and Charcot-Leyden crystals, which are derived from eosinophils.

Total serum IgE is not as helpful as antigen-specific IgE in the diagnosis of asthma and is elevated in 80% of children with allergen-induced asthma. Allergy skin testing or serologic testing, such as radioallergosorbent testing, is indicated to identify potentially important environmental allergens. Allergens may play a significant role in asthma, and 85% of patients with asthma have a positive skin test reaction to common aeroallergens. Extensive laboratory testing should be reserved for the child with severe disease who may benefit from consultation with an allergy specialist.

Imaging Studies

The child with suspected asthma rarely requires chest radiography unless concern exists for other pathology. Radiographic findings may range from normal to hyperinflation, increased bronchial marking, and atelectasis, especially during acute exacerbation. Infiltration, pneumothorax, pneumomediastinum, and pneumonia are less common findings.

Management

The long-term goals of asthma therapy are listed in Box 96.4.

Assessment measures for asthma should include monitoring of the following: signs and symptoms, pulmonary function through peak flow or respirometry, quality of life or functional status, acute disease exacerbations, pharmacologic therapy, and satisfaction of the child and family with the asthma care.

Selecting the appropriate therapy for the patient with asthma depends on the age, disease severity (Table 96.2), and developmental level of the child; tolerance for a specific pharmacologic agent; and routes of administration. The pharmacologic treatment for symptom control and reduction of inflammation is predicated on the severity of the asthma, as categorized according to National Heart, Lung, and Blood Institute (NHLBI) guidelines. Box 96.5 contains an overview of these medications. Quick-relief

Table 96.1. Parameters Used to Estimate the Severity of Acute Asthma

Sign/Symptom	*Mild*	*Moderate*	*Severe*
Respiratory rate	Normal	Increased	Increased >2 standard deviations
Breath sounds	Normal (some end-expiratory wheezes)	Wheezing in inspiration and expiration	Decreased, with or without wheezing
Shortness of breath	None (can speak in sentences)	Can speak in phrases	Speaks only single words
Skin color	Normal	Pale	Pale to cyanotic
Work of breathing	Normal	Moderate retractions; some use of accessory muscles	Severe retractions, nasal flaring, use of accessory muscles
Pulse	Normal	Normal or increased	Increased
Level of consciousness	Normal	Normal	Diminished; may be lethargic or combative
Paradoxical pulse	<10 mm Hg	10–20 mm Hg	20–40 mm Hg
Oxygen saturation	>95%	90%–95%	<90%
Pulmonary function	80% of predicted	50%–70% of predicted	<50% of predicted

Box 96.4. Long-term Goals of Asthma Therapy

- Prevent chronic and disabling symptoms (eg, coughing, sleep disturbances, exercise intolerance, shortness of breath).
- Maintain normal or near-normal pulmonary function.
- Maintain normal activity levels.
- Prevent recurrent exacerbations and minimize the need for emergency department visits and admission to the hospital.
- Provide drug therapy that is effective with minimal side effects.
- Meet the expectations of the child and family for the care of asthma.
- Encourage self-management of asthma.

medications ("rescue meds") are used for acute exacerbations; the long-term control medications are used for chronic therapy. Nonpharmacologic measures are used in a preventive fashion and serve as an adjunct to drug therapy.

Short-term Management

Acute attacks can be managed in the office if the staff is prepared to manage a child in respiratory distress. Otherwise, the child can be referred to the ED. Equipment and supplies for resuscitation of infants and children must be available in offices in which care is provided for children with asthma.

The goal of therapy is to relieve airflow obstruction and prevent respiratory failure. All children with moderate or severe asthma should be placed in a position of comfort and given oxygen by nasal prongs or mask as tolerated. Assessment of work of breathing and the use of pulse oximetry help guide oxygen therapy. Nebulized β_2 agonists (eg, albuterol) are used until symptoms subside. The child may require drug therapy every 20 to 30 minutes. Not only are nebulized β_2-adrenergic agonists more effective than oral medications, they are associated with fewer side effects. Ipratropium bromide used in conjunction with a β agonist in the urgent care setting has been shown to reduce risk of hospitalization. Systemic corticosteroids, which help reduce the inflammation associated with clinical attacks, are indicated in most moderate and severe cases. Response to therapy is determined by clinical assessment of work of breathing, respiratory rate, objective changes in pulmonary function, and pulse oximetry. The child with incomplete response to initial therapy may require several hours of treatment or hospitalization.

Box 96.5. Pharmacologic Therapy: An Overview of Medications Used to Treat Asthma

Long-term Control Medications (Controller Class)

Corticosteroids

Most potent and effective anti-inflammatory medication currently available. Inhaled form is used in the long-term control of asthma. Systemic corticosteroids are often used to gain prompt control of the disease when initiating long-term therapy.

Cromolyn Sodium and Nedocromil

Mild anti-inflammatory medication. May be used as monotherapy in the setting of mild persistent asthma. Can also be used as preventive treatment before exercise or unavoidable exposure to known allergens.

Long-acting β_2 Agonists

Long-acting bronchodilator used concomitantly with anti-inflammatory medications for long-term control of symptoms, especially nocturnal symptoms. Includes salmeterol and formoterol.

Methylxanthines

Sustained-release theophylline is a mild-to-moderate bronchodilator used principally as an adjuvant to inhaled corticosteroids for prevention of nocturnal asthma symptoms. May have a mild anti-inflammatory effect.

Leukotriene Modifiers

Montelukast, a leukotriene receptor antagonist, or zileuton, a 5-lipoxygenase inhibitor, may be considered an alternative therapy to low doses of inhaled corticosteroids, or cromolyn or nedocromil, in the setting of mild persistent asthma.

Systemic Corticosteroids

- Used for moderate-to-severe exacerbations to speed recovery and prevent recurrence of exacerbations.
- Omalizumab (anti-immunoglobulin E), a recombinant DNA-derived humanized monoclonal antibody of the Fc portion of the immunoglobulin E antibody, binds to that portion, thereby preventing immunoglobulin E binding to its high-affinity receptor (FcεR1) on mast cells and basophils, resulting in a decrease in the release of mediators in response to allergen exposure.

Quick-Relief Medications (Reliever Class)

Short-acting β_2 Agonists

Albuterol and levalbuterol are therapy of choice for relief of acute symptoms and prevention of exercise-induced bronchoconstriction.

Anticholinergic Agents

Ipratropium bromide provides additive benefit to inhaled β_2 agonists in acute exacerbations. May be an alternative bronchodilator for the patient who does not tolerate inhaled β_2 agonists.

Table 96.2. Classifying Asthma Severity

Components of Severity		*Intermittent*	*Persistent*		
			Mild	*Moderate*	*Severe*
Classifying Asthma Severity and Initiating Treatment (0–4 years of age)					
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	0	1–2x/month	3–4x/month	>1x/week
	Short-acting β_2 agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Risk	Exacerbation requiring oral systemic corticosteroids	0–1 per year	≥2 exacerbations in 6 months requiring oral systemic corticosteroids, or ≥4 wheezing episodes per 12 months lasting >1 day AND risk factors for persistent asthma		
		Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time. Exacerbations of any severity may occur in a patient in any severity category.			
Recommended Step for Initiating Therapy (See Table 96.4 for treatment steps.)		Step 1: SABA PRN	Step 2: Low-dose ICS	Step 3: Medium-dose ICS and consider short course of OCS	
		In 2–6 weeks, depending on severity, evaluate level of asthma control achieved. If no clear benefit is observed in 4–6 weeks, consider adjusting therapy or alternative diagnoses.			
Components of Severity		*Intermittent*	*Persistent*		
			Mild	*Moderate*	*Severe*
Classifying of Asthma Severity and Initiating Treatment (5–11 years of age)					
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2x/month	3–4x/month	>1x/week but not nightly	Often 7x/week
	Short-acting β_2 agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	Normal FEV_1 between exacerbations FEV_1 >80% predicted FEV_1/FVC >85%	FEV_1 ≥80% predicted FEV_1/FVC >80%	FEV_1 = 60%–80% predicted FEV_1/FVC = 75%–80%	FEV_1 <60% predicted FEV_1/FVC <75%
Risk	Exacerbation requiring oral systemic corticosteroids	0–1 per year	≥2 per year		
		Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time.			
		Relative annual risk of exacerbations may be related to FEV_1.			
Recommended Step for Initiating Therapy (See Table 96.4 for treatment steps.)		Step 1: SABA PRN	Step 2: Low-dose ICS	Step 3: Medium-dose ICS option	Step 3, Medium-dose ICS option or step 4
				Consider short course of OCS.	
		In 2–6 weeks, evaluate level of asthma control that is achieved and adjust therapy accordingly.			

(*continued*)

Table 96.2. Classifying Asthma Severity (*continued*)

Component of Severity		*Classifying of Asthma Severity and Initiating Treatment (≥12 years of age)*			
		Intermittent	*Persistent*		
			Mild	*Moderate*	*Severe*
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2x/month	3–4x/month	>1x week, but not nightly	Often 7x/week
	Short-acting β_2 agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily and more than once on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	Normal FEV_1 between exacerbations FEV_1 >80% predicted FEV_1/FVC >85%	FEV_1 ≥80% predicted FEV_1/FVC normal	FEV_1 >60%, but <80% predicted FEV_1/FVC reduced 5%	FEV_1 <60% predicted FEV_1/FVC reduced <5%
Risk	Exacerbation requiring oral systemic corticosteroids	0–1 per year	≥2 per year		
		Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time. Exacerbations of any severity may occur in a patient in any severity category.			
Recommended Step for Initiating Therapy (See Table 96.4 for treatment steps.)		Step 1: SABA PRN	Step 2: Low-dose ICS	Step 3: Low-dose ICS + LABA	Step 4/5: Medium-/High-dose ICS + LABA
				Consider short course of OCS	
		In 2–6 weeks, depending on severity, evaluate level of asthma control that is achieved. If no clear benefit is observed in 4–6 weeks, consider adjusting therapy or alternative diagnoses.			

Abbreviations: EIB, exercise-induced bronchoconstriction; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroids; LABA, long-acting β_2 agonist; OCS, oral corticosteroids; PRN, as needed; SABA, short-acting β_2 agonist.

Long-term Management

The goals of long-term management are shown in Box 96.6.

Continuous and longitudinal primary care of children with asthma can profoundly affect the disease course. The primary care physician, child, and family must work together to achieve good control of symptoms. Prevention of exacerbations may be accomplished by removal of offending allergens. Minimization of exposure to known allergens and irritants has been shown to decrease symptoms and exacerbation. The most commonly implicated irritants are tobacco smoke; fumes from gas, oil, and kerosene stoves and wood-burning appliances; and sprays and strong odors. House dust mites are microscopic insects that feed on human scales, require humidity greater than 50%, and are found in stuffed furniture, carpets, and mattresses. House dust mite infestation can be reduced by encasing mattresses, blankets, and pillows in mite-proof covers; removing carpeting; and decreasing humidity to less than 50%.

Box 96.6. Therapeutic Goals for the Child With Chronic Asthma

- Maintain a normal, age-appropriate activity level
- Maintain near-normal pulmonary function
- Prevent symptoms such as exercise intolerance, chronic cough, and shortness of breath
- Prevent acute exacerbations of the disease that require acute therapy
- Minimize adverse effects of the drugs used to manage the disease
- Promote self-esteem and a sense of well-being

Allergen immunotherapy may be considered for the patient with asthma when evidence exists of a clear relationship between symptom and exposure to an allergen, and symptoms are poorly controlled with pharmacologic management (eg, medication ineffective, multiple medications are required, patient does not accept

or tolerate medication). Adherence to appropriate medications and in-home peak-flow measurement helps in prevention and control of asthma. Periodic assessment ensures appropriate therapy and compliance with treatment. The physician should make sure that the family can afford the necessary medications. During routine visits, home monitoring and therapy as well as any diaries and records should be reviewed, the child's and family's expectations about the course of the disease should be discussed, and all parties should be allowed to express their concerns about the development of a treatment plan. Other factors, such as rhinitis, sinusitis, and gastroesophageal reflux, which may influence the severity of asthma or the child's quality of life, should be assessed and treated appropriately.

Family members and the affected child should be given a written action plan based on the patient's personal best peak flow (Figure 96.2)

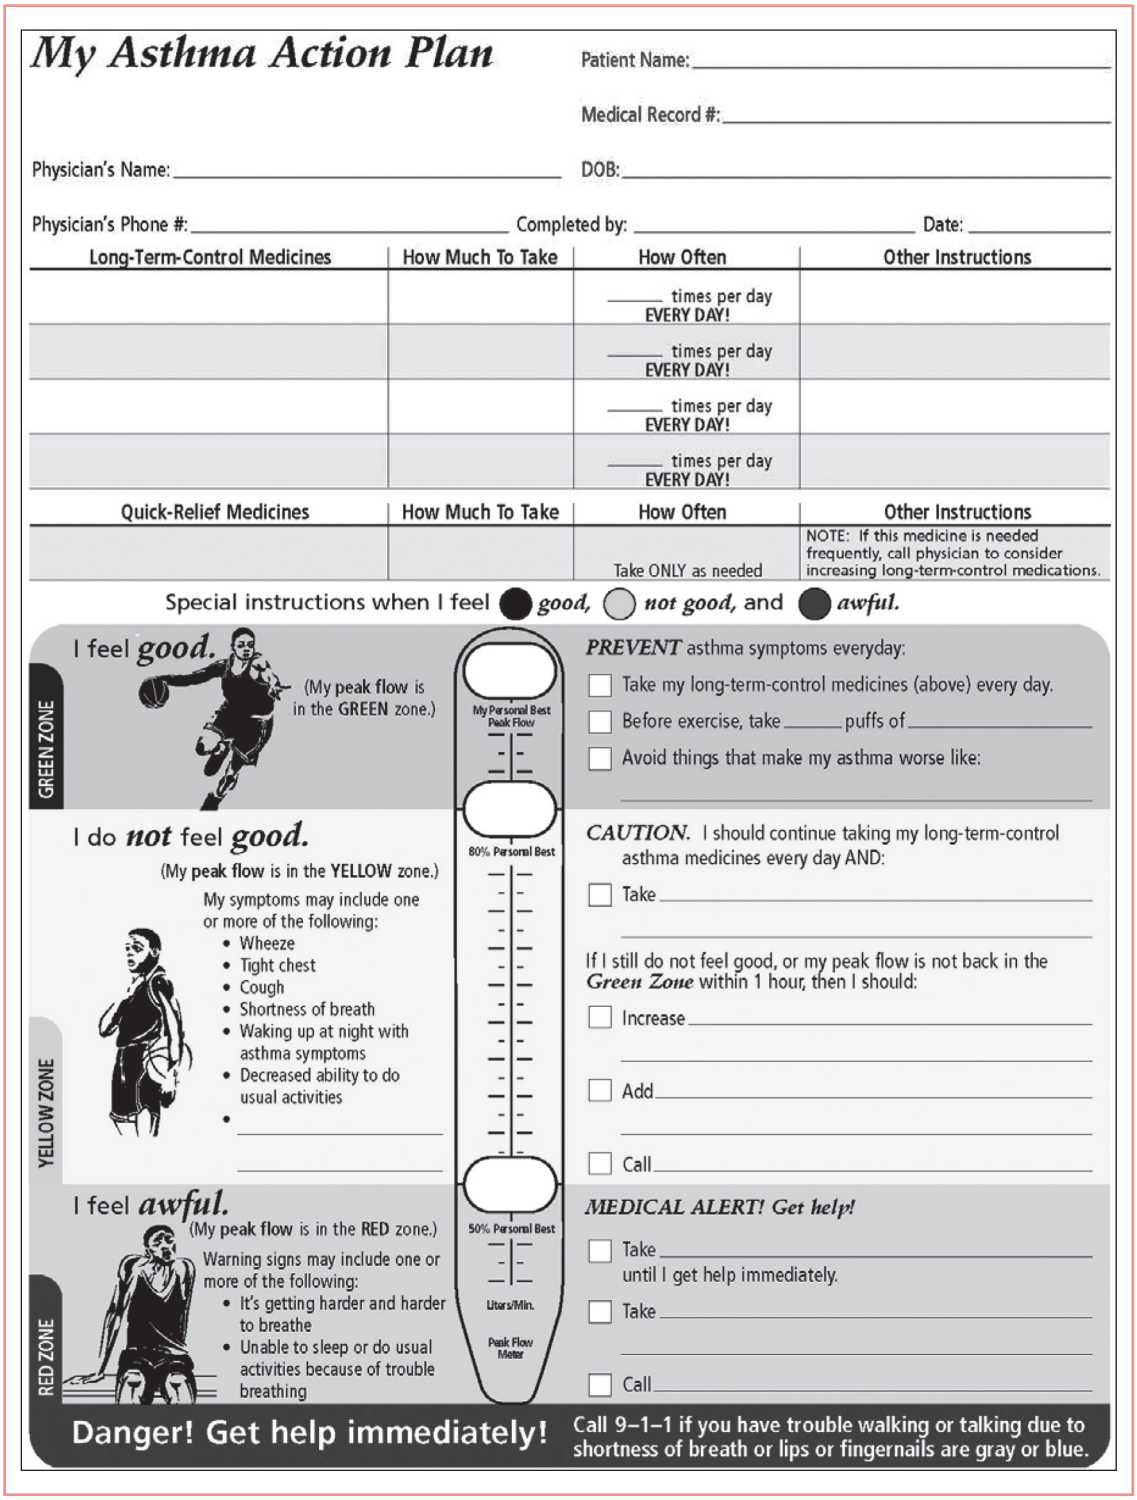

Figure 96.2. Asthma action/medicine plan.

Reprinted from National Heart, Lung, and Blood Institute. *National Asthma Education and Prevention Program. Full Report 2007*. NIH Publication No 07-4051, Revised August 2007. https://www.nhlbi.nih.gov/sites/default/files/media/docs/asthgdln_1.pdf.

and instructed in the use of peak flow meters to indicate when medical treatment is necessary. Some meters have 3 color zones: a green zone, which indicates good airflow; a yellow zone, which signals the need for treatment; and a red zone, which suggests that a visit to the ED may be indicated.

Dynamic Monitoring and Treatment

Asthma rarely remains static over time. Symptoms wax and wane in severity and frequency depending on extrinsic and intrinsic signals (eg, viral infections), allergen exposure, and nonspecific triggers (eg, atmospheric conditions, cigarette smoke, air pollutants). Although assessment of underlying asthma severity is important and serves as a starting point in initiating therapy, assessment of asthma control is more important in dynamic treatment of the patient with asthma. The patient initially classified with intermittent asthma and only prescribed as needing bronchodilator rescue therapy may experience loss of asthma control for long periods of time. At a physician visit during this time, such a patient would be classified as having baseline/underlying intermittent asthma but currently very poorly controlled. Such a patient will require the addition of a long-term controller agent, such as inhaled corticosteroids (ICSs) (ie, step-up therapy). In juxtaposition, the patient with initially rated severe persistent asthma may experience long symptom-free periods (baseline/underlying severity: severe persistent, currently well controlled). In such a patient, therapy can be stepped down. Asthma control is rated similarly to severity (Table 96.3).

Pharmacologic Therapy

The 2007 NHLBI guidelines for asthma management are based on age group: children 0 to 4 years of age, children 5 to 11 years of age, and children 12 years and older (Table 96.4).

Asthma severity is categorized by impairment and risk. Impairment considers the frequency and severity of daytime and nighttime asthma symptoms, use of short-acting β_2 agonist for other than exercise-associated symptoms, effect on activities, and pulmonary function testing. Risk assesses the frequency of asthma exacerbations requiring the use of oral corticosteroids. The most severe level of symptoms, medication use, and other factors defines the level of severity, which determines the long-term approach to management. The patient with intermittent asthma may respond to short-acting bronchodilator as necessary, whereas the child with persistent asthma requires a controller medication (eg, ICS) to reduce inflammation.

Management of asthma is based on its severity and control. For intermittent asthma only, short-acting β_2 agonists are required on an as-needed basis to manage symptoms. Prophylactic use of β_2 agonists, cromolyn, or nedocromil may be administered for exercise-induced asthma before the onset of activity. For mild persistent asthma, daily anti-inflammatory medications (ie, controllers) are required with low-dose ICSs as recommended therapy or alternative monotherapy with cromolyn, nedocromil, or leukotriene modifier agents, such as montelukast. Short-acting β_2 agonists are used for acute exacerbations. For moderate persistent asthma, medium-dose ICSs or low-dose ICSs plus a second agent is recommended, depending on the age group. Second agents include long-acting β_2 agonists, leukotriene modifiers, and theophylline. For severe persistent asthma, usually high-dose ICS plus a second agent is required. Systemic corticosteroids may be required to gain asthma control in the patient with moderate to severe persistent asthma. In the patient with difficult-to-control asthma, especially one experiencing severe exacerbation despite optimal controller therapy, omalizumab has been shown to decrease risk of asthma attacks. Patients of all asthma severities require short-acting β_2 agonists for quick relief of symptoms and prevention of exercise-induced asthma.

Inhaled corticosteroids act topically on lung epithelium, inhibiting cell migration and activation and reducing airway hyperreactivity. They are the most effective anti-inflammatory medication for asthma. Inhaled corticosteroids reduce asthma symptoms, improve lung function, reduce acute exacerbations of asthma, and reduce the risk of death from asthma. Recent data show that ICSs are well-tolerated, safe medications at the recommended dosages.

Leukotriene modifiers interfere with the action of leukotrienes, inflammatory mediators released from mast cells, eosinophils, and basophils. Long-acting β_2 agonists provide at least 12 hours of bronchodilation by stimulating β_2 receptors in the airway, which increases the concentration of cyclic adenosine monophosphate, causing relaxation of airway smooth muscle. Long-acting β_2 agonists should never be used alone; instead, they should be used in conjunction with ICSs in the management of asthma.

A patient may be started at a higher level of medication at the onset to establish prompt control, after which step-down reduction should be implemented to reach the minimum medication necessary to maintain control (Table 96.3).

Biologics

Despite adherent use of ICSs, leukotriene receptor agonist, and long-acting β_2 agonist, a small but significant percentage of patients with asthma have poor asthma control and experience severe asthma exacerbations, such as asthma-related hospitalizations, ED visits, and oral corticosteroid rescue. Anti-IgE therapy (ie, omalizumab) has been used in adults with asthma for more than 20 years, and the 2007 NHLBI asthma guidelines recommend its use in patients age 12 years or older who require steps 5 or 6 of therapy (Table 96.4). Recently, anti-IgE therapy was approved by the US Food and Drug Administration for children as young as 6 years. Anti-interleukin-5 antibodies (ie, mepolizumab, benralizumab) have also been approved by the FDA for treatment of severe asthma and achieve similar results. Other monoclonal antibodies targeting cytokines in atopic asthma are projected to be approved, including anti-interleukin-13 and anti-thymic stromal lymphopoietin antibodies.

Table 96.3. Assessing Asthma Control

Components of Control		Assessing Asthma Control in Children (0–4 years of age) Classification of Asthma Control Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment	Symptoms	≤2 days/week	>2 days/week	Throughout the day
	Nighttime awakenings	≤1x/month	>1x/month	>1x/week
	Short-acting β_2 agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week	Several times per day
	Interference with normal activity	None	Some limitation	Extremely limited
Risk	Exacerbation requiring oral systemic corticosteroids	0–1 per year	2–3 per year	>3 per year
Components of Control		**Classification of Asthma Control (5–11 years of age)** **Well Controlled**	**Not Well Controlled**	**Very Poorly Controlled**
Impairment	Symptoms	≤2 days/week but not more than once on each day	>2 days/week or multiple times on ≤2 days/week	Throughout the day
	Nighttime awakenings	≤1x/month	≥2x/month	≥2x/week
	Short-acting β_2 agonist use for symptom control (not prevention of EIB)	≥2 days/week	>2 days/week	Several times per day
	Interference with normal activity	None	Some limitation	Extremely limited
	Lung function	FEV_1 ≥80% predicted/personal best FEV_1/FVC >80%	FEV_1 = 60%–80% predicted/personal best FEV_1/FVC = 75%–80%	FEV_1 <60% predicted/personal best FEV_1/FVC <75%
Risk	Exacerbation requiring oral systemic corticosteroids	0–1 per year	≥2 per year	
Components of Control		**Classification of Asthma Control (≥12 years of age)** **Well Controlled**	**Not Well Controlled**	**Very Poorly Controlled**
Impairment	Symptoms	≤2 days/week	>2 days/week	Throughout the day
	Nighttime awakenings	≤2x/month	1–3x/month	≥4x/week
	Short-acting β_2 agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week	Several times per day
	Interference with normal activity	None	Some limitation	Extremely limited
	Lung function	FEV_1 ≥80% predicted/personal best FEV_1/FVC >80%	FEV_1 = 60%–80% predicted/personal best FEV_1/FVC = 75%-80%	FEV_1 <60% predicted/personal best FEV_1/FVC <75%
	Validated questionnaires ATAQ ACQ ACT	 0 ≤0.75 ≥20	 1–2 ≥1.5 16–19	 3–4 N/A ≤15

Table 96.4. Stepwise Approach for Managing Asthma by Age Group[a]

Age	*Step 1*	*Step 2[b]*	*Step 3[b]*	*Step 4[b]*	*Step 5*	*Step 6*
0–4 years	SABA PRN	Low-dose ICS Alternative: Cromolyn or montelukast	Medium-dose ICS	Medium-dose ICS + either LABA or montelukast	High-dose ICS + either LABA or montelukast	High-dose ICS + OCS + either LABA or montelukast
5–11 years	SABA PRN	Low-dose ICS Alternative: Cromolyn, LTRA, or theophylline	Low-dose ICS + either LABA, LTRA, or theophylline OR Medium-dose ICS	Medium-dose ICS + LABA Alternative: Medium-dose ICS + either LTRA OR theophylline	High-dose ICS + LABA Alternative: High-dose ICS + either LTRA OR theophylline	High-dose ICS + LABA + OCS Alternative: High-dose ICS + either LTRA or theophylline + OCS
12 years–adult	SABA PRN	Low-dose ICS Alternative: Cromolyn, LTRA, or theophylline	Low-dose ICS + LABA OR Medium-dose ICS Alternative: Low-dose ICS + either LTRA OR theophylline or zileuton	Medium-dose ICS + LABA Alternative: Medium-dose ICS + either LTRA OR theophylline or zileuton	High-dose ICS + LABA AND Consider omalizumab for the patient with allergies	High-dose ICS + LABA + OCS AND Consider omalizumab for the patient with allergies

Abbreviations: ICS, inhaled corticosteroid; LABA, long-acting β_2 agonist; LTRA, leukotriene receptor antagonist; OCS, oral corticosteroids; PRN, as needed; SABA, short-acting β_2 agonist.

[a] At each step, in addition to medication, also address patient education, environmental control, and management of comorbidities.

[b] Steps 2-4 (5 years–adult): Consider subcutaneous allergen immunotherapy for the patient with persistent, allergic asthma.

Adapted from the National Asthma Education and Prevention Program. *Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, 2007*. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH Publication No. 07-4051.

Prognosis

Asthma can result in significant morbidity and mortality if a child is not treated appropriately. The child without longitudinal primary care generally requires expensive therapy in EDs or inpatient settings. A significant number of individuals with asthma have fatal outcomes because of lack of timely and appropriate care. Nearly all these deaths are preventable.

CASE RESOLUTION

The boy requires not only medication but also education for himself and his family as well as longitudinal primary care. It is particularly important to assess possible environmental factors (eg, pets), exposure to smoke, and poor compliance with previous recommendations, all of which have contributed to his recurrent symptoms.

CHAPTER 97

Cough

Nasser Redjal, MD, and Charles H. Song, MD

CASE STUDY

A 3-year-old boy presents with a cough of 4 weeks' duration. Previously, he has had cough with colds, but this cough is persistent and deeper in quality. The cough seemed to develop suddenly when he was playing at a friend's house. It occurs all day and disrupts his sleep at night. The boy has had no nasal congestion, fever, or sore throat. No one at home is coughing, and the boy has not traveled recently. Neither the boy nor his family has a history of allergies or asthma. Over-the-counter cough preparations have not helped relieve his symptoms. On physical examination, growth parameters are found to be normal. The child has a persistent cough with no respiratory distress. Chest examination reveals a normal respiratory rate, no retractions, and no use of accessory muscles, although diffuse expiratory wheezing is noted in the right lower lobe. The remainder of the examination is normal.

Questions

1. What are common parental concerns about cough?
2. What diagnoses should be considered in the child with persistent cough?
3. What findings from the history and physical examination are important in determining the etiology of cough?
4. What diagnostic workup is appropriate?
5. How should the child with cough be treated?

Cough is an essential protective reflex that allows for clearance of secretions and particulates from the airways. Its persistence can be distressing to the pediatric patient and often causes parental anxiety because of uncertainty of its etiology. Cough may be acute, subacute, or chronic. Acute cough lasts less than 2 weeks and often is associated with respiratory tract infections in children. Cough lasting 2 to 4 weeks is subacute, and cough lasting more than 4 weeks is persistent or chronic. In children 15 years and older as well as adults, *chronic cough* usually is defined as persistent cough lasting more than 8 weeks. Parental awareness as well as accessibility to medical care influences the timing of the initial visit to a physician or other health professional during the disease course. Cough may be classified as specific or nonspecific depending on whether an underlying etiology is found, and management of the disease is tailored accordingly.

Epidemiology

Cough is a common reason for pediatric office visits. In the National Ambulatory Medical Care Survey, 6.7% of pediatric office visits involved children who presented with cough. Typically, preschool age children have up to 8 upper respiratory infections with associated cough in a winter season. Persistent cough is also common, with some surveys demonstrating a prevalence of 5% to 10% in 6- to 12-year-old children, with higher rates in younger children. Cough is more common among boys than girls less than 11 years of age and may be less common in developing countries than affluent countries.

Clinical Presentation

Presentation varies considerably depending on the etiology of the cough. Most children have no evidence of respiratory compromise, but some present with respiratory distress. Depending on the underlying etiology, a child may manifest other symptoms of chronic lung disease, such as clubbing and failure to thrive, although most children are found to be in good health.

Pathophysiology

Coughing is a protective reflex that is automatically triggered by cough receptors found throughout the human airway, including the nose, paranasal sinuses, posterior pharynx, larynx, trachea, bronchi, and pleura. They are also found outside the respiratory tract in the ear canal, stomach, pericardium, and diaphragm (Figure 97.1).

Proximal airways (ie, larynx and trachea) are more sensitive to mechanical stimulation, and distal airways are more sensitive to chemical stimulation. Lung parenchymal (ie, bronchiolar and alveolar) tissue contains no cough receptors; thus, pneumonia may not produce a cough. Stimulation of any of these receptors by an irritant, whether mechanical, chemical, thermal, or inflammatory, can initiate the cough reflex. Impulses from stimulated cough receptors traverse afferent nerves (ie, vagus, glossopharyngeal, trigeminal, phrenic) to a "cough center" in the medulla, which itself is under some control by higher cortical centers. The cough center generates an efferent signal that travels down the vagus, phrenic, and spinal motor nerves to expiratory musculature, thereby producing

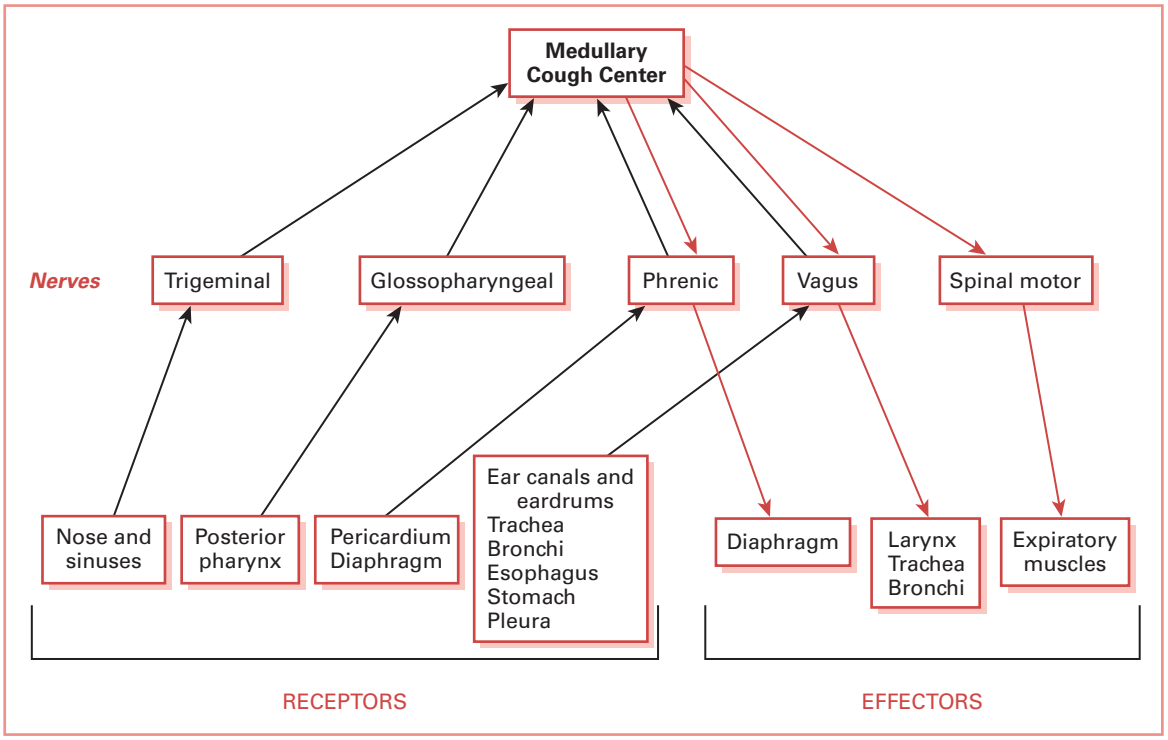

Figure 97.1. The cough reflex.

the cough. The cough center can be voluntarily stimulated or suppressed. Once initiated, the cough reflex propels excess mucus up the airways at the pressures of up to 300 mm Hg and at flows of up to 5 to 6 L/sec.

The cough experienced by patients may be broken down into 4 phases. First, the glottis opens with an inspiratory gasp. Second, the glottis closes with forceful contraction of the chest wall, diaphragm, and abdominal muscles. Third, the glottis again opens with release of airway pressure in an expiratory phase. Fourth, the chest wall and abdominal muscles relax. This process expels mucus or irritants from the airways, helping maintain lung health. The child who does not cough effectively may be at risk for atelectasis, recurrent pneumonia, and chronic airway disease from aspiration or retention of secretions.

Differential Diagnosis

Any pathology present along the airway from the nose to the alveoli can elicit a cough response; therefore, the list of differential diagnoses of cough is long (Box 97.1). Narrowing the list of causes can be accomplished by paying attention to several factors (Box 97.2). Typically, wet (ie, productive) cough tends to point to more specific diagnosis, whereas dry cough may be nonspecific.

The age of the child is an important determinant in the differential diagnosis. Cough presenting during infancy should prompt the physician to consider congenital chest anomalies, such as tracheoesophageal fistula, laryngeal cleft, vocal cord paralysis, and tracheobronchomalacia. Other congenital conditions include heart disease, which can produce a cough as the result of heart failure and pulmonary edema. Congenital mediastinal tumors induce cough if the tumor presses on the airway. Recurrent coughing or wheezing in infancy and early childhood associated with respiratory syncytial virus infection may be early signs of impending asthma in later childhood. Recurrent vomiting during infancy associated with chronic cough is suspicious for gastroesophageal reflux disease (GERD).

The duration of the cough is an important factor in determining the possible etiology. Most acute coughs are caused by a viral respiratory infection. The common viruses involved are rhinovirus, respiratory syncytial virus, human metapneumovirus, and adenovirus in infants and younger children; influenza and parainfluenza are common in children of all ages. All of these viruses affect the upper respiratory tract (common cold) more commonly, usually peaking on day 2 to 3 of illness and resolving in 2 weeks. Other causes of acute cough include asthma, bacterial upper respiratory infection (eg, pharyngitis, sinusitis), and pneumonia. The most commonly involved bacteria are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*.

In some children, especially those with underlying allergy or mild immune deficiency, cough may persist beyond 2 weeks after initial common cold symptoms appear. Virus may spread to the sinuses (ie, acute sinusitis) or to the lungs as pneumonia, bronchitis, or bronchiolitis. A secondary bacterial infection may also involve the sinuses and the lungs.

Cough lasting longer than 4 weeks is defined as chronic, and causes other than those associated with acute cough must be considered. In adolescents 15 years and older and adults, asthma, upper airway cough syndrome (eg, postnasal drip resulting from rhinitis or sinusitis), and GERD are the most common etiologies.

Box 97.1. Causes of Cough

Common

- Asthma
- Protracted bacterial bronchitis
- Upper airway cough syndrome
- Nonspecific cough

Less Common

Congenital Anomalies

- Tracheoesophageal fistula
- Laryngeal cleft
- Vocal cord paralysis
- Mediastinal masses
- Pulmonary malformations
- Tracheobronchomalacia
- Congenital heart disease

Infections (eg, Upper Respiratory, Sinusitis, Pneumonia)

- Viral
  - Adenovirus
  - Human metapneumovirus
  - Influenza
  - Parainfluenza
  - Respiratory syncytial virus
  - Rhinovirus
- Bacterial
  - *Chlamydophila pneumoniae*
  - *Haemophilus influenzae*
  - *Moraxella catarrhalis*
  - *Mycoplasma pneumoniae*
  - Pertussis
  - *Streptococcus pneumoniae*
  - Tuberculosis
- Fungal
  - Blastomycosis
  - Coccidioidomycosis
  - Histoplasmosis

Cardiac Disease

- Congestive heart failure
- Pulmonary hypertension

Chronic Disease

- Ciliary dyskinesia
- Cystic fibrosis
- Eosinophilic lung disease
- HIV infection
- Immunodeficiency syndrome

Allergic Conditions

- Allergic rhinitis
- Asthma
- Serous otitis media

Mediastinal Tumors
Foreign Body Aspiration
Gastroesophageal Reflux
Environmental Irritants
Psychogenic Cough
Drug-induced Conditions
Sarcoidosis
Tourette Syndrome (ie, Tics)

Box 97.2. Diagnosis of Cough in the Pediatric Patient

- Time of onset in infancy or early childhood: congenital lung and heart diseases, tumor, gastroesophageal reflux disease, protracted bacterial bronchitis
- Quality: dry, wet (ie, productive), brassy, honking
- Duration: acute, subacute, chronic, recurrent
- Timing: during the day, at night, on awaking, with exercise
- Fever or upper respiratory infection associated with infectious origin
- Symptoms of rhinorrhea, sneezing, wheezing, and eczema are suggestive of allergic asthma or rhinitis
- Failure to thrive (indicative of chronic disease)

In children younger than 15 years of age, the common causes of chronic cough differ and include asthma, protracted bacterial bronchitis (PBB), upper airway cough syndrome, and nonspecific cough. The diagnosis of cough-variant asthma can be made on the basis of spirometry (for older children), exhaled nitric acid (for older children), and positive bronchodilator response. Protracted bacterial bronchitis is now recognized as among the most common causes of chronic wet cough, especially in children younger than 5 years. The diagnosis is based on clinical criteria of chronic wet cough in the child without other respiratory causes and resolution of the symptom after a 2-week course of antibiotics. Pathogens identified on bronchoscopy, which generally is not necessary for diagnosis, coincide with the common bacteria for upper airway infection. The term "repeated PBB" is used in cases in which more than 3 episodes occur in a single year. Repeated PBB may result in bronchiectasis, and mild immunodeficiency (eg, specific antibody deficiency) should be ruled out.

Clinical findings not compatible with the aforementioned diagnoses warrant consideration of the many less common entities (Box 97.1). Certain infections are noteworthy. Pertussis in the infant and older child may present with cough for months without a classical whoop. Tuberculosis and fungal infections, such as coccidioidomycosis, should also be considered in endemic areas or high-risk populations.

An unexplained persistent cough, primarily in toddlers, may be the result of foreign body aspiration even if the initial aspiration was not observed. A history of choking episodes is absent in approximately 50% of patients, and the chest radiograph appears normal in approximately 20% to 40% of children in whom foreign bodies are noted on bronchoscopy. The foreign object acts as a chronic airway irritant that stimulates coughing, and it may be the cause of recurrent infections.

In older children and adults, drugs such as β-adrenergic receptor antagonists and angiotensin-converting enzyme inhibitors can also induce a chronic cough, likely by increasing the sensitivity of the cough reflex.

Patients previously treated with cytotoxic drugs or thoracic radiation are at risk of interstitial lung disease. Cough along with symptoms of pancreatic insufficiency, recurrent bacterial pneumonia, or failure to thrive are suspicious for cystic fibrosis.

Cough with a history of dyspnea or hemoptysis should prompt evaluation for organic lung disease. Hemoptysis also should raise concerns for an underlying condition, such as bronchiectasis,

cavitary lung disease (ie, tuberculosis, bacterial abscesses), congestive heart failure, hemosiderosis, neoplasm, foreign bodies, vascular lesions, endobronchial lesions, menstrual (ie, ectopic endometrial tissue) bleeding, and clotting disorders.

After all identifiable causes of cough have been ruled out, the diagnosis of nonspecific cough may remain. Unlike a wet cough associated with a specific diagnosis, a nonspecific cough tends to be dry and in most cases resolves gradually over many weeks. Although nonspecific cough is a diagnosis of exclusion, many patients have history of prior viral disease (ie, post-viral syndrome). These patients are best treated with observation and reassurance. Unresolving daytime cough in the otherwise healthy child, however, may be indicative of an underlying neuropsychogenic presentation (eg, tic, Tourette syndrome) and may necessitate referral to a pediatric behavior specialist.

Evaluation

History

A complete history should be obtained of the child who presents with cough (Box 97.3). All symptoms should be noted. Vomiting with cough can be indicative of phlegm production and accumulation of mucus in the stomach, with resultant delayed gastric emptying. In some children with a chief report of vomiting, the cough itself precipitates the vomiting. Posttussive vomiting is characteristic of, but not specific for, pertussis.

Box 97.3. What to Ask

Cough

- How old is the child?
- How long has the child had the cough?
- How frequently does the child cough?
- Does the cough occur at night?
- Does exercise make the cough worse?
- Do any factors, such as environmental irritants, seem to precipitate the cough?
- Does the child have any related infectious symptoms, including fever and nasal congestion?
- Does the child have any other symptoms?
- Has the child had any previous episodes of coughing or associated symptoms?
- Has the child lost weight recently?
- What is the child's birth history?
- Has the child had any pulmonary injuries?
- What is the child's immunization status?
- Does the child have a history of recent travel?
- Has a family member had similar symptoms?
- Does the family have a history of pulmonary disease or allergies?
- Has the child been treated with any medications for the cough? Have they helped?
- Is the child taking any other medications?

The presence of a nighttime cough can be important. Pathologic coughs, including those caused by sinusitis with postnasal drip, gastroesophageal reflux, and asthma, are more likely to occur at night than during daytime.

Physical Examination

A complete physical examination should be performed on all children who present with cough. Growth parameters and vital signs are assessed. Skin is examined for evidence of cyanosis or atopy. Facial petechiae or subconjunctival hemorrhage are indicative of particularly forceful coughing. Extremities are evaluated for fingernail clubbing, which is a sign of chronic pulmonary disease. The nose is assessed for evidence of congestion. Allergic disease produces pale, edematous mucosa, whereas infection results in a more inflamed mucosa. Tympanic membranes are examined and mobility is tested because otitis media can produce a chronic cough. A history of postnasal drip on the sinus area is suggestive of sinus disease. Tonsillar hypertrophy and pharyngeal cobblestone may be suggestive of an underlying allergic disorder as the basis of the cough.

The character of the cough is another important factor, because certain etiologies may be associated with a specific type of cough. A barking cough is consistent with laryngeal edema and croup. A cough with stridor may occur with proximal airway disease, such as laryngomalacia, tracheomalacia, or laryngotracheobronchitis, or in the presence of a foreign body. An inspiratory whoop is characteristic of pertussis or parapertussis. Staccato cough in an infant can be the result of infection with *Chlamydia trachomatis*. The psychogenic or habitual cough is a strange, honking sound, somewhat like that of a Canada goose, that is absent at night and typically is worst and most disruptive during school classes. Chronic paroxysmal cough triggered by exercise, cold air, sleep, or allergens is often seen in patients with asthma. In contrast, a chronic productive (ie, wet) cough is suggestive of a suppurative process and may require further investigation to exclude PBB, bronchiectasis, cystic fibrosis, active infection, immunodeficiency, or congenital malformation.

Respiratory effort, including the use of accessory muscles, is noted. Close attention is paid to breath sounds, taking care to determine whether abnormal sounds occur in the inspiratory or expiratory phase of respiration. Stridor is classically an inspiratory sound (see Chapter 71), whereas wheezing is usually an expiratory sound. Chronic cough and wheeze are often noted in combination. Even in the absence of a history of wheeze, it is important to listen carefully for this finding during the physical examination. Wheezing that is characterized by many different pitches and by starting and stopping at varied points in the respiratory cycle is termed *polyphonic* and in association with cough is strongly suggestive of asthma. Other causes of polyphonic wheezing include viral bronchiolitis, obliterative bronchiolitis, bronchiectasis, bronchopulmonary dysplasia, congestive heart failure, immunodeficiency, bronchomalacia, and aspiration syndromes.

Monophonic wheezing, that is, a single, distinct, 1-pitch wheeze that starts and stops at 1 discrete time, and cough are always suspicious for large airway obstruction caused by foreign body or by tracheomalacia. Extrinsic airway compression such as occurs with

vascular rings, lymphadenopathy, and mediastinal tumors is also associated with monophonic wheezing. Tuberculosis should be considered in the child with a monophonic wheeze, particularly in geographic areas in which the disease is prevalent.

Prolongation of the expiratory phase is associated with wheezing and also is indicative of airway obstruction. Abnormal breath sounds are localized, if possible. Because the character of the cough can establish the diagnosis, listening to the cough is likely the most important aspect of the physical examination. Description of the cough by a parent or guardian may be less diagnostic.

Laboratory Tests

Laboratory studies usually are not necessary in the management of cough. Studies should be ordered with the aim of proving or disproving the most likely diagnosis in a specific patient and should be guided by the history and physical examination.

If the history, physical examination, and chest radiography are suspicious for an infectious etiology, a complete blood cell count with differential and a purified protein derivative skin test or interferon-γ release assay for tuberculosis may be ordered. If possible, appropriate cultures or a rapid polymerase chain reaction-based DNA screening should be done. Most children swallow their phlegm, so sputum may be difficult to obtain. Gastric aspirates can sometimes yield a reasonable sputum specimen for culture; however, this is uncomfortable and is used only when absolutely necessary, such as in the management of tuberculosis. Nasopharyngeal cultures and rapid antigen detecting assays are useful if an infectious etiology is suspected, such as pertussis or various respiratory viruses. If a non-infectious diagnosis is suspected (eg, cystic fibrosis, immunodeficiency), other laboratory tests should be ordered as appropriate (Table 97.1). Allergy skin testing or allergen-specific immunoglobulin E serum testing may be indicated to exclude inhalant allergy.

Imaging Studies

Chest radiography consisting of anteroposterior and lateral views remains the mainstay of the diagnostic evaluation of cough and should be obtained when there are definitive signs on physical examination and chronic cough. A lateral decubitus view can provide additional information about pleural fluid or air trapping. Inspiratory and expiratory radiographs can be obtained if a foreign body is suspected. An area of inflation that does not deflate on exhalation or remains present in the decubitus position is suggestive of a foreign body. Congenital lobar emphysema and unilateral emphysema (Swyer-James syndrome) are rare causes of focal or unilateral hyperinflation. If a nodular pulmonary lesion is found on radiography, bronchoscopy may be the next step to further define the lesion. Bronchiectasis is a characteristic of cystic fibrosis, immunodeficiency, primary ciliary dyskinesia, chronic aspiration, and previous history of severe infection (most commonly adenovirus and pertussis). If sinusitis is suspected, computed tomography of the sinuses can be performed; however, it has poor specificity and carries increased radiation exposure. An upper gastrointestinal radiographic series or a pH probe study aids in defining gastroesophageal reflux if the cough is associated with meals or episodes of vomiting, or if the cough occurs at night.

Table 97.1. Tests to Consider for Evaluation of Chronic Cough

Etiology	*Recommended Tests*
Allergy	Allergy skin test or blood-specific immunoglobulin E test
Asthma	PFT, bronchial hyperreactivity test (eg, methacholine challenge test), exhaled nitric oxide, trial of asthma treatments
Ciliary dyskinesia	Ciliary function tests
Congenital anomalies	Bronchoscopy, chest radiography, CT/magnetic resonance imaging, angiography
Cystic fibrosis	Sweat chloride test, genetic test
Fungal infections	Coccidioidomycosis: antibody assay (precipitin, complement fixation) Histoplasmosis: antibody assay (complement fixation, immunoprecipitating) Serum and urine antigen detection
Foreign body	Chest radiography, bronchoscopy
Gastroesophageal reflux	Barium swallow, 24-hour pH recording, and BAL
Idiopathic pulmonary fibrosis, autoimmune disease	PFT and diffusion CT, autoantibodies
Immunodeficiency	Quantitative immunoglobulins
Pertussis, chlamydia, or other infectious etiologies	Cultures, serology, polymerase chain reaction testing
Purulent infection	Cultures (eg, sputum, BAL), chest radiography, CT, microbiology immunology, sweat test
Sinusitis	Imaging of sinuses on radiography or CT, nasal endoscopy
Tuberculosis	Mantoux test, interferon-γ release assay

Abbreviations: BAL, bronchoalveolar lavage; CT, computed tomography; PFT, pulmonary function test.

In the child with asthma, the chest radiograph may be completely normal. In the cooperative child, further diagnostic testing with pulmonary function tests can be done to demonstrate airway restriction or obstruction. The most helpful test for the diagnosis of asthma may be the response to inhaled corticosteroids and bronchodilator.

Management

Therapy is focused on management of the suspected etiology. For cough-variant asthma without wheezing or respiratory distress, a trial of inhaled corticosteroids and bronchodilators is recommended for a period of a few weeks, after which response is assessed. Pretreatment and posttreatment spirometry, if available, provide additional evidence for a diagnosis of asthma. The young

child with wet cough with suspected PBB and bacterial sinusitis must be treated with appropriate antibiotics for at least 2 weeks. An immunodeficiency workup may be necessary for the child with recurrent history of PBB, sinusitis, and pneumonia. The child with cough that was preceded by choking should be evaluated for foreign body aspiration, whereas progressive cough with weight loss and fevers requires a workup for tuberculosis. Cough with seasonal sneezing and rhinorrhea may necessitate treatment for allergic rhinitis and postnasal drip. Symptoms may be the result of a combination of etiologies, and treatment of 1 pathology may result in only partial improvement; thus, management of the other causes is necessary for full resolution. For example, although therapy with intranasal steroid and antihistamines for 2 weeks results in partial resolution of cough, if GERD is also present the addition of a proton pump inhibitor may result in complete resolution of the symptom. The external ear is innervated by the vagus nerve, and removal of irritants from the external auditory canal may reduce the coughing. Medications that may provoke chronic cough, such as angiotensin-converting enzyme inhibitors, should be changed. For the irritant-induced cough, exposure to tobacco smoke and other irritants must be eliminated.

For many children, however, evidence of a specific disease may be lacking initially based on a detailed history, physical examination, imaging studies, and pulmonary function testing. Many physicians treating adult patients initiate empiric treatment for common etiologies based on American College of Chest Physicians 2006 guidelines: asthma, upper airway cough syndrome and GERD, even in the absence of findings. In children 15 years and older and adults with a normal history, physical examination, and chest radiography, it is reasonable to follow adult protocol. In younger children, the empirical approach also may be tried for the common entities for this age group: asthma, PBB, and upper airway cough syndrome.

When the cough is determined to be nonspecific based on ineffective empirical treatment and absence of other findings, it is necessary for the physician to maintain close communication with the patient and family to share the knowledge and reassure the parent(s) or guardian(s). Cough and cold preparations used to empirically manage allergic conditions in adults have been found to have unacceptable side effects in children. Expectorants and mucolytic agents in cough syrups have little effect on relieving cough. Most over-the-counter children's cough medications are marginally effective, provide no greater benefit than placebo, and may be associated with adverse or paradoxical reactions.

Chronic Cough

Viral infections are the predominant cause of acute cough in children, and reassurance may be the only treatment necessary until resolution of symptoms. Most children do not require treatment; benign agents, such as warm liquids with honey in children 1 year or older, often suffice.

Chronic cough often causes frustration and anxiety among patients and their parent(s)/guardian(s). The physician may be unable to provide a definitive etiology or timely relief of symptoms, resulting in patients seeking answers from multiple health professionals and trying many ineffective over-the-counter products. Key to effective management is developing a partnership with these patients and their families in seeking out the specific causes in a stepwise and thorough manner. It is important to inform patients and parents or guardians that irritation of the airways resulting in chronic cough often takes time to resolve even after the causes are properly managed and the improvement of cough symptoms should be measured in weeks rather than days.

Prognosis

With thoughtful evaluation, it is usually possible to identify the causes of acute and chronic cough. Most symptoms resolve with appropriate therapy. If the cough persists with treatment, alternate diagnoses should be considered.

CASE RESOLUTION

The child's cough began acutely and developed into a chronic cough. The boy has no history of allergies or symptoms consistent with an infectious process. Physical examination reveals localized wheezing. Chest radiography reveals hyperinflation of the right lung. The boy's symptoms and presentation are most consistent with foreign body aspiration, and he is admitted to the hospital for bronchoscopy.

PART 7

Hematologic Disorders

CHAPTER 98

Anemia

Joseph L. Lasky III, MD, FAAP; Moran Gotesman, MD; and Eduard H. Panosyan, MD

CASE STUDY

An 18-month-old girl is brought to the office with a 3-day history of cough, rhinorrhea, low-grade fever, mild scleral icterus, and pallor. During her first week after birth, she had hyperbilirubinemia of unknown etiology that required phototherapy. Her family history is significant for mild anemia in her father; the cause of his condition is unknown. A paternal aunt and grandfather had cholecystectomies while in their 30s.

On physical examination, the girl is tachycardic and tachypneic (no respiratory distress) with scleral icterus and pallor. Her spleen is palpable 3 cm below the mid-costal margin. The remainder of her examination is normal.

Questions

1. What hemoglobin and hematocrit values are associated with anemia?
2. What are the presenting signs and symptoms of children with anemia?
3. What is the appropriate initial evaluation of children with anemia?
4. What emergency situations in children who present with anemia should be recognized by the primary pediatrician?
5. When should a child with anemia be referred to a hematologist?
6. How is the family history relevant in the evaluation of anemia?

Anemia is caused by a reduction in hemoglobin concentration or red blood cell (RBC) count, with resulting decreased oxygen-carrying capacity of blood. Anemia is defined as a hemoglobin or hematocrit value that is less than 2 standard deviations below the mean for age and sex. With this statistical definition, 2.5% of the healthy population can be categorized as having anemia. These values vary throughout infancy and childhood as hematopoiesis evolves from fetal to adult type, and it is important to reference normal age- and sex-related values when interpreting a hemoglobin or hematocrit result (Table 98.1). Additionally, racial variation exists, with black children having lower average hemoglobin values than white children. Cardiopulmonary status should also be considered, because children with cyanotic heart disease or chronic respiratory insufficiency typically have hemoglobin values higher than the normal range and may be functionally anemic when the hemoglobin value falls, even if it is within the lower range of normal.

Epidemiology

Iron deficiency is the most common cause of anemia in childhood, occurring most frequently during late infancy through the first few years of age and again during adolescence. This prevalence pattern corresponds to periods of rapid growth and, when combined with poor dietary intake, can predispose to iron deficiency. Other contributing factors to iron deficiency include preterm birth, blood loss (most commonly menstrual or gastrointestinal [GI]), and GI conditions associated with decreased iron absorption.

Other epidemiologic factors that contribute to anemia are presented in Box 98.1. Anemias with a genetic etiology, including hemoglobinopathies (eg, sickle cell disease, thalassemias), RBC enzyme deficiencies (eg, glucose-6-phosphate dehydrogenase [G6PD], pyruvate kinase), and RBC membrane disorders (eg, hereditary spherocytosis), are commonly diagnosed in childhood. The highest incidence of sickle cell disease, thalassemia, and G6PD deficiency is in individuals of African, Mediterranean, and Southeast Asian descent within the "malaria belt" near the equator, likely reflecting an evolutionary advantage against malaria. Dietary factors can cause impaired hematopoiesis, as in iron, folate, or vitamin B_{12} deficiency. Ingestion of oxidants (eg, fava beans, medications) can trigger hemolysis in persons with G6PD deficiency. Ingestion of toxins, such as lead, can also result in impaired hematopoiesis. Lead poisoning occurs more commonly in children who live in cities and older housing. In an otherwise healthy child, viral infections can cause a pure red cell aplasia (eg, transient erythroblastopenia of childhood), an autoimmune hemolytic anemia, or an aplastic anemia. Children with congenital hemolytic anemias are at risk for hemolytic and aplastic crises associated with infectious illnesses.

Clinical Presentation

The clinical presentation of anemia depends on the age of the child, severity and cause of the anemia, and rapidity of onset (Box 98.2). Typically, anemia is detected on routine screening or as part of an evaluation for an acute illness in a child who is asymptomatic and has no significant physical findings. Children with gradual onset of anemia may be relatively asymptomatic, because time has allowed for compensatory mechanisms, such as plasma volume expansion and increased cardiac contractility, to take place. With severe

Box 98.1. Epidemiologic Factors Related to Anemia

Genetic

- Autosomal-dominant: hereditary spherocytosis
- Autosomal-recessive: most Embden-Meyerhof pathway enzyme deficiencies (eg, pyruvate kinase deficiency), most hemoglobinopathies (eg, sickle cell disease, β-thalassemia)
- X-linked: G6PD deficiency

Ethnic

- Northern European: hereditary spherocytosis, pyruvate kinase deficiency
- Mediterranean (ie, Italian, Greek, North African): β-thalassemia, G6PD deficiency
- African: sickle cell disease, hemoglobin C, hemoglobin D, G6PD deficiency, α-thalassemia trait, hereditary elliptocytosis
- Southeast Asian: α-thalassemia, hemoglobin E, G6PD deficiency

Dietary

- Poor dietary intake (ie, iron, folate, or vitamin B_{12} deficiency)
  - — Iron (excessive cow's milk intake)
  - — Folate (excessive goat's milk intake)
  - — Vitamin B_{12} (vegan diet)
- Poor gastrointestinal absorption
  - — Iron, absorbed in duodenum (small bowel disease)
  - — Folate, absorbed in duodenum and jejunum (small bowel disease)
  - — Vitamin B_{12}, absorbed in terminal ileum (surgical resection, pernicious anemia, small bowel disease)
- Ingestion of oxidants (medications such as sulfa drugs, fava beans in G6PD deficiency)
- Toxins (lead)

Socioeconomic

- Living near highways: increased incidence of lead poisoning
- Poverty: associated with pica and lead poisoning

Infectious

- Malaria: heterozygous form of sickle cell disease, thalassemia, G6PD-deficiency confer protection
- Viral infections: transient erythroblastopenia of childhood, autoimmune hemolytic anemias, hemolytic crisis in patients with congenital hemolytic anemias
- Parvovirus: aplastic crisis in patients with hemolytic anemias
- Viral hepatitis: aplastic anemia

Abbreviation: G6PD, glucose-6-phosphate dehydrogenase.

Box 98.2. Diagnosis of Anemia in Children

- Pallor, fatigue
- Scleral icterus
- Hepatosplenomegaly
- Lymphadenopathy
- Weight loss
- Congestive heart failure

anemia, easy fatigability and exercise intolerance can develop, and pallor, fatigue, headache, dizziness, and irritability may occur. Pallor, tachycardia, tachypnea, edema, and, in severe cases, outright congestive heart failure (CHF) may be noted on examination. Children with an abrupt drop in hemoglobin from blood loss or hemolysis present more acutely with signs of tachycardia, tachypnea, and possible hypotension and shock. If the anemia is caused by acute hemolysis, accompanying jaundice, icterus, and dark urine may be seen.

Pathophysiology

Erythrocytes develop from pluripotent stem cells within the bone marrow under the influence of various hematopoietic growth factors. Erythropoietin is the primary growth factor regulating RBC production and is produced primarily by renal interstitial peritubular cells. The primary function of the erythrocyte is the delivery of oxygen to tissues for aerobic metabolism, and hemoglobin is the main intracellular protein of the erythrocyte. Hemoglobin consists of 4 polypeptide subunits, each containing an active heme group that is capable of binding to an oxygen molecule. A normal erythrocyte has a life span of approximately 120 days and is subsequently removed from circulation as it passes through the reticuloendothelial system. Under steady state conditions, the daily 1% loss of aged erythrocytes is compensated by a normal active erythropoiesis. It is also important to note that red cell loss is greater (1.5%) and life span is shorter (90 days) during the late fetal and early neonatal period. Anemia occurs when an imbalance exists between erythrocyte production and destruction. It can arise from conditions resulting in decreased production, increased destruction (ie, hemolysis), or blood loss. Deficient production may be caused by nutrient deficiency (ie, iron, folate, vitamin B_{12}), bone marrow failure (acquired or inherited), or bone marrow infiltration (eg, malignancy). Increased destruction of erythrocytes can occur as a consequence of disorders intrinsic to the erythrocyte (eg, hemoglobinopathy, enzymopathy, membranopathy) or extrinsic factors (immune or nonimmune etiologies).

Differential Diagnosis

The differential diagnosis of anemia can be determined by considering the underlying mechanism of anemia, whether decreased production, increased destruction, or blood loss, and the size of the erythrocyte (ie, mean corpuscular volume [MCV]). The differential diagnosis of anemia based on pathophysiology and erythrocyte size can be found in Table 98.2 and Box 98.3. In determining the cause of

Table 98.2. Differential Diagnosis of Anemia Based on Pathophysiology

Pathophysiologic Mechanism	*General Diagnostic Features*	*Specific Diagnostic Features*
Decreased Production of RBCs	***Evidence of decreased production: ↓ reticulocytes***	
Marrow infiltration		Pancytopenia caused by bone marrow infiltration with leukemia, neuroblastoma, etc
Secondary to tumor infiltration		
Secondary to infiltration with nonmalignant cells		
Lipidoses		Lipid-filled macrophages
X-linked lymphoproliferative disorder		Hepatosplenomegaly
Osteopetrosis		Poor growth and bony encroachment on cranial nerve foramina
Decreased production of hematopoietic elements (bone marrow failure)		
Decreased RBC production only		
Constitutional: Congenital hypoplastic anemia		Multiple physical deformities
Acquired		
Acquired pure red cell aplasia		Associated with thymoma
Transient erythropenia of childhood		Associated with parvovirus infection
Decreased RBC and WBC production		
Constitutional		
Fanconi syndrome		Multiple physical deformities
Shwachman syndrome		Pancreatic insufficiency

(*Continued*)

Table 98.2. Differential Diagnosis of Anemia Based on Pathophysiology (*continued*)

Pathophysiologic Mechanism	*General Diagnostic Features*	*Specific Diagnostic Features*
Decreased production of RBCs, WBCs, and platelets (aplastic anemia)		
Constitutional		
Fanconi syndrome		Multiple physical deformities
Shwachman syndrome		Pancreatic insufficiency
Acquired: aplastic anemia		History of hepatitis B, toxin exposure, idiopathic
Dietary deficiency		
Iron deficiency		↓ MCV, ↓ MCH, ↑ RDW, ↓ serum iron, ↓ serum ferritin, excessive cow's milk intake
Folic acid deficiency		↑ MCV, ↑ RDW, megaloblastic marrow, low serum and RBC folate
Vitamin B_{12} deficiency		↑ MCV, ↑ RDW, megaloblastic marrow, low serum B_{12} levels, Schilling test
Vitamin C deficiency		Clinical scurvy
Protein deficiency		Kwashiorkor
Hypothyroidism		Low T4, elevated TSH
Increased Production (Hemolysis)	***Evidence of hemolysis: ↑ reticulocytes***	
Intrinsic RBC defects		
RBC membrane defects (spherocytosis, elliptocytosis)	Hyperbilirubinemia	+ Osmotic fragility, spectrin deficiency (hereditary spherocytosis)
RBC enzyme defects (G6PD deficiency, pyruvate kinase)	LDH (RBC)	+ Enzyme assays
Hemoglobin defects	MCV may be increased if reticulocytes high	
1. Qualitative defects (sickle cell anemia, HbC, HbE)		Hb electrophoresis
2. Quantitative defects (thalassemia)	MCV low with thalassemia	HbA_2 (β-thalassemia), targets cells
Extrinsic RBC disorders		
Immune		
Isoimmune hemolytic anemia (eg, ABO, Rh incompatibility)		+ Antiglobulin test
Autoimmune hemolytic anemia		
Idiopathic		+ Antiglobulin test
Secondary: postviral, autoimmune disorders, Evans syndrome		+ ANA Concomitant thrombocytopenia or neutropenia Concomitant renal disease (HUS)
Nonimmune (eg, DIC, HUS)		
Blood Loss	***Reticulocytes normal (acute loss), ↑↓ (chronic)***	
Overt (eg, splenic sequestration, gastrointestinal, nasal bleeding)	↑ Reticulocytes (chronic loss, not iron deficient)	Sickle cell anemia (splenic sequestration)
Occult (eg, bleeding Meckel diverticulum, pulmonary hemosiderosis)	↓ Reticulocytes (chronic loss, iron deficient); may have rapidly falling hematocrit	Pulmonary infiltrates iron deficiency (pulmonary hemosiderosis)

Abbreviations: ANA, antinuclear antibodies; DIC, disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase; Hb, hemoglobin; HUS, hemolytic uremic syndrome; LDH, lactate dehydrogenase; MCH, mean corpuscular hemoglobin; MCV, mean corpuscular volume; RBC, red blood cell; RDW, red cell distribution width; TSH, thyroid-stimulating hormone; WBC, white blood cell.

Box 98.3. Differential Diagnosis of Childhood Anemias Based on Red Blood Cell Size

Hypochromic, Microcytic Anemia (Low MCV)

- Iron deficiency anemia
- Thalassemias
- Lead poisoning
- Anemia of inflammation or chronic disease

Normochromic, Normocytic Anemia (Normal MCV)

- High reticulocyte count
  - — Intrinsic red cell disorders
- Hemoglobinopathies (hemoglobin SS disease)
- Enzymopathies (G6PD, PK)
- Membranopathies (HS)
  - — Extrinsic red cell disorders
- Immune-mediated
- Nonimmune (thrombotic thrombocytopenic purpura [eg, hemolytic uremic syndrome])
- Low reticulocyte count
  - — Pure red cell aplasia (congenital hypoplastic anemia, TEC)
  - — Pancytopenia (marrow failure or infiltration)

Macrocytic Anemia (Increased MCV)

- Folate deficiency
- Vitamin B_{12} deficiency
- Congenital hypoplastic anemia
- Myelodysplastic syndromes
- Chemotherapy agents

Abbreviations: G6PD, glucose-6-phosphate dehydrogenase; HS, hereditary spherocytosis; MCV, mean corpuscular volume; PK, pyruvate kinase; SS, 2 sickle β-globin genes; TEC, transient erythroblastopenia of childhood.

anemia, the reticulocyte count is the most useful test in ascertaining whether the anemia is caused by decreased production or increased destruction. A reduced reticulocyte count indicates decreased marrow production, whereas an elevated reticulocyte count is strongly suggestive of hemolysis. Anemia based on erythrocyte size can be classified as microcytic (low MCV), normocytic (normal MCV), or macrocytic (high MCV). Microcytic anemias reflect a defect in hemoglobin synthesis and are most commonly the result of iron deficiency, thalassemia, lead poisoning, and chronic disease. Macrocytic anemias reflect a relative decrease in DNA synthesis during impaired erythropoiesis and are usually of nutritional origin (ie, vitamin B_{12} or folate deficiency). The many other causes of anemia commonly fall into the normocytic category and can be further divided based on the reticulocyte count. Etiology and erythrocyte size, the 2 systems for classification of anemia, are not mutually exclusive—simultaneous application of these systems enables the pediatrician to make a primary diagnosis of anemia and determine its probable causes.

Microcytic Anemias

Iron deficiency is the most frequent cause of microcytic anemia in childhood and occurs as a result of inadequate intake and increased requirements resulting from growth, blood loss, and malabsorption of iron. As iron deficiency evolves, depletion of iron stores occurs first, followed by iron-deficient erythropoiesis without anemia, finally resulting in iron deficiency anemia. The combination of rapid growth and inadequate iron intake is responsible for the common occurrence of iron deficiency anemia in toddlers and adolescents. Many young newborns and infants are spared because of adequate iron stores acquired in utero and the ingestion of iron-fortified formulas. Exclusively breastfed newborns and infants may require supplemental iron before 6 months of age and should be evaluated for anemia. Preterm newborns are the exception, because they have lower baseline iron stores. (Much of the iron stores are acquired by the fetus in the third trimester.) As iron stores become depleted during late infancy and cow's milk is introduced into the diet, the ever-growing older infant/toddler becomes at risk for iron deficiency. Excessive intake of cow's milk during the first few years after birth predisposes to iron deficiency because cow's milk has minimal bioavailable iron (<1 mg/L). Large intake of cow's milk results in early satiety and prevents adequate intake of other iron-containing foods. Iron deficiency is often further compounded by trace amounts of GI blood loss resulting from GI mucosal damage or cow's milk allergy enteropathy. Adolescents, particularly menstruating females, are also prone to iron deficiency because of the pubertal growth spurt and suboptimal dietary habits. In young infants and children older than 3 years, purely dietary iron deficiency is uncommon, and an evaluation for blood loss or malabsorption is warranted. Blood loss can occur as hematochezia or melena (eg, inflammatory bowel disease, diarrhea, Meckel diverticulum, polyp, ulcer), menorrhagia, epistaxis, hematuria, or rarely as pulmonary bleeding (eg, pulmonary hemosiderosis). Iron is absorbed primarily in the duodenum, and several dietary factors (eg, coffee, tea) as well as primary intestinal disorders can impair absorption (ie, celiac disease).

The *thalassemias* are a heterogeneous group of inherited anemias that are characterized by impaired or absent synthesis of the α or β chains that make up the normal adult hemoglobin tetramer. Beta-thalassemias are caused by a decrease in the production of β-globin chains. Anemia observed in the severe forms of β-thalassemia occurs as a result of ineffective erythropoiesis. This is because of the instability of excess α chains, which precipitate and cause oxidative damage to the cell membrane, resulting in premature destruction of the erythrocyte within the bone marrow. Erythrocytes that do survive in circulation have a shortened life span because of increased hemolysis. Severe forms (ie, compound heterozygous or homozygous state) are classified as β-thalassemia intermedia or β-thalassemia major depending on the clinical presentation and degree of anemia. Individuals with β-thalassemia major develop a severe anemia during the first year after birth because decreasing levels of fetal hemoglobin ($\alpha 2\gamma 2$) cannot be replaced by normal adult hemoglobin ($\alpha_2\beta_2$). Hemoglobin values fall to the range of 3 to 4 g/dL, and regular transfusions are required. Individuals with β-thalassemia intermedia usually present later in life and do not require early intervention with blood transfusions. In these patients, hemoglobin values are in the 7 to 8 g/dL range, and individuals may be intermittently transfusion dependent. Individuals with β-thalassemia

trait (ie, β-thalassemia minor), the heterozygous form, have a mild microcytic anemia with a hemoglobin that is approximately 2 g/dL below the normal mean for age. Clinically it is an asymptomatic anemia; however, it is of diagnostic relevance in that it must be distinguished from iron deficiency anemia, which may be a concomitant problem.

The α-thalassemias are caused by a decrease in the production of α chains and typically are milder than β-thalassemias. This is because the excess of β chains that occurs in α-thalassemia is more stable, resulting in less membrane damage and intramedullary erythrocyte destruction. Humans have 4 α-globin genes. Individuals with a deletion of 1 α-globin gene are silent carriers and are asymptomatic, with a normal hemoglobin value and MCV. Individuals with the 2-gene deletion have α-thalassemia trait and have a very mild microcytic anemia that is asymptomatic. Three-gene deletion causes hemoglobin H disease, a moderate chronic hemolytic anemia that may be intermittently transfusion-dependent. This occurs primarily in individuals of Southeast Asian descent. Four-gene deletion causes hydrops fetalis, an almost universally fatal condition that essentially results in fetal CHF and intrauterine demise.

Although lead inhibits heme synthesis and red cell function on many levels, microcytic anemia is a late finding of lead intoxication. Iron deficiency and lead poisoning often occur together, and the relationship between the two is complex. Pica is a risk factor for lead ingestion. In the presence of lead, iron uptake by the erythrocyte is diminished and iron deficiency increases lead retention and toxicity. Intestinal absorption and uptake of lead by red cells is decreased in the presence of iron. Additionally, iron deficiency and lead poisoning both tend to occur in individuals of lower socioeconomic status, and both are exacerbated by concomitant nutritional deficiencies.

Anemia of inflammation or chronic disease may occur in children with chronic infections, generalized inflammatory disorders (eg, rheumatoid arthritis), and some cancers. It is characterized by a decrease in serum iron and iron-binding capacity, an increase in ferritin, and the presence of iron in bone marrow macrophages indicating impaired iron mobilization from storage sites. Increased synthesis of hepcidin, an iron regulatory hormone, under the influence of inflammatory cytokines seems to be responsible for the hypoferremia observed in anemia of inflammation. Generally, anemia of inflammation is mild and may be microcytic or normocytic.

Macrocytic Anemias

Folate and vitamin B_{12} deficiency cause a macrocytic anemia as a result of defective erythroid precursor nuclear maturation and megaloblastic changes in the bone marrow. Folate is absorbed in the duodenum and jejunum and is widely available in meats, green leafy vegetables, and cereals. Because of the ubiquity of folate, dietary deficiency is uncommon; however, newborns and infants fed exclusively goat's milk are at risk because of the exceedingly low levels of folate in goat's milk. Individuals with chronic hemolytic anemias may also become folate-deficient because of high bone marrow activity and increased demand.

Vitamin B_{12} is available from animal sources and is actively absorbed in the terminal ileum in association with intrinsic factor. Vitamin B_{12} deficiency can occur in individuals with a strict vegan diet (or in exclusively breastfed newborns and infants of women following a strict vegan diet); however, it usually occurs as a result of malabsorption. Decreased absorption can occur in the setting of pernicious anemia secondary to decreased intrinsic factor, surgical resection (ie, following necrotizing enterocolitis), and GI disease.

Other causes of macrocytic anemias include congenital hypoplastic anemias, myelodysplastic syndromes, chemotherapeutic agents (eg, methotrexate), and hypothyroidism.

Normocytic Anemias

Normocytic anemias can be classified as hemolytic (ie, associated with a reticulocytosis) or hypoplastic (eg, reticulocytopenia). Hemolytic anemias can be further divided into disorders that are intrinsic or extrinsic to the RBC. Intrinsic RBC disorders include hemoglobinopathies, enzymopathies, and membranopathies.

Sickle cell disease is the most common hemoglobinopathy worldwide and is concentrated in individuals of African or mixed African descent. Inheritance of 2 sickle β-globin genes (ie, hemoglobin SS) is the most common form; however, other significant sickle syndromes include hemoglobin SC, $S\beta^+$ thalassemia, and $S\beta^0$ thalassemia. Hemolytic anemia and painful vasoocclusive episodes are the hallmarks of sickle cell disease. The anemia is generally well tolerated, with hemoglobin values ranging from 6.5 to 8.5 g/dL with an associated reticulocytosis (5%–15%). The 2 most common hematologic complications in sickle cell disease are aplastic crises and splenic sequestration, both of which can cause an acute drop in hemoglobin. Aplastic crises typically are the result of infection with parvovirus, which temporarily causes the complete cessation of red cell production. Splenic sequestration occurs most commonly in infants and young children with sickle cell disease, often in association with a viral illness. Large amounts of blood can be quickly trapped in the spleen, causing hypovolemia, shock, and massive splenomegaly. See Selected References for further information on and excellent reviews of this multisystem disorder.

Glucose-6-phosphate dehydrogenase deficiency, the most common RBC enzyme deficiency, is an X-linked recessive hereditary disease that renders the red cell susceptible to oxidant stress and hemolysis. Several variants have been defined; however, the most common variants are those associated with acute intermittent hemolytic anemias with exposure to oxidant stresses (eg, fava beans, medications). Variants associated with chronic hemolytic anemias are very rare.

Pyruvate kinase deficiency is the most common red cell enzyme defect and causes a chronic congenital hemolytic anemia. The degree of hemolysis is variable, ranging from a mild, fully compensated hemolytic process without anemia to a transfusion-dependent anemia. Individuals with severe hemolysis may be chronically jaundiced and may develop the clinical complications of chronic hemolytic states (eg, gallstones, transient aplastic crises in association with infections, folate deficiency, and infrequently, skin ulcers). *Hereditary spherocytosis* is the most common red cell membranopathy and is characterized by the presence of spherical-shaped erythrocytes on the peripheral blood smear. Increased membrane fragility caused by defects in proteins of the red cell membrane

(ie, spectrin, ankyrin, band 3, protein 4.2) results in membrane vesiculation and membrane loss and the assumption of a spheroidal shape. Hemolysis occurs when these spherocytes are then trapped within the spleen. Clinically, the degree of hemolysis varies from mild anemia to severe transfusion dependence. Complications of a chronic hemolytic state, such as gallstones, aplastic crises, and folate deficiency, also may be observed.

Hemolytic anemias that are caused by factors extrinsic to the red cell can be further classified as immune-mediated or nonimmune. Immune-mediated anemias may be the result of alloantibodies that occur in the setting of neonatal Rh or ABO incompatibility or transfusion reactions. Autoantibodies may occur in association with infection, autoimmune disorders, malignancy, or drugs. In children, autoantibodies (ie, warm immunoglobulin G, cold immunoglobulin M) are often seen in association with a viral illness or mycoplasma infection. Nonimmune hemolytic anemias include thrombotic thrombocytopenic purpura and macroangiopathy anemias caused by a myriad of etiologies, including infections, drugs, toxins, burns, and artificial heart valves.

Anemia resulting from reticulocytopenia can be congenital or acquired and can occur in isolation or in the setting of pancytopenia. *Congenital hypoplastic anemia* (ie, *Diamond-Blackfan anemia*) is a ribosomal disorder that causes a congenital pure red cell aplasia that presents early in infancy. The bone marrow typically shows red cell aplasia with a paucity of red cell precursors, and the red cells may be normocytic or macrocytic. Associated congenital anomalies, such as craniofacial anomalies, radial abnormalities, and renal and cardiac defects, occur in approximately 25% of affected individuals. Transient erythroblastopenia of childhood is an acquired anemia resulting from reticulocytopenia that typically occurs following a viral illness. Usual age of presentation is between 2 and 3 years in an otherwise healthy child, and complete recovery is the natural course. Aplastic processes, such as idiopathic aplastic anemia and hereditary Fanconi syndrome, usually present with neutropenia or thrombocytopenia in addition to anemia.

Evaluation

History

When evaluating an infant or child with anemia, the age, rapidity of symptom onset, MCV, and suspected underlying mechanism of anemia direct the history (Box 98.4). In most instances, it is important to inquire about dietary habits, with particular attention paid to the type and amount of milk ingested per day (number of bottles/ounces). Ingestion of more than 24 ounces of cow's milk per day should raise suspicion of iron deficiency anemia. Medication use, potential toxin ingestion (eg, lead), or a history of pica should be determined as well. Additionally, potential sources of blood loss (eg, hematochezia, melena, menorrhagia, hematuria, epistaxis, pulmonary) should be addressed. Acute onset of jaundice, icterus, or dark urine is suggestive of hemolysis and should elicit questions about possible triggers (eg, fava beans, medications, illnesses). A personal history of neonatal hyperbilirubinemia or a family history of anemia, gallstones, cholecystectomy, or splenectomy is suggestive of a congenital hemolytic anemia. Acute onset of hemolysis with a viral illness is consistent with an autoimmune hemolytic anemia. Individuals with a marrow failure syndrome often present with a prolonged history of increased fatigue and pallor, with occasional history of previous red cell transfusions prior to diagnosis. In acquired marrow failure states, such as aplastic anemia, the history is occasionally consistent with antecedent hepatitis, a viral syndrome, or, rarely, exposure to toxins (eg, benzene, toluene-containing compounds), or use of oral chloramphenicol, which is commonly available over the counter in Latin America.

Box 98.4. What to Ask

Anemia

- Does the child eat meat?
- Does the child drink too much milk (>24 oz/day)?
- Has the child had any bleeding recently?
- Has the child had a recent illness?
- Is the child taking any medications?
- Have the child's eyes appeared yellow?
- Does the child have a family history of anemia, jaundice, gallstones, or splenectomy?
- Did the child or siblings have jaundice at birth requiring phototherapy or exchange transfusion?
- Was the child born preterm, and if so, how early?

Physical Examination

Most children who present with anemia have a normal physical examination. Depending on the degree of anemia, pallor, tachycardia, or tachypnea may be present. In severe cases of anemia (ie, hemoglobin <3 g/dL) with chronic onset and in moderate anemia (ie, hemoglobin 3–7 g/dL) with acute onset from blood loss, CHF can occur. Other physical findings are unique to certain red cell disorders. Infants with sickle cell disease may present with dactylitis, a form of painful crisis that manifests as swelling of the digits associated with pain and sometimes fever. Splenomegaly can occur with sickle cell disease (in younger children, prior to autosplenectomy), β-thalassemia major and intermedia, and red cell membrane disorders, most commonly hereditary spherocytosis. In children with severe chronic hemolysis, regardless of etiology, classic facies (often called thalassemic facies) with frontal bossing and flattened nasal bridge can occur, caused by thinning of the facial bones from brisk intramedullary hematopoiesis. Children with congenital hypoplastic anemia or Fanconi syndrome may have physical anomalies, such as thumb or radial abnormalities, short stature, cardiac or renal anomalies, and developmental delay. Aplastic anemia or malignant infiltration of the bone marrow may present with concomitant neutropenia and thrombocytopenia. In the patient with neutropenia (ie, absolute neutrophil count <1,000/mL), signs of fever or infection may be present. If the patient is also thrombocytopenic, bruises, petechiae, and mucosal bleeding from the mouth, nose, and GI tract may also be present. With malignancy, such as leukemia, lymphadenopathy and hepatosplenomegaly may also be observed. Severe

Vitamin B_{12} deficiency can result in neurologic findings such as ataxia, impaired vibratory sensation, or even psychiatric symptoms.

Laboratory Tests

Complete blood cell count and peripheral blood smear provide a wealth of information and should be evaluated closely to narrow the differential diagnosis. The first step is to determine if the child is truly anemic by referencing the normal hemoglobin and hematocrit values for the child's age and sex. The second step is to evaluate the red cell indices. The MCV is a direct measure of red cell size and allows for classification of the anemia as microcytic, normocytic, or macrocytic (Figure 98.1). The mean corpuscular hemoglobin is a calculated value that typically parallels the MCV. The mean corpuscular hemoglobin concentration is a measure of the red cell hydration status and is useful when elevated, because an elevated level indicates the presence of spherocytes. The red cell volume distribution width reflects the variation in red cell size; typically, it is normal in patients with thalassemia trait and elevated in the setting of iron deficiency. The RBC count can be useful because it is typically elevated (>5 million/mL) in a child with thalassemia trait and decreased in iron deficiency anemia. Review of the white blood cell and platelet count provides information as to whether other cell lines are affected. The peripheral blood smear provides information on RBC morphology characteristic of different red cell disorders (eg, sickle cells, spherocytes, elliptocytes, schistocytes, bite cells). The presence of polychromasia is suggestive of a hemolytic process. White blood cell morphology can also suggest the etiology of the anemia, such as hypersegmented neutrophils in folate or vitamin B_{12} deficiency and basophilic stippling in lead poisoning. The reticulocyte count provides clues to the underlying mechanism of anemia. An elevated reticulocyte count is consistent with hemolysis or blood loss, whereas a reduced or normal reticulocyte count in the setting of anemia suggests a production problem. If hemolysis is evident, a direct antiglobulin test (ie, Coombs test) should be performed to determine if this is an immune-mediated process. Hemoglobin analysis by isoelectric focusing or high-pressure liquid chromatography is used in the diagnosis of sickle cell disease and related disorders and can help distinguish between α- and β-thalassemia traits.

With the complete blood cell count, peripheral blood smear, and reticulocyte count, a focused differential diagnosis can be generated, and more specific testing can be performed. Additional studies specific for individual hemolytic diseases or particular diseases secondary to marrow failure are summarized in Table 98.2.

Imaging Studies

Imaging studies are rarely required in the evaluation of children with anemia. If performed in children with chronic hemolytic disorders, radiography may reveal "hair-on-end" appearance of bones

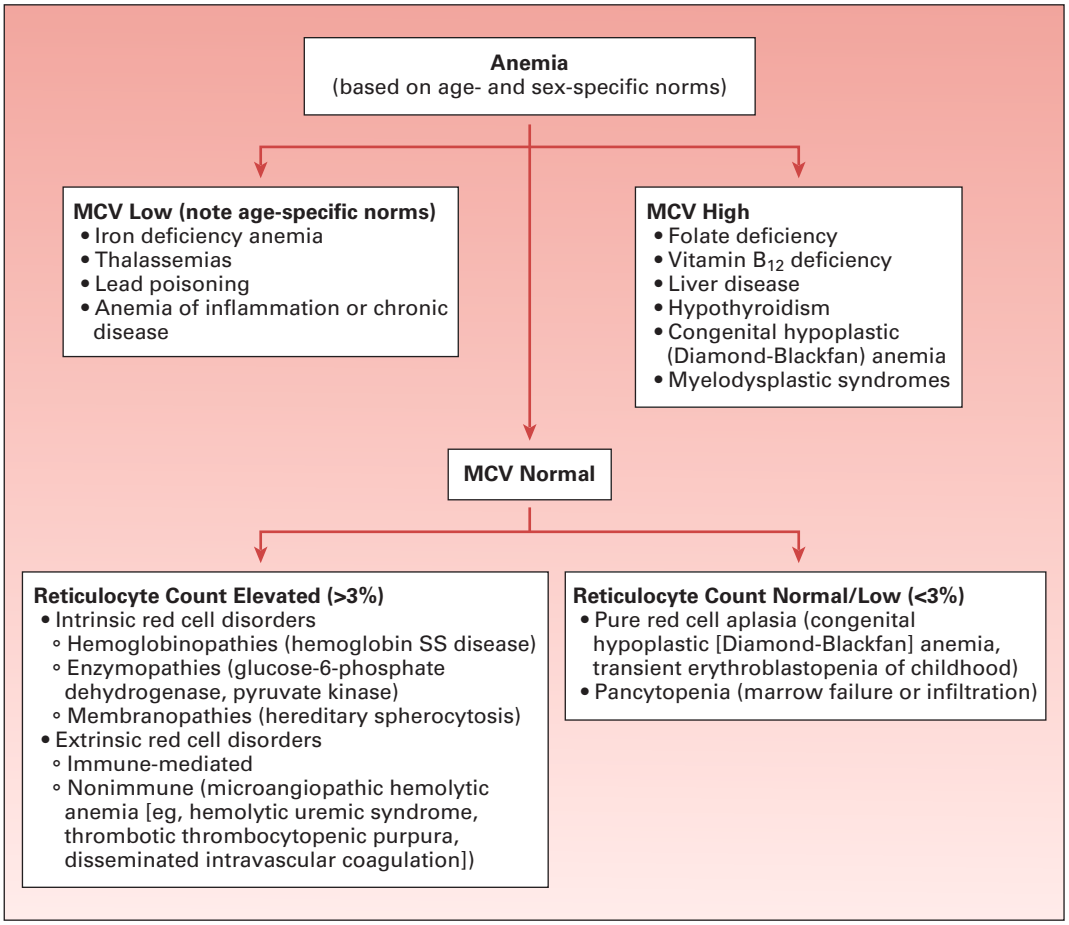

Figure 98.1. Anemia mean corpuscular volume (MCV) classifications.

resulting from increased hematopoiesis. Patients who have anemia associated with lead poisoning may have lead deposition, referred to as "lead lines," in the long bones. Patients with congenital hypoplastic anemia or Fanconi syndrome may have skeletal abnormalities visible on plain radiography.

Management

The treatment of anemia varies depending on the etiology. Nutritional anemias require dietary counseling and nutrient supplementation. With iron deficiency anemia, oral iron supplementation (3–6 mg/kg per day elemental iron divided into 2–3 doses) should generate a brisk reticulocytosis within 7 days, and the hemoglobin should increase by 1.0 g/dL per week thereafter. Therapy should be continued for an additional 6 to 8 weeks after the hemoglobin has normalized to replete iron stores, which can be assessed by monitoring ferritin levels. Dietary education is key to ensure that milk intake is reduced and that iron-rich foods are encouraged. Failure to respond to iron therapy is most commonly the result of noncompliance; however, alternative diagnoses (eg, thalassemia trait), ongoing blood loss, or malabsorption states should also be considered.

Patients with severe thalassemia syndromes (ie, β-thalassemia major) are transfusion-dependent, often requiring transfusions every 3 to 4 weeks to maintain a hemoglobin level ranging from 9 to 10.5 g/dL. With transfusion therapy, progressive iron deposition in tissues occurs, resulting in cardiac, hepatic, and endocrinologic complications, which can be fatal if not prevented. Iron chelation with deferoxamine or deferasirox has improved survival; however, compliance remains an issue. Hematopoietic stem cell transplantation has been performed in patients with severe thalassemias and sickle cell disease.

Depending on the degree of hemolysis and compensation, individuals with congenital hemolytic anemias may require no transfusions, intermittent transfusions to manage anemia during an aplastic crisis, or regular transfusions. Individuals may require folate supplementation and should be monitored for potential complications such as gallstones and aplastic crises. The more severely affected individuals may benefit from splenectomy. Individuals with G6PD deficiency should be counseled on the avoidance of potential triggers of hemolysis.

Two anemia-related conditions—splenic sequestration and severe autoimmune hemolytic anemia—constitute emergencies. Prompt recognition of these conditions is vital if proper treatment is to be initiated. *Splenic sequestration* occurs in infants and young children with sickle cell disease who sequester large volumes of blood within the spleen over a period of hours. This results in rapidly dropping hemoglobin, and the condition clinically resembles anemia because of massive blood loss. The blood pooled in the spleen is not available to the circulation, and affected children are at risk for fatal splenic rupture. Early recognition is essential, and treatment involves emergency volume repletion followed by transfusion or exchange transfusion. Severe autoimmune hemolytic anemia is the second anemia-related emergency. Children with this disorder occasionally present with severe antiglobulin-positive anemia and clinical evidence of rapid hemolysis; their hemoglobin may fall as much as 1 g/dL per hour. Typically, these patients require hospitalization, transfusion, and treatment with high-dose steroids.

The primary treatment of patients with congenital hypoplastic anemia is steroids and RBC transfusions. Most patients (50%–75%) will respond to steroids, and their anemia can be controlled at very low doses. For patients with steroid-refractory anemia, alternative immunosuppressive therapy and RBC transfusions are necessary. Patients with congenital hypoplastic anemia and Fanconi syndrome that is refractory to steroid treatment can be successfully treated with hematopoietic stem cell transplantation.

Previously, hydroxyurea was the only US Food and Drug Administration treatment approved for sickle cell disease. Recently, an oral L-glutamine formulation was approved as a sickle cell disease–modifying medication for patients 5 years of age and older. This approval was based on the results of a phase 3 clinical study, which demonstrated reduction of pain crisis and hospitalizations.

Gene therapy for sickle cell disease is an active field of research, and the first successful case using lentiviral vector for normal β-globin gene delivery was reported in 2017. Even partial expression of normal β-globin provides therapeutic antisickling effect and functional cure, indicating great potential of gene therapy for sickle cell disease.

Prognosis

The prognosis for a child with anemia depends on the underlying cause. The prognosis is excellent for children with anemia caused by nutritional deficiencies that are detected and appropriately managed. Children with transient erythroblastopenia of childhood can expect complete recovery. Most immune-mediated anemias are responsive to therapy; however, if they are associated with an underlying autoimmune disorder, they may have a relapsing course. Children with chronic hemolytic disorders have varying courses depending on the degree of hemolysis. Early diagnosis and intervention through newborn screening for children with sickle cell disease has significantly reduced early mortality for this disease. Children with β-thalassemia major or severe congenital hemolytic anemias are transfusion-dependent and subject to the complications of iron overload, which can be addressed with chelation therapy. Some children with transfusion-dependent congenital hemolytic anemias may be candidates for splenectomy, with normalization of their hemoglobin values postsplenectomy. The prognosis for children with congenital hypoplastic anemia depends on their responsiveness to steroid therapy and need for transfusions. These individuals, along with children with Fanconi syndrome, are also at risk for certain malignancies (eg, acute myeloid leukemia).

When to Refer

Children with anemia caused by chronic inherited or acquired red cell disorders are at risk for complications during the course of their disease and are best served at a center that offers pediatric hematology expertise. Sickle cell disease and severe thalassemias are usually diagnosed by newborn screening programs and are automatically

referred to subspecialists. Any anemia that is complicated by thrombocytopenia or neutropenia also warrants immediate referral to a hematologist.

CASE RESOLUTION

The girl has hereditary spherocytosis. Her history is strongly suggestive of a hereditary hemolytic disorder, and the combination of spherocytes in the peripheral smear, a negative antiglobulin test, and a positive, incubated, osmotic fragility test are diagnostic of the condition. At age 9 years, she undergoes a splenectomy and has no more hemolytic episodes that require transfusions.

CHAPTER 99

Bleeding Disorders

Joseph L. Lasky III, MD, FAAP; Moran Gotesman, MD; and Eduard H. Panosyan, MD

CASE STUDY

A 6-year-old girl presents with a several-month history of recurrent epistaxis. Episodes occur every 2 to 3 weeks, with each episode lasting 15 to 20 minutes. Both nares are affected. Her mother also notes that the girl has always bruised easily. On physical examination, several 2- to 3-cm ecchymoses are noted on her lower extremities. Initial laboratory evaluation includes a complete blood cell count, which is normal (platelet count, 300,000/μL); a normal partial thromboplastin time of 30 seconds; and a normal prothrombin time of 12.5 seconds, with an international normalized ratio of 1:1.

Questions

1. What conditions should be considered when easy bruising is the chief presenting symptom?
2. What is the appropriate laboratory evaluation for children with clinical signs of bleeding?
3. What management is appropriate for the most common pediatric bleeding disorders?
4. What are the common medical complications that children with bleeding disorders experience?
5. When is consultation with a hematologist appropriate in a child who bruises easily?

When evaluating a child with bruising or bleeding symptoms, the major challenge for the pediatrician is ascertaining whether the degree of bleeding is appropriate for the hemostatic stress or whether further evaluation for a potential bleeding disorder is warranted. Bruising and bleeding are common childhood occurrences and usually follow minor injury or trauma. In the child with an underlying hemostatic disorder, non-accidental trauma, or both, however, the bruising or bleeding may be more extensive than expected. A thorough medical history and physical examination and an understanding of hemostasis aids in focusing the laboratory evaluation and elucidating the underlying etiology.

Epidemiology

Bleeding disorders may be inherited or acquired. Of the inherited bleeding disorders, von Willebrand disease is the most common, with a reported prevalence of between 1 in 100 and 1 in 1,000. von Willebrand disease is of autosomal inheritance, affecting males and females equally; more females are diagnosed, however, because of the inherent hemostatic challenges that they experience (eg, menses, childbirth). Hemophilia is the most common severe bleeding disorder, affecting approximately 1 in 5,000 males. Approximately 80% of cases are hemophilia A (factor VIII [FVIII] deficiency) and 20% are hemophilia B (factor IX [FIX] deficiency). Hemophilia is inherited in an X-linked fashion, but one-third of newly diagnosed males have no previous family history and represent new mutations. Other inherited coagulation and platelet disorders are rare (Table 99.1).

Acquired abnormalities of coagulation or platelets are much more common than inherited coagulopathies. Acquired abnormalities may be associated with liver disease, renal disease, malignancy, autoimmune or alloimmune disorder, vitamin K deficiency, infection, disseminated intravascular coagulation (DIC), massive transfusion, medication use, and surgery. Immune thrombocytopenic purpura (ITP) is a common acquired childhood bleeding disorder with an incidence of 4 to 8 per 100,000 children per year. Neonatal alloimmune thrombocytopenia occurs in approximately 1 in 1,800 live births. Common acquired bleeding disorders are also listed in Table 99.1.

Clinical Presentation

Bleeding disorders can manifest in various ways depending on the etiology. Inherited bleeding disorders often manifest during infancy or early childhood; mild disorders, however, may go undiagnosed until later in life. In general, disorders of primary hemostasis (eg, von Willebrand disease, platelet disorders, collagen vascular disorders) manifest with superficial, immediate, mucocutaneous bleeding. Characteristic bleeding symptoms include easy bruising, epistaxis, bleeding gums, menorrhagia, postpartum bleeding, and bleeding with dental extractions or surgeries. Disorders of secondary hemostasis, such as hemophilia A or B, often manifest with deep, delayed bleeding, such as hemarthrosis or muscular hematoma.

Acute onset is typical of acquired bleeding disorders, and they often involve abnormalities of primary and secondary hemostasis. Acute onset of bleeding symptoms in a toxic or ill-appearing child is suggestive of a systemic process, such as sepsis, DIC, malignancy, or hepatic or renal dysfunction. A well-appearing child with acute bleeding symptoms is suggestive of ITP, an acquired inhibitor, or a medication-related cause.

Table 99.1. Inherited Versus Acquired Bleeding Disorders

Disorder	*Inherited*	*Acquired*
Coagulation	von Willebrand disease Hemophilia A (FVIII) Hemophilia B (FIX) Hemophilia C (FXI) FII, FV, FVII, FX, or FXIII deficiency Disorders of fibrinogen • Dysfibrinogenemia • Hypofibrinogenemia • Afibrinogenemia Disorders of fibrinolysis • α_2-antiplasmin Plasminogen activator inhibitor-1 deficiency	Vitamin K deficiency Liver disease DIC Massive transfusion syndrome Disorders of fibrinogen (ie, dysfibrinogenemia, hypofibrinogenemia) • Liver disease • Renal disease • Medication-related Disorders associated with malignancy and therapy (ie, asparaginase) Coagulation inhibitors
Platelet	Quantitative • Thrombocytopenia-absent radius syndrome • Amegakaryocytic thrombocytopenia • Fanconi syndrome Qualitative • Glanzmann thrombasthenia • Storage pool disease • Release defects Quantitative/qualitative • Bernard-Soulier syndrome • Wiskott-Aldrich syndrome • Gray platelet syndrome	Quantitative • Increased destruction — Nonimmune-mediated ■ Hemolytic uremic syndrome ■ Thrombotic thrombocytopenic purpura ■ DIC — Immune-mediated ■ Immune thrombocytopenic purpura ■ Evans syndrome ■ Neonatal alloimmune thrombocytopenic purpura ■ Medications • Decreased production — Aplastic anemia — Malignancy infiltrating bone marrow — Medication Qualitative • Medication-related • Liver disease • Uremia • Post-cardiopulmonary bypass surgery

Abbreviations: DIC, disseminated intravascular coagulation; F, factor.

Pathophysiology

After vascular injury, hemostasis is initiated by exposure of flowing blood to subendothelial collagen and tissue factor (TF). The primary phase of hemostasis results in the production of a platelet plug. von Willebrand factor (vWF), a multimeric glycoprotein (GP) of varying size, attaches to exposed subendothelial collagen and binds platelets via the platelet GPIb-V-IX receptors. von Willebrand factor also serves as a carrier protein for FVIII, thereby localizing FVIII to areas of endothelial disruption. After platelets adhere to vWF, they become activated and release their granular contents, produce thromboxane A_2, and express the fibrinogen receptor GPIIb/IIIa. The release of thromboxane A_2 and other granular contents results in local vasoconstriction and activation of additional platelets and their respective GPIIb/IIIa receptors, thereby facilitating platelet aggregation. Fibrinogen binds to all the exposed activated GPIIb/IIIa sites, clumping the platelets together to form a platelet plug. The platelet plug stops local bleeding and provides a phospholipid surface on which the coagulation reactions of secondary hemostasis occur to form a definitive fibrin plug.

Secondary hemostasis is also initiated at the time of endothelial disruption with exposure of TF to circulating blood. Tissue factor binds to factor VIIa (FVIIa), and this complex serves as the key initiator of in vivo hemostasis by activating other TF:FVIIa complexes, as well as FIX and factor X (FX). Once Fx is activated (by FIXa or TF:FVIIa), FXa, along with its cofactor, factor Va, activates prothrombin (ie, factor II) to thrombin (ie, factor IIa). Thrombin cleaves circulating fibrinogen to fibrin monomers that self-polymerize. Factor XIII then stabilizes the fibrin clot by forming cross-links within the clump of fibrin polymers. These coagulation reactions occur on the surface of the platelet plug and, with the generation of cross-linked fibrin, the primary platelet

plug is converted into a definitive fibrin plug that prevents further bleeding. An overview of hemostasis is depicted in Figures 99.1 and 99.2. Deficiencies or impairments in any of these elements can result in abnormal test results or inadequate hemostasis and excessive hemorrhage.

The delicate balance of hemostasis and thrombosis is maintained by inhibitors (eg, protein C, protein S, antithrombin, TF pathway inhibitor) at each step of the coagulation pathway. These natural anticoagulants prevent excessive thrombus formation. Fibrinolysis is mediated by plasmin, which cleaves fibrinogen and fibrin within a thrombus, which enables restoration of vessel patency following hemostasis. Plasmin is activated by tissue plasminogen activator and urokinase. Fibrinolysis is kept in check by plasminogen activator inhibitor-1 (PAI-1), which inactivates tissue plasminogen activator, and α_2-antiplasmin, which inactivates plasmin. Any defect in the fibrinolytic system that results in increased fibrinolysis can cause excessive bleeding.

Differential Diagnosis

In developing the differential diagnosis for a child with bleeding symptoms, it is important to obtain a thorough bleeding history and perform a thorough physical examination. The age, bleeding pattern, duration of symptoms, family history, and overall clinical status of the child may help narrow the spectrum of possibilities.

Child With Chronic History of Mucocutaneous Bleeding

In a child who presents with a history of easy bruising, epistaxis, or menorrhagia, the primary differential diagnosis includes von Willebrand disease, platelet disorders, and collagen vascular disorders (ie, disorders of primary hemostasis). von Willebrand disease is caused by a quantitative or qualitative defect of vWF. von Willebrand factor plays an important role in both primary hemostasis, by mediating platelet adhesion at sites of vascular injury and secondary hemostasis, by stabilizing FVIII in plasma. von Willebrand disease is one of autosomal inheritance and has 3 types: partial quantitative deficiency of vWF (type 1); qualitative abnormalities of vWF (types 2A, 2B, 2C, and 2D); and the most severe form—complete deficiency of vWF (type 3)—which is caused by homozygous or compound heterozygous mutation and is inherited in autosomal-recessive fashion. Type 1 is the most common form, accounting for 70% to 80% of cases. Bleeding symptoms tend to be mild and are characterized by easy bruising, epistaxis, menorrhagia, and prolonged oozing after minor or major surgeries. Only the most severely affected patients (ie, with type 3 disease) and with very low FVIII levels experience soft tissue bleeding and hemarthroses similar to that of an individual with moderate or severe hemophilia.

Qualitative platelet disorders also manifest with mucocutaneous bleeding, often during infancy. In *Bernard-Soulier syndrome*, platelets lack a functional GPIb-V-IX receptor complex on the platelet

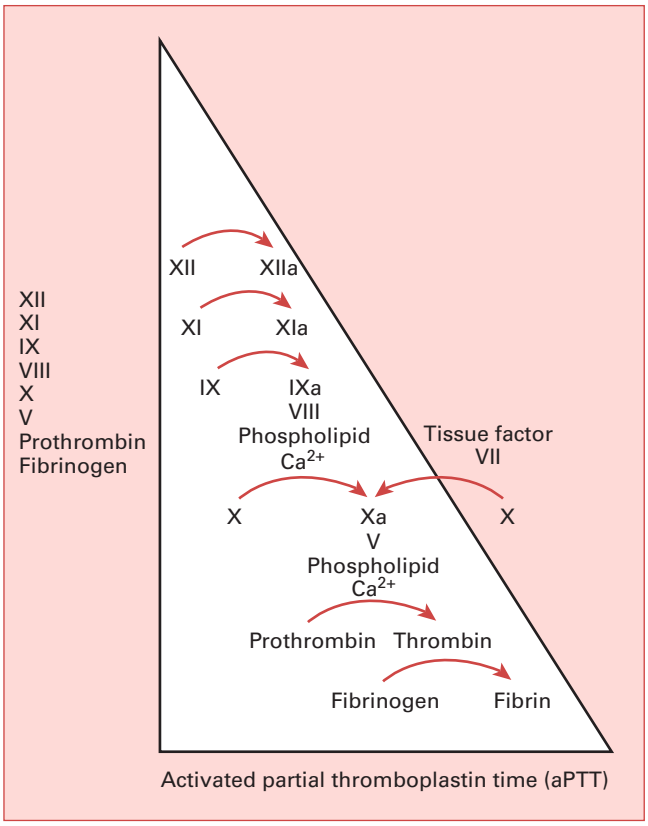

Figure 99.1. Intrinsic pathway reflected by activated partial thromboplastin time. The roman numerals represent factors.

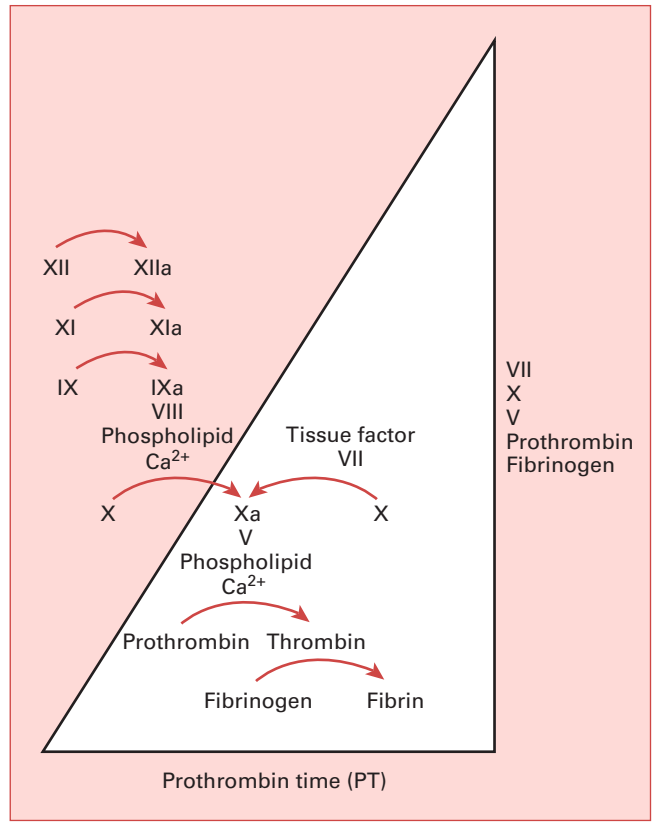

Figure 99.2. Coagulation pathway. Extrinsic pathway reflected by prothrombin time. The roman numerals represent factors.

surface, resulting in defective platelet adhesion to vWF at sites of vascular injury. This autosomal-recessive disorder is usually seen in the presence of consanguinity. The platelets tend to be large on peripheral blood smear, and thrombocytopenia may be present. *Glanzmann thrombasthenia* is characterized by an absence or defect in the platelet membrane GPIIb/IIIa receptor, the main fibrinogen receptor on the platelet surface that enables platelet aggregation. Inheritance is autosomal-recessive, and the condition is most common in the presence of consanguinity. Other qualitative platelet disorders, such as storage pool disease and platelet release defects, also can manifest in a similar manner.

Collagen-vascular disorders, such as Marfan syndrome and Ehlers-Danlos syndrome, may manifest with bruising and bleeding symptoms. This increased bleeding diathesis is caused by an easy disruption of the integrity of the vascular endothelium.

Other rare coagulation disorders to consider in a child with recurrent bleeding symptoms include deficiencies of factor XI, factor XIII (FXIII), PAI-1, and α_2-antiplasmin. *Factor XI deficiency* (ie, *hemophilia C*) is a rare bleeding disorder with a high prevalence in the Ashkenazi Jewish population. It differs from other types of hemophilia in that inheritance is autosomal and symptoms tend to be milder. Bleeding episodes typically occur in response to trauma or surgery; these episodes do not include the deep tissue or intra-articular bleeds characteristic of FVIII and FIX deficiency. *Factor XIII deficiency* is characterized by delayed or prolonged bleeding because the clots formed are friable, resulting from the lack of cross-linkage of fibrin monomers by FXIII. The inheritance is autosomal-dominant, and in the homozygous state it usually manifests in infancy with umbilical cord bleeding or delayed separation, as well as intracranial hemorrhage. Heterozygous individuals may present later in life with delayed or prolonged bleeding after trauma or surgery as well as poor wound healing. Disorders of fibrinolysis (eg, deficiency of PAI-1 or α_2-antiplasmin) also may manifest with prolonged bleeding after trauma.

Child With a History of Deep, Delayed Bleeding

Deep tissue and intra-articular bleeding is the hallmark bleeding pattern of hemophilia. Differential diagnosis for a child who presents with this type of bleeding is hemophilia A (ie, FVIII deficiency) or B (ie, FIX deficiency), FVII deficiency, and type 3 von Willebrand disease. Clinically, hemophilia is classified according to the factor level: less than 1% factor activity (severe), 1% to 5% (moderate), and greater than 5% (mild). The factor level correlates with the bleeding tendency. Males with severe hemophilia can have "spontaneous" bleeds or bleeding with minimal trauma. Males with moderate or mild hemophilia bleed with more significant trauma. The bleeding pattern of hemophilia varies as the child grows. Infants may present with a cephalohematoma or intracranial hemorrhage, particularly if the delivery was complicated by the use of forceps or vacuum extraction. Bleeding with circumcision, heel sticks, or blood draws may also occur. As the infant starts crawling, bruises and soft tissue hematomas on the lower extremities become common. As the toddler becomes upright, the first hemarthroses can occur, typically involving the ankle. The older child incurs hemarthroses primarily of the knees and elbows.

Factor VII deficiency is rare; however, it can manifest with a bleeding pattern similar to that of hemophilia A or B. The patient with type 3 von Willebrand disease, which is characterized by an absence of vWF (the carrier protein for FVIII), may have FVIII levels as low as an individual with severe or moderate hemophilia A. In addition to the characteristic mucocutaneous bleeding that occurs with von Willebrand disease, these individuals also experience deep tissue and intra-articular bleeding.

Well-Appearing Child With Acute Onset of Bleeding Symptoms

Acute onset of bleeding symptoms is consistent with an acquired abnormality of hemostasis. *Acute ITP* is a common acquired bleeding disorder of childhood that is caused by the development of autoantibodies directed against the patient's platelets. These autoantibodies, which cross-react with platelet surface antigens, are thought to develop in response to infection. Typically, a healthy child (usually between ages 2 and 4 years) presents with abrupt onset of bleeding symptoms, diffuse petechiae and bruising, and occasionally, "wet" bleeding (eg, epistaxis, gum bleeding, gastrointestinal [GI] bleeding). Often a history exists of a viral illness or recent immunization. The complete blood cell count (CBC) reveals isolated thrombocytopenia, and large platelets are seen on peripheral blood smear, which is indicative of active marrow and production of young platelets. In approximately 80% of cases, ITP is an acute, self-limited process that resolves within 6 months of diagnosis with or without therapy. *Chronic ITP* exists when the thrombocytopenia persists longer than 6 months. Although it is impossible to predict at diagnosis whether a patient will progress to chronic ITP, certain presenting features are associated with increased risk for chronicity. These include older age at presentation (>10 years), female sex, existing autoimmune disease, and insidious onset of symptoms. In most cases of chronic ITP, the platelet count ranges between 40,000 and 80,000/μL, and bleeding symptoms are minimal.

Acquired coagulation inhibitors are rare in children who do not have an underlying coagulation disorder; however, they can occur in the setting of malignancy or infection or postoperatively. Acquired FVIII deficiency resulting from FVIII inhibitor occurs primarily in the adult population but has been reported in children. Acute onset of severe bleeding symptoms is the common presentation. Antiphospholipid antibodies can cause prolonged partial thromboplastin time (PTT) or prothrombin time (PT); however, these antibodies are not associated with bleeding and are typically transient after a viral illness. If the antiphospholipid antibody is specifically directed against prothrombin, prothrombin levels will be low and the prothrombin time elevated. In this situation, if bleeding occurs it is usually mild and intervention is unnecessary.

Acquired abnormalities of coagulation or platelet function also can occur in association with certain medications. Aspirin and nonsteroidal anti-inflammatory drugs are common medications that

affect platelet function. Warfarin, a vitamin K antagonist, is commonly used as an anticoagulant. One percent to 3% of patients on therapeutic warfarin experience bleeding complications. Chronic antibiotic use can result in vitamin K deficiency and depletion of the vitamin K-dependent factors (ie, II, VII, IX, X).

Ill-Appearing Child With Acute Onset of Bleeding Symptoms

Acute onset of bleeding in an ill-appearing child is suggestive of an acquired systemic process. *Disseminated intravascular coagulation* is a consumptive coagulopathy that can occur secondary to several disorders, including sepsis, trauma, and malignancy. Disseminated intravascular coagulation occurs as a result of endothelial disruption and initiation of abnormal coagulation (ie, fibrin deposition along with depletion of multiple clotting factors, inhibitor proteins, and platelets).

Because the liver is the primary site of synthesis for most of the coagulation factors, liver dysfunction caused by any illness can result in an imbalance in the hemostatic system. Additionally, thrombocytopenia may be present in the patient with chronic liver disease because of portal hypertension and associated splenomegaly with sequestration. Causes of the depletion of vitamin K–dependent factors, such as obstructive jaundice, malabsorptive states (eg, cystic fibrosis), parenchymal liver disease, and chronic antibiotic use, can also predispose the patient to bleeding.

Renal disease with uremia impairs platelet function and may manifest with bleeding symptoms as well. A malignancy that infiltrates the bone marrow, such as leukemia, lymphoma, or neuroblastoma, can cause thrombocytopenia and resultant platelet bleeding. Acquired von Willebrand disease can occur in the patient with Wilms tumor and manifest with mucocutaneous bleeding. Bone marrow failure syndromes, such as aplastic anemia and Fanconi syndrome, also may manifest with thrombocytopenia and associated bleeding.

The Newborn or Infant With Bleeding Symptoms

The newborn or infant who presents with bleeding symptoms may have a congenital bleeding disorder or an acquired condition. Inherited coagulation factor deficiencies (FVII, FVIII, FIX, FXI, FXIII, type 3 von Willebrand disease) and qualitative platelet disorders may manifest in the newborn period with intracranial hemorrhage or cephalohematoma, bleeding with heel sticks or blood draws, umbilical cord bleeding, and bleeding with circumcision. Congenital thrombocytopenia usually manifests within the first year after birth and is associated with other syndromic features. Thrombocytopenia-absent radius syndrome is an autosomal-recessive condition that typically is recognized in the newborn period and is characterized by thrombocytopenia, skeletal anomalies (most commonly radial agenesis), and renal and cardiac abnormalities. Other types of congenital thrombocytopenia include amegakaryocytic thrombocytopenia; Fanconi syndrome (with associated skeletal anomalies); and Wiskott-Aldrich syndrome, which is characterized by eczema, frequent infections, and small platelets.

Neonatal alloimmune thrombocytopenia (NAIT) is a rare condition in which a newborn inherits platelet antigens from the father that are different from those of the mother. The mother becomes alloimmunized to the fetal platelet antigens during pregnancy, similar to the process of erythrocyte alloimmunization resulting from Rh incompatibility. The maternal immunoglobulin G alloantibodies cross the placenta and destroy fetal and newborn platelets, resulting in transient but severe thrombocytopenia in the newborn. Antibodies against the human platelet antigen-1a are responsible for 80% of cases of NAIT among whites. Thrombocytopenia in the newborn or infant can last several weeks, until the maternal antibody is cleared. Unlike Rh alloimmunization, NAIT can occur in the first pregnancy. The risk of intracranial hemorrhage is significant, with a reported incidence of up to 20% in some studies, and it can occur in utero. Neonatal thrombocytopenia also can occur as a result of maternal ITP, with maternal transfer of antibody. Bleeding tends to be mild in this setting, and intracranial hemorrhage is rare. The thrombocytopenia resolves after several weeks. Acquired thrombocytopenia most often occurs in the setting of an ill newborn or infant with sepsis, congenital infection (eg, *Toxoplasma,* rubella, cytomegalovirus, HIV), necrotizing enterocolitis, respiratory distress syndrome, asphyxia, or congenital heart disease. Drug-associated thrombocytopenia also may occur in the hospitalized newborn or infant.

Vitamin K deficiency in the neonate has 3 different presentations. *Classic hemorrhagic disease of the newborn* manifests between days 2 and 7 of age and is the result of immature neonatal liver and impaired clotting factor synthesis, inadequate vitamin K intake, and sterile neonatal gut. With the advent of vitamin K prophylaxis at birth, this form of vitamin K deficiency is rare. *Early hemorrhagic disease of the newborn* manifests in the first 24 hours after birth and is caused by maternal medications that affect vitamin K metabolism (eg, anticonvulsants). *Late vitamin K deficiency* occurs after 1 week of age and is associated with several conditions in which vitamin K stores may be low, such as inadequate intake in breastfed neonates and infants, impaired absorption in neonates and infants with chronic diarrhea, antibiotic use, cystic fibrosis, and other GI disorders. Bleeding symptoms associated with vitamin K deficiency can be severe, with a significant incidence of GI, deep tissue, and intracranial hemorrhage.

Exposures to the superwarfarin vitamin K antagonists found in rat poisons are relatively common in children but are usually asymptomatic, because it is necessary to ingest a large quantity of rat poison to induce significant coagulopathy. However, this intoxication should be considered in patients presenting with extreme coagulopathy and unexplained elevation of PT and activated PTT (aPTT) secondary to depletion of vitamin K–dependent factors.

Evaluation

History

A thorough bleeding history and physical examination should enable the pediatrician to determine the likelihood of an underlying bleeding disorder. The pattern of bleeding, timing of the symptoms (acute

or chronic), overall health of the child, and family history are important in helping determine the underlying etiology. Box 99.1 lists the pertinent questions to ask when obtaining a bleeding history.

Bruises are common in childhood. Normal bruising that occurs in an active child must be differentiated from pathologic bruising resulting from a possible bleeding disorder or non-accidental trauma. Bruises over exposed bony prominences, such as the anterior tibia or the knee, are common. Bruises of a size inconsistent with the degree of reported trauma, and bruises in unexposed or unusual areas (ie, back, chest, shoulders, upper arms), should alert the pediatrician to a possible bleeding disorder or non-accidental trauma. Linear or geometric bruises are concerning for non-accidental trauma. Epistaxis, another common occurrence, typically is caused by digital trauma or allergic rhinitis. However, epistaxis that is unrelieved by 15 minutes of appropriately applied pressure or epistaxis requiring packing, cautery, or transfusion is highly suggestive of a bleeding disorder. *Menorrhagia*, that is, menstrual flow longer than 7 days, and a history of frequently blood-stained clothes or iron deficiency anemia in the adolescent female are concerning. Persistent or recurrent bleeding with dental extractions (beyond the day of the procedure) or with surgeries also merits a closer evaluation. However, if a child has undergone previous dental extractions or surgeries without bleeding complications, an underlying bleeding disorder is unlikely. A history of deep muscle bleeding or unexplained hemarthroses is suggestive of an inherited factor deficiency.

Box 99.1. What to Ask

Bleeding History

- Does the child have a history of bleeding, or is the child presenting for incidentally discovered abnormal tests (eg, prolonged prothrombin time/activated partial thromboplastin time)?
- Is the bleeding acute or chronic?
  - For acute-onset bleeding
    - What type bleeding is the child experiencing?
    - Is the child well- or toxic-appearing?
    - Is there a history of recent illness?
    - Is the child taking any medications?
    - Does the child have any medical problems?
  - For history of chronic bleeding
    - What type bleeding is the child experiencing?
    - How long has the child been experiencing the bleeding episodes?
- Can you characterize any bruising (eg, location, size, palpable hematoma)?
- If the child has experienced epistaxis (ie, nosebleed), can you indicate duration of bleeding as well as any history of packing, cauterization, or transfusion?
- Has the child experienced bleeding with vaccinations, injections, or minor cuts?
- Has the child experienced bleeding with dental extractions and/or surgeries?
- Can you characterize the child's menses with regard to total number of days of bleeding, whether leaking occurs, whether there is alteration of activities during menses, whether iron deficiency has been diagnosed, whether oral contraceptives are used, and whether the child has a history of transfusion?
- What medications, if any, does the child take?
- What is the obstetric and gynecologic history of female relatives?

Physical Examination

Depending on the underlying bleeding disorder and the time of presentation, the physical examination may be completely normal. In the patient with active bleeding, physical signs may include petechiae, ecchymoses, mucosal bleeding (ie, nasal, oral, vaginal), hematuria, swollen joints (ie, hemarthrosis), or limited range of motion. Children with bleeding associated with an acquired disorder such as infection, malignancy, autoimmunity, or liver or renal dysfunction may have physical signs specific to the underlying illness. Children with bleeding associated with a genetic disorder may have a normal examination or congenital anomalies associated with a particular syndrome.

Laboratory Tests

The extent of laboratory evaluation is dependent on the bleeding history and clinical presentation. Initial laboratory studies for a potential bleeding disorder should include a CBC with a peripheral blood smear, a PT, and an aPTT.

The CBC is useful in providing a platelet count for identification of suspected thrombocytopenia. Additionally, abnormalities in the white blood cell count or red cell indices can provide clues to the underlying process. Microcytic anemia consistent with iron deficiency is suggestive of chronic blood loss and raises suspicion for an underlying bleeding disorder. Pancytopenia is suggestive of an underlying bone marrow failure syndrome or a possible malignancy, such as leukemia. Review of the peripheral blood smear can confirm the presence of thrombocytopenia as well as allow for an assessment of platelet, white blood cell, and red blood cell morphology.

The PT reflects the extrinsic and common clotting pathway, and the aPTT reflects the intrinsic and common pathway of the clotting cascade. In the patient with a prolonged PT or PTT, a 1:1 mixing study should be done to determine whether the prolongation is caused by a factor deficiency or the presence of an inhibitor. *Bleeding time* assesses primary hemostasis (ie, platelet function, vWF, vascular integrity); however, it is rarely performed in pediatric patients because of the unreliability and difficulty of performing this test in children. The *platelet function assay* is a screening test of platelet function used to measure platelet adhesion and aggregation (ie, primary hemostasis).

A stepwise approach to more specific testing is dictated by the clinical presentation and screening test results and is best performed with the consultation of a pediatric hematologist. When an abnormality of primary hemostasis is suspected, the initial evaluation should focus on von Willebrand disease because it is the most common disorder. A vWF panel, which includes vWF antigen, ristocetin cofactor activity (a functional measure of vWF), FVIII activity, and a vWF multimer analysis, should be performed. Many factors, such as stress, inflammation, hormones, exercise, and oral contraceptives, may transiently increase vWF levels, and normal results

are frequently returned in patients with type 1 von Willebrand disease. Repeat testing is often necessary to make the diagnosis and should be pursued if suspicion is high for von Willebrand disease. For the patient with hemophilia or any other suspected factor deficiency, a specific coagulation factor assay must be performed. For the patient with suspected qualitative platelet disorder, either *platelet aggregation studies*, which measure the degree and pattern of platelet aggregation to various agonists, or *flow cytometry*, which measures the platelet surface GP expression, can be performed. Additional studies, such as fibrinogen level, D-dimer assay, fibrin degradation products, thrombin time, factor inhibitor assay, autoimmune studies, liver function tests, serum creatinine test, or blood urea nitrogen test, may be indicated on an individualized basis. Table 99.2 lists the major screening tests for hemostasis.

Imaging Studies

In general, imaging studies are not indicated. In patients with thrombocytopenia, radiographs of the upper extremities may be obtained to rule out Fanconi syndrome and thrombocytopenia-absent radius syndrome. Computed tomography of the head should be considered if intracranial hemorrhage is suspected. In patients with hemophilia, computed tomography of the iliopsoas muscle is indicated if bleeding into the muscle is suspected; however, appropriate factor replacement is a priority over any imaging study.

Management

The management of bleeding disorders is dependent on the underlying abnormality. However, general supportive measures, such as local pressure for bleeding, avoidance of blood draws, and avoidance of medications that affect the function of platelets or hemostasis, are applicable to most clinical scenarios of bleeding.

Treatment of the patient with von Willebrand disease is dependent on the subtype and severity of bleeding symptoms. For mild bleeding symptoms, supportive measures alone may be sufficient, such as applying appropriate pressure for epistaxis, ice pack for bruises, and avoidance of antiplatelet medications. For patients with type 1 von Willebrand disease, desmopressin (eg, synthetic vasopressin) can be used, either as a concentrated nasal spray or intravenously. Desmopressin stimulates endothelial release of vWF and can increase levels 2- to 3-fold. For type 3 and most cases of type 2 von Willebrand disease, replacement therapy with FVIII concentrates containing vWF is necessary for management of significant bleeding episodes. Antifibrinolytic agents, such as aminocaproic acid, are quite effective in the management of mucosal bleeding and can be used alone for mild cases or in conjunction with desmopressin or FVIII/vWF concentrates in more severe episodes of bleeding. For females with menorrhagia, a trial of oral contraceptives is reasonable, because estrogen can increase vWF levels. This response is variable, however, and if it is not effective, use of aminocaproic acid and nasal desmopressin may be necessary.

For most qualitative platelet disorders, management is supportive. Mild bleeding episodes can be managed nonspecifically with antifibrinolytic agents or desmopressin. Platelet transfusions should be reserved for life-threatening bleeds and otherwise avoided because of the risk for developing antibodies.

The management of acute ITP consists of family education, supportive measures, and, in select cases, pharmacologic therapies. The use of pharmacologic therapies in the management of acute ITP remains controversial. In the natural course of acute ITP, the platelet count rises within 1 to 3 weeks of presentation. The rationale for initiating pharmacologic therapies is the theoretical prevention of intracranial hemorrhage; however, the incidence of this complication

Table 99.2. Laboratory Evaluation for Hemostasis

Laboratory Test	*Measured Hemostatic Function*
Complete blood cell count	Platelet count.
Peripheral blood smear	Platelet morphology.
aPTT	Factors I, II, V, VIII, IX, XI, XII (intrinsic and common pathway).
PT	Factors I, II, V, VII, X (extrinsic and common pathway).
aPTT and PT mixing studies	Performed in the patient with prolonged aPTT/PT. Patient plasma and normal plasma is mixed 1:1, and the aPTT/PT is repeated. If aPTT/PT corrects, a factor deficiency exists; if not, an inhibitor exists.
Bleeding time[a]	Primary hemostasis (platelets, vWF, endothelial integrity).
Platelet function assay-100 screen	Primary hemostasis (platelets, vWF).
Thrombin time	Fibrinogen.
vWF panel	vWF antigen (amount of vWF), ristocetin cofactor activity (function of vWF), factor VIII activity, vWF multimer analysis (distribution of multimers).
Coagulation factor assays	Specific factor activity.
Platelet aggregation studies	Platelet function. Platelets are exposed to agonists; the degree of aggregation and pattern of the response is unique to various qualitative platelet disorders.

Abbreviations: aPTT, activated partial thromboplastin time; PT, prothrombin time; vWF, von Willebrand factor.

[a] Not recommended in pediatric patients.

is less than 0.5%, and there are no data which confirm that any of the currently available therapies actually prevent this complication. As opposed to waiting, the platelet count increases more rapidly with pharmacologic intervention and a significant bleeding complication may be prevented. In those at risk for persistent ITP, the use of pharmacologic intervention will not reduce the likelihood of developing chronic ITP. The decision to treat must be individualized, taking into consideration the child's age, bleeding symptoms, and activity level, as well as the parental anxiety level. Treatment options include observation without medical therapy, corticosteroids, intravenous gamma globulin, and anti-D immunoglobulin. Anti-D immunoglobulin can be used only in patients who are Rh positive. In all cases, parents should be instructed to avoid the use of aspirin, ibuprofen, and other antiplatelet medications; avoid intramuscular injections; and postpone immunizations and allergic desensitization injections that may exacerbate the degree of thrombocytopenia. Physical activity should be limited, with specific instruction to avoid activities that may cause head injury. Parents also should be educated about the signs and symptoms of an intracranial hemorrhage and given instructions on what to do in the event of an emergency. Therapeutic options for chronic ITP include observation without therapy, corticosteroids, regular infusions of intravenous immune globulin (IVIG) or anti-D immunoglobulin (for Rh-positive patients), immunosuppressive agents, rituximab, and laparoscopic splenectomy. Rituximab is a chimeric monoclonal antibody directed against CD20 (which is found primarily on the surface of B cells) and has been shown to be effective in managing chronic ITP and other autoimmune conditions. Management of acute bleeding in NAIT includes transfusion of maternal washed platelets and IVIG. If maternal washed platelets are not available, random platelets, preferably crossmatched or negative for human platelet antigen-1a, can be used along with IVIG.

Prevention and early management of bleeding episodes, family education, and good well-child care are important in providing comprehensive hemophilia care. The current standard of care for patients with severe hemophilia is prophylaxis, intravenous factor replacement therapy on a regular schedule, whether every other day, 3 times a week, or twice a week depending on the type of hemophilia, to prevent bleeding episodes. Prophylaxis is usually initiated during the first few years of age. A subcutaneous central venous catheter is inserted for this purpose and, as the child grows, the parents, and eventually the child, are taught how to administer factor by peripheral infusion. Prompt treatment of acute bleeding episodes is essential to prevent long-term complications. In 30% of patients with hemophilia A and 2% to 3% of patients with hemophilia B, an inhibitor to the respective factor can develop. In the presence of an inhibitor, acute bleeding episodes must be managed with bypassing agents, such as prothrombin concentrates or recombinant FVIIa. In the long-term, immune tolerance is attempted by exposing the child to high doses of factor on a daily basis in an attempt to eradicate the inhibitor. Several immune tolerance regimens have been used, with varying success.

More recent efforts in the management of hemophilia have been focused on the development of recombinant factor products with extended half-lives, which requires fewer injections for disease control. A major international study demonstrated that treatment with plasma-derived FVIII is associated with a lower incidence of inhibitors compared with recombinant FVIII. Novel approaches for patients with inhibitors include non-factor bypass agents (eg, anti-tissue-factor pathway inhibitor) or the bispecific antibody emicizumab, which bridges FIX and FX in lieu of replacing FVIII in hemophilia A when inhibitors are present.

Acquired causes of coagulation or platelet abnormalities can be managed supportively or by replacing the deficiency or removing the offending causative agent. Children with DIC may be given fresh frozen plasma, cryoprecipitate, and platelets as needed while the underlying etiology of the DIC is treated. In children in whom vitamin K deficiency is the suspected cause of bleeding, 1 dose of vitamin K should correct the coagulopathy within 12 to 36 hours. Depending on the underlying cause of vitamin K deficiency, regular replacement may be required, as during prolonged antibiotic therapy. Clinically important bleeding in children who have ingested superwarfarin rodenticide may necessitate GI decontamination in addition to administrations of fresh frozen plasma and high-dose vitamin K.

Prognosis

Most patients with inherited bleeding disorders have an excellent prognosis if the diagnosis is made in a timely fashion and appropriate intervention is initiated.

Patients with von Willebrand disease usually have mild bleeding symptoms and, with appropriate education and intervention, have an excellent prognosis. Patients with hemophilia also have an excellent prognosis with early diagnosis, family education, prophylaxis, and early treatment of bleeds. With the advent of prophylaxis, the severe hemophilic arthropathy that plagued prior generations of males with hemophilia has been largely averted or minimized. In addition, the use of recombinant factor products and highly purified plasma-derived products in the pediatric population has largely eliminated the risk for viral transmission. Acute ITP resolves spontaneously by 6 months following diagnosis in 80% of cases, regardless of pharmacologic intervention, and the risk for significant hemorrhage is exceedingly low. Most cases of chronic ITP resolve with time, and significant bleeding complications do not usually occur.

When to Refer

Most cases of elevated PT/PTT are the result of nonspecific inhibitors that are transient and do not cause bleeding. Generally, subspecialty referral is not required. Often routine ITP can be managed by a primary pediatrician; however, if the diagnosis is in question, a hematologist should be consulted. Patients with hemophilia and other severe bleeding disorders are usually diagnosed in infancy and require close follow-up with a pediatric hematologist in the setting of a comprehensive hemophilia treatment center.

CASE RESOLUTION

A vWF panel was performed and revealed a vWF antigen of 20%, ristocetin cofactor activity of 30%, FVIII activity of 40%, and a normal multimer analysis. The girl was diagnosed with type 1 von Willebrand disease. A desmopressin challenge was performed in the clinic, and she had an excellent response. She was prescribed nasal desmopressin and aminocaproic acid for use in significant bleeding episodes.

CHAPTER 100

Lymphadenopathy

Eduard H. Panosyan, MD; Moran Gotesman, MD; and Joseph L. Lasky III, MD, FAAP

CASE STUDY

A 12-year-old girl is brought to the office with swelling of the anterior cervical nodes, which has persisted for 2 weeks. Intermittent fever with temperatures as high as 38.3°C (101°F) and decreased appetite have been associated with the condition. On physical examination, her temperature is 38.0°C (100.4°F) and her other vital signs are normal. Three to 4 nontender nodes 1 to 2 cm in diameter are present bilaterally. The remainder of the examination is normal.

Questions

1. When is lymphadenopathy of medical concern?
2. What are the clinical features of childhood diseases that present as cervical lymphadenopathy?
3. What are the diagnostic approaches to the evaluation of children with lymphadenopathy?
4. What is an appropriate therapeutic approach to cervical lymphadenopathy in children?

Lymphadenopathy is among the most common clinical problems encountered in pediatrics. Palpable lymph nodes are a source of anxiety for parents, often prompting a visit to the pediatrician for evaluation. Although most cases are caused by a benign, self-limited infectious process, lymphadenopathy may also signal a serious underlying systemic illness. It is important for the pediatrician to make this distinction so that appropriate diagnostic and therapeutic measures can be initiated when necessary.

Epidemiology

Lymphadenopathy occurs frequently in childhood, and even healthy children may have palpable lymph nodes in the anterior cervical, inguinal, and axillary regions. Localized lymphadenopathy is mainly caused by an infectious etiology, whereas generalized lymphadenopathy occurs with systemic illnesses, such as systemic infections (ie, viral, bacterial, protozoal, fungal), autoimmune disorders, storage disorders, and malignancies.

Clinical Presentation

Lymphadenopathy may be localized or generalized on presentation. *Localized* or *regional lymphadenopathy* refers to enlargement of lymph nodes within contiguous regions, whereas *generalized lymphadenopathy* involves more than 2 noncontiguous lymph node groups (Box 100.1). Infection is the most frequent cause of localized lymphadenopathy in children. The anterior cervical lymph node region is the most commonly involved area because it is affected by upper respiratory infections (URIs), which occur frequently in childhood. Bilateral cervical lymphadenopathy often occurs in viral and bacterial URIs, and the nodes tend to be soft, mobile, and nontender. Viruses such as Epstein-Barr virus (EBV) and cytomegalovirus (CMV) can present with prominent posterior cervical lymphadenopathy as well as generalized adenopathy and occasionally hepatosplenomegaly. Direct bacterial invasion of lymph nodes produces lymphadenitis, which typically is unilateral, tender, erythematous, and fluctuant. Subacute or chronic lymphadenopathy may be caused by atypical mycobacterial infections, tuberculosis, cat-scratch disease, EBV, CMV, toxoplasmosis, coccidioidomycosis, or HIV. Generalized lymphadenopathy is concerning for an underlying systemic illness (ie, infection, autoimmune process, storage disease, malignancy). Lymphadenopathy resulting from malignancy typically is characterized by fixed, firm, nontender lymph nodes in the setting of other signs and symptoms, such as fever, pallor, night sweats, and weight loss.

Pathophysiology

Lymph nodes are an integral part of the immune system in which phagocytic cells filter both microorganisms and particulate matter and antigens are presented, thereby provoking a cellular or humoral mediated lymphocyte response. Lymph nodes

Box 100.1. Diagnosis of Lymphadenopathy in Children

- Enlarged lymph nodes
- Fever
- Tenderness or warmth over the lymph nodes (signs of inflammation [ie, lymphadenitis])
- Antecedent infection (eg, pharyngitis, upper respiratory infection, otitis media, skin and soft tissue infections)
- Pallor
- Weight loss
- Bone pain
- Night sweats

Table 100.1. Lymph Node Drainage Patterns

Group	*Drainage Pattern*
Occipital	Posterior scalp
Preauricular	Superficial orbital and periorbital tissue, temporal scalp
Submental/ submandibular	Mouth
Cervical	Mouth, pharynx, ear, parotid gland, deep structures of neck (ie, thyroid, larynx, trachea, upper esophagus)
Supraclavicular	Head, neck, arms, lungs, mediastinum, and abdomen
Mediastinal	Lungs, heart, thymus, esophagus
Axillary	Chest wall, breast, upper extremity
Abdominal	Abdominal organs, pelvis, lower extremities
Iliac and inguinal	Lower extremities, genitalia, buttocks, pelvis

are distributed in groups throughout the body and drain specific regions (ie, head, neck, axilla, mediastinum, abdomen, extremities) (Table 100.1). Enlargement of a lymph node may be caused by proliferation of lymphocytes intrinsic to the lymph node (as a physiologic immune response or a malignant transformation) or infiltration by either pathogens or extrinsic inflammatory or metastatic malignant cells.

Differential Diagnosis

The duration and extent of lymphadenopathy, that is, localized versus generalized; characteristics of the lymph nodes; and presence of associated symptoms help focus the differential diagnosis. A list of common causes of lymphadenopathy in children is provided in Table 100.2.

Localized lymphadenopathy is most often caused by an infectious etiology. Acute bilateral cervical lymphadenopathy is most frequently caused by viral URIs (ie, respiratory syncytial virus, adenovirus, parainfluenza and influenza viruses) or EBV and CMV, which can also cause generalized adenopathy. Bacterial pharyngitis (most commonly *Streptococcus* species) and oral infections or dental abscesses can present with cervical adenopathy. Unilateral lymphadenitis is most often caused by *Staphylococcus aureus,* followed by *Streptococcus pyogenes,* anaerobes, and other species. When the condition appears subacute, the following etiologies should be considered: cat-scratch disease, tuberculosis (ie, scrofula), atypical mycobacteria, toxoplasmosis, tularemia, and, less commonly, histoplasmosis, brucellosis, and syphilis. Cervical lymphadenopathy can also occur with Kawasaki disease, with high fever (5 days' duration); redness, swelling, and desquamation of extremities; nonpurulent conjunctivitis; rash; and swollen lips and tongue.

Generalized lymphadenopathy may be caused by systemic infections (eg, EBV, CMV, HIV, toxoplasmosis), autoimmune disorders (eg, juvenile idiopathic arthritis, systemic lupus erythematosus), storage disorders (eg, Niemann disease, Gaucher disease), histiocytic disorders (eg, Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis), drug reactions (eg, phenytoin), or malignancies. Malignancies include leukemia and lymphoma (Hodgkin and non-Hodgkin) as well as solid tumors that can metastasize to lymph nodes (eg, neuroblastoma, rhabdomyosarcoma). With neoplastic infiltration, enlarged nodes are generally nontender, firm, rubbery, and immobile. In Hodgkin disease, the nodes enlarge sequentially, with involvement spreading from 1 chain to the next. Supraclavicular or epitrochlear adenopathy is strongly suggestive of malignancy.

Several head and neck lesions that occur in the pediatric population are often confused with cervical lymphadenopathy. These lesions include cystic hygromas, branchial cleft cysts, thyroglossal duct cysts, and epidermoid cysts. These are congenital malformations that often present as a neck mass in the young child and can easily be mistaken for a lymph node, particularly if infected (see Chapter 94).

Evaluation

History

A thorough history and review of symptoms is essential in determining the underlying etiology of lymphadenopathy in children. Inquiries should be made about the duration of the lymphadenopathy, rate of nodal enlargement, and occurrence of associated fever and other constitutional symptoms, such as bone pain, weight loss, fever, and night sweats. Recent illnesses or infections, insect or animal bites, and local trauma should be determined. A history of distant travel, recent emigration from countries with endemic tuberculosis (eg, Mexico, Central America, Southeast Asia), recent travel to areas with endemic histoplasmosis (eg, southeastern United States) or coccidioidomycosis (eg, San Joaquin Valley, CA), a detailed history of pet contact (eg, cats or kittens, which can transmit toxoplasmosis and cat-scratch disease), and exposure to ill contacts, particularly individuals known to have tuberculosis, are also important (Box 100.2). In addition, it is important to obtain a history of chemical exposure and steroid use.

Physical Examination

When evaluating a child with lymphadenopathy, the enlarged nodes should be examined and measured at their widest diameter and evaluated for evidence of erythema, tenderness, and warmth, all of which are suggestive of infection. The characteristics of the

Box 100.2. What to Ask

Lymphadenopathy

- How long have the nodes been enlarged?
- Was the child sick before the swelling began?
- Does the child currently have any symptoms, such as fever, weight loss, pallor, night sweats, or anorexia?
- Does the child come in contact with any animals, particularly cats?
- Has the child traveled anywhere?
- Is the child taking any medications?
- Has the child been in contact with anyone who is ill?

Table 100.2. Differential Diagnosis of Lymphadenopathy in Children

Diagnostic Category	*Clinical Features*	*Laboratory Features, Initial Radiologic Studies*
Infections		
Viral (EBV, CMV, rubella, HIV)	Usually generalized, not purulent or tender; may have hepatosplenomegaly	EBV/CMV with atypical lymphocytes on peripheral blood smear, viral titers, and PCRs
Mycobacterial (TB, atypical mycobacteria)	Usually localized; often tender, red, fluctuant	PPD, chest radiograph, QuantiFERON-TB Gold
Bacterial (staphylococcal and streptococcal infections, cat-scratch disease, tularemia, plague, diphtheria)	Usually localized; often tender, red, fluctuant	Titers (cat scratch), Gram stain/culture
Protozoal (toxoplasmosis)	Generalized	Titers
Spirochete (syphilis)	Usually localized in primary, may be generalized in secondary	Titers
Fungal (histoplasmosis, coccidioidomycosis)[a]	May be generalized	Titers
Neoplastic Conditions		
Hodgkin lymphoma[b]	Often associated with "B" symptoms (eg, fever, weight loss, night sweats), pruritus	ESR (can be >100), LDH, elevated eosinophils, anergy, elevated ferritin, chest radiography
Non-Hodgkin lymphoma	See Hodgkin lymphoma	Abdominal ultrasonography
Leukemia	Generalized lymphadenopathy, hepatosplenomegaly, petechiae, purpura, pallor	Cytopenias (ie, leukopenia, neutropenia, thrombocytopenia, anemia); lymphocytosis and blasts on peripheral blood smear (not always absent), hyperuricemia, hyperkalemia, hyperphosphatemia, elevated LDH
Solid tumors (eg, rhabdomyosarcoma, neuroblastoma)	Depends on location and character of underlying malignancy	Imaging such as CT or MRI
Langerhans cell histiocytosis	Eczema, failure to thrive, bony lesions, diabetes insipidus, proptosis, hepatosplenomegaly, and early teeth eruption all possible	Characteristic pathology with Birbeck granules and CD1a+
Sinus histiocytosis with massive lymphadenopathy	Lymphadenopathy involving cervical, axillary, inguinal, and mediastinal nodes	Presence of histocytes in lymph nodes as well as extra nodal sites
Autoimmune Disorders		
Juvenile idiopathic arthritis[c]	Generalized lymphadenopathy seen in systemic form (eg, Still disease), such as fever, hepatosplenomegaly, evanescent rash, arthritis	ESR, anemia, negative ANA, and rheumatoid arthritis in JRA (eg, Still disease)
Lupus[d]	Arthritis, butterfly facial rash, effusions (lung, joint, cardiac), CNS involvement, nephrotic syndrome	ESR; positive ANA; anti-double-stranded DNA; C3, C4, or CH50 levels; anemia; low platelets; proteinuria
Other		
Storage disorders (eg, Niemann disease, Gaucher disease)	Generalized lymphadenopathy, hepatosplenomegaly	Characteristic pathology on biopsy
Drugs (eg, phenytoin)	Generalized lymphadenopathy	None
Sarcoidosis[e]	Bilateral hilar lymphadenopathy, noncaseating granulomas (ie, lung, liver)	Serum angiotensin-1–converting enzyme, serum lysozyme

Abbreviations: ANA, antinuclear antibody; CMV, cytomegalovirus; CNS, central nervous system; EBV, Epstein-Barr virus; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; JRA, juvenile rheumatoid arthritis; LDH, lactate dehydrogenase; PCR, polymerase chain reaction; PPD, purified protein derivative; TB, tuberculosis.

[a] Suspicion should be raised based on regional incidence.

[b] Common among individuals of higher socioeconomic status, adolescents.

[c] Equal incidence in boys and girls.

[d] Increased incidence in girls.

[e] In black individuals and those of Irish heritage.

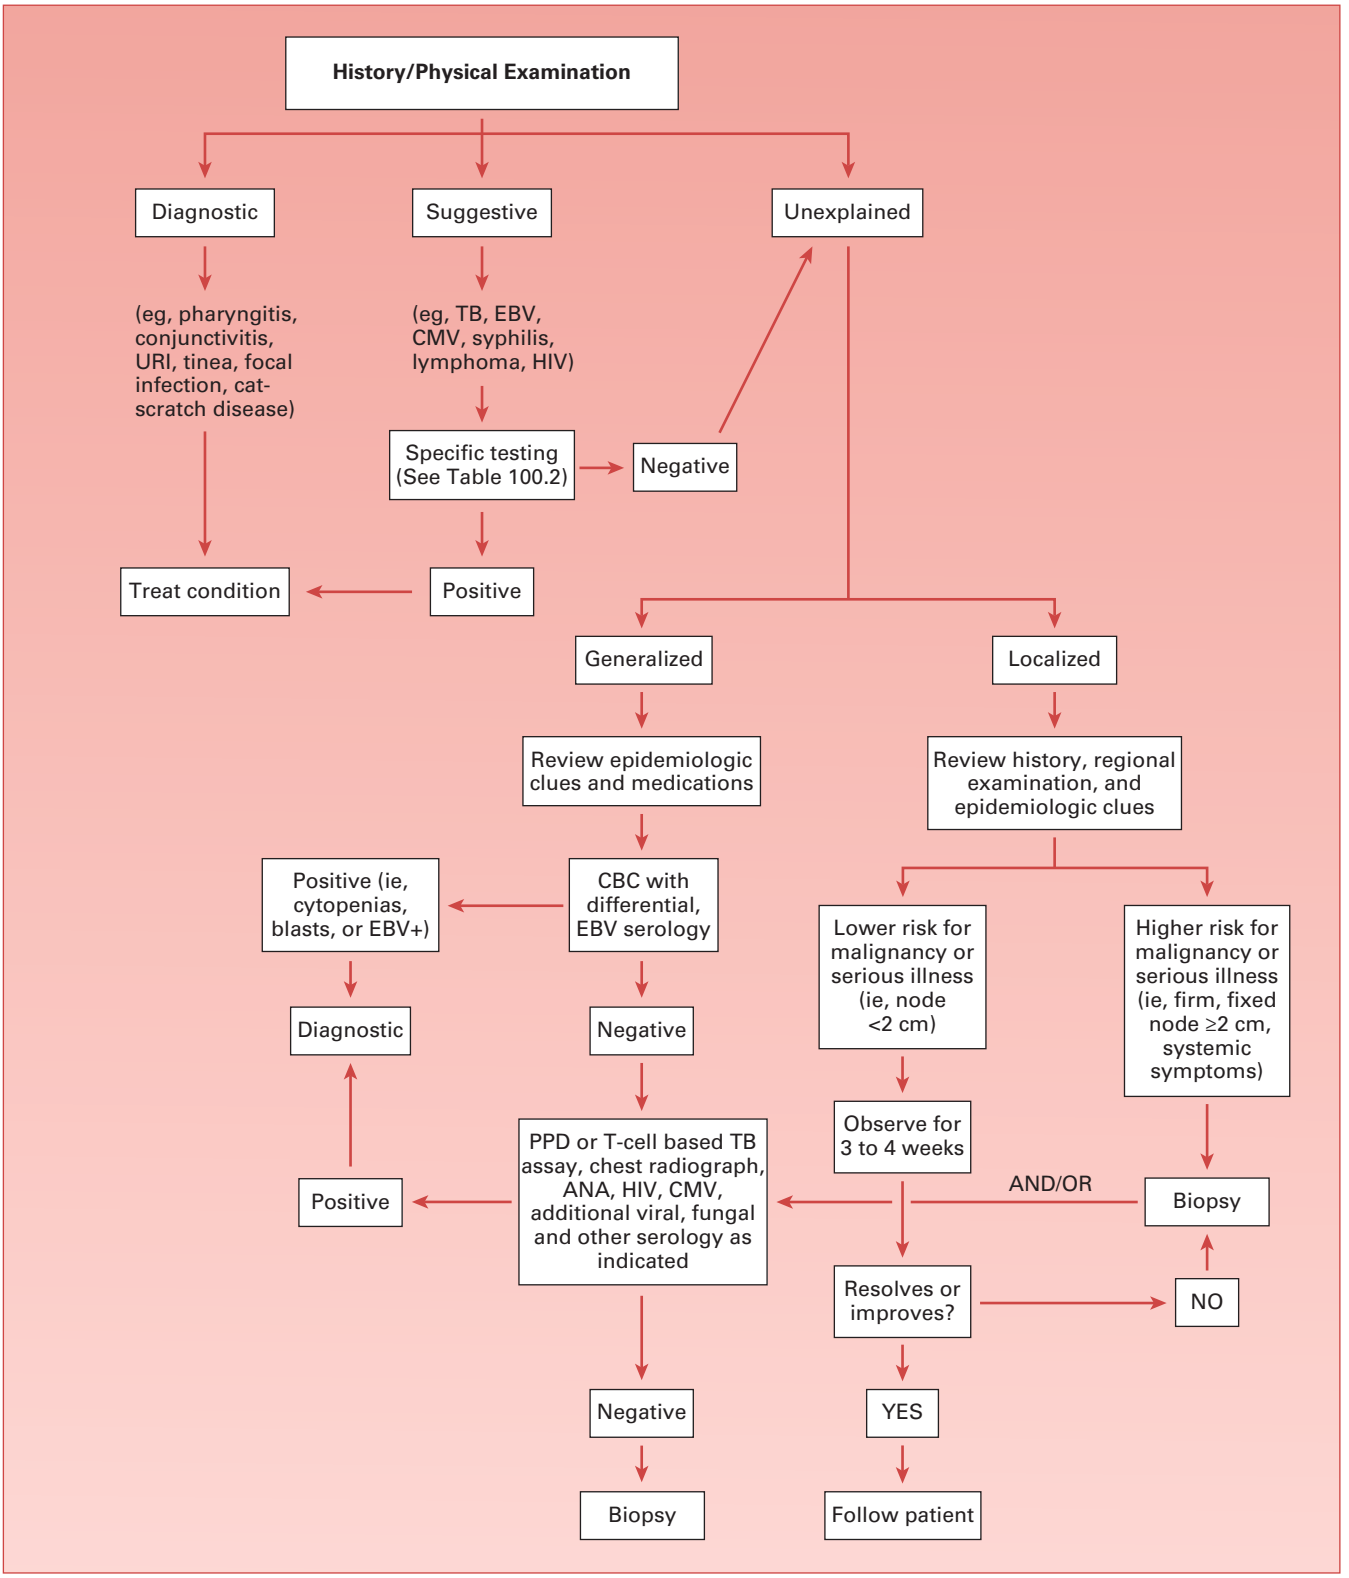

Figure 100.1. Approach to the management of lymphadenopathy.

Abbreviations: ANA, antinuclear antibody; CBC, complete blood count; CMV, cytomegalovirus; EBV, Epstein-Barr virus; PPD, purified protein derivative; TB, tuberculosis; URI, upper respiratory infection.

Adapted with permission from Ferrer R. Lymphadenopathy: differential diagnosis and evaluation. *Am Fam Physician*. 1998;58[6]:1313–1320.

enlarged lymph node should be noted (eg, soft, firm, rubbery, mobile, matted, tender, discrete). The surrounding skin and soft tissue region that is drained by the involved lymph node should be examined for signs of inflammation or skin breakdown. The extent of the lymphadenopathy should be determined, and the presence or absence of hepatosplenomegaly should be noted.

Laboratory Tests

In most cases, a thorough history and physical examination can establish the likely diagnosis without any laboratory testing. If studies are deemed necessary, a complete blood cell count, peripheral blood smear, tests of renal and hepatic function, and tumor lysis laboratory tests are useful to screen for an underlying systemic illness that may be associated with lymphadenopathy. Lymphocytosis with atypical lymphocytes on peripheral blood smear is consistent with a viral etiology, such as EBV or CMV. Leukocytosis with a left shift is suggestive of a bacterial etiology. Cytopenias or blasts on peripheral blood smear are concerning for leukemia. Uric acid, phosphorus, and lactate dehydrogenase are typically elevated in the setting of leukemia or lymphoma. An erythrocyte sedimentation rate is nonspecific but may be helpful. Depending on the clinical scenario, serum antibody studies and viral polymerase chain reactions for various infections may be warranted (ie, EBV, CMV, HIV, *Bartonella henselae* for cat-scratch disease, *Bartonella quintana* for trench fever). Additionally, testing for tuberculosis or serologic tests for fungal disease should be considered. Newer T-cell–based assays for tuberculosis, such as interferon-γ release assay or QuantiFERON-TB Gold, have been suggested for testing any individuals age 5 years and older with suspected infection. In younger children, tuberculin skin testing is still suggested. In lupus and juvenile idiopathic arthritis, an antinuclear antibody assay may be positive and complement levels may be reduced.

If infectious lymphadenitis is suspected, an aspirate for a Gram stain and culture may be helpful, particularly if the infection has been unresponsive to empiric antibiotics. If *any* concern exists for malignancy, however, a fine needle aspiration is *not* the preferred method for diagnosis. An excisional biopsy should be performed so that the entire lymph node and its architecture can be visualized and adequate samples for testing are available. See Figure 100.1 for the suggested approach to generalized lymphadenopathy in children.

Imaging Studies

A chest radiograph should be obtained from any child with significant lymphadenopathy if suspicion exists for an underlying systemic process. If leukemia or lymphoma is suspected, a chest radiograph is obtained to evaluate for an anterior mediastinal mass. Other imaging studies are not routinely performed; however, if the nature of an enlarged lymph node requires further definition, ultrasonography can be performed. Massive lymphadenopathy in the head and neck region may warrant evaluation with computed tomography or magnetic resonance imaging. In the setting of malignancy, additional radiographs are obtained for staging purposes.

Management

Management is dictated by the underlying cause of lymphadenopathy (Figure 100.1). Cervical lymphadenopathy associated with URIs typically resolves without intervention. Bacterial lymphadenitis can be managed with a trial of antibiotics with antistaphylococcal and antistreptococcal coverage. With the exception of cervical adenopathy caused by atypical mycobacteria, which requires surgical removal, underlying fungal and mycobacterial diseases should be managed with appropriate antifungal or antibacterial agents. Malignancies may require multimodal therapy with surgery, chemotherapy, or targeted therapy or radiation, depending on the specific diagnosis and stage (see Chapter 152).

Prognosis

The outcome of lymphadenopathy depends entirely on the underlying etiology. In most cases, the cause is infectious and the lymphadenopathy is self-limited or resolves with the use of appropriate antibiotics. Lymphadenopathy associated with an underlying systemic illness may have a more chronic or relapsing course, depending on the disease.

CASE RESOLUTION

The bilateral nature of the swelling and lack of tenderness of the nodes are quite worrisome and are suggestive of systemic involvement. The girl underwent a throat culture and an intermediate purified protein derivative skin test, and a chest radiograph was obtained; the results of all these evaluations were negative. A complete blood cell count revealed leukocytosis with 28,000 white blood cells per deciliter (60% lymphocytes) with a normal hemoglobin and platelet count. A heterophile test result for infectious mononucleosis was positive. Supportive measures were implemented, and the child made a complete recovery in 3 weeks.

PART 8

Cardiovascular System

CHAPTER 101

Heart Murmurs

Robin Winkler Doroshow, MD, MMS, MEd, FAAP

CASE STUDY

A 6-year-old girl is brought to the office for a physical examination for school. Her medical history is unremarkable, and her growth and development have been normal. She is asymptomatic. Her physical examination is normal except for a grade 2 of 6 low-pitched vibratory systolic ejection murmur that is loudest at the left lower sternal border, with radiation to the apex and upper sternal border. The murmur increases to grade 3 of 6 with the patient in the supine position.

Questions

1. What is the significance of a heart murmur in an asymptomatic child? How reassuring are a negative history and the absence of other physical findings?
2. What workup should be done by the primary care physician?
3. What are the consequences of not recognizing a murmur as being innocent? What are the consequences of an inadequate workup?
4. When should the physician refer a child to a specialist for consultation?

Asymptomatic children with heart murmurs are commonly encountered by physicians. A murmur is a finding rather than a medical sign or symptom, because it is detected incidentally at an examination conducted for another purpose.

Correct assessment of the significance of a heart murmur is important to ensure appropriate treatment of children with heart disease. Complications of undiagnosed cardiac disease in children include progressive hemodynamic impairment, endocarditis, and even sudden death.

The misinterpretation of an innocent murmur as organic in nature can also be a source of stress, primarily in the form of parental anxiety. Unnecessary restriction of activities may result, which can have a negative effect on children's school and social lives as well as self-image. As adults they may be denied health insurance, life insurance, and certain types of employment. Additionally, misdiagnosis is financially costly and uses limited resources, with unnecessary tests and doctor visits, as this "nondisease" is evaluated and followed.

Epidemiology

An estimated 50% of healthy children have heart murmurs. The overall incidence of congenital heart disease (CHD), including symptomatic cases, is just under 1%, most of which are identified prenatally (by ultrasonography) or in the newborn period (by pulse oximetry screening [see Chapter 103]). Some children with CHD have no murmur. Therefore, approximately 98 of 100 murmurs noted during childhood are "innocent" (ie, have no organic basis).

Clinical Presentation

Heart murmurs are usually detected on routine examination for well-child care or on evaluation for an unrelated problem. Innocent murmurs are not associated with signs or symptoms, because they are normal findings. Most of the symptoms sometimes associated with organic murmurs (ie, murmurs of heart disease) are related to the presence of congestive heart failure (CHF) (see Chapter 104) and usually become evident during infancy. Some children with murmurs come to medical attention with reports of exercise intolerance or chest pain. It is necessary to determine whether these problems are truly referable to the heart, which is uncommon (see Chapter 105).

The noting of a murmur in a child for the first time may be considered a "new murmur," which in the adult can be a serious finding heralding new onset of acquired heart disease, such as mitral insufficiency resulting from poor ventricular function or aortic insufficiency resulting from infective endocarditis. In the pediatric patient, these findings are rare. Much more commonly, a murmur not previously noted may be heard for the first time for benign reasons. These murmurs are referred to as innocent murmurs and may vary by patient age or the position in which the child is examined. Previously very soft murmurs may be more pronounced under different conditions, such as fever or anxiety. Murmurs that are predominantly audible in the supine position may not have been noted when the child was examined only in the upright position, or vice versa. The lower heart rate and better level of cooperation of the child, compared with the infant, may allow the examiner to identify a murmur not heard on previous examinations.

Pathophysiology

A murmur is a sustained sound that can be detected with a stethoscope placed on the chest. This sound is produced by turbulence of blood flow in the heart or great vessels. This turbulence may be caused by structural abnormalities (eg, aortic valve stenosis), benign or normal flow patterns (discussed later in this chapter), or exaggeration of normal flow patterns (as in high-output states, such as fever, exercise, anxiety, or anemia, and sometimes termed "functional").

Not all significant heart disease in children is heralded by a murmur. Structural heart disease may be silent and be indicated by other findings. For example, transposition of the great arteries results in cyanosis, anomalous pulmonary venous return in pulmonary edema and hypoxia, and anomalous origin of the left coronary artery from the pulmonary artery in CHF. Acquired heart disease, such as Kawasaki disease, myocarditis, or cardiomyopathy, often produces no murmur.

The common innocent murmurs are better recognized than understood. Because they occur in normal, healthy individuals, few hemodynamic or anatomical data exist to correlate with the murmur, and in some cases pathophysiology is conjectural. Still murmur, which once was thought to be the result of easily appreciated aortic valve flow, is now believed to result from vibration of normal fibrous bands ("false tendons") that cross the left ventricle. This murmur may also be heard in children who have undergone spontaneous closure of a membranous ventricular septal defect, with a small residual aneurysm in the septum. The pulmonary flow murmur seems to be caused by normal flow across the pulmonary valve, perhaps made more apparent because of high cardiac output, close proximity to the chest wall, and, in adolescent females, mild anemia. The venous hum is attributed to turbulence at the confluence of the innominate veins, which is exacerbated in the upright position by gravity.

The *physiologic peripheral pulmonic stenosis murmur*, which is an innocent murmur found in newborns, is produced by turbulence at the origins of the left and right pulmonary arteries. Because less than 10% of the combined ventricular output of the fetus goes to these branches, they are small and arise at a sharp angle from the main pulmonary artery. When postnatal circulation abruptly requires the entire cardiac output to enter these vessels, a relative stenosis is encountered. This physiologic stenosis resolves gradually with remodeling of the pulmonary artery tree by 2 to 3 months of age.

Differential Diagnosis

In healthy children, the differential diagnosis of a heart murmur includes innocent murmurs and murmurs resulting from structural lesions, most of which are congenital. Although the specific features of a particular murmur usually provide many clues to the diagnosis, in the current era, the main task of the primary care physician is to correctly identify the patient who requires cardiology referral. It is therefore important to develop and maintain auscultatory skills. No written or visual material is a good substitute for practice with recordings and actual patients. A good quality stethoscope, with both diaphragm and bell correctly sized for the patient, and snugly fitting but comfortable earpieces, is essential. Conditions should be optimized: The patient should be kept comfortable and, if necessary, distracted, and extraneous environmental noise should be minimized.

Some features may alert examiners to the organic nature of a murmur. Although very loud murmurs (grades 4–6; ie, with associated precordial thrill) usually are not innocent, some innocent murmurs may be as loud as grade 3, particularly with high cardiac output (eg, fever, anxiety, anemia). Diastolic murmurs and continuous murmurs, other than the easily recognizable venous hum, are usually pathologic, as are high-pitched and harsh murmurs, which are better heard with the diaphragm of the stethoscope. Murmurs that change strikingly with body position are rarely the result of CHD.

The common innocent murmurs of childhood are recognizable on auscultatory examination. *Still murmur*, or the "innocent vibratory murmur," is a low-pitched, vibratory, or musical murmur that sounds like a groan. Because of its low frequency, the murmur is better heard with the bell. It is loudest at the left lower sternal border but often is distributed widely over the precordium. This murmur often is quite loud, particularly in the supine position, and is extremely common in school-age children, although it also may be heard in the infant. The characteristics of the murmur itself are diagnostic, although the absence of other findings is supportive.

The *pulmonary flow murmur*, which usually is heard in older children, is a short, blowing systolic ejection (ie, crescendo-decrescendo) murmur localized to the left upper sternal border. It may be louder with the patient in the supine position.

The *venous hum* is a soft continuous murmur, similar to the sound heard in a seashell. Because of its constancy, it is often overlooked. This murmur is commonly heard in preschool and school-age children. Loudest in the right infraclavicular area, it may also be heard on the left. This murmur is highly variable with head and neck position and compression of the neck veins, which may increase or diminish it. It usually disappears with the patient in the supine position.

The physiologic peripheral pulmonic stenosis murmur, an innocent murmur found in newborns, is best heard at the upper left sternal border. This blowing systolic ejection murmur radiates strikingly over the lung fields into the back and both axillae. Typically, it disappears by 3 months of age, whereas the murmur of true stenosis of the pulmonary arteries persists.

Evaluation

History

The history may be helpful in assessment of the child with a murmur. If a thorough history shows that the child has no symptoms, this suggests the absence of severe heart disease and helps exclude many major or complex defects as well as CHF. The absence of symptoms does not, however, exclude several common defects that may require intervention (Table 101.1).

The most common cardiac symptom reported by children or their parents is easy fatigability (Box 101.1). This is difficult to quantitate. Determining exercise intolerance on the basis of history is quite subjective; of course, it may be the result of noncardiac

Table 101.1. Common Organic Heart Murmurs in Asymptomatic Children

Lesion	*Other Clues*
Atrial septal defect	Fixed split second heart sound S_2
Ventricular septal defect (small to moderate)	Loud heart sounds
Patent ductus arteriosus (small to moderate)	Full or bounding pulses
Pulmonic stenosis	Systolic ejection click
Aortic stenosis	Systolic ejection click; suprasternal thrill
Coarctation of the aorta	Weak or absent femoral pulses

Box 101.1. What to Ask

Heart Murmur

- Is the child easily tired? Is the sleeping/napping pattern normal for age?
- Does the child keep up with other similarly aged children?
- If the child is having a good time—for example, at a park or a party—how is the child's endurance?
- Does the child have a family history of congenital heart disease?
- Was the child exposed antenatally to possible cardiac teratogens, such as maternal diabetes?
- Does the child ever report chest pain, either at rest or with activity?
- Does the child ever appear blue?
- Does the child perspire excessively?

causes and may be unrelated to the murmur. Easy fatigability during infancy may be reported as slow or poor feeding. Chest pain, a common symptom in adults with heart disease, is rarely cardiac in origin in children (see Chapter 105). A history of rapid breathing, excessive sweating, and other symptoms referable to CHF is suggestive of organic heart disease. Central cyanosis (ie, involving the oral mucosa rather than the perioral area or the fingers) may be reported occasionally by parents of children with cyanotic CHD but often is not recognized.

Physical Examination

The physical examination often gives strong clues to the cardiac diagnosis beyond the murmur itself. Even in children with known CHD, the nonauscultatory portions of the examination are critical in assessing the cardiac status (ie, how the patient is tolerating the defect). Vital signs, preferably obtained with the child at rest or sleeping, yield information about cardiac status more than specific diagnosis. Tachypnea and tachycardia are present in CHF. A normal resting respiratory rate (ie, <60 breaths/minute in infants) argues strongly against CHF. Blood pressure is normal in most patients with CHD. It may be useful to measure blood pressure in the legs, especially if coarctation of the aorta is suspected because of diminished pulses in the lower extremities or a pulse oximetry difference between upper and lower extremities.

The growth pattern may reflect the presence of any chronic illness, including hemodynamically significant CHD. Affected patients, particularly infants and children with large left-to-right shunts (with or without CHF) gain weight poorly. Height and head circumference are usually normal, although in more severe or prolonged situations height may also be affected.

A complete cardiac examination should be performed. The patient should be assessed for chest asymmetry, which is a sign of long-standing cardiomegaly. Whether the precordial impulse is hyperdynamic should be noted. Extra sounds (eg, clicks, rubs, gallops) should be noted as well. The physician should determine whether the second heart sound is normal in intensity and in width and motion of splitting (ie, variation with respiration).

Additional pertinent findings include lethargy, dysmorphic features suggestive of a genetic syndrome, noncardiac anomalies commonly associated with CHD, central cyanosis, and clubbing. Hepatomegaly occurs in children with CHF. The peripheral pulses should be normal in volume, neither diminished (eg, pedal pulses in coarctation) nor bounding (eg, in patent ductus arteriosus), and equal in all extremities. The temperature and capillary refill of the extremities in children who are not chilled reflect adequacy of the peripheral circulation.

Diagnostic Studies

Routine laboratory studies are not warranted in the evaluation of most murmurs. Electrocardiography is indicated in cases in which heart disease is known or strongly suspected, but a normal echocardiogram may not rule out significant CHD, particularly in the infant. A chest radiograph may be helpful in this setting, but its potential benefits usually are outweighed by the risks of discomfort and radiation exposure. In the case of some tests, such as echocardiography and magnetic resonance imaging, the manner in which the examination is performed varies depending on the suspected diagnosis; direct input from a cardiologist may be necessary to maximize the yield from these studies. Such tests are not suitable for screening purposes and should be obtained only after consultation with a pediatric cardiologist.

Management

If a heart murmur is suspected of being organic in origin because of its features or associated findings, referral to a pediatric cardiologist is indicated. For the young infant (particularly the newborn), the level of concern is high because of the serious risks inherent in ductus-dependent defects (see Chapter 103), which may present with a simple murmur. Newborns with critical heart pathology typically are identified before hospital discharge, particularly in areas in which pulse oximetry screening is routinely performed. Thus, a newborn with a murmur who "passes" the oximetry screen and has an otherwise normal examination (including femoral pulses) does not require echocardiography or cardiology consultation on an emergent basis.

Although urgency is not warranted in the case of a child who is asymptomatic, parental and physician anxiety can best be allayed

by proceeding to consultation promptly (ie, within weeks). In some cases, a repeat examination may be useful before deciding whether to consult a specialist, particularly if the murmur is initially heard under nonphysiologic conditions, such as fever. Typically, the determination of whether to perform tests and which to perform is best left to the specialist. Not all cardiologists perform all tests on all patients. Because pediatric cardiologists are particularly skilled and experienced in cardiac auscultation, an examination by a confident specialist, at a cost which is an order of magnitude less than that of echocardiography, may be all that is indicated. Innovative methods are under development to enable long-distance auscultation via telemedicine using digital recordings obtained by the primary physician, and even computer-aided auscultation of heart murmur. These approaches may be particularly helpful in overcoming geographic challenges in underserved populations or populations distributed over a large geographic area (ie, rural populations).

Management of organic heart disease in infants and children is also best done by specialists. Treatment may include medications, interventional catheterization, or cardiac surgery. Communication between the primary care physician and the cardiologist, however, is essential to delivery of optimal patient care.

If the murmur is innocent, physicians must complete the steps listed in Box 101.2.

Box 101.2. Steps for Managing an Innocent Heart Murmur in the Pediatric Patient

1. Inform the child and family about the presence of the murmur. Even if the murmur is benign, patients have a right to know that it was heard. In addition, they are likely to be examined by other clinicians who will report it, which may result in the erroneous suspicion of either a new murmur or negligence on the part of the first examiner.
2. Clearly explain the diagnosis to the parent(s)/guardian(s) and, depending on patient age, the child. It is essential that they understand that this is a normal finding rather than a minor abnormality. In some cases, it may be appropriate to notify teachers or athletic coaches to prevent misunderstanding. Physicians must stress that no further evaluation is necessary and no restrictions are indicated. Printed brochures that explain innocent murmurs are available from organizations such as the American Heart Association.
3. Document the description of the murmur and the diagnosis itself in the medical record. If the examiner possesses a digital stethoscope, a recording of the murmur may be entered into the patient's electronic health record. A murmur that is clearly and unequivocally innocent, with no evidence of heart disease, should not affect the child's access to insurance, participation in sports, etc. Medical documentation also helps protect patients from unnecessary reevaluations in the future.
4. Proceed no further. No laboratory studies or consultations need be performed. If the evaluation has been completed by a specialist because of suspicion of CHD by the referring physician, no follow-up with the specialist is indicated. The child is referred back to the primary care physician.

Prognosis

The prognosis for children with heart murmur depends on the cause of the murmur. Children with an innocent murmur, who by definition have normal hearts, have a normal prognosis—with 1 exception. If parents or guardians mistakenly believe their children to have heart disease, they may treat the children inappropriately (eg, unnecessary testing, restriction of activities). As a result, children may develop sedentary habits and inferior self-image.

With appropriate medical attention, the prognosis is normal or near normal in most patients with CHD. Children with minor defects not requiring intervention (eg, small ventricular septal defect, mild pulmonic stenosis) need only infrequent cardiology follow-up visits. Endocarditis prophylaxis, previously recommended in such cases, is no longer recommended because of its high risk/benefit ratio. With the development of refined cardiac surgery and interventional catheterization, even children with the most complex cardiac anomalies currently have a good outlook with respect to both quality of life and life expectancy.

CASE RESOLUTION

The healthy girl with no history of cardiovascular symptoms has a heart murmur and an otherwise unremarkable physical examination. The murmur is a typical Still (ie, innocent vibratory) murmur, which is identifiable by its low-pitched, vibratory quality. No further evaluation is necessary. The diagnosis is explained, the girl and her parents are reassured, and the murmur and diagnosis are noted in the medical record.

CHAPTER 102

Palpitations

Robin Winkler Doroshow, MD, MMS, MEd, FAAP, and Nefthi Sandeep, MD

CASE STUDY

A previously healthy 10-year-old girl presents to your office with a report of an episode of a "racing heart." The episode occurred approximately 1 week before the clinic visit while she was watching television. Her heart suddenly started pounding hard, and the sensation stopped just as suddenly approximately 30 minutes later. During the episode, the child's mother felt the girl's chest and noted that her heart was beating extremely fast and hard. The child looked scared during the episode but was in no respiratory distress and was alert. Her parents drove her to the local emergency department, but the symptoms stopped en route. On arrival in the emergency department, the girl was fine and had normal vital signs and physical examination and a normal result on electrocardiography. In retrospect, she recalls having had brief such episodes in the past.

Questions

1. What is the significance of palpitations in an otherwise well child?
2. How likely is this symptom to be cardiac in origin, and if so, how likely is it to be life-threatening?
3. How can transient cardiac events be documented?
4. What does the primary care physician need to do and know before referring the child to a cardiologist?

The term *palpitations*, which is currently used more by medical personnel than by patients, refers to a sensation of increased awareness of the heart beating faster, harder, or less evenly than expected. Frequently used lay terms for this perception are "racing," "fluttering," or "pounding of the heart." Some patients simply report a sudden unexplainable feeling of being afraid, or they may interpret the symptom as pain or other indescribable discomfort in the chest.

Epidemiology

The prevalence of palpitations is unknown. Palpitations are a fairly common reason for referral of pediatric patients to cardiologists, although it is a significantly less common reason than murmurs or chest pain. Because articulating this complaint requires significant verbal skills as well as bodily awareness, it is not usually reported before age 3 or 4 years; beyond this threshold, it may occur at any age. Cardiac arrhythmia, which is the most likely significant cause of this symptom, occurs at any age—even in utero—but the presenting symptom in younger patients usually reflects secondary or tertiary physiological changes, such as altered mental status, color change, syncope, or respiratory distress.

Clinical Presentation

As with chest pain, patients' descriptions of symptoms of palpitations are quite varied. Palpitations are almost always episodic, with a sudden sensation of the heartbeat taking the child by surprise. Because this feeling may be alarming or at least disconcerting (even to adults), the patient may not have been a reliable observer and thus, the report of the episode or episodes may be lacking in clarity or detail. The sense of alarm may stem from the unexpected nature of onset of the palpitations, interpretation in an older child or an adult observer that a dangerous cardiac event (eg, heart attack) is occurring, or misinterpretation of a rapid heartbeat as a reflection of fear. It is also not unusual to see a child entirely unconcerned about this symptom accompanied to the visit by an extremely concerned parent.

Almost all patients with palpitations report its occurrence in the absence of other medical issues, as in the case study at the beginning of this chapter.

Pathophysiology

Palpitations are a subjective symptom and may reflect a cardiac issue (most commonly arrhythmia), anxiety, or simply increased somatic awareness. Only the first of these issues has a significant component of abnormal physiology.

The degree to which cardiac function may be compromised in cases of arrhythmia depends on the nature of the rhythm, heart rate, duration of the episode, and presence or absence of underlying cardiac disorders, whether congenital or acquired. In ventricular tachycardia (VT), the heart rate is usually in the range of 150 to 180 beats per minute, and filling is not seriously impaired; however, loss of atrioventricular synchrony and inefficient ventricular emptying result in poor cardiac output in most cases. In addition, VT can deteriorate to ventricular fibrillation, with essentially no functional cardiac output, which is a life-threatening situation. Supraventricular tachycardia (SVT) is by far the most frequently diagnosed sustained arrhythmia in the pediatric population. It is characterized by a substantially higher heart rate (often >250 beats per minute), with relatively less time in diastole and more in systole.

This increased heart rate results in compromise of ventricular filling and secondarily of the cardiac output, as well as an unfavorable myocardial supply-demand ratio, which may cause angina-like chest pain. Atrioventricular block is uncommon in otherwise healthy children and is more likely to produce presyncope or syncope than palpitations; however, the latter may also occur. Atrial ventricular block impairs cardiac output by a decrease in ventricular rate and loss of atrioventricular synchrony.

Some patients report erratic, very brief pounding sensations caused by single premature ventricular contractions (PVCs), whereas other patients are unaware of this common arrhythmia (Figure 102.1). Those patients who do perceive them are sensing the increased cardiac output of the immediate post-PVC beat as a "thump" and rarely experience associated symptoms. Premature atrial contractions are quite common but are rarely perceived by the patient.

Palpitations related to anxiety disorders often are associated with other catecholamine-induced symptoms, such as dyspnea or tremor; these somatic symptoms may dominate over psychiatric symptoms and divert the physician's attention from the pursuit of a psychological cause.

Differential Diagnosis

The differential diagnosis of palpitations is summarized in Box 102.1. In cases of sudden onset of isolated rapid pounding of the heart, SVT (which includes reentrant SVT, junctional tachycardia, ectopic atrial tachycardia, and atrial flutter) is the most common cardiac cause of such pounding (Figure 102.2). One study found that 35 of 238 consecutive children whose rhythms were transmitted transtelephonically during palpitations had SVT; no other significant arrhythmias were found in the other 203 patients. Despite the rarity of them, other tachyarrhythmias and bradyarrhythmias must be considered, however, because of the poorer prognosis associated with them and the importance of instituting therapy to manage them.

Sinus tachycardia in the absence of anxiety may be experienced by individuals with decreased stroke volume, such as patients with myocarditis or cardiomyopathy, either of which may manifest with palpitations. Children undergoing stimulant therapy for attention-deficit/hyperactivity disorder experience palpitations with surprising infrequency, perhaps because their slight overall increase in heart rate is chronic rather than episodic. Cardiac arrhythmias in this setting are no more common than in the general pediatric population. However, stimulants in the form of so-called energy drinks are becoming increasingly popular in the adolescent and preadolescent population and may result in inappropriate sinus tachycardia. Caffeine is the main active ingredient in most energy drinks. Other beverages, including guarana, also have inotropic and chronotropic properties. Use of drugs, such as amphetamines, likewise may result in sinus tachycardia, but patients rarely experience symptomatic discomfort. Hyperthyroidism is associated with sustained sinus tachycardia, which patients occasionally report and can also progress to significant cardiac arrhythmias.

Psychogenic palpitations are quite common in childhood, occurring in approximately 50% of pediatric patients with anxiety disorders and panic disorder. Such palpitations may be the presenting symptom and should not be dismissed by the physician as

Box 102.1. Differential Diagnosis of Palpitations in Children and Adolescents

Cardiac Arrhythmias

- Atrioventricular block (rare cause)
- Premature atrial contractions (uncommon cause)
- Premature ventricular contractions (common cause)
- Sinus tachycardia
  - Caused by high-output states, such as hyperthyroidism and anemia (uncommon cause)
  - Caused by low cardiac output, such as in patients with myocarditis or cardiomyopathy (rare cause)
  - Caused by stimulants, such as amphetamines, β agonists, and caffeine (common cause)
- Supraventricular tachycardia (common cause)
- Ventricular tachycardia (rare cause)

Psychogenic

- Hypochondria (common cause)
- Panic attacks and other anxiety disorders (uncommon cause)
- School phobia (common cause)

Other

- Somatic hyperawareness (common cause)

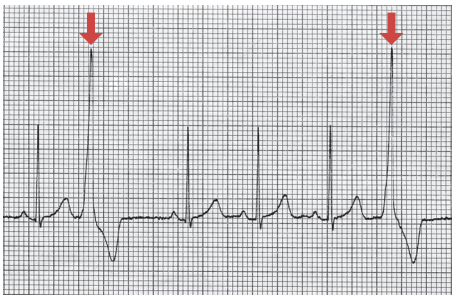

Figure 102.1. Electrocardiogram showing premature ventricular contractions (arrows).

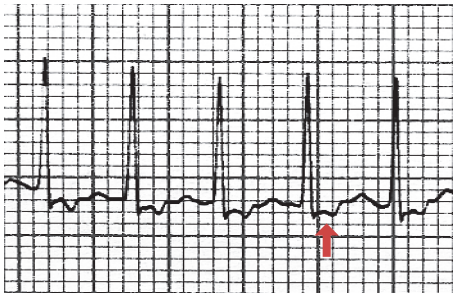

Figure 102.2. Electrocardiogram showing supraventricular tachycardia at 257 beats per minute. Note ST depression (arrow) caused by relative myocardial ischemia.

unimportant. For patients in whom anxiety disorders are ruled out, diagnosing somatic hyperawareness, such as is often seen in healthy adolescents (eg, "My heart speeds up when I take a test"), may reassure the patient that there is no underlying cardiac disease.

Evaluation

The history and documentation of cardiac rhythm are critical to the evaluation of children with palpitations. The history guides the physician in determining which direction to pursue and, in particular, how extensive an arrhythmia workup is required. When arrhythmia is suspected, documentation (ie, "capturing" the arrhythmia) is essential prior to intervention.

Obtaining a complete history and physical examination helps the pediatrician establish a level of concern about the likelihood of cardiac causes for the palpitations. That, in turn, guides elective referral to a cardiologist, emergent referral to an emergency department (ED) or hospital, elective referral to a psychologist or psychiatrist, or, alternatively, management of the condition without further referral.

History

It is important to obtain as much descriptive information as possible directly from the child as well as any witnesses (Box 102.2). Language such as "very fast" may be interpreted differently by different people and, thus, is not helpful. A witness can also report whether the patient had a change in color, respiratory pattern, or mental status.

Palpitations of abrupt onset and offset are more likely to reflect paroxysmal cardiac arrhythmias, while sinus tachycardia resulting from stimulants or anxiety is more likely to have a gradual onset and resolution. Some arrhythmias may be triggered by certain events or actions, such as exertion, emergence from anesthesia, or exposure to stimulants (eg, β agonists).

Box 102.2. What to Ask

Heart Palpitations

- What does it feel like? If the heartbeat is fast, how fast?
- What symptoms are associated with the palpitations?
- Do the symptoms start gradually or abruptly? How do they end? Can the patient cause them to end?
- How frequent are the episodes, and how long do they last?
- Are the episodes precipitated by certain events?
- How disruptive are these symptoms to activities of daily living?
- Does the child have a history of cardiac problems, such as congenital heart disease or other symptoms, that point to an underlying defect?
- Did the onset of these episodes correlate with other life or medical events?
- Is the child taking or using stimulant medication or beverages that might be contributing to these symptoms?
- Is there a family history suggestive of cardiac arrhythmia, such as sudden unexpected death or long QT syndrome?

The presence or absence of associated symptoms may help determine the seriousness of a cardiac event. Ventricular arrhythmias, such as sustained VT, often cause an abrupt decrease in cardiac output, resulting in loss of consciousness or even sudden death. Brief episodes of SVT may not be associated with any symptoms other than the palpitations themselves; however, a sustained episode of SVT may be associated with fatigue, breathlessness, chest pain, nausea, or dizziness.

Most children reporting palpitations have no relevant medical history. However, patients with past history of congenital heart disease (particularly if it was treated surgically), inflammatory heart disease (eg, myocarditis), or exposure to cardiotoxins (eg, anthracycline chemotherapeutic agents) are more likely to have experienced a significant arrhythmia than others and are less likely to tolerate arrhythmia well. In these settings, prompt and thorough evaluation is essential. As mentioned previously, if patients become alarmed, they also may experience symptoms reflective of increased catecholamine output (eg, breathlessness, pallor), thereby complicating the assessment. These additional symptoms may respond to reassurance that there is no underlying cardiac disease even when the palpitations persist.

The physician must also elicit family history for evidence of heritable rhythm disorders (eg, long QT syndrome [LQTS]) or events (eg, unexpected sudden death) that may be suggestive of such an inherited disorder.

Physical Examination

The physical examination of the patient presenting with isolated episodic palpitations is rarely contributory. The cardiac rhythm and rate should be noted, but rarely are they directly indicative of a diagnosis. Findings such as a heart murmur or gallop may point toward a previously unidentified underlying cardiac disorder.

Laboratory Studies

In the primary care setting, laboratory studies are rarely necessary to make the determination of whether to refer the patient. Typically, the history and physical examination suffice. In the setting of significant suspicion of arrhythmia, the cardiology consultant considers various studies with a focus on documenting the rhythm during symptoms and seeking evidence of underlying causes of arrhythmia (Table 102.1).

Electrocardiography

Electrocardiography (ECG) is a readily available test that is often diagnostic if obtained during an episode of palpitations. Parents should be instructed to take the child to an urgent care center or ED promptly if the child experiences a prolonged episode (eg, lasting 1 hour) and request that ECG be done immediately on arrival. In the absence of symptoms at the time of the visit, often the ECG does not aid in diagnosis. It is important, however, to evaluate for conditions that predispose a patient to arrhythmia. For example, patients with Wolff-Parkinson-White syndrome are predisposed to SVT, and patients with LQTS are predisposed to VT, in particular, to

Table 102.1. Laboratory Tests Used in the Evaluation of Palpitations in Pediatric Patients

Test	*Information Provided*
ECG	Diagnostic if obtained during symptoms Underlying predisposition to palpitations, such as Wolff-Parkinson-White syndrome or long QT syndrome
Holter monitor (ambulatory ECG)	Passively captures rhythm during symptomatic episodes during a 24- or 48-hour recording period Results are subsequently downloaded
Event detector	Patient-activated Captures rhythm during symptoms over an extended period (eg, 30 days) Real-time download
Implantable monitor	Captures rhythm during symptoms over an extended period (≤3 years) Some devices allow real-time monitoring
Patch monitor	Passively captures rhythm up to 14 days Results are downloaded after the patch has been removed from the patient
Exercise test	Provocation of symptoms or arrhythmia in patients with symptoms that are induced by exercise
Electrophysiology study	Provokes arrhythmias Identifies additional conducting pathways that support arrhythmias Opportunity to intervene (eg, ablation)
Echocardiography	Identifies underlying structural or functional cardiac disorder
Cardiac magnetic resonance imaging	Assesses cardiac anatomy in complex congenital heart disease Evaluates for arrhythmogenic right ventricular cardiomyopathy and scarring caused by myocarditis
Hematocrit	Identifies underlying anemia
Thyroid function tests	Identify underlying hyperthyroidism
Toxicology screening	Identifies drug exposure

Abbreviation: ECG, electrocardiogram.

torsades de pointes (Figures 102.3 and 102.4). Either of these conditions may be only intermittently apparent on a surface ECG; thus, their absence on a single tracing does not exclude them.

Documenting Cardiac Rhythm During Symptomatic Episodes

Documentation of cardiac rhythms during symptomatic episodes is the key to making a diagnosis of arrhythmia and, more often, to ruling out arrhythmia as a cause of palpitations. Multiple techniques are available, each with advantages and disadvantages. The

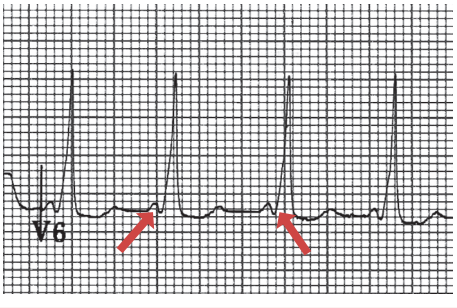

Figure 102.3. Electrocardiogram from a patient with Wolff-Parkinson-White syndrome. Note the short PR interval (left arrow) and the delta wave (right arrow) created by preexcitation.

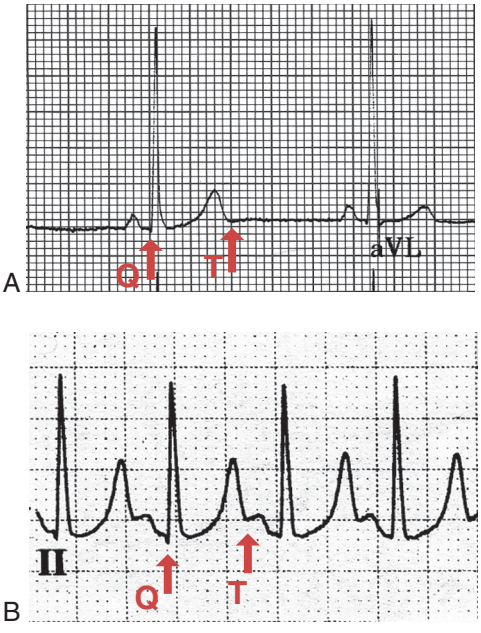

Figure 102.4. A, Normal QT interval. B, Prolonged QT interval. Onset of Q wave and end of T wave indicated by arrows.

Holter monitor is a well-established, sensitive, high-quality random 24- to 48-hour tracing. Only in cases with very frequent (ie, almost daily) palpitations is it likely to capture the symptomatic rhythm itself; however, in some cases subclinical arrhythmias such as brief bouts of SVT may go unnoticed by the patient but are captured on the Holter monitor. The test is readily available but not well tolerated by very young children; it is not monitored by clinicians or technologists in real time; and its value is substantially undermined in cases in which an accompanying symptom diary is not maintained. Similar to ECGs, Holter monitors have excellent specificity (ie, low rate of false-positive results) but poor sensitivity (ie, high rate of false-negative results) resulting from recording during a symptom-free period; thus, a negative result with a Holter monitor does not definitively rule out an arrhythmia. Additional advantages of the Holter monitor include the ability to detect intermittent preexcitation, and the option to quantify the burden of ventricular ectopy.

Less frequent episodic palpitations are more often captured on *event detectors*, also known as *transtelephonic monitors*, which are small devices that can be taken home with the patient for several weeks and used to capture the ECG in the event of symptoms. The recording is transmitted by analog or cellular telephone to a doctor's office or monitoring service. Most transtelephonic monitors are *post-event monitors*, which require the patient to actively produce the recording. With this method, however, the onset of the arrhythmia is not captured. These obstacles may be overcome with use of a *loop-type event recorder*, which continuously records and erases a short loop of ECG. The patient depresses a button when experiencing the symptoms, and the device saves the previous 2 to 3 minutes, thereby enabling capture of the onset of the arrhythmia or even an arrhythmia that has ceased by the time the patient activates the device. Some of these devices may also be programmed to automatically record in certain situations, such as when the heart rate exceeds a selected threshold. Loop recorders require the continuous wearing of stick-on leads with wires, and patient tolerance for them is low.

As technology continues to improve, the range of diagnostic monitor options increases. New *adhesive patch monitoring devices* (eg, Zio, iPatch) are less invasive and less costly than implantable monitors and may be kept in place on the skin for up to 14 days. These devices are wireless, lightweight, single-use, and water resistant. Patch monitors have been studied extensively in the adult population, and early cross-sectional studies in children are promising. The duration of use is an important advantage over the Holter monitor, because 40% to 50% of arrhythmias in ambulatory children occur more than 48 hours from the start of monitoring, which is beyond the reach of a Holter monitor, which records for not more than 48 hours (Figure 102.5). Regardless whether arrhythmia is triggered by a particular symptom, 90% of arrhythmias are diagnosed within 7 days. Current models that have been approved by the US Food and Drug Administration do not allow real-time monitoring; the data can be analyzed only after the patch has been removed from the patient.

Some patients benefit from a small *implantable monitor* (eg, Reveal), which can either automatically record the ECG when certain parameters are met or be activated by the patient. This device is not commonly used in pediatric patients; however, it may be quite helpful for rhythm documentation of infrequent but potentially serious events, such as extended unexplained syncope or near-miss sudden death. Minor surgery is necessary for implantation and for removal up to 3 years later. A newer version, the Reveal LINQ, is injected subcutaneously under local anesthesia. Some models allow real-time monitoring, and others require downloading after removal.

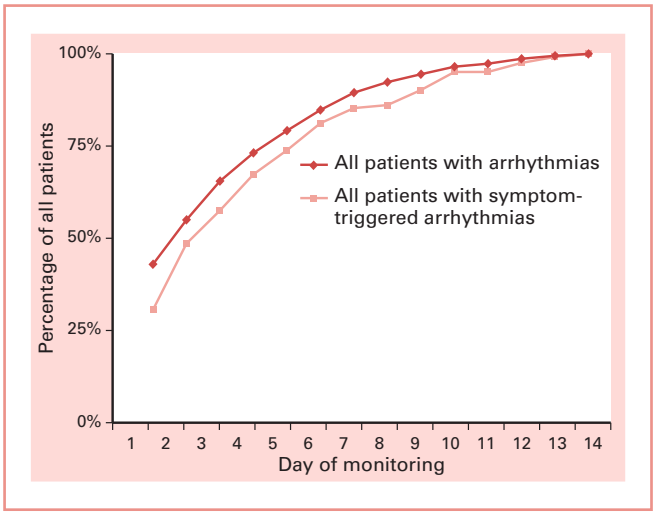

Figure 102.5. Graph showing cumulative yield of arrhythmia detection by patch monitor in children in a 14-day period. Among patients with arrhythmia, the condition was identified by day 7 of monitoring in 90% of patients, but it was identified in only 56% of patients through day 2 of monitoring.

Smartphone-based monitoring, which is designed for use in the home, requires purchase of specific hardware and software, followed by deployment by the patient or a caregiver. This method was recently introduced for use in adult cardiology patients, in whom it is well suited to distinguish paroxysmal atrial fibrillation from sinus rhythm. The utility and reliability of this technology in pediatric patients have not yet been demonstrated.

Stress Testing

In select cases in which physical exercise consistently triggers palpitations, a treadmill or bicycle exercise test may occasionally be used to provoke the symptom.

Electrophysiology Study

In the case of strong suspicion for a serious arrhythmia that cannot be captured using any of the previously described methods in a reasonable time period, invasive electrophysiology testing may be performed to diagnose provocable arrhythmias (eg, VT) or abnormal conducting pathways that do not manifest on the surface ECG. These complex studies are not without risk and are performed only by experienced pediatric cardiac electrophysiologists who have the advantage of performing a highly detailed arrhythmia evaluation

in a controlled setting, testing for short-term drug effects, and also intervening with ablation if needed.

Echocardiography

In the absence of history, symptoms, or physical findings suggestive of underlying heart disease, echocardiography is unlikely to be abnormal. However, it may be helpful for the patient with 1 of these risk factors, and it is recommended for the patient with a high-risk rhythm (eg, VT). Particular emphasis is placed on evaluation of ventricular function. Abnormal contractility may result in arrhythmia, while persistent arrhythmia may result in abnormal contractility.

Cardiac Magnetic Resonance Imaging

In patients with ventricular arrhythmias of unknown etiology, cardiac magnetic resonance imaging may be diagnostic for arrhythmogenic right ventricular cardiomyopathy. Echocardiography is not sensitive for this diagnosis. Cardiac magnetic resonance imaging is also sensitive for fibrosis because of the presence of inflammation in patients with previously undiagnosed myocarditis.

Blood Tests

Many cardiologists screen for thyroid dysfunction in patients with isolated tachyarrhythmias. Doing so is rarely productive, however, particularly in the absence of physical findings such as resting sinus tachycardia, tremor, or sweating. Anemia of at least moderate degree may cause sinus tachycardia or a pounding sensation resulting from high stroke volume; thus, a complete blood cell count may be considered in some cases.

Toxicology Screen

Patients experiencing tachyarrhythmias in an acute setting should be evaluated for possible drug abuse as an underlying cause.

Management

The most common outcome of this type of evaluation is that cardiac arrhythmia is ruled out. When one of the methods of documentation described previously demonstrates normal sinus rhythm during the symptoms, reassurance is all that is needed. Most commonly, pediatric patients evaluated for palpitations have no evidence of cardiac arrythmia and upon monitoring have a normal sinus rhythm. These patients and their families are usually reassured by their normal test results and no further intervention is necessary.

If sinus tachycardia is documented during symptoms, the underlying cause, whether medical or psychosomatic, should be diagnosed and managed appropriately. Minor, clinically insignificant cardiac arrhythmias (eg, isolated low-grade PVCs) usually do not require treatment; reassurance of the patient and parent(s)/guardian(s) is sufficient management.

Several options exist for managing clinically significant cardiac dysrhythmia, and the appropriate method is selected based on the nature of the rhythm and its risk to the patient. Serious ventricular arrhythmias (eg, VT) may require aggressive treatment, such as antiarrhythmic medication, beta blockers, or, in some cases, insertion of an implantable cardioverter-defibrillator. A cardiac electrophysiologist diagnoses VT and initiates the appropriate management.

Supraventricular tachycardia is the most frequently diagnosed clinically significant arrhythmia in children. Beyond the newborn period and in the absence of underlying heart disease, these rhythms are not life-threatening unless they are sustained for very long periods (eg, days), which is uncommon. These rhythms may, however, be quite unpleasant and highly disruptive. The child who experiences infrequent, fleeting episodes of well-tolerated SVT may not require any intervention. However, preexcitation persisting into the second decade may warrant ablation to prevent sudden death in the event of atrial fibrillation. For more troublesome cases, pharmacologic management is usually well tolerated and highly efficacious in preventing recurrences. Currently, results are excellent with interventional catheterization, such as cryoablation or radiofrequency ablation of accessory pathways, and risks to the patient are low. Use of interventional catheterization may enable the child to be free from not only the arrhythmia but also of the need to take daily medications.

In patients with documented SVT, recurrences may result from pharmacologic breakthroughs. In many instances, the recurrence of SVT can be interrupted by use of vagal maneuvers (eg, Valsalva maneuver) or the application of cold water or ice to the face. The use of these maneuvers is not recommended in patients who have not yet had an arrhythmia diagnosis established.

Prognosis

For patients for whom the concern for heart disease is low and for those for whom it is excluded or found not to be clinically significant, the prognosis is the same as for other children. Patients with paroxysmal SVT usually respond well to pharmacologic management, although some experimentation may be necessary to find the best-tolerated and most effective treatment. In the absence of the rare complication of complete heart block, ablative procedures yield an excellent prognosis and often are curative.

The prognosis is less certain for children with serious ventricular arrhythmias, particularly in the setting of arrhythmogenic right ventricular cardiomyopathy, LQTS, or myocarditis. However, the evolution of implantable cardioverter-defibrillators suitable for children has already resulted in improved quantity and quality of life.

CASE RESOLUTION

The child wore a Holter monitor, during which time she was asymptomatic. She was then issued an event detector and 2 weeks later successfully recorded and transmitted her electrocardiogram during an episode of palpitations. It demonstrated SVT at a rate of 250 beats per minute that terminated spontaneously after 20 minutes. Her parents elected to have her undergo electrophysiology study, which demonstrated an aberrant pathway that was successfully ablated without complication. At the 1-year follow-up visit, the patient was free of palpitations, on no medications, and participating actively in age-appropriate activities.

CHAPTER 103

Cyanosis in the Newborn

Robin Winkler Doroshow, MD, MMS, MEd, FAAP

CASE STUDY

A 3,500-g (7.7-lb) term male neonate born to a 29-year-old, gravida 2 para 2, healthy mother by spontaneous vaginal delivery is well until 24 hours of age, when a nurse notes that he is cyanotic. On examination, he appears blue but in no distress. The vital signs are axillary temperature of 37°C (98.6°F), pulse of 130 beats per minute, respirations of 40 breaths per minute, and blood pressure of 80/60 mm Hg in the right arm. His general appearance is normal except for the cyanosis. His heart sounds are normal, and no murmur is heard. His liver is not palpable, and the peripheral pulses are normal and equal in all extremities. Capillary refill is normal. Oxygen saturation is 65% by pulse oximetry.

Questions

1. What are the causes of cyanosis in newborns?
2. What is the appropriate evaluation of cyanosis in newborns?
3. How urgent is the assessment? What are the risks and benefits of further evaluation?
4. Which aspects of management should be initiated by a primary care physician at a community hospital?
5. Which types of treatment should be undertaken by the consulting pediatric cardiologist at the referral center?

Cyanosis is a bluish appearance of the skin resulting from the presence of reduced hemoglobin in the tissues. Central cyanosis, which is detected initially in the oral mucosa and nail beds but is generalized when severe, indicates at least 4 to 5 g/dL reduced hemoglobin. Hypoxemia is usually the cause. This condition is frequently present in neonates with pulmonary pathology but is also among the most common presentations of severe congenital heart disease (CHD).

Because cyanotic CHD in newborns may be life-threatening, it must not go undiagnosed. Most diagnostic studies have minimal risk. Even the risk of cardiac catheterization, which is rarely indicated, is relatively low in this setting. Most of the lesions that cause cyanotic CHD can be palliated or corrected, and the prognosis is good.

Epidemiology

Cyanotic CHD occurs in approximately 2 to 3 of every 1,000 live births. Approximately 80% to 90% of these patients, usually those that are most severely affected, are detected prenatally or in the first 30 days after birth. Failure to diagnose major cyanotic CHD before newborn discharge, however, occurs in at least 10% of cases, resulting in unnecessary morbidity and mortality. Newborns with low pulmonary blood flow or lesions causing poor mixing most often present with obvious cyanosis, although initially they otherwise appear well and comfortable. Those with high pulmonary flow are less blue and often present first with congestive heart failure (CHF) or a murmur; however, the condition may be detected earlier using screening pulse oximetry.

Although fetal diagnosis continues to improve, most cyanotic CHD is not diagnosed before birth. The antenatal history, gestational age, birth weight, and delivery room examination are unremarkable. Failure to identify CHD in the setting of routine obstetric ultrasonography does not rule it out; the sensitivity of such scans in the general population is very low. Congenital heart disease is more likely in some situations that can be anticipated prenatally (Box 103.1). In these settings, increased suspicion may result in antenatal detection using specialized echocardiography.

Clinical Presentation

Neonates with cyanotic CHD often present within the first week after birth with cyanosis of the oral mucosa. In more severe cases, generalized cyanosis occurs. The abnormal color may be more apparent with effort (eg, feeding, passing stool) or crying. Respiratory distress, which is heralded by grunting, nasal flaring, and retractions, is minor or absent in many newborns with cyanotic CHD; this is in striking contrast to those with respiratory disease, such as respiratory distress syndrome or aspiration pneumonia. In cases of severe hypoxia, metabolic acidosis results in poor perfusion and

Box 103.1. Factors Associated With Increased Risk of Congenital Heart Disease

- Genetic syndromes (eg, trisomies, DiGeorge syndrome)
- Certain extracardiac anomalies (eg, omphalocele, forearm anomalies)
- High incidence of congenital heart disease in the family
- Maternal diabetes if poorly controlled during the first trimester
- Fetal exposure to cardiac teratogen (eg, lithium, isotretinoin)
- Fetal or neonatal arrhythmia other than premature atrial beats

compensatory tachypnea with hyperpnea, a key sign of critical heart disease. Additional findings depend on the nature of the causal lesion (Box 103.2). It is important to note that the absence of associated physical findings does not exclude cyanotic CHD.

Because of the dangers of overlooking ductus-dependent CHD and the suboptimal sensitivity of the physical examination to detect it, all US states (and many other nations) now mandate that newborn screening include pulse oximetry determination(s) prior to discharge, usually at 24 hours of age. This test, often called CCHD (for critical CHD) screening, is a highly sensitive, specific, and cost-efficient means of detecting cyanotic CHD before the cyanosis or other findings become apparent. It allows initiation of intervention (discussed later in this chapter) prior to ductal closure, thereby maintaining the baby's perfusion and oxygenation, and decreasing morbidity and mortality. This approach, which became widespread at the beginning of the 21st century, is likely to become the most common means of diagnosing life-threatening heart disease in the newborn.

For the purposes of this discussion, the term "cyanosis" includes a positive CCHD screen, even if the infant does not appear blue to the naked eye.

Pathophysiology

Cardiac cyanosis is caused by right-to-left shunting so that systemic venous blood bypasses the pulmonary circulation and enters the systemic circulation. Two conditions usually are necessary to produce this type of shunting: a communication (eg, septal defect) for shunting across the blood and a cause (eg, pulmonic stenosis) for shunting away the blood from the lungs. The most notable exception is simple transposition of the great arteries (TGA), in which the fundamental connections are abnormal and all systemic venous blood is directed to the systemic arterial circulation. Lesions associated with cyanosis may be divided into 3 groups: low pulmonary blood flow (LPBF), high pulmonary blood flow (HPBF), and poor mixing.

The *LPBF group* consists of tetralogy of Fallot, pulmonary atresia with intact ventricular septum, and nearly any combination of defects that includes pulmonary atresia or severe pulmonic stenosis. Pulmonary flow is diminished and may derive entirely from the ductus arteriosus while it remains patent. Aside from obvious cyanosis (and associated oxygen saturation <80%), neonates often appear well.

Box 103.2. Diagnosis of Cyanosis in the Newborn: Possible Associated Findings

- Low oxygen saturation
- No improvement with oxygen
- Heart murmur
- Tachypnea
- Increased perspiration
- Abnormal cardiac silhouette on radiograph
- Abnormal electrocardiogram
- Abnormal echocardiogram

The *HPBF group* includes truncus arteriosus, single ventricle, and combinations of defects that involve mixing of oxygenated and unoxygenated blood and little or no obstruction to pulmonary flow. Although a right-to-left shunt is present, the left-to-right shunt is even greater. Pulmonary venous return is therefore voluminous and contributes disproportionately to systemic output. Cyanosis is less apparent; saturation is greater than 80% and may be as high as 95%. Pulmonary flow increases over the first days and weeks after birth as the pulmonary vascular resistance falls and CHF develops, as in patients with isolated shunt lesions (eg, ventricular septal defect). Some neonates with HPBF lesions also have obstruction to systemic blood flow (eg, coarctation of the aorta, hypoplastic left heart syndrome) and may depend on the ductus arteriosus to carry some or all of this flow.

The *poor mixing group* is limited to TGA and its variants. The right and left circuits are in parallel rather than in series, and survival depends on interchange of oxygenated and unoxygenated blood between them. Most newborns with poor mixing present with marked cyanosis (ie, saturation <80%), as with patients in the LPBF group.

Severe hypoxemia (ie, partial pressure of oxygen [PO_2] <35 mm Hg for the average newborn) is not compatible with prolonged survival. Neonates experience tissue hypoxia, anaerobic glycolysis, and metabolic acidosis. Respiratory compensation may occur initially. Even with a normal pH, however, the presence of metabolic acidosis (ie, large base deficit) indicates life-threatening hypoxia, necessitating immediate intervention, without which death ensues in a matter of hours.

Differential Diagnosis

The major causes of cyanosis are cardiac (Box 103.3) and respiratory (Box 103.4). Diagnoses in the latter group include problems of the lung, chest, airway, or respiratory drive.

Persistent fetal circulation, or persistent pulmonary hypertension of the newborn, is perhaps the condition that is most often confused with cyanotic CHD. In this condition the heart and great vessels are structurally normal; however, high pulmonary vascular resistance, which is common in postterm newborns with perinatal distress or pulmonary disease, causes blood to shunt away from

Box 103.3. Cyanotic Congenital Heart Defects

Low Pulmonary Blood-flow Lesions

- Tetralogy of Fallot
- Pulmonary atresia with intact ventricular septum
- Complex lesions with severe pulmonary stenosis or atresia
- Obstructed total anomalous pulmonary venous return

High Pulmonary Blood-flow Lesions With Mixing

- Truncus arteriosus communis
- Tricuspid atresia
- Transposition with ventricular septal defect

Poor Mixing (ie, Transposition of the Great Arteries)

Box 103.4. Noncardiac Causes of Neonatal Cyanosis

- Persistent fetal circulation
- Upper airway obstruction (eg, choanal atresia)
- Pulmonary infection (eg, group B streptococcal infection)
- Aspiration (eg, meconium aspiration syndrome, tracheoesophageal fistula)
- Pulmonary hypoplasia (eg, Potter syndrome, diaphragmatic hernia)
- Respiratory distress syndrome (eg, in preterm neonates)
- Thoracic hypoplasia (eg, thanatophoric dwarfism)
- Hypoventilation (eg, neurologic depression)

the lungs at the foramen ovale and ductus arteriosus. Profound cyanosis that is unresponsive to supplemental oxygen, particularly in postductal sites (eg, lower extremities), may be the only abnormal finding, and echocardiography is required to exclude CHD.

Pulmonary cyanosis may be caused by infection (eg, group B streptococcal pneumonia); aspiration (eg, meconium, tracheoesophageal fistula); pulmonary hypoplasia (eg, oligohydramnios sequence, diaphragmatic hernia); respiratory distress syndrome (eg, preterm); or a host of other problems of the lung, chest, or airway. Neurologic depression may produce hypoventilation with resultant hypoxia.

Evaluation

Evaluation of the newborn with cyanosis must be expeditious so that management is not delayed. In some cases, therapy may be initiated before the evaluation is complete. All available data, including the statistical likelihood of CHD and the risk-benefit ratio of the treatment, must be considered.

History

Review of the history may be helpful, particularly in certain situations, such as in newborns with pulmonary disease (Box 103.5). It is important to note that a negative response to any or all of the questions does not render cyanotic CHD unlikely; in fact, negative responses are noted in most patients with cyanotic CHD.

Box 103.5. What to Ask

Newborn With Cyanosis

- Has the neonate been in any distress?
- Has the neonate had difficulty feeding?
- Was the neonate suspected of having a heart problem prenatally (eg, fetal arrhythmia, abnormal heart on ultrasonography)?
- Does the mother have diabetes?
- Did the mother take any drugs—prescribed or not—during the pregnancy?
- Was the mother ill during the first trimester?
- Is there a positive family history of congenital heart disease or other birth defects?
- Did any perinatal problems occur (eg, passage of meconium in utero)?

Physical Examination

Peripheral cyanosis, also known as acrocyanosis, involves the extremities and the circumoral area. This is a normal finding in newborns and does not reflect the arterial desaturation of cyanotic CHD. Central cyanosis involves the oral mucosa but may be generalized. It may be the only abnormal physical finding in cardiac patients; however, a careful, thorough examination often yields information about the underlying cardiac defect and overall circulatory status. External anomalies or abnormal phenotypic appearance may be indicative of a genetic disorder with associated cardiac anomalies. Dyspnea (eg, grunting, nasal flaring, intercostal retractions) is more common with lung disease, but tachypnea (ie, rapid respiration) is common with severe heart disease and pulmonary problems. Tachypnea results from CHF in the setting of HPBF lesions and hyperpnea (ie, deep breathing) resulting from metabolic acidosis in patients with severe hypoxia or impaired perfusion. Poor perfusion is also manifested by abnormal color (ie, a gray or ashen appearance if combined with cyanosis), cool extremities, delayed capillary refill, and diminished pulses.

The peripheral pulses must be palpated in all extremities. Abnormalities or discrepancies between extremities should be confirmed by measuring blood pressures. Weak pulses may occur in the setting of cardiogenic shock, and bounding pulses may be noted with diastolic runoff lesions, such as patent ductus arteriosus or aortic insufficiency. Pulse quality and blood pressure may differ between extremities if an aortic arch abnormality, such as coarctation, is present. The abdominal examination may reveal hepatomegaly in patients with CHF; alternatively, it may reveal abnormal situs, as in Ivemark syndrome, which usually is associated with complex cyanotic CHD.

The cardiac examination may disclose a loud murmur if an obstruction such as pulmonary stenosis is present. The examiner should note, however, that atresia—a total obstruction—produces no murmur. Heart sounds may be loud and the precordium hyperdynamic, particularly in newborns with HPBF. Splitting of the second heart sound confirms the presence of 2 patent semilunar valves; however, this finding is often difficult to appreciate even in healthy newborns.

Laboratory Tests

Several laboratory studies are available for evaluating congenital heart disease (see Chapter 104, Table 104.1). As in CHF, initially it is more important to determine whether the patient has heart disease than to obtain a precise, complete diagnosis. In cyanotic CHD, sophisticated studies such as echocardiography, magnetic resonance imaging, and catheterization usually are necessary to make a detailed diagnosis.

The suspicion of arterial hypoxemia should be confirmed by pulse oximetry, an indirect measurement. This method is readily available and noninvasive but has shortcomings. Perfusion must be adequate to obtain a reading. Accuracy is diminished at saturations below 75%, although the presence of profound hypoxia can still be

confirmed. Cyanotic CHD cannot be ruled out by pulse oximetry, however, because readings of 100% saturation may reflect PO_2 values ranging between 75 and 250 mm Hg (Figure 103.1). Arterial blood gases are more accurate than pulse oximetry and provide important additional information about ventilation and acid-base status. Arterialized capillary gases may suffice if perfusion is adequate.

Oxygenation may differ between the extremities in newborns with certain lesions (eg, coarctation). The site of sampling should be noted. If possible, the saturation should be measured at sites proximal and distal to the ductus arteriosus (ie, the right arm and either leg).

A shunt study, also known as a hyperoxia challenge, may be performed to determine whether a right-to-left cardiac shunt is present, particularly if echocardiography is not readily available. Pure oxygen (fraction of inspired oxygen in gas [FiO_2] = 1.00) is given for 5 to 10 minutes by hood. In patients with LPBF or TGA, increasing the inspired oxygen does not affect the oxygenation of the blood because the blood cannot enter the lungs; this is a positive result. In patients with pulmonary disease or hypoventilation, oxygenation increases strikingly, often to a PO_2 exceeding 200 mm Hg; this negative result rules out cyanotic CHD.

A blunted shunt study, which is characterized by a rise in PO_2 but rarely to levels above 150 mm Hg, is seen in patients with severe pulmonary disease and in those with HPBF lesions. With such lesions the pulmonary venous blood is high in volume, and the rise in its saturation causes a definite rise in arterial oxygenation. This effect is exaggerated by the further increase in pulmonary flow resulting from the vasodilating effect of oxygen.

A positive shunt study may be identified with pulse oximetry. It is difficult or impossible, however, to distinguish between a blunted study and a negative study with this tool. The oxyhemoglobin dissociation curve is flattened at the upper end, and the saturation changes very little over a wide range of PO_2 (Figure 103.2). Although capillary gases may be equally inaccurate in this range, directly measured arterial blood gases are highly reliable. Additionally, they may reveal hypercapnia, with or without respiratory acidosis, which is suggestive of a pulmonary cause for the hypoxia.

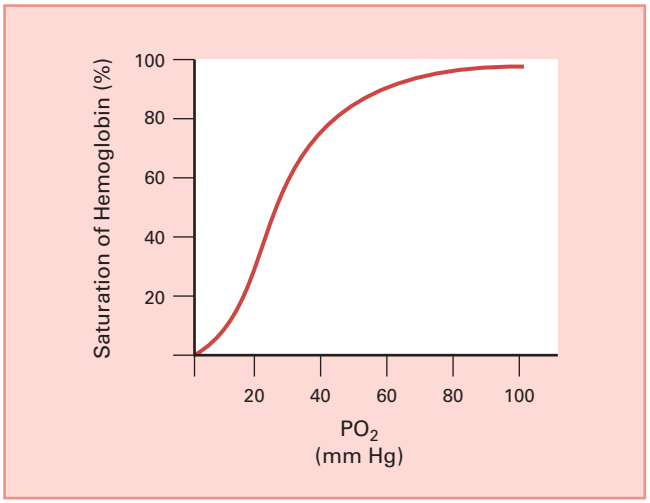

Figure 103.2. Oxyhemoglobin dissociation curve. Note that the position of the curve itself may vary with temperature, pH, partial pressure of oxygen (PO_2), and 2,3-diphosphoglycerate.

Electrocardiography (ECG) is a relatively inexpensive, readily available noninvasive test. It does not often help distinguish cyanotic CHD from other causes of cyanosis, however, particularly for those health professionals who lack experience with neonatal ECG. The normal range is large in neonates, with much overlap between normal and CHD. Care must be taken in correctly placing the leads and minimizing artifacts; incorrect technique may elicit a false-positive result.

Imaging Studies

Chest radiography is a relatively inexpensive and readily available test that often is extremely helpful in differentiating between cardiac and noncardiac disease. Pulmonary disease is often readily apparent on chest radiography. This test also helps define the cardiac diagnosis broadly but not precisely. Patients with LPBF lesions have small hearts and diminished pulmonary blood flow. In contrast, patients with HPBF lesions have large hearts and increased flow, such as is seen in neonates with simple left-to-right shunts. With many cyanotic lesions, the cardiac silhouette is abnormal in configuration (eg, boot-shaped heart in tetralogy of Fallot) or position (eg, dextrocardia in patients with heterotaxy syndrome), but this finding may be obscured by the generous thymus in the newborn. Transposition of the great arteries may be more misleading; pulmonary flow may be increased despite the severe cyanosis, and the heart size may be normal. An apparently normal radiograph does not exclude TGA.

Under optimal conditions, echocardiography enables the physician not only to recognize CHD but to identify details of anatomy and physiology. Conversely, a properly performed, complete, negative echocardiogram rules out CHD. The performance of a high-quality study requires the appropriate equipment (with high-resolution imaging), an experienced sonographer, and an experienced cardiologist for interpretation. In the absence of these elements, preliminary

echocardiography, such as bedside limited echocardiography by the emergency physician, may be used cautiously as a screening device as part of the initial assessment to confirm the presence of heart disease before referral to a specialist. It is not, however, of adequate sensitivity to rule out some life-threatening congenital heart defects, such as anomalous drainage of pulmonary veins or anomalous origin of coronary arteries. Recently, availability of telemedicine for echocardiography has helped fill this gap in some hospitals and avoid some unnecessary transports. When significant suspicion exists for cyanotic CHD, the patient should be referred even if echocardiography has not yet been performed.

Management

Initial management prior to cardiac consultation (often with transfer to another institution) includes surveillance, assistance, supportive care, and direct medical management.

Close surveillance, including transfer to the highest level of neonatal care available, use of a cardiopulmonary monitor and continuous pulse oximetry, frequent monitoring of vital signs, and repeat physical examinations, is begun as soon as cyanotic CHD is identified. Even if the newborn is feeding well, it is best to suspend feedings because of the likelihood of spontaneous deterioration and the emergent need for invasive procedures. An orogastric tube is placed to decompress the stomach, reducing the work of breathing as well as the risk of aspiration. At least 1 secure intravenous line should be placed for administration of fluids, glucose, and medications. Expeditious establishment of umbilical arterial catheterization allows close monitoring of arterial blood gases and blood pressure. The latter may be difficult to measure by cuff in the compromised newborn.

While undertaking these measures, the physician should make every effort to seek assistance from a pediatric cardiologist. A neonatologist may be consulted if a pediatric cardiologist is not immediately available. Much advice may be obtained by telephone. Additionally, plans for immediate consultation or transfer of patients may be discussed in this way.

The need for supportive care depends on the case. In the absence of metabolic acidosis or impaired perfusion, no special measures are indicated in this category. In some cases, intravenous fluid boluses, inotropic agents, and other treatments may be necessary as part of early management. Mechanical ventilation should be used in patients with metabolic acidosis, whether compensated or uncompensated, because of the increased oxygen requirement produced by hyperventilation and the tendency for tiring, resulting in superimposed respiratory acidosis.

The temptation to give supplemental oxygen for more than the few minutes necessary to perform a shunt study is great but must be resisted. Oxygen is rarely helpful and may be harmful in this setting. In neonates with TGA or LPBF lesions, oxygenation is not affected. In newborns with HPBF lesions, oxygenation is usually adequate in room air (saturation >80%), and an increase in FiO_2 may exacerbate CHF. Patients at greatest risk for deterioration resulting from administration of oxygen are those with total anomalous pulmonary venous return with obstruction, in whom pulmonary arteriolar vasodilation precipitates severe pulmonary edema and secondary right heart failure. Oxygen may also directly constrict the ductus arteriosus on which the cyanotic newborn may depend.

The possibility of ductal dependency should prompt consideration of administering the ductus dilator, prostaglandin E1 (PGE_1). This lifesaving treatment may be started before definitive diagnosis of cyanotic CHD. In newborns who remain adequately oxygenated (ie, no acidosis) and perfused, the drug can be prepared but administration deferred pending consultation. The benefits of giving PGE_1 to neonates with severe hypoxia or compromised perfusion far outweigh the risks, which include apnea and fever. A dramatic improvement often occurs within seconds to minutes, which supports the diagnosis of a ductal-dependent lesion and enables the physician to stabilize the patient until more definitive evaluation and intervention can take place.

Prognosis

If untreated, LPBF lesions and TGA are usually fatal during infancy, most often during the neonatal period, because of severe hypoxia. Untreated HPBF lesions may result in death in infancy from CHF or complications, such as pneumonia. If the systemic blood flow is ductus dependent (eg, interruption of the aortic arch), death occurs shortly after ductal closure, usually during the first week after birth. Even when the outcome is not fatal, delayed diagnosis may result in a suboptimal outcome, including end-organ injury, such as renal dysfunction or neurologic sequelae.

With early recognition and intervention, however, the prognosis for newborns with cyanotic CHD is surprisingly good in the absence of a genetic syndrome (eg, trisomy 18) or a major complicating extracardiac malformation (eg, neural tube defect). If neonates are diagnosed before the onset of severe circulatory compromise, they can be stabilized and evaluated promptly, and palliative or corrective procedures can be performed in the operating suite or catheterization laboratory. Most of these patients survive well into adulthood with a good quality of life. Newborns with lesions in which all 4 chambers are adequate in size (eg, tetralogy of Fallot) have a better lifetime prognosis than those with a hypoplastic chamber (eg, tricuspid atresia). Currently, even neonates with abnormalities such as Ivemark syndrome (ie, asplenia syndrome) or hypoplastic left heart syndrome have a reasonable outlook with complex staged reconstructive surgery or heart transplantation.

CASE RESOLUTION

Marked hypoxia is present in the absence of other cardiac findings, such as a heart murmur. The oxygen saturation does not rise after the newborn breathes 100% oxygen for 10 minutes. The chest radiograph shows a small, boot-shaped heart and diminished pulmonary blood flow, and ECG is normal. Transport is arranged. Because of the marked cyanosis, infusion of PGE_1 is begun, and saturation increases to 80%, with the PO_2 rising from 33 mm Hg to a safer 48 mm Hg. The neonate is transferred to a tertiary care center, where consultation is obtained. Echocardiography is also performed, which demonstrates tetralogy of Fallot with pulmonary atresia. A modified Blalock-Taussig shunt is placed in the newborn period, and complete repair using a pulmonary artery homograft is performed at 1 year of age.

CHAPTER 104

Congestive Heart Failure

Robin Winkler Doroshow, MD, MMS, MEd, FAAP, and Deepa Mokshagundam, MD, FAAP

CASE STUDY

A 2-month-old boy is brought to the office by his mother, who reports that her son has been eating poorly and breathing oddly for the past few days. The perinatal history is unremarkable. A heart murmur was noted at the 1-month checkup.

The infant is quite thin and irritable. Physical examination shows that the baby's weight, which was at the 50th percentile at birth, is now at the fifth percentile; his height, which was at the 50th percentile, is now at the 25th percentile. He is afebrile, and his heart rate is 165 beats per minute, with respirations 70 breaths per minute and shallow but without respiratory distress. The skin is pale and diaphoretic, and the mucous membranes are pink. Examination of the head and neck is normal; no jugular distention is present. The lungs are clear. The precordium is hyperdynamic, and the heart sounds are loud; a prominent systolic murmur is audible at the left lower sternal border. The liver edge is palpable 4 cm below the right costal margin in the right midclavicular line, and the spleen is not palpable. The extremities are thin, with normal pulses and no edema. Capillary refill is slightly delayed.

Questions

1. What are the signs of cardiac disease in infants and children?
2. What are the signs of congestive heart failure in children? How do these signs in children differ from those in adults?
3. What underlying disorders can cause congestive heart failure in young infants?
4. What is the appropriate emergent treatment for infants with congestive heart failure?

Congestive heart failure (CHF) is the most common symptomatic presentation of serious heart disease in infants. Although this condition also occurs in older children, an estimated 90% of cases of CHF in the pediatric population begin in the first year after birth. In infants and young children, CHF is most often caused by structural congenital heart disease (CHD); in older children, acquired cardiomyopathy and myocarditis are more prevalent. Compensatory mechanisms are fewer and less successful in small infants. Other causes of CHF are included in Box 104.1.

Epidemiology

The prevalence of CHF in children is approximately 0.1%. Most cases result from CHD, which occurs in 0.8% of live births. Each year, approximately 14,000 pediatric patients are hospitalized for management of CHF in the United States. The prevalence of CHD varies little by geography, ethnic group, or sex, but it is much more common in children with recognizable genetic syndromes (eg, Down syndrome, Turner syndrome). Rheumatic fever, which is far more prevalent in developing countries, is a rare cause of CHF in the United States.

Clinical Presentation

Most commonly, initial symptoms of CHF in an infant take the form of parental concerns about feeding. Comments are often vague (eg, "My baby is not a good eater") but may be more precise (eg, "He is taking less formula with each feeding"; "He is taking longer to nurse"). The parent or caregiver may also describe rapid breathing, excessive sweating, or decreased activity, but usually only on specific questioning. The older child with CHF may report subjective symptoms, such as shortness of breath.

Box 104.1. Causes of Congestive Heart Failure in Children

Volume Overload
- Left-to-right shunt (eg, ventricular septal defect)
- Bidirectional shunt (eg, truncus arteriosus)
- Valvar insufficiency (eg, mitral regurgitation)
- Extracardiac conditions (eg, anemia, arteriovenous malformation)

Pressure Overload
- Outflow obstruction (eg, coarctation of aorta)
- Inflow obstruction (eg, obstructed anomalous pulmonary veins)
- Vascular resistance (eg, hypertension, chronic obstructive pulmonary disease)

Myocardial Dysfunction
- Intrinsic conditions (eg, cardiomyopathy, anthracycline toxicity)
- Inflammatory conditions (eg, viral myocarditis, rheumatic fever)
- Coronary insufficiency (eg, anomalous left coronary artery)

Arrhythmias
- Tachyarrhythmia (eg, paroxysmal supraventricular tachycardia)
- Bradyarrhythmia (eg, third-degree atrioventricular block)

Congestive heart failure may also be detected on examination during routine infant checkups or evaluations for non-cardiac symptoms. In the child with CHF, careful assessment of the physical findings, including vital signs, reveals tachypnea, tachycardia, and hepatomegaly and often signs of underlying structural heart defects, such as a murmur (Box 104.2).

Pathophysiology

High cardiac output may result in CHF in the infant with a large left-to-right shunt. Myocardial contractility is relatively normal, and the child remains on the "normal" line of the Starling curve, which relates cardiac output to diastolic volume (also called *preload)* or pressure (Figure 104.1). The shunt requires a very large volume of output, primarily to the pulmonary bed. Although the heart may be able to meet this demand, preload is high, resulting in "congestive" signs and symptoms (eg, tachypnea, hepatomegaly). In more severe cases, systemic output may be compromised, resulting in hypotension, decreased systemic perfusion, renal failure, and metabolic acidosis.

Left-sided failure resulting in elevated pulmonary venous pressure produces increased lung water. Initially, this fluid is interstitial, and it does not interfere with gas exchange but does trigger reflex tachypnea. Minute volume is kept normal by decreasing tidal (ie, breath-to-breath) volume, resulting in shallow, rapid breathing (sometimes called "happy tachypnea" because of the absence of dyspnea). Only when the ability of the pulmonary lymphatics to drain this fluid is overcome by large volume does fluid accumulate in the alveoli; rales and respiratory distress, or dyspnea, result and gas exchange may be compromised.

Right-sided failure caused by an elevated systemic venous load usually produces more volume than pressure load on this system, possibly as a result of the greater venous compliance in infants compared with adults. The liver becomes quite distended and is easily palpated. As long as the liver can absorb the increased venous volume, the portal pressure does not rise, and splenomegaly does not occur. Because the venous pressure rises very little, jugular distention, which is always difficult to detect in the young infant, rarely occurs; edema is also rare.

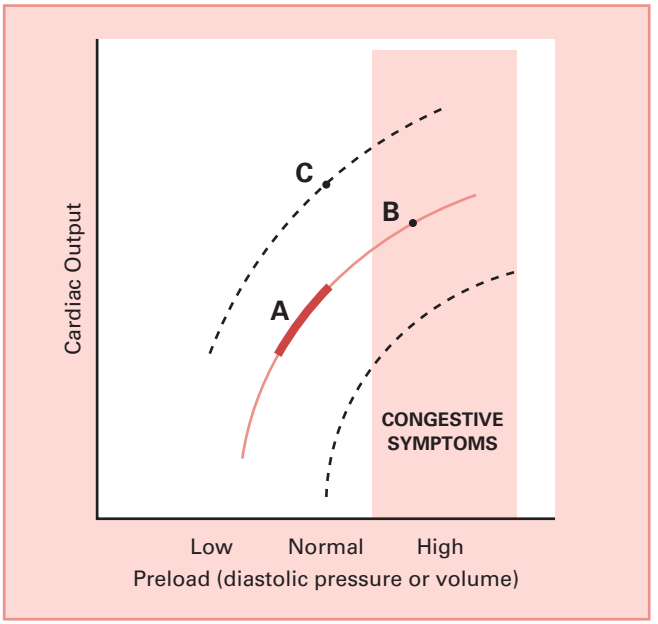

Figure 104.1. Relationship of cardiac output to preload. The solid curve represents normal myocardial contractility, and the dotted curves represent impaired function (shifted downward) and the positive inotropic state (shifted upward). A, Normal range (no heart disease). B, Left-to-right shunt with congestive heart failure (CHF). Note that overall output is high, but most of it is shunted. C, Same situation as B but after treatment for CHF. Cardiac output is the same or better, but preload is now out of the range that results in congestive symptoms.

Box 104.2. Diagnosis of Congestive Heart Failure in the Pediatric Patient

Infants and Toddlers

- Tachycardia
- Tachypnea
- Hepatomegaly
- Sweating
- Decreased feeding
- Irritability
- Easy fatigability
- Poor weight gain

Older Children

- Shortness of breath
- Exercise intolerance
- Peripheral edema
- Abdominal discomfort (eg, hepatomegaly)
- Orthopnea

The left and right (ie, systemic and pulmonary, respectively) circulations are more interdependent in infants and younger children than in older children and adults. As a result, in infants and younger children bilateral heart failure is much more common than right-sided or left-sided failure alone. Although this means that recognition of CHF may be easier in younger patients, determination of the underlying condition may be more difficult because the clues are less specific. For example, in an adult with left-sided failure, the differential diagnosis includes mitral, but not tricuspid, valve disease.

Differential Diagnosis

In the presence of tachycardia, tachypnea without dyspnea, and hepatomegaly, the diagnosis of CHF is straightforward. Congestive heart failure is most commonly confused with major respiratory infections, such as bronchiolitis and pneumonia. Pulmonary infections frequently are associated with dyspnea as well as tachypnea, impaired gas exchange, and other respiratory findings. Rhinorrhea, cough, fever, or wheezing may also be present. Rales may accompany pneumonia but are rare in CHF of infancy or early childhood. Hyperinflation caused by lung disease may result in a false

impression of hepatomegaly. In some children, CHD, CHF, and respiratory infections coexist and compound one another to increase morbidity and mortality, as is seen with respiratory syncytial virus.

Signs of structural heart disease, such as a murmur or absent femoral pulses, may support the diagnosis of CHF. Severe CHF, with low cardiac output or even shock, has a broader differential diagnosis. In addition to cardiac causes, sepsis, hypovolemia, and disorders associated with inborn errors of metabolism should be considered.

Evaluation

History

The history should include specific questions about feeding and growth (Box 104.3). Poor feeding, which is often a nonspecific symptom in infants with chronic or subacute illness, results from tachypnea and fatigability in infants with heart disease. Growth failure may result from poor feeding and increased cardiopulmonary work. The physician should specifically query the parent or caregiver about possible excessive sweating or rapid breathing in infants, because that information may not be volunteered.

Physical Examination

The diagnosis of CHF is primarily based on clinical findings, and physical examination is essential. The resting respiratory rate must be precisely counted, because the infant with CHF most often exhibits tachypnea without dyspnea. The liver edge is palpable more than 1 cm below the right costal margin in the midclavicular line, and the extent of enlargement mirrors the severity of the CHF.

The physical examination may also provide clues about the underlying cause of CHF, such as a heart murmur or gallop, or pulses that are weaker in the lower extremities than the upper extremities.

In the older child or adolescent, physical findings are more similar to those of the adult with CHF. Additional findings that may be present in the older child or adolescent include jugular venous distention, basilar rales, and peripheral pitting edema.

Box 104.3. What to Ask

Congestive Heart Failure

Infants

- How has the infant been feeding? Does the infant get out of breath or appear exhausted?
- Has the infant's growth pattern changed recently?
- Does the infant tire easily? With eating?
- Does the infant perspire excessively, especially with efforts such as feeding?
- Does the infant breathe rapidly, even at rest?

Children

- Has a significant change in exercise capacity occurred?
- Has any significant weight loss or weight gain occurred?
- Have there been any episodes of atypical syncope? Palpitations?
- Is there any family history of cardiomyopathy or heart transplantation?

In infants and children with severe CHF, in whom cardiac output is declining, flow to end organs is compromised. The skin is cool and pale or ashen, and capillary refill is delayed; additionally, the peripheral pulses are diminished. Mental status may be affected, resulting in lethargy or even unresponsiveness (see Chapter 74).

Diagnostic Studies

Many diagnostic studies can be performed to assess the heart, including electrocardiography and echocardiography (Table 104.1). Some procedures are quite costly, however, and some are invasive and therefore carry risk. The value of most of these tests depends

Table 104.1. Diagnostic Studies Used in the Evaluation of Heart Disease in the Pediatric Patient

Test	*Information*
Chest radiography	Presence and direction of shunt Hints concerning specific diagnosis (and possible pulmonary disease ruled out)
Serum BNP or NT-proBNP	Presence and severity of congestive heart failure
ECG	Cardiac rhythm and conduction Chamber overload Coronary insufficiency
Ambulatory ECG	Subacute rhythm assessment Correlation of symptoms with rhythm
Oximetry	Presence and severity of hypoxemia
Arterial blood gases	Hypoxemia Acid-base status
Hematocrit	Anemia Polycythemia
Troponins; CK MB	Presence and acuteness of myocardial injury or ischemia
Exercise test	Quantitation of exercise tolerance Provocation of symptoms or arrhythmia
Echocardiography	Specific structural diagnosis and hemodynamics Chamber enlargement and systolic and diastolic function Presence of pericardial effusion
Cardiac magnetic resonance imaging or computed tomography	Specific structural diagnosis and hemodynamics Chamber enlargement and function
Cardiac catheterization	Specific structural diagnosis and hemodynamics Cardiac electrophysiology
Tilt test	Autonomic function

Abbreviations: BNP, brain natriuretic peptide; CK MB, creatine kinase enzyme (1 of 3 forms of creatine kinase) found primarily in heart and skeletal muscle cells; ECG, electrocardiography; NT-pro BNP, N-terminal pro–brain natriuretic peptide.

on the expertise of the individuals who perform and interpret them. It is important to remember that although test results and consultation with a pediatric cardiologist may be invaluable in the identification of the underlying lesion, these procedures usually are not required to make a diagnosis of CHF.

Pressure or volume overload of the ventricles causes them to release the neurohumoral peptide brain natriuretic peptide (BNP), which acts as a natural natriuretic, diuretic, and vasodilator. Studies in adults have demonstrated that blood levels of BNP and its more stable precursor, N-terminal proBNP (NT-proBNP) are elevated in CHF, and the degree of elevation closely reflects severity of CHF. This test, which may be performed at the bedside on very small samples of blood, may be used to distinguish between CHF and other similar disorders, such as acute pulmonary disease. Because it closely parallels changes in severity of CHF, this test may also be used to track response to treatment. Recent studies in children suggest that the test may be similarly useful in the pediatric population.

In the child with severe CHF, further studies are indicated. Arterial blood gases show evidence of metabolic acidosis resulting from tissue anoxia, with respiratory compensation in early stages and superimposed respiratory acidosis in later stages. A complete blood cell count shows leukocytosis caused by stress. It may not differentiate between heart disease and sepsis, however (Figure 104.2).

Imaging Studies

Because elucidation of the structure and function of the heart is central to assessment of the underlying cause of CHF in the pediatric population, imaging studies play a key role in evaluation of these patients. Moreover, these tests (particularly echocardiography) may be used as a means of tracking response to treatment. The echocardiogram may provide clues to the underlying pathology but does not aid in the diagnosis of CHF.

Chest radiography, preferably the anteroposterior and lateral views, may be quite useful as a supportive study. It may show cardiomegaly, pulmonary venous congestion, and hyperinflation. Cardiomegaly is most commonly caused not by myocardial dysfunction but by volume overload from the shunt. In the absence of cardiac enlargement, the diagnosis of CHF must be seriously questioned. (However, CHF may occur in the absence of cardiomegaly in total anomalous pulmonary venous return with obstruction, which usually presents in the first week after birth in association with hypoxia.) Pulmonary venous congestion occurs in left-sided heart failure, but increased pulmonary arterial flow from a left-to-right shunt often obscures the congestion. Hyperinflation resulting from peribronchial edema is also a common finding.

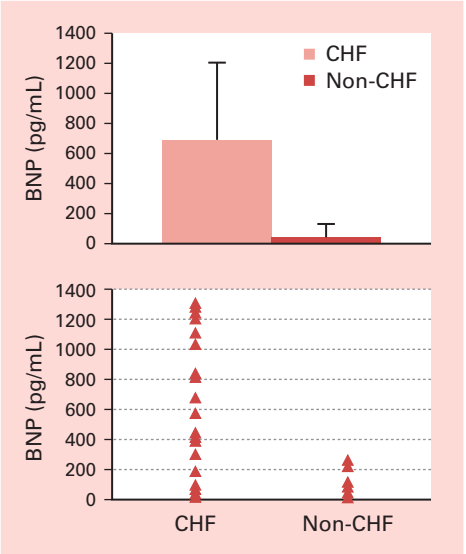

Figure 104.2. Utility of brain natriuretic peptide (BNP) in differentiating congestive heart failure (CHF) from lung disease in pediatric patients with respiratory distress.

Adapted from Koulouri S, Acherman RJ, Wong PC, Chan LS, Lewis AB. Utility of B-type natriuretic peptide in differentiating congestive heart failure from lung disease in pediatric patients with respiratory distress. *Pediatr Cardiol.* 2004;25[4]:341–346, with permission from Springer Science + Business Media.

Management

All infants and children with CHF should be under the care of a pediatric cardiologist, often in concert with a pediatrician, intensivist, or neonatologist. Prompt referral to a cardiologist aids not only in management of the CHF but also in assessment and management of the underlying disorder.

Most evidence about management of CHF derives from studies conducted in adults, whose etiology (eg, ischemic heart disease) and pathophysiology are quite different from those in most pediatric patients with CHF. Additionally, the numbers of pediatric patients with CHF are significantly lower and therefore do not lend themselves to statistically meaningful clinical trials. The heterogeneity of causes in children also contributes to this obstacle.

The pharmacologic treatments for pediatric CHF fall into a small number of categories based on mechanism of action (Table 104.2). Preload can be optimized by the administration of diuretics and vasodilators, and afterload can be optimized by the use of arteriolar dilators, some of which also have inotropic effects. Contractility is enhanced by inotropic agents, and antiarrhythmics control tachycardia and bradycardia to optimize heart rate. The most effective control of CHF is attained when more than 1 mechanism is used.

Inotropes and diuretics are used in the initial management of CHF in children. Inotropic support results in a shift to a higher Starling curve (Figure 104.1), which allows affected patients to maintain the high volume output necessitated by the underlying CHD at lower diastolic pressures, thus alleviating congestive symptoms. Digoxin, a form of digitalis, is commonly used when cardiac output is not severely impaired and is therefore often used in outpatients. This agent is readily available, consistently absorbed, safe in the therapeutic range, and easy to administer orally. If digoxin is initially given at the maintenance dose (10 mcg/kg/day), therapeutic levels are not attained for approximately 1 week; therefore, loading is preferable but may require hospitalization. Digoxin is well tolerated and rarely causes side effects. Because of its safety and reliability of absorption, blood levels need not be checked unless overdose is suspected (eg, history

Table 104.2. Therapy for Pediatric Congestive Heart Failure

Disease Severity	*Therapy Type*	*Example*
Chronic (ambulatory)	Cardiac glycosides	Digoxin
	Diuretics	Furosemide, spironolactone
	Angiotensin-converting enzyme inhibitors	Enalapril, captopril
	Angiotensin receptor blockers	Losartan potassium
	Selective beta blockers	Carvedilol, metoprolol
Acute (inpatient)	Diuretics	Furosemide, bumetanide
	β agonists	Dobutamine, dopamine
	Phosphodiesterase inhibitors	Milrinone, amrinone
	Vasodilators	Nitroprusside, oxygen, inhaled nitric oxide
Severe, Refractory	Mechanical support	Extracorporeal membrane oxygenation, ventricular assist
	Organ replacement	Cardiac or cardiopulmonary transplantation
	Exogenous brain natriuretic peptide	Nesiritide

of over-administration, toxic ingestion, unexplained vomiting, second- or third-degree heart block). In the neonate, blood levels may be difficult to interpret because of the presence of natural digoxin-like immunoreactive substance in the blood.

The elevated diastolic preload of CHF is the result of neurohumorally mediated sodium and water retention. Diuretics reverse this phenomenon. Furosemide, a potent loop diuretic that is available in an oral suspension and is fairly well absorbed, is the most frequent drug of choice for the outpatient. Initially, furosemide may be given intravenously or intramuscularly rather than orally, which reduces the time to onset of action and is more effective. Such treatment also supports the patient while digoxin loading is in progress. Spironolactone, a less potent diuretic, may be used in combination with furosemide for its potassium-sparing effects and may also reduce the deleterious histopathologic and structural changes known as *myocardial remodeling* that can accompany CHF.

Fluid and sodium restriction, which is often used in adults with CHF, is difficult to achieve with infants because of their predominantly or exclusively liquid diet. High-calorie diets using concentrated formulas, complex carbohydrate additives, or medium-chain triglyceride oils may reduce the intake of free water and the effort of feeding without compromising caloric intake. In older infants and children with CHF, salt intake is more easily modified and should be minimized.

Certain pediatric patients with chronic CHF may benefit from the addition of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers to their regimen. These arteriolar dilators help control afterload and have been shown to be effective in children with dilated cardiomyopathy and those with a large left-to-right shunt, such as ventricular septal defect (VSD). Recent observations suggest that third-generation beta blockers, such as carvedilol, may be useful to control chronic CHF in children with dilated cardiomyopathy. Randomized, controlled clinical trials in adults with similar pathology have been quite encouraging, despite poor understanding of the mechanism involved; similar trials in children have thus far been disappointing.

The child with acute, severe, or refractory CHF may require additional medications or interventions, necessitating hospitalization, often in an intensive care unit. These therapies include β agonists and phosphodiesterase inhibitors for inotropic support and vasodilators for afterload reduction, correction of anemia (eg, transfusion), treatment of fever (eg, antipyretics), and reduction of metabolic demands (eg, ventilatory support, bed rest, sedation). Diuretics, usually given intravenously, provide effective control of congestive symptoms. Because of the importance of fluid balance and nutrition in the child hospitalized with CHF, close and accurate monitoring of fluid intake and output, measurement of daily weight, and measurements of serum electrolytes are essential data in the management of CHF. Feeding is often problematic because of its increased workload, conflict with the increased work of breathing, and diminished circulation to the gut. In some cases, tube feedings may be an option; in others, all enteric feedings must be discontinued and hydration and nutrition maintained intravenously.

In a minority of cases, CHF is refractory to all these measures. This may occur with very severe acute myocarditis, with long-standing cardiomyopathy of various causes, and during the postoperative period after complex CHD surgery. Additional options include *resynchronization therapy*, in which an artificial pacemaker alters the sequence of ventricular depolarization and contraction, and mechanical support, such as extracorporeal membrane oxygenation and ventricular assist devices. Exogenous recombinant BNP (ie, nesiritide), which has shown some promise in the setting of adult CHF, may be helpful. In some cases, replacement of the ailing heart or heart-lung unit by transplantation may be the only remaining alternative.

Ultimately, the best management for pediatric CHF is often treatment of the underlying disorder. In many instances, failure to do so results in limited or no success of other treatment modalities. The degree of urgency depends on the nature of the disorder and the severity of the CHF. For example, in the neonate with a ductus-dependent lesion, such as hypoplastic left heart syndrome, maintenance of ductal patency with prostaglandin E_1 is crucial to initial management. In the infant with CHF caused by supraventricular tachycardia, prompt conversion to normal sinus rhythm is often the only treatment necessary. Congestive heart failure caused by severe anemia responds dramatically to correction of hemoglobin levels, often using exchange transfusion to avoid additional acute volume overload. Cor pulmonale, which occurs in children with severe chronic lung disease, is most responsive to measures directed at improving the lung disease or decreasing pulmonary vascular resistance (eg, supplemental oxygen, inhaled nitric oxide),

or systemically administered pulmonary vasodilators (eg, sildenafil citrate). Congestive heart failure caused by structural CHD (the most common situation) typically can be reversed with surgery or interventional catheterization to palliate the problem (eg, pulmonary artery banding in certain cases with large net left-to-right shunts) or correct the defect (eg, repair of VSD). It is rarely necessary to "tolerate" prolonged, uncontrolled CHF in children or to manage the condition aggressively at the expense of a major change in lifestyle.

Family counseling is essential and should begin when CHF is identified. In addition to providing a general description of the cardiac defect and CHF, the physician must take care to make several additional points and clarifications. The meaning of the term *heart failure,* which is commonly thought by nonmedical professionals to refer to a sudden deterioration of heart function or even cardiac arrest, must be clarified. It is also important to stress that the affected infant should be treated as normally as possible, with the exception of administration of medicines and keeping medical appointments. Contrary to popular belief, most infants with cardiac conditions are not fragile. Addressing quality-of-life issues, such as parental or caregiver concern, assuaging guilt, and normalizing existence, are key responsibilities of the medical professional.

Prognosis

In most young infants and children with CHF, the prognosis is excellent. Congestive heart failure responds well to treatment, and the underlying defect usually can be corrected or at least palliated. "Catch-up" growth occurs with remission of CHF, and children have the potential to reach their genetically determined height and weight. Without cardiac surgery for CHD, CHF often remits spontaneously over months or years as a result of positive developments, such as maturation of compensatory mechanisms or spontaneous improvement in the defect (eg, decrease in the size of a VSD), or as a result of negative developments, such as increase in pulmonary vascular resistance because of long-standing high pulmonary artery pressure and flow (ie, Eisenmenger syndrome). In this latter case, the CHF remits at the cost of increasing cyanosis and substantial morbidity and mortality.

CASE RESOLUTION

The case study is typical of an otherwise normal infant with a large VSD who becomes symptomatic with the development of CHF. The baby's growth failure can be attributed to the chronicity of his illness.

The loud murmur and presentation in infancy are strongly suggestive of underlying structural CHD as the cause of CHF. The time of onset of CHF is also suggestive of a specific mechanism. Onset that is slightly delayed after birth is suggestive of a lesion with changing postnatal hemodynamics, such as left-to-right shunt, that has increased as pulmonary resistance has fallen. (A ductus-dependent defect would have presented more acutely and severely in the first week after birth.)

This infant responded fairly well to oral diuretics and digoxin but continued to grow slowly and tire easily, and the VSD showed no signs of spontaneous reduction in size. He underwent surgical repair of the VSD at 5 months of age with an excellent result and no longer has symptoms or requires medication. His growth parameters are now within normal limits, and his prognosis is excellent.

CHAPTER 105

Chest Pain

Robin Winkler Doroshow, MD, MMS, MEd, FAAP

CASE STUDY

A previously healthy 13-year-old boy comes to the office with a report of recurrent chest pain, occurring approximately once a week over the past 2 months. The pain is stabbing in nature, is located at the mid-sternum, is not associated with any other symptoms, and occurs randomly, both at rest and with exercise. It lasts for 2 to 3 minutes, is ranked by the patient as 4 on a severity scale of 10, and subsides spontaneously. He does not appear very concerned about the pain, but his mother is quite anxious to have it checked out. His teacher has sent him home from school twice because of the pain, and the soccer coach will not let him play until he is cleared by a doctor. His physical examination is unremarkable.

Questions

1. What is the significance of chest pain in an otherwise healthy child?
2. How likely is serious heart disease to be heralded by chest pain?
3. How much testing, and what type, is appropriate in the workup for chest pain?
4. Which patients with chest pain should be referred to a cardiologist? To other specialists?

Chest pain in children is among the most common reasons for referral to a pediatric cardiologist, second only to heart murmurs. It is, however, 1 of the least common presenting symptoms of cardiac disease. In fact, from an etiologic standpoint, it would be more suitable to include this chapter in the section on gastrointestinal disorders, respiratory problems, psychological and psychogenic disorders, or hematology, rather than cardiology (Figure 105.1).

Perhaps the strongest reason for addressing chest pain in the cardiology section, along with discussions of heart murmurs, cyanosis, and congestive heart failure, is that it is the greatest fear of the patient, parent or caregiver, and physician that chest pain could herald a serious—even lethal—heart problem in an otherwise healthy pediatric patient. This fear is exacerbated by 2 social phenomena in the United States: the widespread press given to cases of sudden unexpected death in young, apparently healthy athletes (who had not, in fact, experienced chest pain in most cases), and the appropriately high level of concern for the underdiagnosis of ischemic heart disease in the adult population. Public information targeting the adult with chest pain may, unfortunately, be misinterpreted as applying to the child as well. It is this apprehension, and the associated medicolegal defensive posture, that so often drives the patient and the referring primary care physician to seek cardiology consultation and testing. The frequency of such referrals has increased 4- to 5-fold in the past 2 decades, resulting in increasingly inefficient resource utilization.

Epidemiology

The epidemiology of pediatric chest pain is not well studied. Published retrospective studies have attributed chest pain to cardiac causes in 0.25% of patients treated in emergency departments (EDs), 0.3% treated in an outpatient clinic, and 1% treated in a pediatric cardiology clinic.

In the primary care office setting, chest pain is the third most frequent pain symptom, after abdominal pain and headache, accounting for more than 600,000 office visits a year in the United States. The most common age range is 8 to 18 years, peaking between 11 and 13 years of age. No sex or ethnic predilection exists, although the etiologic distribution may vary by sex.

Cardiac causes of chest pain are quite uncommon for 2 reasons. Such pain is either a rare symptom in a common cardiac disorder (eg, aortic stenosis) or caused by a rare condition (eg, anomalous origin of coronary artery [AOCA]).

Clinical Presentation

Substantial variability exists in the symptom of chest pain in children (Box 105.1). Some pediatric patients experience a single, protracted, severe episode that results in a visit to the ED. In that setting, the patient may have other signs or symptoms of an acute medical problem, such as fever, shortness of breath, or hypotension, raising the level of suspicion for a serious organic cause.

More frequently, children report repeated episodes occurring sporadically over a period of months or even years. The pain may be induced or exacerbated by exercise, deep breathing, lying down, or eating. It can begin and end abruptly or gradually. It may be accompanied by other symptoms, which may help in making a diagnosis. In cases in which the pain occurs with exercise, the physician must determine whether it is a consistent, predictable experience, or is unpredictable, as well as whether it is associated with dizziness or syncope.

Box 105.1. What to Ask

Chest Pain

- What is the pain like? Where is it located? Does it radiate? How severe is it?
- How long has the child been having pain? Did it begin after trauma? How often does the pain occur? How long does it last? Does it start and end suddenly?
- What brings on the pain? Is it related to exercise and, if so, is it consistent?
- Does the child have associated symptoms with the pain, such as syncope, shortness of breath, palpitations, fever, nausea, sour taste, wheezing, or cough?
- Does the child at other times have cardiac symptoms, such as easy fatigability, cyanosis, exertional dyspnea, edema, or syncope?
- Does the child's medical history include potentially pertinent disorders, such as asthma, gastroesophageal reflux disease, psychiatric problems, heart disease, or sickle cell disease?
- How much of an effect is the pain having on the child's life? Is the child missing school or sports?
- Is there a family history of sudden unexpected death, recurrent syncope, or known genetic syndrome?

Up to 97% of children evaluated for chest pain have no serious medical history, and most have an unremarkable physical examination.

Pathophysiology

The pathophysiology varies based on the underlying cause of the pain, and the differential diagnosis is diverse (Box 105.2). It is important for the patient, parent or caregiver, and physician to understand that thoracic or abdominal pain, and visceral pain in particular, is poorly localized. This makes it difficult to distinguish between esophagitis and cardiac ischemia, for example; hence, the term "heartburn" for the former condition. Precordial pain may

[a] Common cause of chest pain.
[b] Uncommon cause of chest pain.
[c] Rare cause of chest pain.

originate from any intrathoracic organ or from the chest wall itself, and the patient cannot identify the source of the discomfort, which in itself is a cause of distress.

Cardiac causes are a heterogeneous category that are best characterized as ischemic or nonischemic in origin (Box 105.3). None of these causes is common. Ischemic chest pain, or angina, is caused by a drop (often sudden) in the myocardial oxygen supply/demand ratio, causing pain or, in rare cases, sudden death. This may occur because of diseased coronary arteries as in adults, resulting from accelerated coronary atherosclerosis, but such an occurrence is quite rare in the pediatric population. Angina may occur in the patient with progeria, mucopolysaccharidosis, post-transplantation coronary disease, or severe familial hypercholesterolemia. Alternatively, it may occur as a result of previous inflammation (as with coronary aneurysm in Kawasaki disease), resulting in coronary artery stenosis. A congenital AOCA from the opposite sinus of Valsalva (Figure 105.2) or from the pulmonary artery may result in ischemia resulting from compression of the anomalous vessel between the great arteries, obstruction from a slit-like orifice at the origin, or, in the case of the pulmonary artery, low pressure and low saturation in the perfusing blood.

The chest pain that occurs in a small minority of patients with severe left ventricular outflow obstruction (ie, aortic valve stenosis and hypertrophic obstructive cardiomyopathy) likely is also the result of ischemia. The already diminished supply/demand ratio resulting from hypertrophy and hypertension of the left ventricle falls further with strenuous exercise, causing pain and/or arrhythmia.

With use of drugs, such as cocaine, chest pain may be attributable to arrhythmia, myocardial hypoperfusion, or a combination of these. This may present as chest pain or overt collapse, in some cases with cardiac arrest.

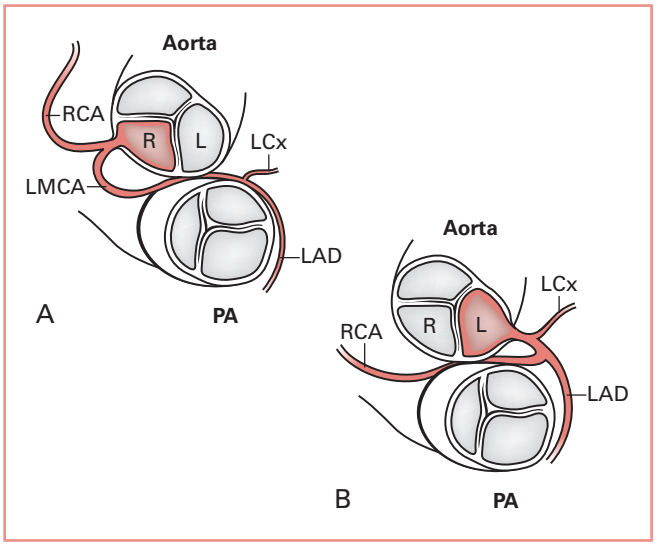

Figure 105.2. Schematic diagram of the 2 forms of anomalous origin of coronary artery from the wrong sinus that are associated with myocardial ischemia. A, Anomalous origin of the left main coronary artery (LMCA) from the right sinus of Valsalva. B, Anomalous origin of the right coronary artery (RCA) from the left sinus of Valsalva. In each case, the anomalous coronary artery can be seen coursing between the aorta and pulmonary artery (PA).

Abbreviations: L, left aortic sinus; LAD, left anterior descending; LCx, left circumflex; R, right aortic sinus.

Box 105.3. Cardiac Causes of Chest Pain in Children

Ischemic

- Tachyarrhythmia (eg, supraventricular tachycardia, ventricular tachycardia)[a]
- Cocaine abuse[a]
- Aortic stenosis[b]
- Hypertrophic obstructive cardiomyopathy[b]
- Anomalous origin of coronary artery[b]
- Accelerated coronary atherosclerosis, such as in progeria, hyperlipidemia, and cardiac transplantation[b]
- Coronary artery stenosis secondary to Kawasaki disease[b]

Nonischemic

- Pericarditis (eg, viral, bacterial, autoimmune, postoperative)[a]
- Mitral valve prolapse[a]
- Myocarditis[b]
- Aortic root dissection, such as in Marfan syndrome[b]

[a] Uncommon cause of chest pain.

[b] Rare cause of chest pain.

Although many children with cardiac arrhythmias are asymptomatic or present with palpitations, dizzy spells, or syncope, some do report chest pain. In the case of the younger child, this may reflect an inability to express the discomfort of palpitations as other than "hurting." Additionally, transient ischemia occurs in some individuals with tachyarrhythmia, such as paroxysmal supraventricular tachycardia (SVT), because of high myocardial oxygen consumption and shortened diastole, which compromises perfusion. In these patients, ST segment depression may be seen on electrocardiography (ECG) during the arrhythmia and may persist for several minutes after the arrhythmia is terminated.

Nonischemic cardiac causes of chest pain include pericarditis and, less commonly, myocarditis, aortic dissection, and mitral valve prolapse. The most common form of inflammatory heart disease is acute viral infection; acute bacterial pericarditis is more severe and associated with greater systemic toxicity. Connective tissue disease, such as lupus erythematosus and juvenile rheumatoid arthritis, is frequently associated with immune-mediated pericarditis, as is the postpericardiotomy syndrome that occurs shortly after cardiac surgery. In these disorders the pain is the result of inflammation of the pericardium and epicardium, which directly stimulates the many sensory nerve endings in this area.

Aortic dissection also results in direct stimulation of pain fibers, in this case in the aortic wall. It is rare in the normal pediatric population but may occur in the setting of Marfan syndrome and

related disorders. Chest pain also occurs in patients with mitral valve prolapse, but it is often difficult to establish a clear causal relationship in this setting. A large percentage of patients with chest pain have a diagnosis of gastroesophageal reflux disease (GERD).

Differential Diagnosis

The differential diagnosis of pediatric chest pain is presented in Box 105.2, with cardiac causes listed in Box 105.3. The relative frequencies of these causes vary in reported series (Figure 105.1); however, all studies report higher frequencies of respiratory, idiopathic, traumatic, and psychogenic etiologies and low frequencies of cardiac etiologies (typical range, 1%–5%) in patients with no previous cardiac history. These data must be viewed as approximations because the ultimate etiologic classification of cases in these series usually is not based on a definitive result but rather an attribution by the physician involved. Therefore, cultural factors and individual preferences may result in higher reported rates of "idiopathic" chest pain in some centers, "chest wall pain" in others, and "anxiety disorder" in yet others. Chest wall pain may be the result of trauma or inflammation of the costochondral cartilages (ie, Tietze syndrome). Some studies report a higher incidence of cardiac etiologies because they so classify any patient with chest pain with a cardiac finding (eg, premature beats, abnormal ECG), regardless of whether it may explain the pain. Among children referred to a cardiologist for evaluation of chest pain, nearly 50% have a psychiatric diagnosis of at least moderate severity; in 29% of referred children, the psychiatric disorder is of marked severity. Anxiety disorders predominate in this subpopulation, but depression also is seen more commonly than in the general population. These children may be referred to a mental health specialist. Other specialists who may become involved in the care of patients with symptoms of chest pains include gastroenterologists (eg, for gastroesophageal reflux) or pulmonologists for lung conditions (eg, for asthma).

Evaluation

Evaluation of the child with chest pain must include a thorough, methodical history and careful physical examination. In many cases such evaluation is sufficient for diagnosis and the formulation of a management plan. "Red flags" that are suggestive of a cardiac cause are listed in Box 105.4.

History

The major questions to be addressed are outlined in Box 105.1. Because many pertinent details must be included in the history of present illness and because these details often are provided in a variable sequence, some physicians find it helpful to use a printed format as a guide. Some offer a questionnaire for the patient or parent/caregiver to complete. Witnesses to the episodes may provide additional helpful information, especially if the patient is not verbally expressive. A witness may estimate a pain score based on observation, which may differ substantially from the patient's self-assigned score.

Pain that occurs repeatedly over time is less likely attributable to an organic cause of a serious nature, particularly if it is not reproducible. A severe, protracted episode (eg, lasting hours) is more likely to be organic in origin. The location of the pain has not been a strong predictor of diagnosis in published series. The timing and association of pain with other symptoms, however, may provide major clues. Reflux esophagitis may occur after eating, more often when a patient is supine or very active, and may be accompanied by a sour taste; it may be relieved by eating or use of an antacid. Associated symptoms that may raise a red flag for a cardiac cause include syncope, palpitations, sweating, and nausea; reproducible pain at a particular level of exertion also has in increased likelihood for being anginal. Because pain and accompanying anxiety may cause sinus tachycardia, which can be interpreted by the patient as palpitations, it is important for the physician to get a sense of the heart rate experienced by patients with that symptom. Children can be asked to tap their chest or clap their hands as fast as the heart was racing during the palpitations; serious tachyarrhythmias, such as SVT and ventricular tachycardia, are usually quite rapid.

Box 105.4. Red Flag Items That Warrant Cardiology Referral for Pediatric Chest Pain

Patient History
- Chest pain with exertion
- Exertional syncope
- Chest pain that radiates to the back, jaw, left arm, or left shoulder
- Chest pain that increases with supine position
- Chest pain that is temporally associated with fever >38.4°C (>101.1°F)

Past Medical History
- Hypercoagulable state
- Arthritis/vasculitis
- Immobilization

Family History
- Sudden unexplained death
- Cardiomyopathy
- Hypercoagulable state

Physical Examination
- Respiratory rate >40 breaths per minute
- Temperature >38.4°C (>101.1°F)
- Ill-appearing
- Painful/swollen extremities
- Non-innocent murmur (see Chapter 101)
- Distant heart sounds
- Gallop
- Loud pulmonic component of S2
- Pericardial friction rub
- Peripheral edema

The presence of other symptoms may suggest etiology of the chest pain. For example, fever and malaise are common in the setting of pneumonia, pleurisy, or pericarditis. In exercise-induced asthma (EIA), chest pain may be related to exertion and is also accompanied by cough and/or wheezing. Shortness of breath, which may be related to pulmonary pathology, may also reflect anxiety or pain with movement.

In pediatric patients with psychogenic pain, other symptoms of anxiety or depression may be reported, although not necessarily simultaneously with the chest pain and often preceding it in onset. A history of recent stressors may be elicited. These patients may also report other recurrent somatic symptoms.

The nature, severity, and abruptness of the pain may also yield diagnostic clues. Exercise-induced asthma is often described as a chest "tightness," usually is gradual in onset, and lasts beyond the exertion itself. *Precordial catch syndrome*, a poorly understood disorder also known as *Texidor twinge,* is a sudden sharp, localized pain that is exacerbated by deep breathing and lasts only seconds or minutes. In contrast, *slipping rib syndrome*, in which the cartilaginous tips of ribs 8, 9, and 10 become transiently subluxated, produces pain at the costal margin, is quite sensitive to movement, and is often associated with a "popping" or "slipping" sensation in the affected area. The pain of GERD usually is described as "burning" and may awaken the patient from sleep. In contrast, the pain of angina is reported as "crushing" and may radiate to the left arm or the neck. The diffuse pain of pericarditis often is ameliorated by sitting forward. Aortic dissection, a rare cause of chest pain in children, results in an acute, tearing sensation and usually is diagnosed in the ED.

A history of recent chest trauma is suggestive of chest wall injury as the cause of pain; however, the fall or sports mishap may be forgotten if the onset of the pain is not temporally associated with the event. Chest wall pain also may result from overuse, as in weight lifters, or from inadequate breast support, as in female runners. Substance use, particularly with cocaine, may be disclosed if the patient is questioned in private. In some cases cocaine use may have occurred several days before the onset of pain.

A positive medical history may help the physician identify the underlying diagnosis. In the child with sickle cell disease, acute chest syndrome must be considered early in the assessment. A history of respiratory disease may point to either an acute respiratory infection or EIA. Depending on the cardiac diagnosis, the child with known heart disease who may experience benign chest pain is more likely to have a cardiac etiology than otherwise healthy peers. Most congenital heart defects, for example, do not cause pain but may raise the level of anxiety in the family and result in the perception or exaggeration of chest pain. Of greater concern is a history of heart disease that may affect myocardial perfusion, such as Kawasaki disease affecting the coronary arteries, or cardiac surgery involving the coronary arteries (eg, arterial switch operation for transposition of the great arteries).

The family history must not be overlooked. Although in most cases pediatric chest pain is not the result of a hereditary disorder, some of the more severe causes may be hereditary, such as hypertrophic cardiomyopathy, some arrhythmias, asthma, sickle cell disease, and aortic dissection in Marfan syndrome. It also has been noted that the child with nonorganic chest pain (eg, psychogenic pain) may have a close relative who has undergone recent heart surgery or a had heart attack, bringing attention to the heart during a time of emotional stress.

A complete review of systems is essential in the assessment of the child with chest pain because of the wide range of differential diagnoses.

Physical Examination

A careful physical examination is imperative. In the child with no history of serious illness, the examination should be focused on, but not limited to, the chest. General inspection will immediately aid in distinguishing between the acutely ill child and the otherwise well child with chest pain. Abnormal vital signs, such as fever, tachycardia, or tachypnea, are associated with acute etiologies, such as infection or inflammation. The child's pain level should be quantified with the aid of a pain scale. If the patient is dyspneic, pulse oximetry should be measured.

The chest wall should be examined for signs of trauma and for tenderness. Care must be taken with the latter because it is easy to elicit a false-positive examination for costochondritis, for example, because the costochondral junctions have some degree of normal tenderness, as do the breasts of female patients. Asymmetry of tenderness and a report that the pain produced is similar to that experienced is suggestive of chest wall injury. In the patient with rib injury, the pain can be elicited not only on direct palpation but also indirectly by compression of the thoracic cage from another location. In a girl with inadequate breast support, the breast ligaments may be symmetrically tender.

Auscultation of the lungs and heart yields useful clues to diagnosis, especially in the child with an acute inflammatory process (eg, rales, rub) and in the child with left ventricular outflow obstruction, such as aortic stenosis (eg, murmur). It is important to remember, however, that many organic causes of chest pain, such as GERD, EIA, intermittent arrhythmias, and AOCA, are undetectable on physical examination if the patient is not experiencing the pain at the time of the visit.

Other aspects of the physical examination may also aid in the evaluation of the child with chest pain. Jugular distention, hepatomegaly, and peripheral edema are suggestive of congestive heart failure or pericardial effusion with tamponade. The child's behavior pattern and interaction with parent or caregiver may be suggestive of a psychological disorder, such as anxiety or depression. Poor dentition and halitosis in an adolescent with weight loss may be a sign of bulimia as a source of esophagitis. Excessive signs of trauma, such as multiple ecchymoses, may be indicative of coagulopathy and also raise the possibility of nonaccidental trauma. Marfanoid habitus is suggestive of a connective tissue disorder with secondary aortic involvement.

Laboratory and Imaging Studies

A variety of diagnostic studies is available. It is incumbent on the physician to select studies appropriate to the individual patient, guided by the history and physical examination findings.

In the patient presenting with acute chest pain (often to the ED), the need for tests is increased because the differential diagnosis more often includes serious, even life-threatening, disorders compared with that of the child with chronic recurrent pain. Per published series, chest radiography has a reasonably high yield of positive findings. A negative radiographic finding is reassuring in ruling out pathology such as pleural effusion, pneumonia, pneumothorax, pneumomediastinum, and thoracic tumor; however, it cannot be used to exclude most cardiac etiologies. More detailed imaging, such as magnetic resonance imaging, may be necessary when major chest trauma is reported or aortic dissection is suspected. Dyspnea or hypoxemia, particularly in the setting of recent immobilization or in an adolescent female taking oral contraceptives, is suspicious for pulmonary embolism, for which a spiral computed tomography or nuclear perfusion scan is indicated. A D-dimer assay may be positive but is not highly sensitive for pulmonary embolism in children.

Although ECG is routinely performed as part of the evaluation for acute chest pain in children, it is rarely helpful in establishing a diagnosis other than arrhythmia, which may be suspected from the history or physical examination. Changes in ST segment may reflect pericardial irritation or myocardial ischemia if the ECG is performed at the time of the pain. If ongoing myocardial ischemia is suspected, myocardial enzymes (ie, creatine kinase-MB [CK-MB] fraction, troponin I) should be measured and toxicology screening performed. If signs of acute infection (eg, fever) are noted, a complete blood cell count, erythrocyte sedimentation rate or C-reactive protein level, and appropriate cultures are indicated. Echocardiography is highly sensitive and specific for pericardial effusion and should be performed early in the evaluation of the patient with chest pain and jugular distention, a friction rub, fever, or ST segment elevation on ECG.

In the patient who presents with chronic recurrent chest pain, the likelihood of serious pathology is quite low. In the setting of a normal physical examination a reassuring history, the yield of "screening" tests such as chest radiography and ECG is extremely poor, and the cost in dollars and anxiety is not justifiable. In most cases the history and physical examination are adequate to identify a focused selection of diagnostic tests, if any are necessary. For example, in the patient who describes pain suggestive of esophagitis endoscopy or an upper gastrointestinal series may be appropriate. When EIA is suspected, pulmonary function testing is appropriate, in some cases with an exercise challenge. Strong suspicion for psychogenic causes should prompt further psychological evaluation at the initial encounter, including querying the patient about suicidal ideation; further testing or consultation may be indicated.

The finding of a murmur of left ventricular outflow tract obstruction is an indication for echocardiography to confirm the diagnosis and yield further details to guide management. A history of palpitations or syncope may be suggestive of arrhythmia. Electrocardiography may be diagnostic for Wolff-Parkinson-White syndrome as a substrate for SVT; however, normal ECG does not rule out arrhythmia if the patient is asymptomatic at the time of the study. In such a patient, an ambulatory ECG, such as a Holter or patch monitor or a transtelephonic event detector may enable documentation of the rhythm during an episode of pain. Consistent exertional pain merits evaluation for ischemia, with resting ECG and often exercise stress testing. However, it is important to note that these studies can be negative between episodes in patients with AOCA. A diagnosis of AOCA can be identified on echocardiography, but only if the study is deliberately directed toward that diagnosis; therefore, the study should be done in a pediatric echocardiography laboratory, and the sonographer must be aware of the diagnosis in question. Further delineation of this anatomy usually requires computed tomography angiography.

Management

The management of pediatric chest pain depends on the underlying diagnosis or lack thereof. Strong suspicion of cardiac pathology, either on the basis of history and physical examination or on the basis of subsequent testing as described previously, warrants prompt referral to a pediatric cardiologist. Management may include surgery (eg, for AOCA), antibiotics, nonsteroidal anti-inflammatory drugs, pericardiocentesis (eg, for pericarditis), antiarrhythmics, interventional catheterization (eg, balloon angioplasty, radiofrequency ablation), or some combination of these treatments.

Short-term nonsteroidal anti-inflammatory drugs are helpful for chest wall pain resulting from overuse, trauma, costochondritis, or slipping rib syndrome. In a minority of cases, local injection with an anesthetic may be necessary.

In some cases, therapeutic trials may be considered to arrive at a diagnosis. A child with suspected esophagitis may be given an antacid at the time of the pain. If the pain is relieved, further workup and treatment can proceed accordingly. Similarly, a pediatric patient with suspected EIA, particularly one with a previous history of reactive airways disease, may benefit from a trial of an inhaled bronchodilator at the time of the pain.

In the exceedingly common setting of benign chest pain, such as with minor chest wall trauma, mild somatization, or occasional reflux esophagitis, the most important step in management is reassurance of the patient and family that this is not an indication of a serious disorder. It is essential for the physician to clarify how this conclusion has been reached and why further testing is not appropriate.

A frequent observation in this setting is that most families do not require a definitive diagnosis of the cause of the pain. If a serious disorder is excluded, which is necessary because 50% of patients believe that chest pain indicates heart disease, all parties are reassured. Follow-up studies have demonstrated that at least 80% of patients in this category do not seek further medical attention for their chest pain, nor do they return for follow-up.

Prognosis

The outcome depends on the underlying diagnosis. Most cases of benign chest pain resolve spontaneously, often within a short time after evaluation. Psychogenic chest pain has a greater tendency for recurrence than other forms. Even with serious and potentially life-threatening causes of chest pain, early diagnosis and intervention usually results in an excellent outcome.

CASE RESOLUTION

The patient and his parents are assured that he has no evidence of a serious medical or psychiatric problem. His heart is strong, his lungs clear, and his circulation good. The patient and family are reassured that chest pain in otherwise healthy children may be mysterious but is common and rarely is a sign of illness. They are gently but definitively advised that the patient requires no further evaluation at this time, but that if the problem does not resolve itself, the child should return for reevaluation.

The boy is delighted to hear that he may return to full sports participation, which is confirmed in writing to the coach. The parents are relieved and grateful for the attention and reassurance of the physician. At subsequent office visits for other purposes, the patient reports no more episodes of chest pain.

CHAPTER 106

Hypertension

Gangadarshni Chandramohan, MD, MSc, FASN, FAAP, and Michael Nguyen, DO

CASE STUDY

A 16-year-old girl is seen in the emergency department with a history of persistent headaches of 2 weeks' duration. She has been having occasional headaches for the past 2 years, which have been treated primarily with acetaminophen. She denies any recent weight loss, hair loss, joint pain, sweating, or palpitations. She has no history of swelling of her eyes or legs or blood noticed in the urine. She was born preterm at 30 weeks' gestational age and was kept in the hospital for 2 weeks. She has no history of urinary tract infection. Her 34-year-old mother and 58-year-old maternal grandmother have been on antihypertensive agents for the past several years; however, she has no family history of renal or heart disease. She is an average student. Her diet includes mostly meat and refined carbohydrates, such as bread and pasta. Additionally, she regularly eats salty snacks but drinks soda only occasionally. She has never been involved in any physical activity on a regular basis. She has never been sexually active and denies the use of illicit drugs, alcohol, or tobacco. She denies taking any medication prior to this visit, including oral contraceptives.

The physical examination is remarkable for a girl with weight, height, and body mass index above the 95th percentile for age. Her pulse is 85 beats per minute, and her blood pressure is 158/78 mm Hg in the right arm in the supine position. Equal pulses are palpable in all 4 extremities. Blood pressure is 164/92 mm Hg in the right lower extremity. Funduscopic examination reveals evidence of arteriovenous nicking but no papilledema. Normal breath sounds are noted on chest examination, along with an active precordium with the apical impulse shifted to the left. No murmurs are heard. The liver is palpable 1 cm below the right costal margin. The neurologic examination is unremarkable; no focal neurologic deficit is present. Urinalysis is normal. Hemoglobin is 11.2 g/dL, and hematocrit is 33%. Sodium is 139 mEq/L, potassium is 3.8 mEq/L, chloride is 102 mEq/L, and bicarbonate is 22 mEq/L. Blood urea nitrogen is 15 mg/dL, and serum creatinine is 0.9 mg/dL. Electrocardiography shows left ventricular enlargement. Computed tomography of the head is normal.

Questions

1. What is the definition of hypertension in children and adolescents?
2. What are the causes of hypertension in children and adolescents?
3. What is the appropriate evaluation of hypertension in children and adolescents?
4. What are the comorbid conditions and long-term complications associated with essential (ie, primary) hypertension?
5. What is the appropriate emergency treatment of symptomatic hypertension?
6. What is the long-term management of children and adolescents with essential hypertension?

Hypertension (HTN) has become a highly concerning chronic noncommunicable medical condition among children and adolescents in the past few decades because of a multitude of factors including, but not limited to, increasing prevalence of childhood obesity, survival of children with renal anomalies, and children born preterm who often sustain hypoxic injuries to the kidneys. *Hypertension* is blood pressure (BP) that is elevated above the normative BP data based on age, sex, and height.

Hypertension takes primary and secondary forms. Primary HTN is the most predominant cause among pediatric patients in the United States. General characteristics of patients with primary HTN include age of 13 years or older, family history of HTN, and overweight or obesity. Primary HTN in pediatrics has become a major public health concern. Secondary HTN is proportionally more prevalent among younger children and has an underlying cause that, if identified, may be curable, thereby eliminating the need for lifelong medical treatment. Renal and renovascular disease are the most common causes of secondary HTN. With early diagnosis and intervention, however, the long-term adverse consequences of HTN can be prevented. Children who are expected to be at increased risk for end-organ (ie, heart, central nervous system, kidneys, eyes) damage are those with persistently elevated BP, high body mass index (BMI), excessive weight gain, comorbid conditions (eg, type 2 diabetes), and a family history of HTN.

Normal Blood Pressure and Definition of Hypertension

Systolic and diastolic BP gradually increase from the newborn period through adolescence; therefore, age-appropriate norms should be used to classify a BP reading as normal or hypertensive. The stages and age-appropriate values of HTN are defined by the American

Academy of Pediatrics (AAP) "Clinical Practice Guideline (CPG) for Screening and Management of High Blood Pressure in Children and Adolescents," published in August 2017. The newer version of the previous BP chart published by AAP CPG compared with the previous guidelines *The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents* excluded children with obesity in the analysis and included height values rather than height percentiles for easier reference.

The classification of BP consists of normal BP, elevated BP, stage 1 HTN, and stage 2 HTN. In the most recent AAP CPG, the term "prehypertension" was replaced with "elevated BP." Currently, the stages of HTN are defined differently for children younger than 13 years than for adolescents age 13 years or older (Table 106.1, Table 106.2, and Table 106.3). For neonates and for infants age 1 through 12 months, similar guidelines for diagnosing HTN apply (Table 106.4, Table 106.5A, and Table 106.5B). For a diagnosis of HTN, measurement in any of the ranges provided must be noted on 3 or more occasions.

Definition of White Coat Hypertension and Masked Hypertension

It is well known that BP measurements are dynamic and can be misleading in a single clinic visit. Recent knowledge from ambulatory BP monitoring (ABPM) has contributed substantially to the understanding of HTN in children by revealing different BP responses under different circumstances. Ambulatory BP monitoring is continuous and assesses changes in BP over a 24-hour period, noting changes in BP at various intervals throughout the day and night. Ambulatory BP monitoring has helped identify 2 situations in which the BP measured during the clinical visit may significantly differ from home: white coat HTN and masked HTN (Table 106.6).

Table 106.1. Definition of Hypertension in Children and Adolescents

	Definition	
Term	*<13 years*	*≥13 years*
Normal BP	Systolic and diastolic BP <90th percentile for age, sex, and height	<120/<80 mm Hg
Elevated BP	Average systolic or average diastolic BP of 90th–94th percentiles for age, sex, and height	120/<80 mm Hg to 129/<80 mm Hg
Stage 1 hypertension	Average systolic and/or diastolic BP ≥95th percentile through the 94th percentile + 12 mm Hg for age, sex, and height with measurements obtained on ≥3 occasions	130/80 mm Hg to 139/89 mm Hg
Stage 2 hypertension	Average systolic and/or diastolic BP >5 mm Hg above the 95th percentile for age, sex, and height	≥140/90 mm Hg

Abbreviation: BP, blood pressure.

With *white coat HTN*, isolated elevated BP measurements in the hypertensive range are noted in the clinic, but the patient has otherwise normal values outside the medical setting. White coat HTN can account for a significant number of elevated BP readings in clinics, possibly in up to 50% of patients. These isolated elevated values may result in a misinterpretation of a child's actual BP values.

With *masked HTN*, however, the child or adolescent at risk for HTN has normal BP measurements in the office but has hypertensive BP measurements outside the office. The child with masked HTN is twice as likely as a child who is not hypertensive to have a family history of HTN. If the child also has a high pulse rate and elevated BMI, the child is at increased risk for developing a cardiovascular disorder. It is important to promptly identify and diagnose masked HTN because left untreated, it can put the patient at significant risk for end-organ damage, resulting in stroke, left ventricular hypertrophy (LVH), visual impairment, and/or renal failure. Studies have shown a significant direct association between not only elevated BP and left ventricular mass index but also between white coat and masked HTN and left ventricular mass index. The prevalence and long-term implications of the latter 2 types of HTN remain unclear.

Accurate Method of Measuring Blood Pressure

It is essential to obtain an accurate BP measurement in children. Several factors can influence BP measurement, and proper planning is important to optimize the likelihood of obtaining an accurate measurement. Prior to measurement, the child should be seated for 3 to 5 minutes with the back supported and with the feet uncrossed and resting on a firm surface to ensure an accurate reading. An appropriately sized BP cuff should be used based on the child's arm circumference and length; the inner cuff width should be approximately 40% of the arm circumference midway between the olecranon and the acromion, and the length should be greater than 80% around the arm circumference at the same point to avoid an inaccurately high reading (Figure 106.1). The right arm should be used for consistency in comparison with standard tables. In addition to using a variety of cuff sizes, it is recommended to use a thigh cuff in children and adolescents whose BMI is greater than the 95th percentile and in cases in which all standard arm cuffs are too small. For the child with suspected coarctation of aorta, the child should be in a prone position, lying on a flat surface, and the thigh cuff should be placed at the mid-thigh level. Of note, the BP in the lower extremities is usually 10% to 20% higher than the brachial artery pressures (Table 106.7).

Various other factors to consider to minimize errors while measuring BP include the patient's posture (ie, sitting versus lying down) and level of the arm in relation to level of the heart (ie, the elbow should be at the level of the heart). It is also important that the child remain calm and not be anxious or agitated while the measurement is taken. Additionally, the person taking the measurement must ensure that the child has not ingested any stimulants (eg, caffeinated beverages, dietary supplements) that could artificially increase BP measurement within 30 to 60 minutes before testing.

NIH publication 05–5267.

Various methods of monitoring BP are used in pediatric practice, including manual auscultatory aneroid sphygmomanometers and oscillometric automated devices, the latter of which use mean arterial pressure to calculate systolic and diastolic BP. The pediatrician should ensure that all devices are validated for pediatric ages using a resource such as www.dableducational.org. Oscillometric devices are known to correlate significantly with arterial BP, although a tendency exists for higher systolic and slightly higher diastolic pressures with portable devices. Therefore, according to the 2017 AAP CPG, after obtaining a BP reading with elevated BP using an automated oscillometric device, BP measurements must be repeated twice more and an average of the measurements calculated. If the BP remains elevated, the BP should be confirmed using a manual auscultatory aneroid device.

Epidemiology

Based on the current definition of persistent HTN in children, the prevalence of HTN in the pediatric population is approximately 4% to 5%; however, the prevalence of HTN is 10% in children with elevated BP who are at risk for HTN. Hypertension can vary depending on patient factors such as age, ethnicity, and geographic distribution as well as type of HTN. Recent data suggest that the overall prevalence of HTN has decreased among children of normal weight in the past decade. Among children with obesity, however, recent studies indicate that the prevalence of HTN is between 2- and 5-fold, compared with children of normal weight. Prevalence of HTN varies by the study population and the age group studied. Hypertension in pediatrics remains a major health issue because of increasing prevalence of obesity, survival of preterm infants, and cultural and lifestyle changes, including increases in stress and sedentary behavior. As in adults, HTN is more common among black and Hispanic children compared with white children. Furthermore, adolescents and those from urban areas tend to have higher prevalence of HTN compared with younger children and those from rural areas. Recent evidence has also shown that parental socioeconomic status is a risk factor for development of HTN in childhood, with low income populations disproportionately affected. Primary care providers should recognize at-risk patient populations to identify HTN promptly and treat it appropriately to avoid long-term cardiovascular complications.

Secondary HTN is more common among infants and young children and is associated with other conditions, including most commonly renal and/or renovascular disease. Secondary HTN also can be caused by cardiovascular disease, such as coarctation of aorta or prior surgical repair of cardiovascular lesions, endocrine disorders, or environmental exposures. Children who require hospital admission for HTN usually have secondary HTN, which may have been triggered by an acute event—often volume overload.

Occasionally, the cause of HTN is uncertain. In many such children, the acutely increased BP resolves with appropriate medical intervention, and most children do not require long-term treatment. What is certain, however, is that essential HTN in childhood increases the risk for adult HTN and metabolic syndrome.

Etiology and Pathophysiology

An increase in BP results from an increase in peripheral resistance or cardiac output or a combination of these. In 90% to 95% of adults, the precise cause of HTN is uncertain; hence, the term essential, primary, or idiopathic HTN. Historically, HTN was considered secondary to an underlying disorder in more than 80% of children, and fewer than 20% of cases were idiopathic; however, this was true only in children with very severe HTN. Adolescents with obesity and mildly elevated BP in whom no etiology of HTN is identified often have a family history of HTN and are classified as having essential HTN.

Many factors play a role in the development of essential HTN. Research reveals variable degrees of alteration in cardiac output, extracellular fluid volume, peripheral resistance, renin-angiotensin system, aldosterone, electrolyte balance, catecholamines, sympathetic nervous system, natriuretic hormones, prostaglandins, kinins, antidiuretic hormone, insulin response, endothelin, nitric oxide (ie, endothelium-derived relaxing factor), and others. Whether these abnormalities are primary or secondary and what their exact role is in the pathogenesis of essential HTN remains uncertain.

Additionally, several maternal factors, such as smoking, alcohol consumption, diet, obesity, diabetes, and hypothyroidism/hyperthyroidism may influence epigenetic pathways. Epigenetic changes occur as a result of methylation or acetylation of the noncoding gene segment (ie, histones) that can change the chromosomal configuration and result in activation or inhibition of a specific gene transcription (ie, turning the gene on or off), which may result in abnormal developmental. This hypothesis has been further supported by data demonstrating an association between fewer nephrons (resulting from underexpression of genes responsible for branching) in children who were born small for gestational age and later developed HTN. Thus, it is quite important to optimize maternal health to prevent potentially long-term adverse effects on the fetus.

Other important factors in the development of HTN include ethnicity, heredity, stress response, sleep apnea, obesity, hyperlipidemia, and increased salt intake. Studies showing that weight reduction in patients with obesity results in reduced BP strengthen the argument that obesity contributes to HTN.

Secondary HTN is more likely to exist in very young children with HTN, those who meet the criteria for stage 2 HTN, and those with systemic symptoms of HTN. The etiology of secondary HTN varies based on patient age and the nature of the HTN, that is, whether the condition is acute or chronic. Renal abnormalities account for 70% to 80% of secondary HTN in children. The pathogenesis of the HTN may be related to an increase in extracellular fluid volume (eg, acute glomerulonephritis, chronic renal failure), an increase in renin-angiotensin II activity (eg, renal artery stenosis, renin-producing tumor, pheochromocytoma, reflux nephropathy), or a combination of both mechanisms (eg, a patient with chronic renal failure caused by reflux nephropathy). Additionally, in young children, HTN may rarely be caused by a disorder with a single gene mutation that affects different pathways related to renal sodium handling.

Clinical Presentation

In most children, elevated BP, white coat HTN, masked HTN, and stage 1 HTN usually are asymptomatic. With stage 2 HTN, however, a child can develop headache or blurring of vision and, less commonly, nosebleed, changes in mental status, vomiting, and cardiac complaints (eg, chest pain, palpitations). Acute presentations of HTN are divided into 2 categories: hypertensive urgency and hypertensive emergency. *Hypertensive urgency* is defined by the sudden development of elevated BP without evidence of severe end-organ damage or life-threatening symptoms but may present with more mild symptoms, such as headache and vomiting. A *hypertensive emergency,* often called *hypertensive crisis,* in comparison, is defined by obvious signs of significant end-organ damage and life-threatening symptoms, such as encephalopathy, seizure, papilledema, retinal hemorrhage, and kidney injury. In children, these conditions usually are caused by secondary HTN rather than primary HTN. Cases of hypertensive urgency and hypertensive emergency both warrant immediate evaluation and referral to an emergency department for treatment.

Differential Diagnosis

An effort should be made to identify the cause of HTN in all young children because only 30% of them are likely to have essential HTN. In older children and adolescents with mildly elevated BP, essential HTN is the most likely diagnosis. In the setting of stage 1 or 2 HTN, however, a detailed history, complete physical examination, and simple laboratory tests to identify etiology should be completed (Boxes 106.1 and 106.2).

Evaluation

Blood pressure measurement should be part of the annual routine physical examination for all children older than 3 years and for all hospitalized children. If BP is normal in the annual examination, routine BP measurements between that examination and the next annual examination are not required. Regardless of age, however, all children with risk factors such as history of prematurity, congenital heart disease, recurrent urinary tract infections, renal disease, or chronic systemic illnesses, should undergo BP measurement as a routine part of every visit.

The physician also should verify that an appropriately sized cuff is being used for BP measurement and that efforts have been made to put the child at ease. Many children develop mild increases of BP (which can extend into the hypertensive range) when they visit a doctor's office because of anxiety or apprehension (ie, white coat HTN). In the patient with a BP measurement in the elevated, stage 1, or stage 2 HTN ranges, BP should be reassessed with at least 2 additional measurements in the same clinic visit by oscillometric or auscultatory BP and the values averaged. If the averaged BP remains elevated based on oscillometric technique alone, BP should be remeasured twice by auscultation with stethoscope and appropriate sphygmomanometer by a trained professional to confirm the reading.

Box 106.1. Causes of Acute or Intermittent Increases in Blood Pressure in Children

Renal
- Acute glomerulonephritis
- Hemolytic uremic syndrome
- Henoch-Schönlein purpura nephritis
- Renal trauma
- Renal artery or vein thrombosis
- After renal biopsy
- Acute obstructive uropathy
- After genitourinary surgery
- Blood transfusion in the patient with renal failure
- After kidney transplant or with transplant rejection

Drug-induced
- Corticosteroids
- Amphetamine overdose
- Phencyclidine hydrochloride overdose
- Cocaine overdose
- Anabolic steroids
- Oral contraceptives
- Excessive erythropoietin use in the patient with end-stage renal disease
- Cyclosporine A and tacrolimus

Central Nervous System
- Increased intracranial pressure (eg, subdural hematoma, meningitis, tumors)
- Encephalitis
- Poliomyelitis
- Guillain-Barré syndrome
- Porphyria
- Familial dysautonomia

Miscellaneous
- Wrong blood pressure cuff size
- Anxiety, apprehension (ie, white coat hypertension)
- Pain
- Fracture
- Immobilization
- Orthopedic procedures, especially leg lengthening and those requiring traction
- Abdominal wall defect
- Burns
- Leukemia
- Stevens-Johnson syndrome
- Bacterial endocarditis
- Hypernatremia
- Hypercalcemia
- Heavy metal poisoning

Box 106.2. Causes of Chronic Hypertension in Children

Renal
- Scarred kidney resulting from pyelonephritis or vesicoureteral reflux nephropathy
- Chronic glomerulonephritis
- Connective tissue disease (ie, systemic lupus erythematosus, Henoch-Schönlein purpura)
- Hydronephrosis
- Renal dysplasia, multicystic dysplastic kidney
- Polycystic kidney disease
- Solitary renal cyst
- Tumors (ie, Wilms, hemangiopericytoma [renin-producing])

Renal Vascular Lesions
- Renal artery stenosis (ie, fibromuscular dysplasia)
- Renal artery thrombosis, especially in the newborn after umbilical artery catheterization
- Renal vein thrombosis
- Renal artery lesions with neurofibromatosis, tuberous sclerosis

Other Vascular Lesions
- Coarctation of aorta (ie, thoracic, abdominal)
- Polyarteritis nodosa and other vasculitic disorders

Endocrine
- Corticosteroid treatment
- Neuroblastoma or other neural crest tumors
- Pheochromocytoma
- Congenital adrenal hyperplasia with 11-β-hydroxylase deficiency or 17-α-hydroxylase deficiency
- 11-β-hydroxysteroid dehydrogenase deficiency
- Liddle syndrome
- Primary aldosteronism
- Dexamethasone-suppressible hyperaldosteronism
- Hyperthyroidism
- Hyperparathyroidism
- Cushing syndrome

Central Nervous System
- Intracranial hemorrhage
- Intracranial mass
- Sleep apnea/disordered breathing

Essential (Primary) Hypertension

The most recent AAP CPG recommends that, if available, ABPM should be performed for confirmation of HTN in children and adolescents with office BP measurements in the elevated BP category for more than 1 year or with stage 1 HTN over the course of 3 clinic visits to confirm diagnosis. Ambulatory BP monitoring may also help identify masked HTN or an elevated BP state in a child by detecting the usual nocturnal dips in BP. Additionally, routine performance of ABPM should be strongly considered in the child or adolescent with a high-risk condition, such as a history of repaired coarctation of aorta, chronic kidney disease, obstructive sleep apnea, type 1 or 2 diabetes, heart transplant, or kidney transplant. In these select patients, ABPM is performed to assess HTN severity and determine if the circadian BP pattern is abnormal, which may be the first sign

of a BP disorder and an increased risk for target organ damage. Additionally, in the patient in whom white coat HTN or masked HTN is suspected, ABPM is the only reliable measure that could confirm either condition. Furthermore, ABPM can help identify whether the child's blood pressure returns to normal during sleep. Failure of the blood pressure to decrease overnight indicates a pathological basis for the hypertension.

Despite the benefits of ABPM, the apparatus is cumbersome, the study is costly, and sleep may be disturbed by the cuff inflation, thereby influencing the results. Additionally, few outpatient clinics have access to ABPM and insurance may not cover the test. Ambulatory BP monitoring requires trained technicians to effectively place devices and extract data. As an alternative to ABPM, home BP monitoring 3 times a day for 7 days with accurate logging can be done. Blood pressure devices used at home should be evaluated in the clinic for accuracy and validation for a pediatric population. Some studies have shown home monitoring to be as effective as ABPM, and home monitoring is currently used by many practitioners. Therefore, home or school BP monitoring should be considered as an alternative to ABPM.

History

The history is the first step in evaluating the etiology of elevated BP. Information should be obtained about symptoms that may be associated with HTN, such as headaches and visual difficulties (Box 106.3). The physician should also inquire about duration of gestation, birth weight, prenatal and perinatal complications, use of umbilical artery catheterization, unexplained fevers during infancy and early childhood, previous urinary tract infections, dark urine, bed-wetting, swelling of extremities, and renal disease. Additionally, the physician should elicit information about the child's physical growth, BP recordings during previous physical examinations, eating and nutritional habits (especially salt intake), use of drugs (including illicit drug use), and family history of HTN and renal disease.

Physical Examination

A thorough physical examination is essential for determining the etiology of HTN and the extent of target organ damage. Poor physical growth or short stature may be indicative of an underlying condition, such as Turner syndrome or chronic renal disease with or without renal failure; it may also be the consequence of long-standing severe HTN alone. Fundus examination is diagnostic for whether HTN has been severe and chronic, resulting in arterial changes, exudate, hemorrhages, or papilledema. Tachycardia may be indicative of heart failure or thyrotoxicosis. The child's pulses should be palpated in the upper and lower extremities, and BP should be measured in all 4 extremities to evaluate for coarctation of aorta and other vascular lesions.

A heart murmur may be detected in the patient with coarctation of aorta. Some patients may present in heart failure secondary to chronic severe HTN or renal disease with fluid retention. Abdominal examination may reveal the presence of masses caused by cystic kidney, Wilms tumor, or neuroblastoma or tenderness, especially in the costovertebral angle. Bruits sometimes may be heard anteriorly, over the lower portions of the left or right upper quadrants in patients with renal artery stenosis. The presence of café au lait or depigmented spots on the skin may be secondary to neurofibromatosis or tuberous sclerosis, respectively, and may contribute to HTN.

Box 106.3. What to Ask

Hypertension

- Does the child have any symptoms associated with hypertension (eg, headache, dizziness, nosebleed, visual difficulty, shortness of breath)?
- Have blood pressure readings been obtained during previous routine physical examinations?
- Has the child had any hematuria, generalized swelling of the body (ie, edema), enuresis (eg, nocturia), burning urination, previous urinary tract infection, or other kidney problems?
- How much salt does the child ingest? Does the child routinely add extra salt on most foods and frequently like to eat salty foods?
- How has the child been growing?
- Does a history exist of use of illicit drugs or oral contraceptives?
- Does a family history exist of hypertension, renal disease, autoimmune disorders, or endocrine diseases?

Laboratory Tests

The extent of laboratory evaluation depends on clinical findings, the nature of the HTN (eg, stage 1 or 2, acute or chronic), and whether an etiology is apparent or obscure. Laboratory studies can be done in 3 phases to minimize unnecessary cost and patient discomfort. Box 106.4 lists suggested laboratory workups for patients with stage 1 or 2 HTN.

The presence of hematuria, heavy proteinuria, pyuria, or elevated blood urea nitrogen or plasma creatinine is clearly indicative of a renal disorder as the cause of HTN and warrants appropriate renal evaluation. A kidney biopsy should be performed to diagnose glomerulonephritis, and radiologic investigations, such as ultrasonography and nuclear medicine scintigraphy, can help identify scarred kidney, hydronephrosis, cystic kidney, or tumor.

The presence of electrolyte abnormalities, such as hypokalemia, hypochloremia, and metabolic alkalosis, is indicative of increased mineralocorticoid hormone activity on a primary or secondary basis (Box 106.5). Endocrine-based causes of HTN in children are uncommon, and tests such as plasma or urinary fractionated metanephrines and catecholamines, plasma cortisol, thyroid-stimulating hormone, and triiodothyronine are indicated based on the clinical evaluation to diagnosis neuroendocrine tumors, Cushing syndrome or disease, or hyperthyroidism, respectively (Box 106.2).

Imaging Studies

Currently, the AAP CPG recommendation is that echocardiography should be performed at the time of initiation of pharmacotherapy for the management of HTN. In several studies, LVH is present even in children with untreated mild, white coat, or masked HTN, especially in children with overweight. In such cases in which signs of cardiac involvement exist, echocardiography should be considered.

Newer recommendations also include obtaining sleep studies in patients with overweight to evaluate for obstructive sleep apnea, which can contribute to the development of HTN and LVH. Evidence suggests that with appropriate treatment to improve sleep apnea, BP normalizes and end-organ damage is prevented.

Box 106.4. Laboratory and Radiologic Evaluation of Stage 1 or 2 Hypertension in the Pediatric Patient

Phase 1: Initial Evaluation (To Identify Common Causes of Hypertension and Evaluate for Cardiac End-Organ Damage)

1. Urinalysis (urine culture if indicated)
2. Complete blood cell count, serum electrolytes, blood urea nitrogen, and creatinine; lipid profile, liver profile, and hemoglobin A_{1C} for patients with obesity
3. Urine toxicology screening in adolescent patients

Phase 2: More Extensive Evaluation (To Rule Out Rare Causes of Hypertension)

1. Calcium, phosphorus, and PTH
2. Plasma renin activity and plasma aldosterone, cortisol, and TSH
3. Plasma fractionated catecholamines and metanephrines
4. Renal Doppler ultrasonography
5. Enalapril- or captopril-enhanced Tc 99m mertiatide renal scintigraphy
6. Renal arteriography (selective if necessary)
7. Echocardiography at any point before starting pharmacologic treatment

Phase 3: Identify Specific Etiologies (Studies Done Mostly by Specialists)

1. Diuretic renal scintigraphy, DMSA scintigraphy, or voiding nuclear cystography
2. Renal biopsy
3. Specific imaging studies, including nuclear scintigraphy to rule out pheochromocytoma or neuroblastoma
4. 24-hour urine HVA and VMA (obtain only if plasma fractionated catecholamines and metanephrines are >5 times higher than the normal range)
5. Other endocrine, neurology, or cardiology studies

Abbreviations: DMSA, 99mTc dimercaptosuccinic acid; HVA, homovanillic acid; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone; VMA, vanillylmandelic acid.

Box 106.5. Disorders Associated with Abnormal Electrolytes

Primary Basis

- Primary aldosteronism
- Glucocorticoid remediable aldosteronism
- Adrenogenital syndrome with 11-β-hydroxylase deficiency or 17-α-hydroxylase deficiency
- Liddle syndrome
- 11-β-hydroxysteroid dehydrogenase deficiency
- Apparent mineralocorticoid excess

Secondary Basis

- Renovascular hypertension
- Renin-producing tumor
- Reflux nephropathy

If the history, physical examination, and initial investigation do not reveal the etiology of severe HTN, renovascular disease should be considered and plasma renin activity and aldosterone level should be obtained and renal Doppler ultrasonography performed (Box 106.4). In the patient with suspected narrowing of the renal artery, however, interventional renal angiography is the standard for both diagnostic and therapeutic purposes should a patient require angioplasty or stent placement during the study.

Gene Studies

Gene studies are rarely indicated but should be considered in young children with markedly elevated BP, signs of end-organ damage, and findings suggestive of a single gene-related condition. A positive study is diagnostic; however, a negative result does not exclude an underlying genetic disorder. With advancement in the field, more commercial tests to diagnosis genetic etiologies of HTN are available, and it is crucial that pediatricians use these tests to optimize management, particularly in a very young child in whom a genetic form of HTN is suspected.

Management

Management is predicated on identifying the cause of the HTN. Initial treatment of the patient with elevated BP should be conservative, consisting of lifestyle modifications, including a healthy and well-balanced diet that is low in sodium and rich in fruits and vegetables. Additionally, the patient should be encouraged to optimize sleep. Nutrition and/or weight management referrals should be considered when appropriate. The patient with elevated BP should be followed up within 3 to 6 months. If BP normalizes, annual well-child care visits may be resumed. If the patient has persistent elevated BP for greater than 12 months, however, a diagnostic evaluation should be conducted and the patient referred to a specialist in cardiology or nephrology.

The child with stage 1 HTN initially may be managed with nonpharmacologic measures unless the patient is symptomatic or has significant cardiovascular risk factors (eg, diabetes, hyperlipidemia) and has a strong family history of HTN, stroke, or myocardial infarction at a young age. These measures include supportive care, reduction in sodium intake to approximately less than 2 g a day, weight reduction if the child has obesity, and use of biofeedback. The latter may consist of basic relaxation techniques, such as yoga or mediation, or more advance measures, such as thermal biofeedback accomplished by adjusting skin temperature, electromyography to release muscle tension, or neurofeedback focusing on electrical brain activity, most of which are in-facility programs.

The primary care physician is in an ideal position to help children achieve target BP and weight and protect against long-term cardiovascular complications. Promoting healthy cardiovascular exercise with concrete, attainable goals in addition to providing optimal diet plans that are culturally and socioeconomically appropriate to the individual child and family are crucial to empowering children and their families. Although every community is unique, primary care physicians should become familiar with local resources to assist patients, including available dietitians, social workers, and local health care organizations.

The child with stage 1 HTN should be reevaluated 1 to 2 weeks after the initial reading with 4-extremity BP measurements and

peripheral pulse evaluation. If after a 3- to 6-month observation period or 3 clinic visits with BP persistently in stage 1 HTN, pharmacologic treatment should be initiated and the physician should give consideration to performing a more thorough laboratory evaluation.

Drug therapy may begin with a beta blocker (eg, atenolol), a calcium channel blocker (eg, amlodipine besylate, isradipine), an angiotensin-converting enzyme inhibitor (eg, enalapril), an angiotensin II blocker (eg, losartan potassium), or a diuretic agent (eg, hydrochlorothiazide) (Table 106.8). Risk factors must be taken into consideration when instituting a treatment plan. For example, the child with obesity who has a family history of HTN may also have chronic kidney disease. In such a case, treatment should be

Table 106.8. Recommended Doses for Select Antihypertensive Agents for Use in Children and Adolescents With Hypertension

Class	*Drug*	*Starting Dose*	*Interval*	*Maximum Dose**
Angiotensin-converting enzyme inhibitors	Benazepril**	0.2 mg/kg/day up to 10 mg/day	QD	0.6 mg/kg/day up to 40 mg/day
	Captopril**	0.3–0.5 mg/kg/dose	BID-TID	6 mg/kg/day up to 450 mg/day
	Enalapril**	0.08 mg/kg/day	QD	0.6 mg/kg/day up to 40 mg/day

	Lisinopril**	0.07 mg/kg/day up to 5 mg/day	QD	0.6 mg/kg/day up to 40 mg/day
	Quinapril	5–10 mg/day	QD	80 mg/day
	Ramipril	2.5 mg/day	QD	20 mg/day
Angiotensin-receptor blockers	Candesartan	4 mg/day	QD	32 mg/day
	Irbesartan	75–150 mg/day	QD	300 mg/day
	Losartan**	0.75 mg/kg/day up to 50 mg/day	QD	1.4 mg/kg/day up to 100 mg/day
α- and β-adrenergic antagonists	Labetalol**	2–3 mg/kg/day	BID	10–12 mg/kg/day up to 1.2 g/day
	Carvedilol	0.1 mg/kg/dose up to 12.5 mg BID	BID	0.5 mg/kg/dose up to 25 mg BID
β-adrenergic antagonists	Atenolol**	0.5–1 mg/kg/day	QD-BID	2 mg/kg/day up to 100 mg/day
	Bisoprolol/HCTZ	0.04 mg/kg/day up to 2.5/6.25 mg/day	QD	10/6.25 mg/day
	Metoprolol	1–2 mg/kg/day	BID	6 mg/kg/day up to 200 mg/day
	Propranolol	1 mg/kg/day	BID-TID	16 mg/kg/day up to 640 mg/day
Calcium channel blockers	Amlodipine**	0.06 mg/kg/day up to 5 mg/day	QD	0.6 mg/kg/day up to 10 mg/day
	Felodipine	2.5 mg/day	QD	10 mg/day
	Isradipine**	0.05–0.15 mg/kg/dose	TID-QID	0.8 mg/kg/day up to 20 mg/day
	Extended-release nifedipine	0.25–0.50 mg/kg/day	QD-BID	3 mg/kg/day up to 120 mg/day
Central α-agonists	Clonidine**	5–10 mcg/kg/day	BID-TID	25 mcg/kg/day up to 0.9 mg/day
	Methyldopa**	5 mg/kg/day	BID-QID	40 mg/kg/day up to 3 g/day
Diuretics	Amiloride	5–10 mg/kg/day	QD	20 mg/day
	Chlorothiazide	10 mg/kg/day	BID	20 mg/kg/day up to 1.0 gram/day
	Chlorthalidone	0.3 mg/kg/day	QD	2 mg/kg/day up to 50 mg/day
	Furosemide	0.5–2.0 mg/kg/dose	QD-BID	6 mg/kg/day
	HCTZ	0.5–1 mg/kg/day	QD	3 mg/kg/day up to 50 mg/day
	Spironolactone**	1 mg/kg/day	QD-BID	3.3 mg/kg/day up to 100 mg/day
	Triamterene	1–2 mg/kg/day	BID	3–4 mg/kg/day up to 300 mg/day
Peripheral α-antagonists	Doxazosin	1 mg/day	QD	4 mg/day
	Prazosin	0.05–0.1 mg/kg/day	TID	0.5 mg/kg/day
	Terazosin	1 mg/day	QD	20 mg/day
Vasodilators	Hydralazine	0.25 mg/kg/dose	TID-QID	7.5 mg/kg/day up to 200 mg/day
	Minoxidil	0.1–0.2 mg/kg/day	BID-TID	1 mg/kg/day up to 50 mg/day

BID, twice-daily; HCTZ, hydrochlorothiazide; QD, once-daily; QID, four times daily; TID, three times daily.

* The maximum recommended adult dose should not be exceeded.

undertaken not only in an attempt to control BP using medications appropriate for a patient with kidney disease but also for weight reduction, dietary modifications, and increased physical activity. For the adolescent who smokes cigarettes, cessation of smoking is essential as well.

For the patient with asymptomatic stage 2 HTN, laboratory and diagnostic studies and a nephrology or cardiology referral should be done within 1 week, but ideally, within a few days of documenting stage 2 HTN. When possible, the pediatrician should contact the specialist by email or telephone to obtain advice about the immediate need to initiate treatment. In addition to lifestyle modification, combination therapy or the use of additional drugs, such as alpha blockers (eg, prazosin hydrochloride), alpha and beta dual receptor blockers (eg, labetalol hydrochloride), peripheral vasodilators (eg, hydralazine hydrochloride, minoxidil), or centrally acting drugs (eg, clonidine) is recommended (Table 106.8). The use of 1 or more of these drugs controls BP in most patients within a satisfactory range with a limited number of side effects. Patients with renal artery stenosis can be successfully treated with balloon dilatation or stent placement. If the procedure is unsuccessful or stenosis recurs, surgical correction is usually successful.

If a patient develops any signs of severe neurologic or cardiac symptoms, or has BP greater than 30 mm Hg above the 95th percentile (ie, >180/120 mm Hg in an adolescent), immediate referral to an emergency department for evaluation and treatment is mandatory. Hypertensive emergencies require rapid intervention with intravenous medications, such as labetalol hydrochloride, nicardipine hydrochloride, or sodium nitroprusside. Hypertensive urgencies may be managed initially with the aforementioned intravenous medications, oral labetalol hydrochloride, or an angiotensin-converting enzyme inhibitor. In either hypertensive emergencies or urgencies, the goal is to reduce the BP by approximately 20% to 25% of the presenting values in the first 8 hours. In the following days to weeks, BP is gradually reduced to within normal values. According to the AAP CPG, the goal of intervention for patients with HTN is BP less than the 90th percentile or less than 130/80 mm Hg.

Management of HTN must involve the patient's family. A holistic approach with the family and consideration of socioeconomic, behavioral, nutritional, and cultural factors provides the most effective treatment.

Prognosis

The long-term outcome of HTN in the pediatric patient depends on the underlying etiology. In the child or adolescent with severe HTN, BP control improves growth and overall well-being. The very long-term (ie, 40- to 50-year) prognosis for the child with persistent, mild essential HTN is largely unknown; however, adequate BP control should prolong life and reduce cardiovascular, central nervous system, renal, and retinal morbidity. In untreated or poorly controlled HTN the prognosis is poor. The prognosis is significantly worse in patients with poorly controlled HTN and obesity and hyperlipidemia, which is associated with severe cardiovascular morbidity and mortality in adults.

Prevention

Although no specific predictors exist for the development of HTN later in life, it is likely that early childhood health plays a role. Children who are small at birth and undergo rapid catch-up growth seem to have a higher incidence of obesity and HTN later in life. Overall, infants fed mother's milk have lower rates of HTN as adults. As a result, it has been postulated that encouraging breastfeeding may have a protective effect. It is important to be aware that preterm and small for gestational age infants are often given high-density carbohydrate and lipid supplements for rapid weight gain. Studies have shown that rapid weight gain during the first 2 years after birth correlates strongly with adverse cardiovascular health in adulthood. Later in life, limiting intake of sodium and caffeine may reduce rates of HTN in adolescents. Programs aimed at preventing childhood obesity likely will prevent HTN as well.

CASE RESOLUTION

Because of the elevated BP and evidence of end-organ dysfunction (ie, LVH), the patient is diagnosed as having stage 2 essential HTN. Her history of prematurity raises the possibility of renal artery thrombosis or stenosis secondary to umbilical artery catheter. First, dietary modifications (ie, diet low in refined sugar and sodium) and increasing physical activity should be addressed. Second, because the patient has evidence of LVH and early changes of retinopathy, appropriate antihypertensive medication to control the BP should be initiated. A calcium channel blocker or beta blocker can be used. Renal Doppler ultrasonography is appropriate to determine kidney size, extent of kidney damage, and blood flow to the kidneys.

PART 9

Genitourinary Disorders

CHAPTER 107

Disorders of Sexual Differentiation

Jennifer K. Yee, MD, and Catherine S. Mao, MD

CASE STUDY

A term neonate is being evaluated in the newborn nursery. The mother received prenatal care from the eighth week of gestation, reportedly had no problems during the pregnancy, and took no medications except prenatal vitamins with iron. She specifically denies taking any progesterone-containing drugs. Her previous pregnancy was uneventful, and her 3-year-old son is healthy.

On physical examination, the newborn is active and alert, with normal vital signs. Aside from a minimum amount of breast tissue bilaterally, the physical examination is unremarkable, except for the genitalia. The labioscrotal folds are swollen bilaterally with slight hyperpigmentation and mild rugae. No masses are palpable in the labioscrotal folds. The clitoris/phallus is 1.5 cm in length. Labioscrotal fusion is present, with a very small opening at the anterior aspect. The urethra cannot be visualized.

Questions

1. What conditions should be considered in the newborn with a disorder of sexual differentiation?
2. What should the family of a newborn with a disorder of sexual differentiation be told about the sex of the newborn?
3. What key historical information should be obtained from the family of the newborn with a disorder of sexual differentiation?
4. What laboratory studies must be obtained to aid in the diagnosis?
5. What psychosocial issues should be addressed with the family while the neonate is in the newborn nursery?

Disorders of sexual differentiation (DSDs) in newborns can result in ambiguous genitalia and are classified according to chromosomal status and gonads present. This standard classification, using newer nomenclature with previously used nomenclature in parentheses, includes 46,XX DSD (ie, female pseudohermaphroditism), 46,XY DSD (ie, male pseudohermaphroditism), ovotesticular DSD (ie, true hermaphroditism), and 46,XX testicular DSD or 46,XY gonadal dysgenesis (ie, complete or mixed gonadal dysgenesis). Gonadal dysgenesis in 45,X and 46,XX individuals does not present with ambiguous genitalia but is also classified as a DSD.

A multidisciplinary team should be involved in the care of the newborn with a DSD. In addition to the general pediatrician, significant members of the team include nurses, social workers, neonatologists, pediatric endocrinologists, geneticists, and surgeons. The role of the primary care physician cannot be underestimated, however, because this professional is always involved in the initial evaluation of the newborn and often has an established relationship with the family.

Epidemiology

The prevalence of ambiguous genitalia in newborns is approximately 1 in 3,000 to 4,000 live births. The 46,XX DSD is characterized by female chromosomes (46,XX), normal ovaries and müllerian structures, and virilized external genitalia. The most common DSD—46,XX DSD—is most often caused by congenital adrenal hyperplasia (CAH). Neonatal screening studies suggest that the incidence of CAH is 1 in 5,000 to 15,000 live births per year.

The 46,XY DSD occurs in genetic males (46,XY) who have testes but with insufficient masculinization of the external genitalia. This disorder most commonly results from androgen insensitivity. Ovotesticular DSD is a rare condition in which ovarian and testicular tissues are present. Seventy percent to 80% of affected individuals have the 46,XX karyotype, and the morphology of the external genitalia varies widely.

The 46,XY gonadal dysgenesis is characterized by ambiguous genitalia or a female phenotype with a normal XY karyotype. The affected neonate may have a specific gene abnormality that results in abnormal testicular development and often streak gonads. Reports indicate that this condition is the second most common form of ambiguous genitalia. The affected newborn with chromosomal mosaicism (45,X/46,XY) is considered to have mixed gonadal dysgenesis.

Clinical Presentation

Variability in the phenotypic and clinical presentation of these disorders is considerable (Box 107.1). The newborn with DSD with ambiguous genitalia may have an enlarged clitoris or small phallus and varying degrees of labioscrotal fusion. Signs of virilization

Box 107.1. Diagnosis of Disorders of Sexual Differentiation

- Indeterminate or ambiguous genitalia
- Enlarged clitoris or small phallus
- Hyperpigmented, rugated labia majora that may be fused
- Blind-ending or absent vaginal pouch
- Phenotypic male neonate with hypospadias or bilateral cryptorchidism
- Phenotypic female neonate with an inguinal hernia or mass

in the female newborn might include hyperpigmented labia and presence of labial rugae. Other findings suggestive of 46,XX DSD are perineal hypospadias or an inguinal hernia. More dramatic presentations, such as severe dehydration and shock in a neonate, are associated with CAH of the salt-wasting form. Females with gonadal dysgenesis often present in adolescence with primary amenorrhea (see Chapter 61). Turner syndrome (45,XO) is a common cause of gonadal dysgenesis and may present with additional clinical features; 46,XX "pure" gonadal dysgenesis is a distinct entity.

Pathophysiology

To appropriately evaluate and interpret laboratory results of the neonate with ambiguous genitalia, it is important to understand the physiology of sexual differentiation and how deviations from this process result in DSD.

Normal Sexual Differentiation

Before an embryo reaches 6 weeks, germ cells migrate from the yolk sac into the undifferentiated bilateral gonads. Both wolffian and müllerian duct systems are present, and the embryonic gonads of males and females are indistinguishable at this time.

If a Y chromosome is present, a testes-determining factor known as sex-determining region Y (SRY) induces differentiation of these gonads into testes by stimulating *SOX9* (SRY-related gene) expression in the gonads, thus blocking female development. This process involves the formation of seminiferous tubules that surround the germ cells. Leydig cells begin to produce testosterone, which in turn acts on the wolffian duct to result in male internal genitalia: vas deferens, epididymis, and seminal vesicles. Concurrently, *SOX9* acts with steroidogenic factor 1, resulting in regression of the müllerian ducts secondary to Sertoli cell production of anti-müllerian hormone, also known as müllerian-inhibiting substance. The formation of normal male external genitalia is dependent on the conversion of testosterone to dihydrotestosterone (DHT) via 5-α-reductase. Dihydrotestosterone then combines with a specific androgen receptor, which allows formation of the phallus and scrotum from the previously undifferentiated external genitalia. The process primarily involves growth and fusion. Later in gestation, the testes migrate into the scrotum.

The development of undifferentiated gonads into female organs is dependent on the absence of the Y chromosome and the presence of 2 intact and normal functioning X chromosomes. Because androgens are not produced and anti-müllerian hormone is not present, the wolffian duct degenerates and the müllerian duct develops into the internal female structures: fallopian tubes, uterus, and upper vagina. Fusion of undifferentiated external genitalia does not occur in the absence of DHT; thus, the external genitalia develops into the labia, and the genital tubercle becomes the clitoris. Female differentiation was previously believed to be the default development in the absence of SRY; however, recent studies support the existence of female determining factors (ie, R-spondin1 and Wnt signaling molecule Wnt4).

Disorders of Sexual Differentiation

Congenital adrenal hyperplasia is the most common cause of virilization of the female and is an autosomal recessively inherited defect. Congenital adrenal hyperplasia is the result of an enzymatic deficiency in the pathway for synthesis of cortisol and aldosterone from cholesterol. The most common of these enzymatic defects is 21-α-hydroxylase deficiency. Other less common defects are 11-β-hydroxylase deficiency and 3-β-hydroxysteroid dehydrogenase deficiency. Lipoid adrenal hyperplasia results from a defect in the steroidogenic acute regulatory (StAR) protein enzyme that transports cholesterol across the mitochondrial membrane for steroid synthesis. A rare form of CAH is cytochrome P-450 oxidoreductase deficiency, which can be associated with Antley Bixler syndrome. Prenatally, circulating levels of androgens are abnormally high from the overproduction of precursors in the steroid synthesis pathways. As a result, the external genitalia of the fetus, which are controlled by androgens, are virilized in the female. Internal female organs, however, are normal because their development is not influenced by androgens. Males with the common forms of CAH (21-α-hydroxylase and 11-β-hydroxylase deficiency) may exhibit hyperpigmentation and increased rugosity but otherwise have normal external genitalia.

Approximately two-thirds of patients with classic CAH resulting from 21-α-hydroxylase deficiency have the salt-wasting form. Because of low levels of aldosterone, sodium resorption in the renal tubules is reduced, resulting in hyponatremia and hyperkalemia. If this salt-wasting condition goes undiagnosed and unmanaged, shock and death may result in the first few weeks after birth. Newborn screening programs are currently in place in all 50 US states. These programs screen for elevated 17α-hydroxyprogesterone, targeting identification of patients with 21-α-hydroxylase deficiency, and are less sensitive for detection of neonates with 11-β-hydroxylase deficiency and 3-β-hydroxysteroid dehydrogenase deficiency.

The 46,XY DSD is secondary to insufficient testosterone production or insensitivity at the cellular level. Androgen insensitivity, the most common cause of this disorder, is the result of an abnormality or a reduction in the number of androgen receptors. Not all affected individuals present with ambiguous genitalia at birth because the spectrum of sensitivity is broad. If the androgen receptor is completely nonfunctional or absent, the external genitalia are those of a normal female (ie, complete androgen insensitivity syndrome). In

the setting of partial function of the androgen receptor, genital ambiguity occurs. This is an X-linked condition that affects only 46,XY individuals; however, 46,XX females are carriers and pass the mutation to their offspring.

Other causes of 46,XY DSD are inadequate testosterone production secondary to low levels of fetal gonadotropins; defects in testosterone synthesis from enzyme deficiencies or disruption of electron transport; failure to convert testosterone to DHT as a result of 5-α-reductase deficiency; deficient müllerian duct-inhibiting substance, which can be autosomal recessive or X-linked recessive; and intrauterine loss of both testes secondary to torsion or another prenatal event. Causes of testosterone deficiency resulting in 46,XY DSD include CAH caused by defects of StAR, P-450 side-chain cleavage, 3-β-hydroxysteroid dehydrogenase, 17-α-hydroxylase, and P-450 oxidoreductase.

Although SRY is considered to be the sex-determining region, defects in SRY explain only approximately 15% of XY gonadal dysgenesis. A loss of function mutation in *SOX9* results in camptomelic dysplasia with XY sex reversal. More recently, an abnormality of a gonad-specific regulatory region of *SOX9* resulted in isolated XY gonadal dysgenesis. Steroidogenic factor 1 mutations have been estimated to account for up to 13% of cases of XY gonadal dysgenesis.

Although most causes of ambiguous genitalia are related to chromosomal abnormalities and inherited enzymatic defects, exogenous sources of hormones can affect the differentiation of sexual organs. In most cases, the effect is minimal and no ambiguity occurs. Masculinized female external genitalia can occur, however, depending on the timing and duration of prenatal exposure to androgens or other virilizing drugs. Currently, the most commonly used androgens are likely anabolic steroids. A neonate may even be exposed prenatally through transdermal passage to the mother from a family member using androgen creams. An adrenal tumor or poorly controlled CAH in the mother will also result in virilization of the female fetus. The progestin in birth control pills does not have sufficient androgen action to cause a problem.

Differential Diagnosis

The differential diagnosis of ambiguous genitalia depends on the classification of the DSD (Table 107.1). Some causes of this condition can be life-threatening and must be recognized immediately (eg, salt-wasting CAH).

Evaluation

History

The general obstetric history should be reviewed, although it may not be helpful in all cases. Likely the most important source of information on family history can be derived from family pedigrees (Box 107.2). The mother of the affected newborn should be interviewed thoroughly for any clinical findings that might suggest her as the source of androgens. Undiagnosed chromosomal disorders, consanguinity, and recurrent medical conditions may be established or inferred from the family background.

Table 107.1. Classification and Causes of Disorders of Sexual Differentiation in the Newborn

Disorder	*Causes*
46,XX DSD	Congenital adrenal hyperplasia
	Maternal androgen ingestion
	Maternal virilizing hormones
	Idiopathic (associated with dysmorphic syndromes)
46,XY DSD	Biochemical defects in testosterone biosynthesis (eg, enzyme deficiencies)
	Androgen insensitivity (eg, complete or partial receptor defects)
	5-α-reductase deficiency
	Persistent müllerian duct syndrome
	Gonadotropic failure
	Dysgenetic testes
	Bilateral vanishing testes syndrome
	Idiopathic (associated with dysmorphic syndromes)
Ovotesticular DSD	Chimerism
46,XX testicular DSD or 46,XY complete gonadal dysgenesis	Chromosomal mosaicism

Abbreviation: DSD, disorders of sexual differentiation.

Box 107.2. What to Ask

Ambiguous Genitalia

- Did the mother take any medications containing estrogen, progestational agents, or androgens during the pregnancy? Did she use any other virilizing drugs, such as danazol, during pregnancy?
- Was the mother in contact with anyone using hormonal creams or gels?
- Does the mother have poorly controlled congenital adrenal hyperplasia or an adrenal tumor? Does the mother have any virilizing symptoms that suggest she should undergo an evaluation for these conditions?
- What is the mother's prior obstetric history?
- Did she have any problems with any previous pregnancies?
- Does a history exist of any unexplained neonatal deaths, particularly in male offspring?
- Are her other children growing and developing normally?
- Does a family history exist of ambiguous genitalia, including microphallus, hypospadias, and cryptorchidism?
- Does a family history exist of sterility, female hirsutism, or amenorrhea?
- Are the parents or other family members consanguineous?

Physical Examination

A complete physical examination of the newborn must be performed in the nursery, in addition to a detailed assessment of genitalia. In particular, the presence of dysmorphic features (eg, microcephaly, low-set ears, micrognathia) that are suggestive of a chromosomal abnormality should be appreciated. The areola should be examined for any evidence of hyperpigmentation, and the inguinal area should be palpated for any masses or hernias.

A thorough genital examination should be performed. The appearance and size of the labioscrotal folds should be noted in terms of pigmentation, presence of rugae, and size. The physician should keep in mind that normal female labia majora may not completely cover the labia minora and that the labia may be extremely underdeveloped in the preterm newborn. The physician should determine whether any masses are palpable in what appear to be the labia and whether the testes are palpable in what appears to be the scrotum. The size of the phallus/clitoris should be measured; in term neonates, a normal stretched phallus is at least 2.5 cm long, whereas a normal clitoris should not exceed 1 cm. The labioscrotal folds should be spread apart to look for a vaginal introitus. The presence of posterior labioscrotal fusion, which may preclude this, confirms the suspicion of indeterminate genitalia. The *clitoral index*, that is, the product of the clitoral transverse and sagittal dimensions, and the anogenital distance can be determined by an experienced physician. Limited data on these measurements in normal children are available in the literature. The location of a urethral meatus should be noted, because if hypospadias and cryptorchidism occur together, the chance of DSD is approximately 50%. A rectal examination may help detect the presence of a uterus or prostate but may be difficult to perform.

Laboratory Tests

The most important laboratory study to obtain is a karyotype, which can be performed in 24 to 48 hours by many laboratories. Examination of Barr bodies in a buccal smear is not recommended because this test is unreliable. Additionally, a serum electrolyte panel should be ordered in the nursery and electrolyte levels monitored closely if CAH is suspected. A serum 17-α-hydroxyprogesterone level is mandatory in evaluation for CAH. Other intermediate metabolites, such as 11-deoxycortisol, androstenedione, dehydroepiandrosterone-sulfate, and sex steroids (ie, testosterone, DHT) also can be measured to evaluate for androgen excess or deficiency. Measurement of 17-ketosteroids and pregnanetriol in the urine may provide supportive data in the neonate with ambiguous genitalia, especially in one in whom the gonads are not palpable.

A human chorionic gonadotropin stimulation test may be performed to measure response in testosterone production if ovotesticular DSD is suspected.

Imaging Studies

Pelvic ultrasonography is effective in determining if müllerian structures are present, but this technique is not as useful for locating the gonads. If the gonads are not palpable, magnetic resonance imaging of the pelvis may be considered. Genitography can aid in visualizing the duct structures under fluoroscopy.

Management

An interdisciplinary team consisting of a pediatrician, pediatric endocrinologist, medical geneticist, urologist, social worker, and psychologist or psychiatrist should be involved in the care of the newborn with DSD with ambiguous genitalia. With such management, all aspects of care can be addressed in an efficient and comprehensive manner. A consensus statement on management of infants with DSD was published in 2006 and proposed ethical guidelines for management were published in 2010.

Initial Phase: Delivery Room and Newborn Nursery

If the sex of the newborn is uncertain, it should not be assigned in the delivery room. The parent or parents and nursing staff should be notified immediately of the ambiguity, and a unisex name should be assigned, such as "Baby Smith" rather than "Baby Boy Smith" or "Baby Girl Smith." Hospital nameplates should also reflect a sex-neutral status in wording and color. The physician should congratulate the parent or parents on the birth of the child, then inform them of the genital ambiguity. The physician should advise the parent or parents that additional tests are necessary to determine the baby's sex. The parent or parents should be encouraged not to speculate on the sex of the newborn in the meantime.

During the initial hours after birth, parents may have difficulty comprehending the condition. An open line of communication must be maintained with the family, even while waiting for test results. Parents should be assured that sex assignment will be made as soon as possible and that more information will follow with test results. Sex assignment can potentially be made within 3 to 5 days or even earlier in some institutions because most preliminary laboratory results are reported in 24 to 48 hours. However, some cases may require more extensive workup, such as a trial of testosterone in partial androgen insensitivity, so sex assignment for these neonates may take more time. The interval of time to sex assignment, therefore, must be individualized. Necessary radiographic studies should be ordered as soon as possible.

Intermediate Phase: Psychological Issues

Several psychological issues should be addressed at the time of diagnosis. Alleviation of parental anxiety about the cause of the condition should be the priority; general questions can be answered as well. For example, a parent may be unclear about what to tell others about the sex of the newborn and may find this process quite awkward. Additionally, the parent or parents should be educated about normal sexual differentiation. The pediatrician must emphasize that during the first 6 to 8 weeks of gestation, sexual organs are undifferentiated. Ambiguous genitalia should be explained as overdevelopment or underdevelopment. For parental perspective, genital ambiguity can be compared with another type of birth defect, such as a cardiac septal defect.

The primary care physician must also assess the level of sophistication of the parent or parents as well as their cultural and/or religious beliefs about gender identity and sexual orientation. The sex preference for the newborn should be addressed. The physician should ask whether a boy or girl was hoped for and whether strong parental feeling existed about a particular sex. The medical team can also help the family establish a plan for the newborn concerning what to share with the extended family and how much detail they want to disclose. After the initial meeting and while awaiting laboratory data, other questions about sexual orientation, puberty, fertility, and self-esteem may arise.

Final Phase: Sex Assignment

After the karyotype is confirmed and the type of DSD has been considered, team members should meet with the family to discuss sex assignment before discharge from the hospital. Traditionally, sex assignment was based on size of the phallus, potential response to androgen stimulation, and potential for fertility. More recently, additional factors have been recognized as important in sex assignment, including in utero brain exposure to androgens and likely adult gender identity, quality of sexual function with or without surgery, and psychosocial risk for patient and family in the event of gender dysphoria. The parent or parents must be involved in this decision and must understand the potential outcome. Some investigators strongly believe that sex reassignment and genital surgery should be discussed with the patient at a later date and that assignment during the neonatal period be avoided. Such an approach involves consistent counseling for the patient, open discussion among the family, and involvement of a primary care physician who is willing to work diligently with the patient and family. Support groups should also be offered regardless of the decision about sex assignment.

The physician should reiterate the detailed information about the origin of the condition. The timing and nature of any future hormonal treatment and surgical procedures should be addressed as well. The parent or parent should be urged to move beyond the issue of ambiguous genitalia after a decision about sex has been made. After that, the parent or parents must make decisions about activities such as birth announcements and inquiries about the neonate's sex from extended family, siblings, and babysitters. The entire medical team should offer the parent or parents encouragement concerning their parenting ability.

Additional Management

Hormone replacement therapy is indicated for some newborns with ambiguous genitalia. Cortisol replacement is mandatory in the newborn with CAH at daily physiologic doses of 10 to 20 mg/m^2. In the newborn with salt-wasting or classic 21-α-hydroxylase deficiency, mineralocorticoid replacement is indicated. Oral fludrocortisone should be administered at doses that suppress plasma renin activity to normal levels without causing hypertension.

Testosterone or estrogen replacement is necessary at puberty for the patient with a disorder in which the gonads did not develop or were surgically removed. For disorders involving micropenis, injections of testosterone cypionate at regular intervals may be used to increase the length and width of the phallus. Recombinant human growth hormone replacement may also be considered for short stature in the patient with mixed gonadal dysgenesis.

Surgical procedures may be necessary in many cases but can be done later in infancy. In the patient with partial androgen insensitivity, surgery may be deferred until later in life because of the high rate of gender dysphoria known to occur among these patients. Although laparoscopy or laparotomy may be indicated for a gonadal biopsy, this is generally not needed in the neonatal period for sex assignment. A gonadectomy is indicated prophylactically in all phenotypic females with all or part of a Y chromosome because of the potential for malignant conversion of gonadoblastoma. Clitoral reduction and recession, vaginoplasty, and labioscrotal reduction are usually performed if the newborn is to be raised female. For the newborn to be raised male, orchiopexy, hypospadias repair, and chordee release often are indicated, but these surgical procedures may be difficult. In some specific cases, however, surgery should be delayed until response to medical treatment is evaluated. For example, in CAH, clitoral size may decrease with glucocorticoid replacement.

Psychological support for the patient and family will be necessary during the child's growth and development into adulthood. Issues of gender identity, gender role, and sexual orientation require ongoing discussion with the patient and parent or guardian. Gender dissatisfaction may occur later in life.

Prognosis

The prognosis for most newborns with ambiguous genitalia is excellent. Problems arise with undiagnosed CAH, which may result in shock and death in the neonatal period if unrecognized and untreated. Otherwise, children should be able to live long, healthy lives after their families have accepted the diagnosis. Amenorrhea in females and sterility in males or females must be addressed during adolescence, at which time psychological services should be provided.

CASE RESOLUTION

The newborn has ambiguous genitalia. The parents should be informed immediately of this finding, and all references related to sex should be avoided. A karyotype and 17-α-hydroxyprogesterone analyses should be performed immediately. Additionally, serial serum electrolyte panels should be performed starting at 12 to 24 hours after birth. The physician should meet with the family to further discuss DSDs and explain the diagnostic workup. General psychological services and information about support groups should be provided as well.

CHAPTER 108

Inguinal Lumps and Bumps

Sara T. Stewart, MD, MPH, FAAP

CASE STUDY

A 2-month-old boy presents to your office for evaluation of a lump that has been evident in his right groin for the past week. The lump has been coming and going, and his mother notices that it is larger when he cries. Today, the lump is prominent, and the infant seems fussy. He has been crying more often than usual and vomited once today. His history is remarkable for having been born at 32 weeks of gestation by spontaneous vaginal delivery. Birth weight was 1,500 g (3.3 lb), and he did well in the nursery, with no respiratory complications. He was sent home at 4 weeks of age and has had no other medical problems. He breastfeeds well and has normal stools.

Physical examination reveals a well-nourished, irritable infant in no acute distress. His vital signs demonstrate mild tachycardia and a temperature of 37.8°C (100°F). His abdomen is soft, and the genitourinary examination is significant for a swelling in the right inguinal area that extends into his scrotum. The mass is mildly tender and cannot be reduced. The remainder of the examination is normal.

Questions

1. What are the possible causes of an inguinal mass?
2. How does age affect the diagnostic possibilities?
3. How does the physician differentiate between acute and nonacute conditions?
4. What diagnostic modalities can help with the diagnosis?
5. What are the treatment options for inguinal masses?
6. What, if any, are the long-term consequences of inguinal masses?

Inguinal masses arise from disease in normal tissue in the inguinal area or from ectopic tissue, frequently of embryologic origin. A child may present with the chief report of an inguinal mass, and the mass may be located anywhere along the inguinal canal to the scrotum or labia (Figure 108.1). Along the inguinal canal, a mass might be an enlarged lymph node, a retractile testis, an ovary, or a synovial cyst. At the inguinal ring, a mass might also be a testis or an ovary, or an inguinal hernia. In the scrotum, swelling can result from hernia, hydrocele, varicocele, trauma, or testicular pathology. The labial lesion can be secondary to trauma; an ectopic ovary; mixed gonadal tissue; an actual testis, as in testicular feminization; or a Bartholin cyst. The differential diagnosis and subsequent evaluation vary based on the location of the mass, patient age, and the acuity of presentation of the mass.

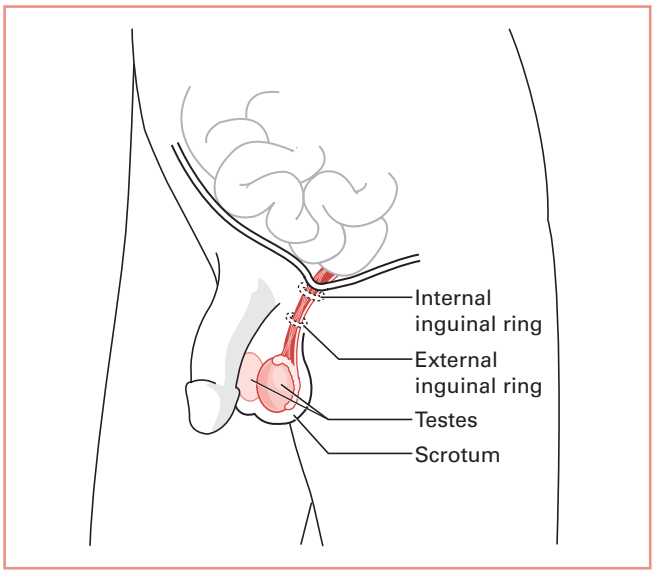

Figure 108.1. The inguinal area of a male individual.

Epidemiology

Inguinal masses are a fairly frequent finding reported in the office setting. The usual cause is an enlarged lymph node, but hernias and hydroceles are also common. The most common surgical procedures performed in children are to repair hernias and hydroceles. The prevalence of inguinal hernias has been estimated to be 1 to 4 per 100 live births. There is a 60% risk of incarceration in the first 6 months after birth if the hernia is left untreated. For this reason, surgical correction is recommended early. Hernias are present on the right side in 60% of cases, are present on the left side in 30%, and are bilateral in 10%. Of affected children, males outnumber females 4:1. Femoral and direct hernias are more common in girls. Certain conditions are associated with an increased incidence of hernias (Box 108.1). The most significant predisposing factor is preterm birth, with hernias reported in 30% of newborns weighing less than 1,000 g (<2.2 lb) at birth.

For the other common acute scrotal lesions, 1 out of 160 males experience either testicular torsion or torsion of the appendix testis. Testicular torsion may occur in utero, but the peak

Box 108.1. Conditions Associated With Increased Risk for Hernia in the Neonate

- Abdominal wall defect
- Ascites
- Connective tissue disease
- Cystic fibrosis
- Family history
- Low birth weight
- Mucopolysaccharidosis
- Preterm birth
- Undescended testis
- Urologic malformations

incidence of testicular torsion occurs in the perinatal period and again at puberty. Torsion of the appendix testis is most likely to occur between ages 7 and 10 years. Varicoceles occur in pubertal and postpubertal males, with a fairly high rate of up to 15%. Testicular tumors are rare in childhood, occurring in 0.5 to 2.0 per 100,000 children and accounting for only 1% of all pediatric solid tumors. In adolescence, however, testicular cancer is the most common cause of cancer in young males and may affect as many as 1 in 10,000.

Clinical Presentation

The child with an inguinal mass presents acutely or nonacutely. In the acute presentation, the swelling occurs rapidly and is associated with pain. The associated systemic symptoms of nausea and vomiting may occur. Inguinal pathology should be suspected in any child with abdominal pain. The involved area may be extremely tender. Nonacute masses appear more slowly. Some may be present from birth. They may come and go, especially with crying or straining. Nonacute masses usually are not tender and are not associated with systemic symptoms (Box 108.2).

Box 108.2. Diagnosis of Inguinal Masses

Acute

- Rapid onset
- Painful
- Tender
- Nausea and vomiting
- Fever
- Overlying skin red
- Cremasteric reflex absent

Nonacute

- Slower onset
- Not painful
- May fluctuate in size
- Cremasteric reflex present

Pathophysiology

Pathophysiological developmental features of an inguinal mass vary depending on the cause of the mass. An enlarged lymph node may result from proliferation of intrinsic lymphocytes or inflammatory infiltrate from infection (eg, lymphadenitis). The etiology of lymphadenopathy is extensive (see Chapter 100). Any of these processes can occur in the inguinal nodes. An enlarged node also can be secondary to metastatic infiltration from another cell line and can represent tumor spread.

A hydrocele develops secondary to failure of obliteration of the patent processus vaginalis during embryologic development. During the 27th to 28th weeks of gestation, the testicle, gubernaculum, and processus vaginalis descend from the peritoneum through the inguinal canal into the scrotum. The processus vaginalis begins closing before birth and attaches to the testis, forming the tunica vaginalis testis. The closure is complete by 1 to 2 years of age. Failure of closure results in a hydrocele if the processus vaginalis fills with fluid and results in a hernia if intra-abdominal contents intermittently descend through the processus vaginalis. Either of these may bulge into the inguinal canal and scrotum. The *incarcerated hernia* is one that cannot be reduced and that places abdominal contents at risk for vascular compromise. This condition is a surgical emergency.

Sometimes a parent or guardian may misinterpret a normal testicle in the process of descent as an abnormal mass. A delay in the normal descent process of the testis occurs occasionally, and the testicle may not be in the scrotum at the time of birth. Torsion of the testis after it has reached the scrotum can occur in the newborn if the testis twists on the spermatic cord. Similarly, the testicle also can twist in the pubertal period on its own vasculature within the tunica vaginalis. This frequently occurs secondary to a high attachment of the tunica vaginalis to the spermatic cord, allowing the testis to hang freely, like a bell clapper. Both types of torsion cause vasculature compromise and an ischemic testis, and both types are surgical emergencies.

Likewise, a vestigial remnant called the "appendix testis" can twist, resulting in vascular compromise of that localized part of the testis.

Pathologically, a traumatic scrotal mass is usually a hematoma, although testicular rupture may occur if the tunica albuginea of testis is torn as a result of trauma. Testicular neoplasms in prepubertal children tend to be germ cell tumors. Yolk sac tumors, teratomas, and mixed germ cell tumors with infiltration of their respective cell lines are the usual diseases found.

A varicocele, another scrotal mass, is caused by increased pressure within the venous drainage of the testicle with subsequent dilatation of the veins, producing a mass. Because of the anatomy of the venous drainage, 90% of varicoceles occur on the left side.

Infections of the epididymis or testis can cause an inflammatory infiltrate and swelling. In female individuals, infection of the Bartholin gland in the labia creates an abscess and results in an acute, painful mass.

Differential Diagnosis

Location, acuity, and patient age aid in establishing the differential diagnosis. Nonacute masses, which have a slow onset and are not painful, include lymphadenopathy, a retractile testis, hydrocele, hernia, varicocele, tumor, and ectopic ovary. Acute masses that have a sudden onset and are associated with pain include epididymitis, orchitis, testicular torsion, traumatic hematoma, torsion of the appendix testis, lymphadenitis, and incarcerated hernia (Box 108.3).

Skin changes can mimic an acute scrotal mass. Henoch-Schönlein purpura, a vasculitis of unclear etiology, can manifest in the scrotal area. Scrotal edema can also occur acutely.

Testicular torsion occurs most commonly in the newborn period and again at puberty. Incarcerated hernias occur most often in the first 6 months after birth. Varicoceles are almost always noted in adolescence and are located in the upper left area of the scrotum. Testicular tumors occur most commonly in adolescence.

The sex of the patient influences the differential diagnosis of the lesion as well as the workup.

Evaluation

History

A thorough, focused history helps define the differential diagnosis (Box 108.4). Inquiring about systemic symptoms should always be included and, if present, may be suggestive of a more generalized process, such as a tumor or systemic infection. Symptoms of dysuria are suggestive of epididymitis or orchitis. A history of trauma or possible sexual abuse should always be sought. The patient with hernia or testicular torsion may have a positive family history for the same condition.

Box 108.3. Differential Diagnosis of Inguinal Masses

Nonacute

- Ectopic ovary
- Hernia
- Hydrocele
- Lymphadenopathy
- Retractile testis
- Synovial cyst
- Testicular tumor
- Varicocele
- Venous aneurysm

Acute

- Bartholin abscess
- Epididymitis
- Henoch-Schönlein purpura
- Idiopathic scrotal swelling
- Incarcerated hernia
- Lymphadenitis
- Orchitis
- Testicular torsion
- Torsion of appendix testis
- Trauma

Box 108.4. What to Ask

Inguinal Masses

- How long has the mass been present?
- Is it painful?
- Does it come and go?
- Was there a history of trauma?
- Does the child have dysuria?
- Does the child have fever or vomiting?
- Does the child have any other masses?
- Has the child had any lower extremity infections?
- Does a history exist of renal disease?
- Does a history exist of preterm delivery?
- Does a positive family history exist for the condition?

Physical Examination

A complete physical examination should be performed. Evidence of diffuse adenopathy may be present. With an inguinal mass, a concentrated, thorough examination of the inguinal area and lower extremity is necessary. A lower extremity lesion may be indicative of a reactive adenopathy. If the mass is not apparent on inspection and it comes and goes, the physician should ask the parent or guardian to point to the location of the mass. The skin is observed for evidence of erythema, swelling, or bruising. The inguinal canal is gently palpated for a mass, after which the scrotal or labial area is assessed. If the mass is of acute onset, the physician should observe the scrotum (in the male patient) and attempt to localize the tenderness. Incarcerated hernia, testicular torsion, torsion of the appendix testis, epididymitis, and orchitis are extremely tender. Torsion of the appendix testis may present with the classic blue dot at the upper pole of the testis. The physician should attempt to elicit a cremasteric reflex. The presence of this finding is strongly diagnostic for a condition other than testicular torsion. The testis with a horizontal lie may be indicative of a bell clapper deformity. The pain of epididymitis and orchitis is partially relieved when the testis is elevated (ie, Prehn sign). Transillumination of the mass may be helpful. A fluid-filled mass, such as a hydrocele, will definitely transilluminate; incarcerated bowel may transilluminate as well.

Accurate measurement of the mass is necessary. Evaluating the borders of an inguinal mass is important. A hydrocele does not extend into the inguinal canal; therefore, the top border can be felt below the pubis. A hernia will extend into the inguinal canal, so an upper border will not be apparent. Use of gentle pressure to reduce the hernia should be attempted. A hernia that is not readily apparent may be demonstrable by causing the infant to cry and thereby increasing intra-abdominal pressure. The older child should be asked to stand and cough while the inguinal canal is palpated. A varicocele, which feels like a bag of worms, is a nontender mass over the

spermatic cord and is readily palpated if the adolescent patient is in a standing position.

Laboratory Tests

Laboratory tests should be directed toward the most likely diagnosis as determined by the history and physical examination. If an infection is suspected, a complete blood cell count should be obtained. If the infection is thought to be epididymitis or orchitis, a urinalysis and urine culture, along with tests for gonorrhea and chlamydia, should also be obtained. If lymphadenopathy is suspected, a complete blood cell count, mononucleosis test, cat-scratch disease test, and possibly a biopsy may be necessary. An inguinal mass in a female may be a normal testes, and chromosomal evaluation may be indicated to diagnose a disorder of sexual differentiation (see Chapter 107). If a tumor is suspected, the α-fetoprotein level, which is elevated in 90% of patients with yolk sac tumors, and β-human chorionic gonadotropin should be assayed.

Imaging Studies

Ultrasonography can be helpful in defining inguinal masses and is the best test to define scrotal contents. It can be useful in differentiating between enlarged lymph nodes, in which a characteristic central echolucent area can be seen, and hydrocele or hernia. Ultrasonography provides accurate information for evaluating tumors. It is the imaging test of choice and can aid in identifying a mass as ovarian or testicular because the ovary is smaller and more echogenic and may have follicular cysts. Color Doppler ultrasonography is the most accurate test for evaluating the scrotum of the patient with acute symptoms to identify a testicular fracture and to assess blood flow in the patient with testicular torsion; however, because of the time required for the test, its use may not be practical in the acute setting. Nuclear imaging may be possible, but the time required for the study may be prohibitive. In the patient with suspected incarcerated hernia, a plain radiograph of the abdomen is helpful to detect signs of intestinal obstruction. Computed tomography and magnetic resonance imaging are only moderately effective in this setting and generally are not recommended.

Management

Many inguinal masses require surgical treatment. Acute symptoms involving the scrotum present a surgical emergency, and it may not be possible to conduct diagnostic studies because of time constraints. If a high probability exists for testicular torsion, immediate surgical exploration of the scrotum is warranted. Surgery within 4 to 8 hours of symptom onset has an excellent rate of a viable testis. The possibility of a viable testis becomes progressively worse if surgery is performed more than 8 hours after symptom onset. After 48 hours, it is unlikely that the testis can be salvaged. If the testis is nonviable, it is removed. It is not necessary to perform surgical exploration for torsion of the appendix testis if the diagnosis is certain.

Surgical intervention may also be indicated in the setting of scrotal trauma, which can cause torsion or testicular rupture. A urologic referral is indicated for assessment.

All hernias require surgical repair at some time. Immediate surgery is indicated for an incarcerated hernia that cannot be reduced. For the hernia that can be reduced, however, elective surgical repair can be scheduled. Controversy exists about the indications for surgery on the contralateral side. An infant younger than 1 year has a 20% chance of developing a hernia on the other side, and most surgeons repair both sides at the same time. Other accepted indications for exploration of the unaffected side include preterm status, twin gestation, left-sided hernia, increased abdominal pressure, and female sex. Currently, some surgeons use laparoscopy at the time of the hernia repair to define a patent processus vaginalis on the opposite side and repair it if patency is found. It is not necessary to repair a hydrocele surgically unless it persists beyond 1 year of age. Because this persistence implies a peritoneal connection and an impending hernia, repair is indicated. Testicular fracture also necessitates surgical repair. Varicoceles are removed if pain is significant, the testicle shows growth retardation, bilateral disease is evident, or the teenager has a solitary testis. Currently, it is possible to perform subinguinal microsurgical varicocelectomy to preserve lymphatic drainage. All testicular tumors are removed. Use of additional antitumor therapy is dependent on the stage and cell line of the tumor.

Infectious inguinal masses are treated according to the specific bacteriologic diagnosis using antibiotics, and incision and drainage as indicated.

Prognosis

After surgical treatment of an inguinal hernia or testicular torsion, the child generally does well. The most significant long-term complication of hernia surgery is subsequent impaired testicular function; additionally, decreased testicular size is noted in up to 27% of cases. Damage to the vas deferens and testicular vessels may impair spermatogenesis and result in an increased incidence of impaired fertility. Surgery for testicular torsion may also be associated with subsequent infertility, particularly if an affected testis is left in place. Two-thirds of affected testicles demonstrate atrophy. For the patient who experiences loss of a testis, the physician should offer a prosthesis in the future because of the potential for significant psychological implications.

The risk of recurrence of a hernia after repair is low. Increased abdominal pressure and history of incarcerated hernia predispose to recurrence, with a rate of up to 12% in children with ventriculoperitoneal shunts. A hydrocele may manifest after varicocele repair.

CASE RESOLUTION

The infant's history of prematurity associated with a mass that comes and goes most likely indicates an inguinal hernia. Based on the additional symptoms of pain, fever, and vomiting and the findings of an inflamed, nonreducible mass on physical examination, a high likelihood exists for the diagnosis of incarcerated hernia. The infant is taken to the operating room, where this diagnosis is confirmed. The hernia is reduced and repaired, and the intestine is noted to be viable. The contralateral side is explored and found to be normal. The infant makes an uneventful recovery.

CHAPTER 109

Hematuria

Elaine S. Kamil, MD

CASE STUDY

A 6-year-old boy is brought to the office for a school entry examination. He was the full-term product of an uncomplicated pregnancy, labor, and delivery. Although he has had 4 or 5 episodes of otitis media, he has generally been in good health. He has never been hospitalized or experienced any significant trauma. He has no known allergies, has been fully immunized, and is developmentally normal. However, his mother states that he has reported occasional mild abdominal pain.

The physical examination is completely normal. Height and weight are at the 75th percentile, and blood pressure is 100/64 mm Hg. Screening tests for hearing and vision are normal. Hematocrit is 42. The urinalysis comes back with a specific gravity of 1.025, pH 6, 2+ blood, and trace protein. Microscopic examination shows 18 to 20 red blood cells per high-power field; 0 to 1 white blood cells per high-power field; and a rare, fine, granular cast.

Questions

1. What disease entities cause hematuria?
2. How should hematuria be evaluated?
3. How does the approach to hematuria differ in children who report dark or red urine?
4. What is the appropriate follow-up of children with asymptomatic microscopic hematuria?

Hematuria is a common problem in pediatric patients, and primary care physicians should have a clear understanding of its pathophysiology, etiology, evaluation, and therapy. Hematuria can be caused by a serious medical problem, or it may be only an incidental finding with no potential for impairment of patient health. Generally, hematuria is categorized as gross or microscopic. The etiology of and approach to hematuria vary based on the severity and symptomatology. *Gross hematuria* is defined as red or brown urine caused by the presence of red blood cells (RBCs). Microscopic hematuria is defined as 3 or more consecutive urine samples with a positive dipstick and 6 or more RBCs per high-power field in a fresh, spun urine sample.

Epidemiology

The prevalence of gross hematuria is approximately 1.3 in 1,000 patient visits (Table 109.1). In 1 series, the causes in approximately one-half of the patients were readily apparent from the intake history or physical examination. The incidence of gross hematuria may increase in the community during an epidemic of a disease, such as acute glomerulonephritis, a condition often associated with gross hematuria. In another series, approximately 30% of children with gross hematuria had glomerular diseases, most commonly immunoglobulin (Ig) A nephropathy. The incidence of kidney stones, another cause of hematuria, is increasing in the pediatric population.

Microscopic hematuria is a more common problem among pediatric patients. Prevalence rates for persistent microscopic hematuria range from 0.5% to 2.0%, but 4% to 5% of school-age children may have microscopic hematuria on a single voided specimen. The incidence is artificially increased in the summer because at that time children tend to visit pediatricians for camp and preparticipation

sports physical examinations that typically include a screening urinalysis.

Clinical Presentation

The child with gross hematuria presents with the sudden appearance of red or brown urine, which may be associated with flank or urethral pain or with a history of trauma. It may occur during or within 1 to 2 weeks of a respiratory infection.

The child with microscopic hematuria may have urinary symptoms (eg, dysuria). In the child who appears well, microscopic hematuria is usually detected on screening dipstick examination or on urinalysis obtained for other indications. In 2007 the American Academy of Pediatrics ceased recommending that routine screening urinalysis be done in asymptomatic children and adolescents. Urinalysis often is still requested as part of camp and preparticipation sport evaluations, however. In Japan, because of a high incidence of glomerulonephritis (primarily IgA nephropathy), annual screening urinalysis is performed in schools and seems to have had an effect on early diagnosis and treatment.

Pathophysiology

Gross Hematuria

Gross hematuria occurs because of the presence of large numbers of RBCs in the urine. Blood may enter the urine because of rupture of blood vessels following trauma or inflammation in the glomeruli or interstitial regions of the kidney. It also may occur as a result of severe inflammation of the bladder wall.

Causes of gross hematuria are listed in Box 109.1. The presence of casts in the urine indicates that the red cells are coming from the glomeruli and suggests the diagnosis of glomerulonephritis. The most common causes of glomerulonephritis in children include acute postinfectious glomerulonephritis (most commomly poststreptococcal), anaphylactoid purpura (ie, Henoch-Schönlein purpura), IgA nephropathy, membranoproliferative glomerulonephritis (MPGN), dense deposit disease, and systemic lupus erythematosus (SLE).

Common causes of gross hematuria in the absence of RBC casts include urinary tract infection from bacteria or certain viruses, renal trauma, bleeding diathesis (eg, hemophilia, idiopathic thrombocytopenic purpura), renal tumors, obstruction of the urinary tract, renal stones, hypercalciuria, and hemolytic uremic syndrome (HUS). Hemangioma in the urinary tract is an extremely rare cause of gross hematuria. In endemic areas, gross hematuria may be caused by schistosomiasis. Another rare cause of gross hematuria is nutcracker phenomenon caused by left-sided renal vein congestion from compression of the renal vein by the superior mesenteric artery. The symptoms of nutcracker phenomenon are distinctive: intermittent gross hematuria associated with left-sided flank pain that is relieved by lying down. Another cause is urethrorrhagia, in which children, typically prepubertal boys, pass bloody urine, usually at the end of their voiding and frequently accompanied by spots of blood in the underwear.

Box 109.1. Common Causes of Gross Hematuria in Pediatric Patients

Glomerular Causes
- IgA nephropathy
- Acute postinfectious GN
- Lupus nephritis
- Membranoproliferative GN
- Dense deposit disease
- Anaphylactoid purpura GN
- Alport syndrome
- Thin basement membrane disease
- Rapidly progressive GN
- Vasculitis, ANCA positive
- Anti–glomerular basement membrane disease
- Hemolytic uremic syndrome

Hematologic Causes
- Sickle cell disease or trait or hemoglobin C
- Hemophilia
- Thrombocytopenia
- Thrombosis (renal arterial or venous)

Structural Causes
- Renal trauma
- Tumor
- Obstruction
- Renal stones
- Polycystic kidney disease
- Foreign bodies

Vascular Abnormalities
- Hemangiomas
- Nutcracker phenomenon
- Arteriovenous malformations

Infectious Causes
- Bacterial urinary tract infection
- Viral cystitis
- Schistosomiasis
- Tuberculosis

Interstitial Diseases
- Acute interstitial nephritis
- Tubulointerstitial nephritis with uveitis

Other
- Hypercalciuria
- Munchausen by proxy
- Urethrorrhagia

Abbreviations: ANCA, antineutrophil cytoplasmic autoantibody; GN, glomerulonephritis; IgA, immunoglobulin A.

Microscopic Hematuria

Microscopic hematuria occurs when small numbers of RBCs enter the urine via tiny ruptures in the glomerular capillary walls or in the capillaries of the tubulointerstitium or bladder lining. One study

showed that otherwise healthy children with microscopic hematuria had increased erythrocyte deformability, making it easier for RBCs to slip through the glomerular capillaries. For purposes of discussion, the following causes of microscopic hematuria are considered: infectious, structural, traumatic, glomerular, and interstitial. Separate consideration of the causes of microscopic and gross hematuria often is helpful, although significant overlap exists. The presence of gross hematuria typically warrants a more rapid, and usually more extensive, evaluation.

Urinary tract infection is among the most common infectious causes of hematuria. Bacterial infections of the bladder or kidney occur much more frequently than viral cystitis. Adenovirus is the most common viral cause of hemorrhagic cystitis and usually is associated with dysuria. Other viral causes include cytomegalovirus, parvovirus 19, and BK polyomavirus nephropathy. Vaginitis in girls and prostatitis in teenage boys also may result in hematuria.

Any type of congenital obstructive uropathy may result in massive dilatation of the urinary tract, which increases the susceptibility for bleeding of the urinary tract, even with trivial trauma. Chronic urinary tract obstruction in children (eg, posterior urethral valves, congenital ureteropelvic junction obstruction) is often asymptomatic. Historically, these conditions typically were diagnosed when children presented with urinary tract infections or gross hematuria after relatively trivial trauma. Currently, congenital urinary tract obstruction typically is diagnosed after a prenatal ultrasonography reveals hydronephrosis in the fetus. Nevertheless, urinary tract obstruction may be detected during an evaluation for asymptomatic microscopic hematuria.

Any tumor of the genitourinary tract may be associated with gross and microscopic hematuria. Pelvic tumors rarely cause urinary obstruction in children, although such tumors frequently cause obstruction in adults. The child with Wilms tumor, the most common childhood renal tumor, usually presents with an abdominal mass but may experience hematuria.

Congenital renal malformations are quite common. Any of these may be associated with hematuria and include polycystic kidney disease, renal dysplasia, medullary sponge kidney, and simple cysts. Patients with polycystic kidney disease may have severe, painful hematuria.

Vascular problems may result in hematuria. Hemangiomas of the kidney, bladder, or ureter are quite rare but may bleed. Arteriovenous malformations also occur infrequently. Hematuria may be a sign of a renal artery or renal vein thrombosis, particularly in sick neonates.

Young children are more susceptible to renal injury, which may result in hematuria, than older children or adults because their kidneys are relatively less protected by the rib cage. Additionally, children may insert foreign objects into the vagina, urethra, and bladder that cause pain and hematuria. Microscopic hematuria has also been described after extremely vigorous exercise, such as marathon running. Child abuse or Munchausen syndrome by proxy should be considered if any suspicions are raised on the basis of the history or physical examination.

Hypercalciuria is another cause of microscopic hematuria. The child with hypercalciuria often has a family history of urinary calculi. Calcium oxalate crystals may be present on microscopic examination of the urine. A urinary calcium-creatinine ratio is best obtained on a first morning, fasting urine sample with reminders to the family that the child should empty the bladder before going to bed. Urinary calcium excretion varies with age. Normal values are listed in Table 109.2.

The 2 types of hypercalciuria are absorptive and renal leak. The child with absorptive hypercalciuria overabsorbs calcium from the gastrointestinal tract, likely because of an exquisite sensitivity to vitamin D, and can be treated with a reduced calcium diet to the recommended daily allowance for age. The child with renal leak hypercalciuria has an inherently higher rate of urinary calcium excretion and may require thiazide diuretics to reduce urinary calcium excretion. Interstitial nephritis, usually resulting from drug exposure, may also cause hematuria. Generally, the patient with interstitial nephritis may exhibit other signs of tubular disease, such as glycosuria, polyuria, or proteinuria.

Glomerular disease may cause gross or microscopic hematuria. Etiologies include acute or chronic glomerulonephritis, such as acute postinfectious glomerulonephritis, MPGN, dense deposit disease, antineutrophil cytoplasmic antibody–associated vasculitis, IgA nephropathy, SLE, thin basement membrane disease or nephropathy, and Alport syndrome. The RBCs originating from glomeruli are dysmorphic, and careful examination of the urine from these patients often reveals RBC casts.

Sickle cell disease, sickle cell trait, and hemoglobin C trait have been associated with gross or microscopic hematuria.

Differential Diagnosis

When a child reports red urine (ie, gross hematuria), the physician must first determine whether it is the result of hematuria or pigmenturia by using a urine dipstick. If the dipstick result is negative for blood, the dark urine is caused by dyes, drugs, or pigments (Table 109.3). If the dipstick is positive for blood, the red color is caused by intact RBCs, hemolyzed RBCs, hemoglobin, or myoglobin;

Table 109.2. Normal Values for Urinary Calcium-Creatinine Ratios[a]

Age	*Urine Calcium-Creatinine Ratio*	*24-Hour Urine Calcium*
Preterm neonate	≤0.82	≤8.9 mg/kg/day[b]
<7 months	≤0.86	
7–18 months	≤0.60	
19 months–6 years	≤0.42	
6 years–adult	≤0.22	<4 mg/kg/day

[a] Samples for calcium-creatinine ratio should be obtained on a fasting, first-voided morning specimen. The calcium and creatinine concentrations must be in the same units (eg, mg/dL) before the ratio is calculated.

[b] For healthy preterm newborns taking no medications. Calcium excretion varies with diet and phosphorus intake, and it is higher if patients are treated with furosemide, xanthines, or glucocorticoids.

Table 109.3. Distinguishing Hematuria From Pigmenturia

Problem	*Urine Color*	*Dipstick*	*Microscopic Appearance*
Hematuria	Red, brown, or red-brown	Positive	Red blood cells
Hemoglobinuria	Red, brown, or red-brown	Positive	Negative
Myoglobinuria	Red, brown, or red-brown	Positive	Negative
Porphyrins	Red	Negative	Negative
Exogenous pigments[a]	Red or orange	Negative	Negative

[a] Some common exogenous pigments include phenytoin, beets, rifampin, nitrofurantoin, sulfas, amitriptyline, methyldopa, phenothiazine, and chloroquine.

the clarification is based on microscopic examination of fresh, spun urine.

The child whose dipstick result is positive for blood but shows no RBCs may have hemoglobinuria or myoglobinuria, or the urine may have been improperly handled en route to the laboratory. Hemoglobinuria may be seen with acute autoimmune hemolytic anemia, drug-induced hemolysis, paroxysmal nocturnal hemoglobinuria, a mismatched blood transfusion, cardiopulmonary bypass, freshwater drowning, and, in some cases, HUS. Myoglobinuria is noted in individuals with rhabdomyolysis. Acute rhabdomyolysis can occur after a crush injury or a very prolonged seizure and in certain susceptible individuals with an inborn error of muscle metabolism. Myoglobinuria also may be occur with the myositis associated with influenza infections. Free hemoglobin and myoglobin are toxic to the renal epithelial cells, mandating generous fluid intake and close monitoring. Serum appears clear in myoglobinuria and pink in hemoglobinuria.

Evaluation

Gross Hematuria

History

The history is crucial to an accurate, efficient, and cost-effective evaluation of patients with hematuria (Box 109.2). The family should be questioned carefully about trauma to the trunk, abdomen, or perineum; recent skin infection or pharyngitis; dysuria; and abdominal or flank pain. The presence of gross hematuria at the onset or the end of urination is associated with bleeding from the urethra or bladder trigone. Parents or guardians should be asked whether the child appears "puffy." A family history of hematuria, kidney disease, hearing loss, SLE, bleeding diathesis, hemolytic anemia, or inborn error of muscle metabolism may be important in the diagnosis.

Box 109.2. What to Ask

Hematuria

- Has the child experienced any recent trauma?
- Has the child had fever or dysuria?
- Does the child have any flank or abdominal pain?
- Does the child have any rashes, joint pains, or edema?
- Does the child have a family history of hematuria, kidney disease, kidney stones, or gross hematuria?
- Is there a family history of bleeding disorders or inborn errors of muscle metabolism?

Physical Examination

A complete physical examination is also essential. Blood pressure should be measured accurately. The skin should be examined thoroughly for rashes or petechiae; the abdomen should be checked carefully for renal masses or tenderness; the genitalia should be examined thoroughly for signs of trauma, masses, or rashes (see Chapter 145); and the joints should be checked carefully for signs of arthritis. Fundi should be examined for any hypertensive changes. Children should be assessed for the presence of edema. Short stature could be a sign of previously undiagnosed chronic renal insufficiency.

A careful cardiac and chest examination is necessary to detect signs of congestive heart failure, a finding sometimes seen in patients with acute glomerulonephritis.

Laboratory Tests

Before obtaining a urine sample, cleaning the genitalia with plain water has been shown to decrease the incidence of false-positive results on urine dipsticks.

Transient microscopic hematuria can be seen in children solely based on the presence of fever and is a benign finding. In children with a pathological basis for their hematuria, careful microscopic examination of a urine sample can help determine whether bleeding originates from the upper or lower urinary tract. Red blood cells originating in the glomerulus have a dysmorphic appearance. The first morning urine sample is the most reliable but is not appropriate in some settings, such as after a motor vehicle crash. Sometimes gross hematuria is so substantial that spinning the urine results in a large pellet of debris that is difficult to examine. In such instances, it is prudent to examine an unspun sample. The presence of RBC casts is indicative of glomerulonephritis; however, the absence of such casts does not rule out this condition.

If the urine shows RBC casts or in the presence of other features that are suspicious for glomerulonephritis, the evaluation should include an antistreptolysin O (ASO) titer, antinuclear antibody (ANA), C3, complete blood cell count and differential with platelet count, blood urea nitrogen and creatinine, serum albumin, and a random urine for a urinary total protein-creatinine ratio. It is important to remember that not all patients with glomerulonephritis exhibit RBC casts.

If the urine shows only large numbers of RBCs, no RBC casts, and no bacteriuria, a complete blood cell count with differential and platelet count, urine culture, and both prothrombin time and partial thromboplastin time should be obtained. A sickle cell test should be considered as well. Hypercalciuria can be evaluated by collecting a first morning sample for calcium-creatinine ratio; a more extensive evaluation to assess risk factors for kidney stones

should include a 24-hour urine analysis that includes assessing urinary calcium, citrate, uric acid, and oxalate.

Imaging Studies

If the urine has large numbers of RBCs, renal ultrasonography should be performed. With gross hematuria and a history of serious trauma, abdominal computed tomography should be performed. Computed tomography without contrast is also an excellent modality to detect kidney stones. A chest radiograph should be obtained of the child with RBC casts to evaluate for evidence of fluid overload. Special renal Doppler ultrasonography studies are indicated if nutcracker phenomenon is being considered in the differential diagnosis.

Microscopic Hematuria

The evaluation of microscopic hematuria is similar to that of gross hematuria. Figure 109.1 outlines an approach to the evaluation of microscopic hematuria.

History and Physical Examination

Because many conditions may cause gross or microscopic hematuria, the same questions for eliciting the history apply to both conditions, and the same careful physical examination is indicated.

Laboratory Tests

Generally, initial evaluation includes a urine culture and a careful microscopic examination of the urine on a fresh sample. If the culture is negative, the hematuria is minimal with no associated proteinuria, and the child is otherwise healthy, the urinalysis should be repeated once or twice over the following 2 weeks. Red blood cell casts always signify a glomerular origin for the RBCs. Casts are best preserved in acidic, concentrated urine. Thus, the first morning urine is the best sample to examine for casts. Red blood cell morphology should be assessed. Red blood cells originating in the glomerulus are dysmorphic and of smaller caliber, whereas those that come from lower downstream have the appearance of normal biconcave disks. Although RBC morphology is best appreciated with the use of a polarizing microscope, with experience, dysmorphic RBCs can be recognized using an ordinary microscope. Red blood cells of glomerular origin have a mean cell volume of 50 μL or less. In contrast, RBCs of nonglomerular origin have a mean cell volume of 80 to 90 μL. The presence of a special form of dysmorphic erythrocyte, the G1 cell, is even more specific for glomerular bleeding. These cells are doughnut shaped and contain 1 or more blebs on their surfaces. However, most urinary microscopic examinations currently are performed by machine, and urine microscopy is becoming a lost art. Many medical schools and residency programs no longer teach students how to perform urine microscopy.

Clotting ability should be determined with a platelet count, prothrombin time, and partial thromboplastin time. A sickle cell test should be performed. Renal function should be screened with a blood urea nitrogen and creatinine, and a urine calcium-creatinine ratio should be determined. A C3, ANA, and ASO titer should also be checked. If a urine dipstick shows more than a trace of protein, a urinary protein-creatinine ratio should also be determined, preferably on a first morning sample. If the family history is positive for renal disease, a hearing screening should be ordered. All immediate family members should have their urine checked for blood.

Analysis of a bloody urine sample with a Coulter counter demonstrates characteristic distribution curves for glomerular and nonglomerular hematuria. This test is not readily available, however.

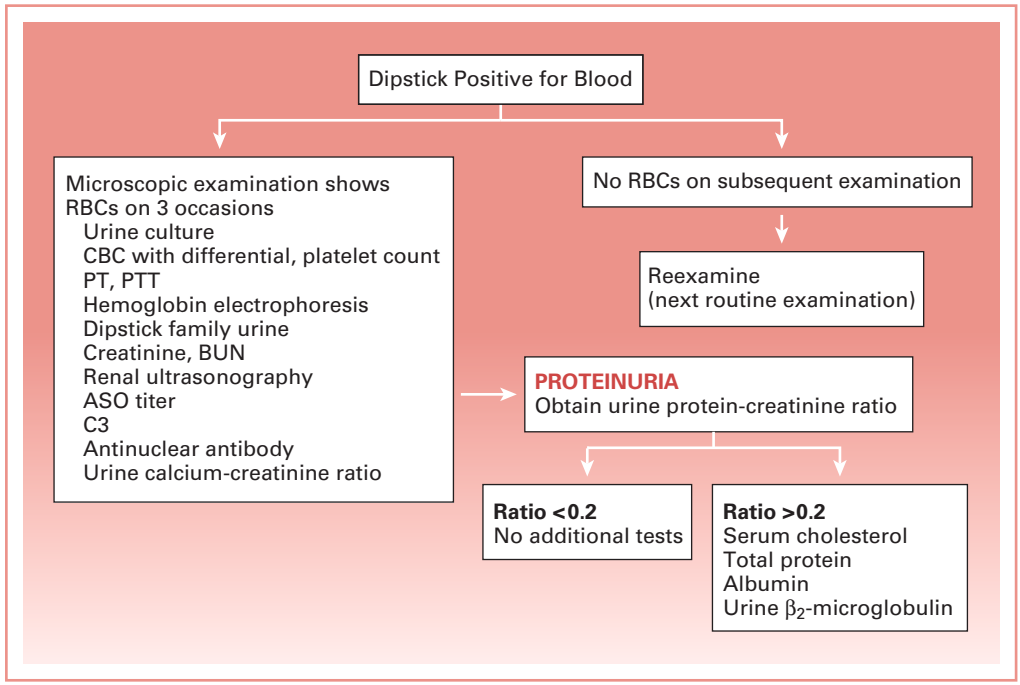

Figure 109.1. Evaluation of asymptomatic, microscopic hematuria.
Abbreviations: ASO, antistreptolysin O; BUN, blood urea nitrogen; CBC, complete blood cell count; PT, prothrombin time; PTT, partial thromboplastin time; RBCs, red blood cells.

Imaging Studies

Renal ultrasonography should be performed to rule out structural abnormalities and tumors. Chest radiographs should be obtained if acute glomerulonephritis is suspected.

Renal Biopsy

The definitive diagnosis of the etiology of hematuria may require a kidney biopsy. Generally, pediatric nephrologists perform kidney biopsies only in select instances after ruling out nonglomerular causes for the hematuria. Indications for renal biopsy in a child with hematuria include an associated abnormal urinary protein excretion, decreased renal function, recurrent macroscopic hematuria, persistently depressed serum complement levels, serologic evidence for SLE, positive antineutrophil cytoplasmic autoantibody (ANCA) testing, hypertension, or a family history suggestive of Alport syndrome or renal insufficiency of unknown etiology.

Glomerular Diseases Associated With Hematuria

Glomerulonephritis

Acute and chronic glomerulonephritis are associated with hematuria. The diagnosis of acute postinfectious glomerulonephritis requires a nephritic urine sediment (ie, RBCs, RBC casts), a low serum complement, and an elevated streptococcal titer (ie, ASO titer, anti-deoxyribonuclease B, positive streptozyme). It is important to document that the serum complement returns to normal within 3 months, because MPGN or dense deposit disease may present in a similar way. The serum complement is chronically depressed in MPGN and dense deposit disease.

The most common form of glomerulonephritis in children is acute poststreptococcal glomerulonephritis. Many patients are asymptomatic, however, and do not come to the attention of physicians. The resulting hematuria may be gross or microscopic. Glomerulonephritis is rarely seen before age 2 years and is most commonly diagnosed in preschool-age and school-age children who typically present with gross hematuria, often with some edema and hypertension. The hypertension may be severe, and occasionally children even have hypertensive seizures. The edema results from transient, acute kidney injury with salt and fluid retention.

Most children with acute poststreptococcal glomerulonephritis experience complete recovery and have an excellent long-term prognosis. Proteinuria is rarely severe enough to cause nephrotic syndrome, and renal failure is rarely serious enough to require dialysis. If hypertension occurs, chest radiography often shows some degree of pulmonary edema, even in the absence of overt clinical signs of congestive heart failure. Any hypertension requires treatment. Other infections cause postinfectious glomerulonephritis, but they are less common and overall less well characterized.

The most common form of chronic glomerulonephritis affecting children is IgA nephropathy. On kidney biopsy, patients have mesangial proliferation with mesangial deposits of IgA as the dominant Ig. In later stages, glomerulosclerosis and interstitial fibrosis are apparent. More than one-third of adults with IgA nephropathy develop end-stage renal disease; the percentage of children who progress to this point is less well known. Gross hematuria in IgA nephropathy is occasionally so severe that patients may pass clots and have flank pain. The presence of persistent proteinuria is considered a poor prognostic sign.

Other forms of primary chronic glomerulonephritis include MPGN, dense deposit disease, mesangial proliferative glomerulonephritis, and membranous nephropathy, which is technically not a form of glomerulonephritis because it usually lacks a significant proliferative component. Children with the previously listed conditions present with hematuria almost always associated with heavy proteinuria.

Secondary forms of glomerulonephritis include lupus nephritis, anaphylactoid purpura, and nephritis associated with various vasculitides, such as Wegener granulomatosis and pauci-immune crescentic glomerulonephritis (eg, ANCA-positive glomerulonephritis). An ANCA panel is indicated in the child with glomerulonephritis and decreased renal function. Children with lupus tend to present with multisystem disease but may have only renal manifestations of the disease. Antinuclear antibody is a good screening test for lupus. If the ANA is positive, C3, C4, and anti-double-stranded DNA should be checked and an antiglobulin (ie, Coombs) test performed.

Anaphylactoid Purpura

Anaphylactoid purpura, also called Henoch-Schönlein purpura, is almost always accompanied by the classic cutaneous vasculitis rash, which is prominent over the lower arms and lower extremities. Abdominal pain may be severe, and affected patients are at risk for developing intussusception. The child with anaphylactoid purpura has microscopic hematuria, which usually clears over time but is occasionally associated with heavy proteinuria and nephrotic syndrome. The child with associated proteinuria is at risk for developing progressive renal disease. All children with anaphylactoid purpura should have their urine monitored for cessation of hematuria or development of proteinuria. The child with heavy proteinuria and suspected anaphylactoid purpura should undergo a diagnostic renal biopsy.

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome is a disease characterized by thrombotic thrombocytopenic purpura, thrombocytopenia, and acute renal failure. Typically, it follows a prodrome of bloody diarrhea resulting from acute colitis caused by a verotoxin-producing strain of *Escherichia coli* (O157:H7), among others, or other enteropathogenic bacteria. The verotoxin is toxic to human endothelial cells. The damaged endothelial cells incite the deposition of fibrin within the glomerular capillaries. These fibrin thrombi result in the shearing of RBCs and consumption of platelets. Several other organisms, such as pneumococcus and *Shigella,* may precipitate HUS. In atypical cases of HUS, the precipitating event may be an upper respiratory infection. Some cases of atypical HUS are familial. The child presents with pallor and severe abdominal pain. Urine output may be diminished as a result of the acute kidney injury, and in many cases dialysis is required. Hypertension may be severe.

Other Glomerular Diseases

Alport syndrome, thin basement membrane disease (ie, benign familial hematuria), focal segmental glomerulosclerosis, and occasionally minimal change disease are also associated with hematuria. Alport syndrome is a disease in which thinning and duplication of the glomerular basement membranes occur. The renal involvement eventually results in end-stage renal disease in males; this outcome is less common in females. Patients or their family members often have nerve deafness or keratoconus. The inheritance of Alport syndrome varies by kindred; it may be autosomal-dominant, autosomal-recessive, or X-linked. The X-linked inheritance is by far the most common mode of inheritance, with female carriers typically being much less severely affected than affected males. Thin basement membrane disease also is characterized by thinning of the glomerular basement membrane; however, the glomeruli are otherwise normal and the clinical course is usually benign. Patients with minimal change disease and focal segmental glomerulosclerosis typically present with nephrotic syndrome but may also have microscopic hematuria.

Management

Gross Hematuria

The management of gross hematuria depends on the underlying cause. The child with a history of trauma should be placed on bed rest pending surgical consultation (see Chapter 76). If the evaluation indicates acute glomerulonephritis and if the child is not hypertensive, careful following as an outpatient is sufficient, with monitoring of blood pressure and renal function with consultation with a pediatric nephrologist. The child with coagulopathy requires treatment specific to the bleeding disorders (eg, intravenous gamma globulin for idiopathic thrombocytopenic purpura). If kidney stones are found, after the acute episode has passed the child should undergo evaluation for stone risk factors.

If some degree of renal insufficiency is present, prompt referral to a pediatric nephrologist is warranted to rule out more unusual causes of glomerulonephritis, for consideration of renal biopsy, and for treatment.

Microscopic Hematuria

Laboratory test results other than urinalysis may be negative in the otherwise healthy child with microscopic hematuria. Some of these children may be recovering from subclinical cases of postinfectious glomerulonephritis, which can cause microscopic hematuria for up to 1 year. Others may have early IgA nephropathy and not yet have significant proteinuria, and some may have thin basement membrane disease or Alport syndrome. As long as a child has normal renal function, normal urinary calcium excretion, normal blood pressure, a negative renal sonogram, no significant proteinuria, and all other tests are normal, it is safe to monitor the asymptomatic child every 3 to 6 months until the problem resolves. The healthy child with an otherwise negative workup who shows no change in clinical state for a period of 1 year may subsequently be monitored annually. If hypercalciuria is detected, a low-calcium diet or treatment with thiazide diuretics may be tried. Increased urinary microalbuminuria has been shown to be predictive of glomerular lesions in children with isolated microscopic hematuria.

Prognosis

The prognosis for the child with hematuria depends on the underlying cause. Compared with microscopic hematuria, gross hematuria is more often associated with serious renal disease, such as acute glomerulonephritis, HUS, or renal trauma. Even so, most children with gross hematuria have a good prognosis, provided the diagnosis is rapidly discovered and appropriate specific therapy is initiated. The child with persistent microscopic hematuria who has no family history of the condition, has a negative evaluation, and does not develop hypertension or proteinuria has an excellent long-term prognosis, although a recent study has shown a small but significantly increased incidence of end-stage kidney disease over 22 years in 16- to 25-year-old individuals with persistent asymptomatic isolated microscopic hematuria.

CASE RESOLUTION

The boy shows no worrisome clinical signs, such as hypertension or significant proteinuria. His urine should be rechecked twice more, and if the hematuria persists, his evaluation should follow the algorithm in Figure 109.1.

CHAPTER 110

Proteinuria

Elaine S. Kamil, MD

CASE STUDY

A 14-year-old boy is brought to the office for a sports-related preparticipation physical examination. He has been previously healthy but had 1 hospital admission at age 2 years for management of a fractured humerus. He has no acute concerns. The family history is positive for diabetes mellitus in the paternal grandfather and lung cancer in the maternal grandfather. It is negative for renal disease and hypertension. The boy's height and weight are at the 75th percentile for age, and his blood pressure is 110/70 mm Hg.

On physical examination the boy is a well-developed, well-nourished, athletic teenager. No abnormal findings are present. The complete blood cell count reveals a hemoglobin of 14.8 g/dL, a hematocrit of 48.3%, and a white blood cell count of 8,400 cells/mm^3 with a normal differential. The urine has a pH of 5, a specific gravity of 1.025, and 3+ protein on urine dipstick test. The rest of the dipstick test is negative. Microscopic examination shows 0 to 1 white blood cell count per high-power field and 0 to 2 hyaline casts per low-power field.

Questions

1. What conditions cause proteinuria?
2. When should the child with proteinuria undergo further evaluation?
3. What type of evaluation should be carried out to assess proteinuria?
4. When should the child with proteinuria be referred to a pediatric nephrologist?

A small amount of protein is normally present in the urine. In children, normal urine protein excretion is less than 100 mg/m^2 per 24-hour period or 4 mg/m^2 per hour. Urine protein levels increase somewhat under certain conditions, such as vigorous exercise, febrile illness, accidental trauma, and congestive heart failure (CHF). Urinary protein excretion in children is also affected by age, sex, and body habitus. Normally the filtered proteins are of small- to medium-size molecular weights, whereas albumin and other larger molecules mostly are not filtered because of their size. Albumin accounts for less than 30% of the proteins in the urine. Most of the protein in the glomerular filtrate is reabsorbed by the tubular cells. Pathologic amounts of protein are present in the urine when the glomerular leak of protein is increased, when the tubules fail to reabsorb the protein filtered by the glomerulus, or if inflammation in the renal interstitium results in the addition of tubular proteins to the urine.

Urinary protein is initially detected by the urine dipstick; however, this method may produce false-positive results in alkaline or highly concentrated urine. A dipstick test that is positive for protein of 1+ in concentrated urine may not correlate with an abnormal 24-hour urinary protein excretion, whereas a dipstick test result of 1+ in very dilute urine may be associated with an abnormal 24-hour urinary protein excretion. Proteinuria is more accurately determined by performing a timed urine collection or a random sample for chemical determination of the ratio of urinary total protein concentration divided by the urinary creatinine concentration (ie, urine TP/Cr).

Epidemiology

The prevalence of proteinuria depends on how the condition is defined. In a Texas study, 10 mg/dL of proteinuria was found consistently in the urine of 2% to 3% of children in 3 consecutive urine samples. When 50 mg/dL was used as the cutoff for proteinuria, however, only 0.4% to 0.7% of boys and 0.4% to 2.5% of girls had proteinuria in 2 of 3 consecutive samples. The prevalence of proteinuria increased with age. In Finland, approximately 11% of school-age children had at least 1 episode of proteinuria of 25 mg/dL on urine dipstick testing when the urine was tested 4 times. Approximately 2.5% of the children had proteinuria on 2 of 4 occasions.

Clinical Presentation

Proteinuria is a laboratory finding that may present incidentally on a screening urinalysis or be detected during the evaluation of a complaint, such as edema, that may be caused by kidney disease. When proteinuria is detected as an incidental finding in the otherwise normal child, the laboratory evaluation of the proteinuria should be delayed until its persistence is confirmed on repeat urine dipstick testing, preferably on a first morning urine sample (Box 110.1). The child with edema and proteinuria most likely has renal lesions or, more rarely, CHF. Additional findings on examination could include the presence of hypertension, ascites, pleural effusions, or the rash of systemic lupus erythematosus or anaphylactoid purpura.

Box 110.1. Diagnosis of Proteinuria

- Presence of proteinuria on dipstick urinalysis (≥1+ confirmed on 3 occasions)
- Random urine TP/Cr >0.2 or 24-hour urine protein >4 mg/m^2/hour
- Orthostatic proteinuria (assessed through separate measurement of afternoon and first morning urine for TP/Cr)

Edema in the absence of significant proteinuria can occur in conditions that cause hypoproteinemia (eg, liver or inflammatory bowel disease) or during allergic reactions.

Pathophysiology

The glomerular capillaries are adapted to permit the filtration of minimal amounts of plasma proteins, particularly those with a small molecular radius. Approximately 320 mg of albumin and 360 mg of low-molecular-weight proteins are filtered by the glomerular capillaries each day. Ninety-five percent of this material is reabsorbed by the proximal tubular cells. Normally, a child may excrete up to 100 mg/m^2 per day of protein. Urinary protein excretion is increased in newborns to approximately 240 mg/m^2 per day and in adolescents to approximately 300 mg/m^2 per day. Adults may normally excrete up to 150 mg/m^2 of protein per day. Only 10% to 15% of this is albumin; the rest of the proteins are other plasma proteins and urinary glycoproteins, such as Tamm-Horsfall protein.

In cases in which increased proteinuria results from glomerular disease, higher than normal levels of urinary proteins are primarily caused by the enhanced filtration of albumin. Abnormal urinary protein excretion is a marker of chronic kidney disease, and attempts to improve proteinuria with angiotensin-converting enzyme inhibitors or angiotensin receptor blockade in this setting have been shown to slow the progression of glomerular diseases. Protein excretion may be increased transiently by any condition that raises intra-glomerular capillary pressure, such as CHF, strenuous exercise, epinephrine use, fever, urinary infection, and surgery. The child or adult with very early diabetic nephropathy or early end-organ damage from hypertension exhibits an elevated urinary microalbumin-creatinine ratio. The child with diabetes or hypertension should undergo regular testing for the urinary microalbumin-creatinine ratio to detect early, reversible glomerular damage.

Individuals with *orthostatic proteinuria* excrete pathologic amounts of protein in their urine while they are upright, but their urinary protein excretion returns to normal when they are recumbent. Some children are affected by this poorly understood, benign condition. Orthostatic proteinuria seems to be more common in athletic adolescent individuals. Normal children exhibit a diurnal variation in urinary protein excretion, but that variation is exaggerated in children with orthostatic proteinuria. A recent careful study of 91 healthy Hispanic and non-Hispanic white children age 6 to 19 years and living in a city in the American Southwest showed that 19.8% of those children had orthostatic proteinuria. It was more common in boys older than 10 years and in those with a body mass index above the 85th percentile for age. Orthostatic proteinuria may be caused by increased pressure in the renal vasculature while the patient is upright. Several investigators have shown that patients with orthostatic proteinuria have partial obstruction of the left renal vein by entrapment between the aorta and superior mesenteric artery while standing.

Differential Diagnosis

The proteinuria may be physiological (ie, secondary to fever or CHF), transient, orthostatic, tubular (as seen in allergic interstitial nephritis), or glomerular. Aminoaciduria as a form of tubular proteinuria may occur, as occurs in certain inborn errors of metabolism.

Evaluation

History

It is important to elicit a complete history in the child with proteinuria (Box 110.2). When asking about a history of swelling, the physician should note that subtle periorbital edema may be present only in the early morning hours. If the proteinuria is detected at a routine screening examination, the conditions under which the urine was obtained should be determined. The child may have been ill with a high fever or have just participated in an athletic event, such as a track meet.

Physical Examination

The physical examination should include a determination of blood pressure and measurement of height and weight. A careful assessment for edema should be made. The skin should be examined for signs of rash, such as that seen in Henoch-Schönlein purpura or healing impetigo. The joints should be inspected for any sign of swelling or joint inflammation. The abdominal examination should include a careful search for ascites or organomegaly.

Box 110.2. What to Ask

Proteinuria

- Was the mother's pregnancy remarkable in any way? What was the child's birth like?
- Did the child have any neonatal problems that may indicate possible renal damage? Was the child born preterm? Did the child have intrauterine growth restriction?
- Is any swelling apparent in areas such as the ankles, abdomen, or periorbital region?
- Has the child had any recent illnesses, particularly pharyngitis or impetigo?
- Does the child have a history of joint pains and skin rashes? (The adolescent with such history may be at increased risk of having a collagen vascular disease.)
- Has the child had any previous urinary tract infections, urinary abnormalities, or dark urine?
- Does the child have a history of hypertension or weight loss or gain?
- Is the family history positive for renal disease?
- Does the child have diabetes mellitus?

Laboratory Tests

The extent of the laboratory evaluation depends on the child's general health (eg, the child is ill with another problem), the amount of proteinuria on urine dipstick, and whether the child has edema. The suggested evaluation is outlined in Figure 110.1. In the nonedematous, otherwise healthy child with proteinuria on urine dipstick, it is prudent to examine the urine sediment and, if negative, recheck the urine dipstick in a few days. If proteinuria of 1+ is consistently present on 2 or more occasions and no hematuria is evident, a first-stage evaluation by assessing a urine TP/Cr is indicated. If the child is ill with a fever or is hospitalized with a serious illness, it is often appropriate to delay evaluation of the proteinuria until the acute illness is under control, provided no associated hematuria, hypoproteinemia, hypertension, or azotemia is present.

In the healthy ambulatory patient with persistent, isolated proteinuria on dipstick urinalysis on 3 occasions, it is important to quantitate the proteinuria (Box 110.3). This may be done simply by ordering a urine TP/Cr. If the ratio is abnormal (≥0.2), the child first must be evaluated for orthostatic proteinuria, which can be ruled out in several ways. The simplest evaluation involves checking a urine dipstick test on a first-voided morning sample and again on an afternoon specimen. This procedure should be repeated on 2 different days. It is critical to be sure the child empties the bladder before going to bed, because urine produced during the evening when the child is nonrecumbent may contain protein and thus give an inaccurate result from the sample obtained the following morning. If the dipstick test for protein from the morning urine is negative on a concentrated acid urine and if the afternoon sample is positive for protein on

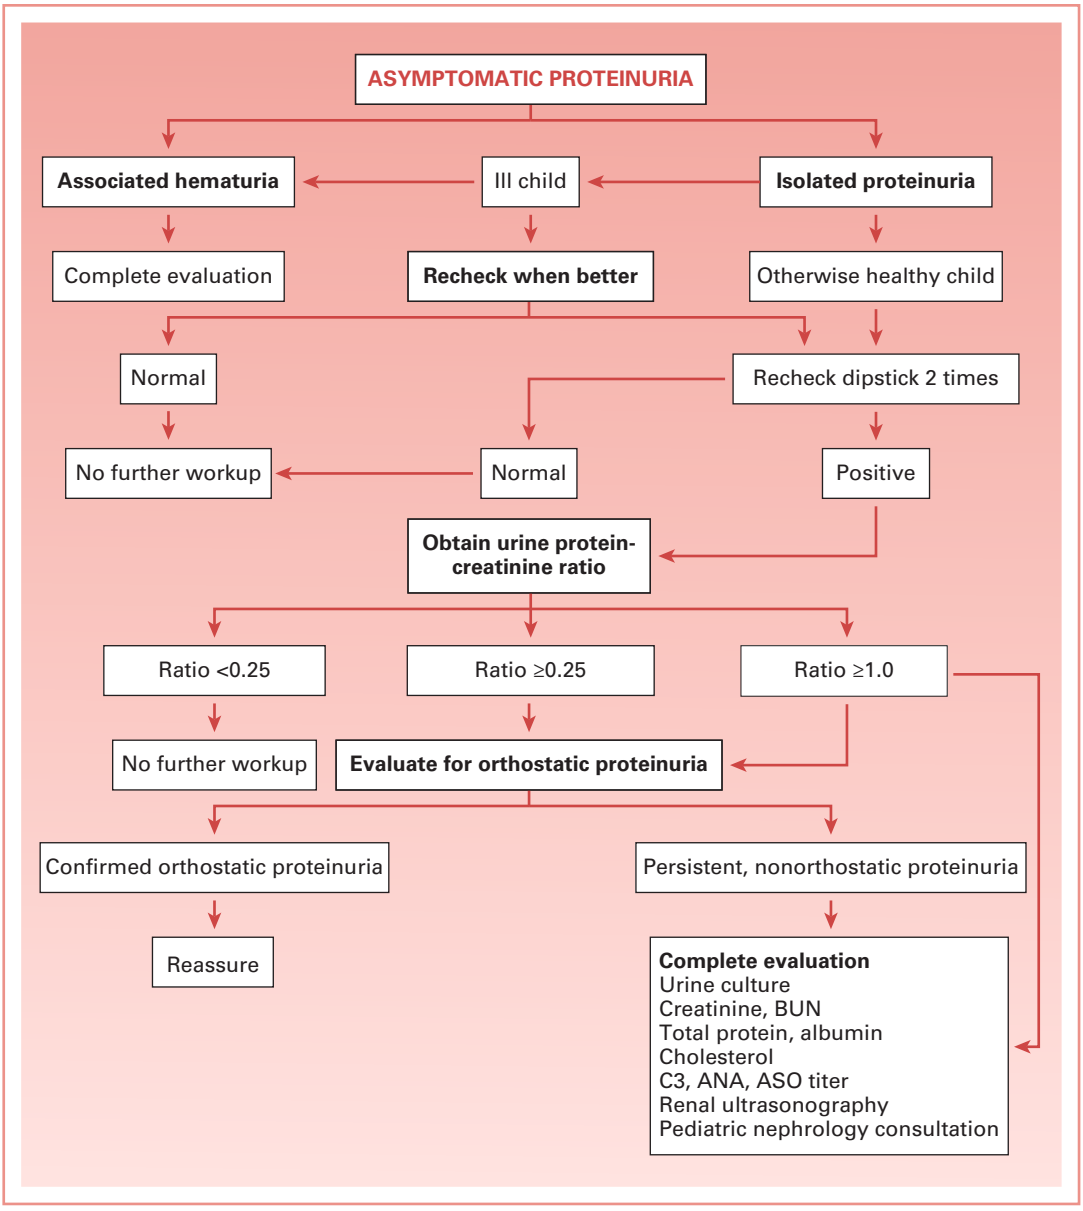

Figure 110.1. Evaluation of children with asymptomatic proteinuria.
Abbreviations: ANA, antinuclear antibody; ASO, antistreptolysin O; BUN, blood urea nitrogen.

Box 110.3. Methods for Assessment of Urinary Protein

Detection of proteinuria by urine dipstick testing is only semiquantitative. This examination is affected by urinary pH and concentration; therefore, more definitive tests are warranted if a patient's urine consistently shows proteinuria on dipstick urinalysis. The sulfosalicylic acid turbidity test is also semiquantitative. When sulfosalicylic acid is added to an aliquot of urine, it precipitates urinary proteins. The amount of turbidity is graded on a scale of 0 to 4+.

Urinary protein is most accurately quantitated by a chemical determination on a timed urine collection (usually 24 hours). The concentration, which is measured in milligrams per deciliter, is multiplied by the total urine volume to determine the milligrams of protein excreted in 24 hours. Twenty-four-hour urine samples are difficult to collect in the young child. However, several studies have shown that a random urine sample for a TP/Cr correlates well with the 24-hour urinary protein excretion. The ratio is determined by dividing the urine protein concentration in milligrams per deciliter by the urine creatinine concentration in milligrams per deciliter. The units must be the same for each component. The urinary TP/Cr is normally less than 0.2. A ratio of 3.5 or greater in an adult or greater than 1.0 in a child is indicative of nephrotic range proteinuria. One study found that proteinuria in combination with leukocyturia (by dipstick testing) likely is indicative of more significant noninfectious renal inflammation.

Occasionally, it is important to determine whether proteinuria has a tubular or glomerular basis. In these instances, a urinary β_2-microglobulin test is helpful. Beta$_2$-microglobulin, a very small protein that is freely filtered at the glomerular level, is nearly completely reabsorbed by the proximal tubules. In instances of tubular injury, such as interstitial nephritis, acute kidney injury, or nephrotoxic renal injury, urinary β_2-microglobulin is increased. With glomerular proteinuria, urine protein electrophoresis shows a heavy preponderance of albumin. The urine microalbumin-creatinine ratio is an excellent indicator of glomerular proteinuria. It is readily available in most laboratories and will detect minimal but pathologic amounts of glomerular proteinuria, such as that seen in early diabetic nephropathy and with early hypertensive glomerular damage.

a concentrated acid urine, the child most likely has orthostatic proteinuria.

A more accurate way of checking for orthostatic proteinuria involves the determination of urine TP/Cr ratios on the first morning and afternoon urine samples. A diagnosis of orthostatic proteinuria can be made if the ratio is normal on the recumbent sample and elevated on the daytime sample. The most accurate (but cumbersome) means of diagnosing orthostatic proteinuria entails collecting 2 timed urine samples, 1 during the hours that the child is up during the day and the other while the child is in bed at night. In most instances of orthostatic proteinuria in children, the total urinary protein excretion is less than 1 g. The urine collected in the recumbent period should contain less than 50 mg/m^2 of protein. If these 2 timed samples meet the criteria for orthostatic proteinuria, it is not necessary to repeat them. It is important to remember, however, that even in renal disease, proteinuria improves somewhat when a patient is recumbent.

If the child does not have orthostatic proteinuria, a 24-hour urine protein excretion may be determined. If the collection of a 24-hour urine sample is impractical, the urine TP/Cr ratio is a reliable alternative. Blood chemistries (eg, blood urea nitrogen, creatinine) should be obtained to determine renal function. Electrolyte status should be assessed with total carbon dioxide as well as serum total protein, albumin, and cholesterol. Serologies should be obtained for antinuclear antibodies, C3, antistreptolysin O titer, and hepatitis B surface antigen if the child comes from a population at risk for hepatitis B.

Twenty-four-hour urine protein excretion should be less than 4 mg/m^2 per hour. The neonate may excrete as much as 150 mg/m^2 per 12 hours, however. Table 110.1 gives a summary of normal urinary protein excretion. If the child has nephrotic range proteinuria or symptoms consistent with nephrotic syndrome (ie, heavy proteinuria accompanied by hypoalbuminemia and hypercholesterolemia), further evaluation is required for nephrotic syndrome (see Chapter 111). If the child does not have nephrotic-range proteinuria, abnormal tubular proteinuria should be ruled out. A normal urinary β_2-microglobulin test rules out tubular proteinuria. Other tubular proteins that may be available using laboratory tests include α_1-microglobulin, retinol-binding protein, and neutrophil gelatinase-associated lipocalin. Generally, consultation with a pediatric nephrologist is recommended if a child has an abnormal 24-hour urinary protein excretion (Table 110.1). If the proteinuria exceeds 1 g per day or if any other minor sign of renal dysfunction or hematuria is present, a biopsy is warranted. A study from Japan showed that in children with constant isolated proteinuria, a urine TP/Cr ratio of >0.5 was predictive of more than minimal glomerular abnormalities on kidney biopsy. Sometimes, the otherwise healthy child with a small amount of isolated proteinuria of less than 750 to 1,000 mg per day is followed by the pediatric nephrologist without a kidney biopsy. However, if this degree of proteinuria persists for 1 year or more, a renal biopsy is warranted.

Imaging Studies

Renal ultrasonography should be obtained to rule out any structural abnormalities but is not indicated in the child with simple orthostatic proteinuria.

Table 110.1. Urinary Protein Excretion by Age

Age	*24-Hour Urine Protein (mg)*	*Urine TP/Cr*
Preterm newborn	14–60	—
Term newborn	15–68	—
2–23 months	17–85	≤0.50
2–4 years	20–121	≤0.2
4–10 years	26–194	≤0.2
10–16 years	29–238	≤0.2

Abbreviation: TP/Cr, ratio of urinary total protein concentration divided by the urinary creatinine concentration.

Management

Most children with normal renal function and normal blood pressure whose evaluation reveals physiological or orthostatic proteinuria should undergo repeat urinalysis on an annual basis. If the proteinuria worsens or if hematuria manifests, a repeat evaluation of renal function is indicated. The child whose initial evaluation reveals persistent, significant proteinuria requires careful follow-up to detect and monitor signs of serious renal disease. This follow-up should include repeat blood pressure measurement and urinalysis every 3 months and repeat chemistries (eg, blood urea nitrogen, creatinine, serum albumin) and urine TP/Cr ratios every 6 months. The child should be treated in consultation with a pediatric nephrologist, whose experience is helpful in reassessing the need for kidney biopsy.

The child with physiological or orthostatic proteinuria who has minimal, persistent proteinuria should be able to follow a full school schedule and be allowed to participate in sports, provided no other contraindications exist. The usual immunization schedule should not be interrupted, and the child should follow a regular diet. No increase in dietary protein is necessary to compensate for the minimal amounts of protein lost in the urine. Results of recent studies in patients with nephrosis have found that a high-protein diet may actually increase urinary protein losses.

Prognosis

The outlook for the child with proteinuria depends entirely on the underlying cause of the proteinuria. The child whose proteinuria is associated with edema or hematuria has an increased likelihood for significant renal disease, such as glomerulonephritis, and the prognosis may be less favorable. If the proteinuria is the result of a form of chronic glomerulonephritis, the child may ultimately develop end-stage renal disease. In the individual with glomerular disease, persistent proteinuria is a strong risk factor for progressive loss of renal function. The child with obesity or hypertension (or both) is at increased risk for developing chronic kidney disease and should be monitored for urinary microalbuminuria as an early marker for kidney disease. If the proteinuria is physiological or orthostatic, however, the long-term prognosis is excellent. Such a child has no greater likelihood than the general population of developing renal functional impairment.

CASE RESOLUTION

It is likely that the evaluation of the healthy teenage boy with isolated proteinuria will reveal that he has orthostatic proteinuria, in which case his long-term prognosis is good.

CHAPTER 111

Nephrotic Syndrome

Elaine S. Kamil, MD

CASE STUDY

A 2-year-old boy is brought to the office because of abdominal distention. He has just recovered from a runny nose that lasted 1 week, with no fever or change in activity. His mother reports that his eyelids were very swollen that morning, and she says that his thighs look "fat." She has noticed that he has fewer wet diapers. He has always been a healthy child, and his immunizations are up to date. The family has a history of asthma and allergic rhinitis. Physical examination shows an active 2-year-old boy. Head and neck examination is clear, except for a few shotty anterior cervical lymph nodes and some minimal periorbital edema. Chest examination reveals some decreased breath sounds at the bases. The abdomen is moderately distended; bowel sounds are active, and a fluid wave is detectable. There is 2+ pitting edema of the lower legs, extending up to the knees. The urine has a specific gravity of 1.030; pH 6; 4+ protein; and trace, nonhemolyzed blood. Microscopic examination shows 4 to 6 red blood cells per high-power field and 10 to 20 hyaline and fine granular casts per low-power field.

Questions

1. What is the differential diagnosis of edema and ascites in previously healthy young children?
2. What criteria are used to determine if children with nephrotic syndrome require hospitalization or can be managed as outpatients?
3. What laboratory evaluation and therapy are instituted initially?
4. What are the important issues to address in parent/guardian education?
5. What is the prognosis of young children with nephrotic syndrome?

Although nephrotic syndrome is not a common childhood disease, every pediatrician can expect to care for 1 to 3 children with nephrosis at some time. Nephrotic syndrome may have serious or even fatal complications, and the disease tends to follow a chronic, relapsing course. Thus, it is important for the pediatrician to become familiar with the signs and symptoms of the disease and with the most current treatment modalities aimed at keeping affected children healthy and active.

Nephrotic syndrome occurs when an individual excretes a sufficient quantity of plasma proteins, primarily albumin, in the urine to cause hypoalbuminemia. Substantial urinary protein losses, hypercholesterolemia, and hypoalbuminemia characterize nephrotic syndrome. The condition is usually accompanied by obvious edema, but occasionally edema is not clinically detectable (Box 111.1).

In children, proteinuria of more than 40 mg/m^2/hour (>50 mg/kg/24 hours) is considered nephrotic range proteinuria. (In adult-sized patients, proteinuria of more than 3.5 g in 24 hours is associated with nephrotic syndrome.) Collection of a 24-hour urine sample is cumbersome in children, and the urinary total protein/creatinine (TP/Cr) ratio done on a random urine sample, preferably a first morning urine, is a useful alternative. Whereas a ratio greater than 3.5 is considered nephrotic range proteinuria in adults with normal renal function, in children a ratio greater than 1.0 may signify nephrotic range proteinuria (see Chapter 110). Twenty-four–hour urine protein losses (g/m^2/day) in children can be estimated by multiplying the urinary TP/Cr by 0.63.

Box 111.1. Diagnosis of Nephrotic Syndrome

- Heavy proteinuria (>40 mg/m^2/hour or 50 mg/kg/24 hours in children)
- Hypoalbuminemia
- Hypercholesterolemia
- Edema

Epidemiology

Minimal change disease (MCD) is the most common form of nephrotic syndrome in childhood. The annual prevalence of new cases of nephrotic syndrome is 2 to 3 in 100,000 children in the population younger than 16 years. The cumulative prevalence of this chronic disease is estimated to be 16 in 100,000. Ninety percent of childhood cases are not associated with any systemic disease, and two-thirds of cases of childhood nephrotic syndrome present before age 5 years. The ratio of boys to girls in young children with nephrotic syndrome is 2:1. By late adolescence, both sexes are equally affected, and diseases other than MCD are much more prevalent in adolescents.

Clinical Presentation

The typical child presenting with nephrotic syndrome is a preschool-age boy who is brought to the physician because he appears swollen to the parents or guardians. Some children are active and

relatively asymptomatic despite the edema, whereas others may be very uncomfortable, with markedly swollen eyelids, abdominal discomfort, scrotal or labial edema, and even respiratory compromise. Usually children have a history of preceding infection, most typically an upper respiratory infection (URI). Children with nephrosis may develop diarrhea secondary to edema of the bowel wall.

Occasionally, children with nephrosis are critically ill because of peritonitis, bacteremia, or, rarely, a major thrombotic episode. Because their immune state is compromised, rapid evaluation and treatment of children with these complications of nephrotic syndrome are essential for survival. The primary peritonitis associated with nephrotic syndrome may be confused with an acute abdomen, such as may be seen with appendicitis. Some children who are experiencing a severe relapse have hypotensive symptoms secondary to intravascular volume depletion.

Pathophysiology

The exact cause of MCD and focal segmental glomerulosclerosis (FSGS) is not known. Recent genetic and biomarker studies suggest that MCD and FSGS are different diseases, although they both exhibit intrinsic structural defects in the glomerular podocyte. For MCD, the best current theory postulates that some stimulus (usually infectious) causes a clone of cells to proliferate and produce 1 or more soluble factors that are toxic to the glomerular epithelial cells (ie, podocytes), which are the cells that maintain the glomerular basement membranes. Active MCD shows a reduction in the net negative charge across the glomerular basement membrane and causes a diffuse abnormality in capillaries throughout the body, resulting in leakage of albumin in the peripheral capillaries and increases in interstitial fluid. The constituents of the glomerular basement membrane and chemicals coating the glomerular epithelial and endothelial cells normally bear a net negative charge. The presence of these negatively charged chemicals creates a charge-selective barrier to filtration. This barrier plays a significant role in the ultrafiltration of macromolecules present in the plasma, enhancing the filtration of molecules bearing a positive electrical charge and retarding the filtration of molecules bearing a negative electrical charge. During episodes of relapse, patients with MCD show a breakdown in the normal charge-selective barrier to filtration, often resulting in massive proteinuria. Kidney biopsies from patients with nephrotic syndrome demonstrate a net reduction in anionic sites during periods of relapse. Additionally, some children have mutations in podocyte proteins (eg, nephrin, podocin) that result in nephrotic syndrome. Children presenting with nephrosis before 1 year of age have a high likelihood of having a genetic mutation causing nephrotic syndrome, and any child with steroid-resistant nephrotic syndrome should also be screened for such genetic mutations.

Recent studies have shown evidence that the soluble factors in FSGS and MCD likely are different. For example, although 70% of patients with FSGS have been shown to have elevated plasma levels of soluble urokinase-type plasminogen activator receptor (suPAR), in patients with MCD the levels are undetectable. Considerable evidence exists indicating that the proteinuria in the patient with MCD or FSGS may be caused by soluble factors. Some patients who develop end-stage renal disease from idiopathic nephrotic syndrome (particularly FSGS) have experienced a relapse of the nephrotic syndrome with massive proteinuria immediately after transplantation of a normal kidney. In 1 instance, a patient with end-stage renal disease from FSGS developed an immediate severe relapse after transplant. The kidney was removed and transplanted into another patient without FSGS, and the kidney functioned normally without proteinuria. Infusion of peripheral blood mononuclear cell products from children with nephrosis induces albuminuria in rats. Removal of serum proteins by adsorption to a protein A Sepharose column or by plasmapheresis has resulted in remission of proteinuria in some patients who have experienced a recurrence of nephrotic syndrome after transplantation. Mixing plasma from a patient in relapse with FSGS with glomeruli in vitro can cause swelling of the glomeruli. The remission of the proteinuria after treatment with immunosuppressive medication provides further evidence that nephrotic syndrome is mediated in some way by the immune system. Children with MCD have been shown to have higher helper T/regulatory T cell ratios than in healthy children.

Normal adults are able to synthesize 12 g (0.4 oz) of albumin per day in the liver, and adults with nephrotic syndrome may synthesize 14 g (0.5 oz) of albumin per day. Therefore, the hypoproteinemia characteristic of nephrotic syndrome cannot be explained completely by measured amounts of urinary protein losses (approximately 3.5 g/day [0.1 oz/day]). The difference between the hepatic synthetic capacity for albumin and measured urinary losses can be explained by protein catabolism in the kidney. Renal tubular epithelial cells reabsorb filtered plasma proteins and catabolize them to amino acids, which then reenter the amino acid pool of the body. Thus, the magnitude of losses of plasma proteins at the glomerular level is far greater than the amount measured in a 24-hour urine sample.

The hypoalbuminemia that occurs in nephrotic syndrome is a result of the massive proteinuria, and the hypercholesterolemia occurs as a consequence of the hypoalbuminemia. The hyperlipidemia is partially the result of a generalized increase in hepatic protein synthesis that also involves overproduction of lipoproteins. Additionally, less lipid is transported into the adipose tissue because the activity of lipoprotein lipase is reduced in adipose tissue during active nephrotic syndrome. Hyperlipidemia is most pronounced in children with MCD. Serum albumin levels and serum cholesterol levels are generally inversely correlated. The hyperlipidemia is the last biochemical abnormality to clear after the child achieves remission from an episode of nephrotic syndrome.

Differential Diagnosis

Nephrotic syndrome is considered primary or secondary. Primary nephrotic syndrome is not associated with a systemic disease, whereas secondary nephrotic syndrome is a feature of a systemic disease, such as anaphylactoid purpura, immunoglobulin (Ig) A nephropathy, or systemic lupus erythematosus (SLE). Most young children with nephrotic syndrome have the primary form of the disease and secondary causes become more prevalent during adolescence.

Children with primary nephrotic syndrome are also classified according to their response to steroid therapy. Affected individuals may be categorized as steroid-sensitive, steroid-dependent, or steroid-resistant. Typically, children who are steroid-sensitive and remain so have MCD; however, a renal biopsy must be performed before the diagnosis of MCD is made. Sensitivity to or dependence on corticosteroids is a critical factor in determining a child's prognosis.

Nephrotic syndrome is also classified by the appearance of the glomeruli on renal biopsy. A summary of the histologic lesions causing nephrotic syndrome appears in Table 111.1. Approximately 95% of young children with nephrotic syndrome have MCD. In these children, light microscopy shows normal-appearing glomeruli. Immunofluorescent microscopy typically is negative but may show some mesangial IgM deposits, and electron microscopy simply shows foot process effacement of the podocytes. In individuals with FSGS, light microscopy may show enlarged glomeruli and glomeruli with segments of sclerosis. Immunofluorescence may reveal some IgM and complement in the sclerotic segments, and electron microscopy shows areas of foot process effacement of podocytes. Biopsies performed later in the disease course show some totally sclerotic glomeruli, areas of interstitial fibrosis, and atrophy. Several recent series have noted an apparent increase in the incidence of FSGS among children with nephrosis.

Other primary renal diseases that can cause nephrotic syndrome in children include membranous nephropathy, membranoproliferative glomerulonephritis (MPGN), IgA nephropathy and other forms of chronic glomerulonephritis, congenital nephrotic syndrome, and diffuse mesangial proliferative glomerulonephritis. Chronic hepatitis B infection may cause membranous nephropathy or MPGN. In endemic areas, the incidence of hepatitis B–associated membranous nephropathy has been reduced since the implementation of universal hepatitis B vaccination programs. Rarely, poststreptococcal acute glomerulonephritis and other forms of postinfectious acute glomerulonephritis may also cause nephrotic syndrome. With the exception of congenital nephrotic syndrome, all these diseases show the presence of immune deposits in the glomerular mesangial regions or along the glomerular basement membrane as well as some element of cellular proliferation, which may be severe. In these disease states, the presence of nephrotic syndrome is indicative of marked injury to the glomerular capillary wall. Neonates with congenital nephrotic syndrome Finnish type have a mutation of the gene encoding the nephrin molecule, a podocyte protein with a large extracellular domain that is an integral part of the glomerular slit diaphragm. These neonates have massive proteinuria beginning in utero and have severe nephrotic syndrome presenting in the first month after birth.

Because of the varying distribution of edema fluid at presentation, nephrotic syndrome may be confused with sinusitis or an allergic reaction (eg, periorbital edema), obesity (eg, ascites), or an abdominal mass (eg, ascites). Other causes of generalized edema, such as congestive heart failure, hypoproteinemia from inflammatory bowel disease, or liver disease, can be easily excluded with routine laboratory testing.

Table 111.1. Distribution of Histologic Type by Age of Onset in Children With Nephrotic Syndrome

Age (years)	MCD[a]	FSGS	MN	MPGN	Other GN
1–4	95%	3%	2%	—	—
4–8	75%	15%	1%	7%	2%
8–16	52%	15%	2%	25%	6%

Abbreviations: FSGS, focal segmental glomerulosclerosis; GN, glomerulonephritis; MCD, minimal change disease; MN, membranous nephropathy; MPGN, membranoproliferative glomerulonephritis.

[a] MCD remains the dominant histologic type through mid-adolescence but becomes relatively less important in later childhood and adolescence.

Evaluation

History

The clinical evaluation should include a careful history (Box 111.2).

Physical Examination

A complete physical examination is necessary. Blood pressure should be monitored, because hypertension or hypotension may occur. The extent of peripheral and central edema, including swelling of the eyelids, should be assessed. The physician should obtain a reliable, overall impression of the child's level of comfort and activity. Examination also should include a careful search for infection, particularly life-threatening infections, such as pneumonia or peritonitis. Examination of the head and neck should focus on signs of recent infection, such as otitis media. The presence of dullness to percussion at the bases of the thorax is consistent with large pleural effusions. Ascites may be minimal or massive. With severe ascites, scrotal or labial edema may occur. The child with a history of abdominal pain should undergo a careful examination for signs of peritoneal irritation. The skin should be inspected for infection and rashes.

Laboratory Tests

The laboratory evaluation of the child with nephrotic syndrome begins with a urinalysis. The dipstick shows 3+ or 4+ protein,

Box 111.2. What to Ask

Nephrotic Syndrome

- Has the child recently had any infections, such as pharyngitis or an upper respiratory infection? Is the child from a group at high risk for hepatitis B or C infection?
- Are the child's eyelids swollen? Do they look more puffy or less puffy at certain times during the day, especially on awaking or after crying?
- Does the child have a history of rashes characteristic of diseases that are associated with nephrotic syndrome?
- Is there a history of fever, oliguria, or abdominal pain?
- Is there a family history of nephrotic syndrome or kidney disease?
- Is the child playful and active, or is the edema so significant that movement is uncomfortable?
- Are the ascites and pleural effusions so severe that some respiratory compromise is evident?

although a dilute urine may be only 2+. Microscopic hematuria may be present in up to 25% of children with MCD. The presence of associated glycosuria in a child with nephrosis who is not on steroid therapy is concerning for FSGS. Careful microscopic examination of the urine is necessary. Casts are seen frequently, because urinary proteins precipitate in the tubules. The casts are hyaline, fine, and coarse granular. White blood cell (WBC) casts are sometimes seen, because some children with nephrotic syndrome may also have increased amounts of leukocytes in their urine. Large amounts of red blood cells (RBCs) and RBC casts are rarely seen in uncomplicated MCD and, if present, indicate another cause for the nephrotic syndrome. If RBC casts are seen together with substantial hematuria, an antistreptolysin O titer should be added to the preliminary evaluation outlined in this section. A random urinary TP/Cr should be done to determine whether the child has nephrotic range proteinuria.

If the urine shows only proteinuria, with perhaps some microscopic hematuria, blood tests should include a complete blood cell count, serum creatinine and blood urea nitrogen, electrolytes, serum calcium, serum albumin, cholesterol, complement component 3 (C3), and antinuclear antibody. The complete blood cell count may show a high hematocrit from hemoconcentration, because many children experience volume contraction as a complication of hypoproteinemia. Children may also have very high platelet counts (sometimes >1 million/μL). The blood urea nitrogen and creatinine help assess renal function. A hyperchloremic metabolic acidosis is sometimes seen. The serum albumin and cholesterol are required to differentiate nephrotic syndrome from other edematous states. A low level of C3 is associated with other renal diseases, such as MPGN, acute postinfectious glomerulonephritis, and SLE. The antinuclear antibody is useful in screening for SLE and other collagen vascular diseases. Hepatitis B serology is helpful in children who come from a population at risk for hepatitis B infection, such as recent immigrants from Southeast Asia or children of individuals who use intravenous (IV) drugs. Although not part of the routine laboratory evaluation, measurement of quantitative Ig often shows low IgG levels and elevated IgM levels. Blood and urine cultures should be obtained from the febrile child and, if signs of peritoneal irritation exist, a culture of peritoneal fluid should be obtained as well. Although not part of the routine evaluation, family history of thrombotic events warrants consideration of a thrombophilia evaluation because of the association between renal vein thrombosis and nephrotic syndrome, particularly in adults.

Imaging Studies

Chest radiographs help assess the severity of pleural effusions in children with marked ascites and respiratory compromise.

Management

Hospitalization

The decision to admit a child with nephrotic syndrome to the hospital is determined by the child's functional status. Any child with severe edema compromising ambulation or respiration should be admitted. Other indications for admission include unstable vital signs, fever, marked oliguria, and hemoconcentration (hematocrit ≥48%–50%). Most children with nephrotic syndrome who are hospitalized are admitted for control of edema or treatment of a complication, such as infection. A child hospitalized with nephrotic syndrome is likely to have the serious complications of infections, thrombosis, and/or acute kidney injury (AKI).

Management of the child in relapse is focused on minimizing edema and preventing complications until the disease can be controlled with immunosuppressive therapy. Intake, output, and weight must be closely monitored. Blood pressure should be followed, although hypertension is not common. If the child has a fever (temperature >38.2°C [>100.7°F]), blood and urine cultures should be obtained and antibiotics started pending culture results. Because of the risk for AKI, nephrotic medications should be avoided if possible. If signs of peritoneal inflammation are evident, paracentesis should also be performed to obtain samples of ascitic fluid for Gram stain, cell count, and culture. Broad-spectrum antibiotics should be given to cover respiratory pathogens, especially pneumococcus, and enteric pathogens. All children who are newly diagnosed with nephrotic syndrome should undergo a purified protein derivative (PPD) test, because immunosuppression associated with steroid therapy may facilitate reactivation of tuberculosis infection. Treatment with corticosteroids should be delayed until confirmation is received of a negative PPD.

Intravenous albumin (25%) should be used selectively, because albumin infusions are expensive, and the infused albumin is excreted rapidly in the urine. Infusions are indicated in the child with marked ascites, scrotal or labial edema, or significant pleural effusion. Infusions are also helpful in maintaining blood pressure and renal perfusion in the septic child with nephrotic syndrome. The usual dose is 1 g/kg, up to 25 g, infused over 2 to 4 hours, with close monitoring of blood pressure. Furosemide (1 mg/kg IV) is usually administered postinfusion. Albumin infusions may be repeated every 12 to 24 hours as necessary. If urine output does not increase after the first or second albumin infusion in the child with oliguria, immediate assessment for the presence of AKI is required (see Chapter 81). The albumin-induced mobilization of edema fluid in children with nephrosis with oliguria from AKI can precipitate pulmonary edema.

The child with nephrotic syndrome has an increased tendency to thromboembolic phenomenon. Increased risk factors for this complication include loss of antithrombin 3 in the urine, age 12 years or older, the existence of a central line, infection, and secondary causes of nephrotic syndrome (eg, SLE).

Supportive Therapy

Diet

Because sodium plays a key role in edema formation, the child with nephrotic syndrome should be placed on a no-added-salt diet that limits dietary sodium to 2 or 3 g per day. Technically, sodium restriction is indicated only during times of relapse, but a consistent no-added-salt diet helps entire families maintain a healthy diet. Even though children with nephrotic syndrome have hyperlipidemia, it

is not advantageous to implement a low-fat diet, because hyperlipidemia is not caused by fat intake and should resolve after the child goes into remission. In general, fluid restriction is not necessary except in unusual circumstances (eg, a steroid-resistant patient with persistent edema). Although earlier teachings recommended the use of high-protein diets, newer research has shown that high-protein diets may in fact increase urinary protein losses.

Activity

Historically, children with nephrotic syndrome were treated with bed rest because the supine position somewhat reduces urinary protein losses. No evidence shows that bed rest has a significant effect on children's clinical state, however. Thus, most pediatric nephrologists recommend that children be allowed full activity. Boys with marked scrotal edema may be more comfortable resting in bed while diuresis is being initiated. The child with nephrotic syndrome should not be isolated from other children and should be allowed to attend school.

Diuretics

Diuretics are often helpful in children in relapse, particularly in children with steroid-resistant disease. Serum potassium levels, as well as clinical signs of intravascular volume, should be monitored. In the child with moderate intravascular volume contraction, the injudicious use of diuretics could precipitate hypotension and increase the risk of thrombosis and AKI. The most commonly used diuretic is furosemide (1–2 mg/kg per dose given orally or via IV). Spironolactone is sometimes added to the diuretic regimen for its potassium-sparing effect.

Long-term Management

The goal of long-term management is induction and maintenance of remission from active nephrotic syndrome. Throughout treatment, it is important to minimize the side effects of medications. Spontaneous remission may eventually occur in the child with MCD; however, because of the 70% historical mortality rate, waiting for a spontaneous remission is unacceptable. Remissions are induced and maintained with the use of immunosuppressive medications. Figure 111.1 summarizes an approach to the overall management of nephrotic syndrome with these agents. A list of commonly used medications and dosages appears in Table 111.2.

Corticosteroids

More than 90% of younger children with primary nephrotic syndrome respond to corticosteroid therapy. Steroids are, therefore, diagnostic and therapeutic, because failure to respond to steroids can be a marker for disease other than MCD or for a genetic cause of nephrotic syndrome. Some children with MCD are steroid-resistant at some time in their disease, however. Steroids can be started promptly in the child with newly diagnosed nephrotic syndrome if the child has no signs of systemic disease, no more than microscopic hematuria, a normal C3 (or results pending), a negative PPD, and normal renal function. Acute infection should be managed with specific antimicrobial therapy to avoid infection-related steroid resistance.

Prednisone is usually started at 60 mg/m^2 per day. It can be given once a day in the morning or divided into 2 daily doses. Some studies have shown that by treating the first episodes of nephrotic syndrome with a prolonged course of corticosteroids (60 mg/m^2/day for 6 weeks followed by 40 mg/m^2 every 48 hours for 2–5 months), children are subsequently less likely to follow a frequently relapsing course. Proteinuria resolves within 2 weeks in many children with MCD and by 4 weeks in more than 90% of children with MCD. Serum albumin normalizes soon after proteinuria clears, but it may be several weeks before hypercholesterolemia returns to normal. The child who does not respond to 4 weeks of daily prednisone may be treated with a course of IV methylprednisolone at a dose of 15 mg/kg/day for 3 to 5 doses before declaring the child steroid resistant.

The pediatrician can easily manage the steroid-sensitive child, but the child with more difficult nephrotic syndrome should be treated in conjunction with a pediatric nephrologist. The child who experiences relapse is treated with daily prednisone (60 mg/m^2) until the urine is protein-free for 3 days. This regimen is followed by 4 weeks of 40 mg/m^2 every other morning. At the end of that 4-week period the prednisone can be either stopped or tapered off over an additional 2 to 4 months, depending on the child's previous relapse pattern. An increased incidence of side effects (eg, cushingoid appearance, hypertension, obesity, glucose intolerance, glaucoma, cataracts, osteopenia, decreased growth rate) occurs when children require frequent courses of prednisone therapy. In the child who experiences frequent relapses, a chronic course of alternate-day steroid therapy may eliminate relapses and reduce steroid toxicity. Usually prednisone 40 mg/m^2 is given every other morning initially for at least 3 months, which is followed by tapering over the subsequent several months to the lowest dose that maintains the child in remission. A recent study found that children on chronic low-dose alternate-day therapy are less likely to experience a relapse after a URI if they receive daily prednisone at their stable prednisone dose for 7 days during the illness.

Other Agents for Difficult Nephrotic Syndrome

Several other treatment options are available if remission is not maintained with alternate-day steroid therapy or if the child develops signs of steroid toxicity. Historically, cyclophosphamide or chlorambucil were the first agents offered to the child with steroid toxicity. Either of these alkylating agents may induce a long-lasting remission that persists for years in the child with steroid-dependent or frequently relapsing nephrotic syndrome. Either agent is started while the child is in remission on steroid therapy, and the steroids are gradually tapered during the course of treatment with the alkylating agent. Historically, a diagnostic renal biopsy was routine prior to starting an alkylating agent. Currently, many pediatric nephrologists proceed with such therapy in steroid-sensitive or steroid-dependent children without a biopsy, provided that renal function is normal. Although initially a daily dose of cyclophosphamide (2 mg/kg) was recommended for 8 weeks, a 12-week course is more likely to induce a prolonged remission and still be safe. The maximum cumulative dose of

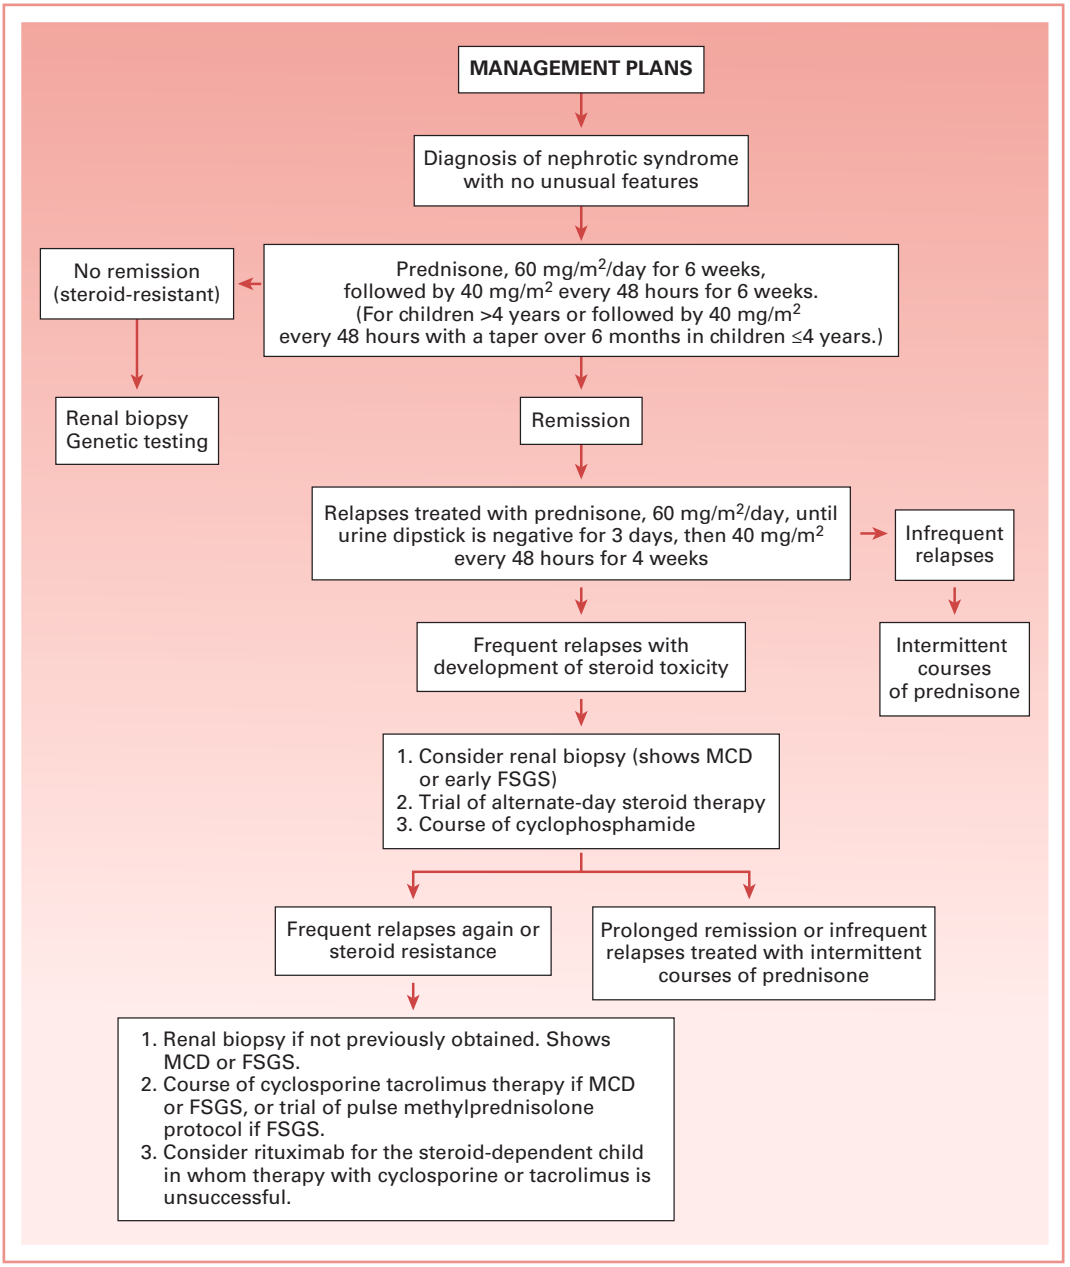

Figure 111.1. Management of nephrotic syndrome in children.
Abbreviations: FSGS, focal segmental glomerulosclerosis; MCD, minimal change disease.

cyclophosphamide should not exceed 168 mg/kg. Chlorambucil at 0.1 to 0.2 mg/kg per day may be given as an alternative to cyclophosphamide, but it may be more toxic.

Potential toxicities of cyclophosphamide include bone marrow suppression with increased risk for infection, alopecia, hemorrhagic cystitis, gonadal toxicity, and possibly a small but indeterminately increased risk of developing a malignancy at some time. Some nephrologists advocate using oral mesna (a medication to miniminize the side effects of chemotheraphy) along with the oral cyclophosphamide to reduce the development of hemorrhagic cystitis. Mesna is always used when individuals receive IV cyclophosphamide. Complete blood cell counts should be monitored weekly, and parents or guardians should be cautioned about the increased risk of overwhelming varicella infections in children who have not yet had a varicella infection or immunization. The cyclophosphamide dose should be withheld if the WBC count falls below 4,000/μL and restarted when the WBC returns to or exceeds 4,000/μL. Alopecia and hemorrhagic cystitis are rare when the recommended dose is used and when children are asked to drink extra fluids while on cyclophosphamide. A 12-week course of cyclophosphamide (2 mg/kg/day) does not seem to increase the risk of infertility, but longer courses are associated with oligospermia, aspermatogenesis, and ovarian dysfunction. Postpubertal individuals may be at greater risk for gonadal toxicity than prepubertal children.

Table 111.2. Treatment Options in Childhood Nephrotic Syndrome

Medication	*Dose*	*Length of Therapy*
Prednisone	Initial course: 60 mg/m^2/day for 6 weeks, then 40 mg/m^2 every 48 hours for 6 weeks	Varies
Cyclophosphamide	2–2.5 mg/kg/day (cumulative dose <168 mg/kg)	12 weeks
Chlorambucil	0.15 mg/kg/day (cumulative dose ≤8.2 mg/kg)	8 weeks
Cyclosporine	2–3 mg/kg every 12 hours, monitor levels, target trough 100–200 ng/mL	Varies
Levamisole[a]	2.5 mg/kg every other day	Varies
Mycophenolate mofetil	12–18 mg/kg every 12 hours; adults, 1–1.5 g every 12 hours	Varies
Tacrolimus	0.05–0.3 mg/day in divided doses, monitor levels, target trough 4–8 ng/mL	Varies
Rituximab	375–1,000 mg/m^2/dose, 2 doses, 2 weeks apart	

[a] Levamisole is no longer available in the United States.

In the child with steroid sensitivity or dependency who has not achieved prolonged remission after cyclophosphamide therapy, a diagnostic renal biopsy is often considered. Renal biopsy is indicated early, however, in the course of illness for the steroid-resistant child. If FSGS is identified on biopsy, treatment may involve a prolonged course of IV methylprednisolone therapy, cyclosporine, or tacrolimus. Therapeutic options for the child with MCD who remains steroid dependent after a course of cyclophosphamide include treatment with mycophenolate mofetil, cyclosporine, tacrolimus, levamisole, or rituximab. Although cyclosporine and tacrolimus are more likely to induce prolonged remission, they maintain remission only while being administered. That is, patients trade steroid dependence for cyclosporine or tacrolimus dependence. Nevertheless, for the child with steroid toxicity, a 12-month course of cyclosporine or tacrolimus allows resolution of the adverse effects of steroids and is generally well tolerated when administered by an experienced physician. Side effects, such as hirsutism and gingival hyperplasia, are frequent at the onset of therapy with cyclosporine. These effects regress as the dose is decreased or the drug is discontinued, however. Hypertension is not uncommon. The most common metabolic abnormality that occurs with cyclosporine use is hypomagnesemia. Long-term therapy may result in significant nephrotoxicity and, rarely, patients experience liver toxicity. Tacrolimus, like cyclosporine, is a calcineurin inhibitor. It has a toxicity profile similar to cyclosporine, but it does not cause gingival hyperplasia or hirsutism and is being used more frequently.

Because of potential toxicity, cyclosporine and tacrolimus should only be prescribed by a physician familiar with the drug. Dosing requirements may change with remission and relapse, and the family and physician should be aware of several drug interactions. Any medication that interferes with the cytochrome P-450 enzyme system in the liver, such as erythromycin, greatly increases cyclosporine and tacrolimus levels and should be used only under extraordinary circumstances. Diarrhea may increase tacrolimus blood levels to a toxic range. The child who requires prolonged treatment with cyclosporine or tacrolimus should undergo follow-up kidney biopsies after 1 or 2 years of therapy to assess for any nephrotoxicity.

Mycophenolate mofetil has been shown to be useful as a corticosteroid-sparing agent in the steroid-dependent, frequent relapsing child. Typically, it is used for at least 12 months because most children relapse if it is withdrawn sooner. Some children have been on this medication for years without apparent adverse events. Levamisole, which is an immune-modulating agent, also has been shown to be useful in the frequently relapsing child. It is not available in the United States, however. Rituximab, an anti-CD20 monoclonal antibody, is also promising for use in the steroid-dependent child. Currently, the use of rituximab should be reserved for the child with continued relapses despite optimal use of prednisone and corticosteroid-sparing agents.

Children with nephrosis who do not achieve good remission with immunosuppressive therapy are given supportive therapy with angiotensin-converting enzyme inhibitors or angiotensin blockers, which reduce proteinuria and have been shown to reduce the progression of glomerulosclerosis. These medications are also first-line therapy for children with nephrosis who develop hypertension. Other supportive measures for children with persistent edema include sodium restriction and the chronic use of diuretics. Genetic testing should be performed early in the steroid-resistant child, and further immunosuppressive therapy should be withheld until the results of the genetic testing are available.

Immunization Issues

Because of the unusual susceptibility to pneumococcal infections, children older than 2 years with nephrotic syndrome should receive the 23-valent pneumococcal vaccine, even if they have previously received the 13-valent conjugated pneumococcal vaccine. The vaccine is best administered while children are in remission, but it produces protective titers even in children who are on alternate-day steroid therapy at the time of immunization. Pneumococcal antibody titers should be measured in patients on multiple immunosuppressive medications, and a second dose of vaccine should be administered to those who do not seroconvert. Influenza vaccine should be administered each autumn to children with nephrotic syndrome using the age-appropriate schedule and dosage.

Some of the routine childhood immunizations (eg, diphtheria-tetanus-pertussis, *Haemophilus influenzae* type b, hepatitis B, inactivated poliovirus vaccine) should be administered by the usual schedule but while the child is in remission, if possible (see Chapter 37). Some controversy exists concerning the use of live-virus vaccines in children who require long-term immunosuppressive therapy.

No vaccines should be administered if a child is currently being treated with an alkylating agent. The measles-mumps-rubella vaccine could potentially cause a relapse. Based on limited data on the use of varicella vaccine in children with nephrosis, it is probably safe to administer varicella vaccine while a child is in remission and not on immunosuppressive medications. It is important to obtain a varicella titer in the child with nephrotic syndrome, because the child who lacks immunity is at risk for overwhelming varicella infection.

Parent/Guardian Education

Because nephrotic syndrome follows a chronic, relapsing course, parent/guardian education is essential for effective long-term management. Parents need to be instructed about using urinary dipsticks to monitor protein excretion. Generally, urine dipsticks should be used daily during periods of active relapse and when medication is being tapered. Otherwise, the dipstick should be checked whenever a child has an infection, including URI; whenever the child looks "puffy"; and weekly when asymptomatic.

Weight should be monitored as well, especially during relapse. The child should be weighed each morning on awaking. Urine output should be measured in more difficult cases. As parents become more familiar with nephrotic syndrome, they will become partners with the physician about medication changes. Parents should also contact the physician about "danger signs," such as fever (temperature >38.2°C [>100.7°F]), significant abdominal pain, and exposure to varicella. If a child does not have protective antibodies against varicella and is taking any immunosuppressive medication (including prednisone), the varicella-zoster Ig should be administered within 72 hours of exposure to varicella. If varicella infection manifests, IV acyclovir should be instituted.

Prognosis

In the preantibiotic era, nephrotic syndrome was frequently fatal, usually because of overwhelming infection. After the introduction of antibiotics, the mortality rate fell significantly. The use of corticosteroids has resulted in a further reduction in mortality. Currently, the mortality rate is approximately 5%, and mortality is caused almost exclusively by infections from encapsulated organisms or thrombosis. The greatest risk of death in children with nephrotic syndrome (approaching 50% over 20 years in some series) is among children with resistance to corticosteroid therapy.

The long-term outlook for most children with nephrotic syndrome is favorable, particularly for steroid-sensitive patients. Relapses often disappear by the completion of puberty. Occasionally, individuals with MCD continue to have relapses into adulthood. Approximately 20% of children with steroid-sensitive MCD still experience relapses 15 years after the onset of their disease. Disease recurrence is highly unlikely if 8 years pass without a relapse. Fewer than 10% of initially steroid-sensitive children with nephrotic syndrome develop end-stage renal disease. This occurs almost exclusively in children with FSGS. Focal segmental glomerulosclerosis may recur after kidney transplants, particularly in young children with aggressive FSGS.

CASE RESOLUTION

The child most likely has MCD. He appears stable enough to be managed as an outpatient and should be placed on a salt-restricted diet and prednisone. The overall prognosis depends on a close interaction among the parents, pediatrician, and consulting pediatric nephrologist.

CHAPTER 112

Urinary Tract Infections

Gangadarshni Chandramohan, MD, MSc, FASN, FAAP

CASE STUDY

A 2-year-old girl is brought to the office with a 1-day history of fever (temperature of 39.4°C [103°F]), vomiting, and mild diarrhea. No history exists of any change in her urinary habits, and she still wears diapers. The child has been somewhat irritable but fully alert.

Physical examination reveals an ill-appearing toddler. Her temperature is 39.2°C (102.6°F), heart rate is 122 beats per minute, respiratory rate is 30 breaths per minute, and blood pressure is 90/60 mm Hg. The neck is supple. Head, eye, ear, nose, throat, chest, heart, abdomen, and genital examinations are normal. Urinalysis shows specific gravity of 1.025, pH 6.0, leukocyte esterase and nitrite both strongly positive, protein trace, and blood trace; the sediment has 15 to 20 white blood cells and 2 to 4 red blood cells per high-power field. The Gram stain shows more than 100,000 gram-negative rods, and the urine culture result is pending.

Questions

1. What are the possible diagnoses for the child with positive leukocyte esterase on urinalysis?
2. What are the indications for hospital admission for the child with a urinary tract infection?
3. What antibiotics are used in the management of urinary tract infection?
4. What is the appropriate diagnostic workup for the child with suspected urinary tract infection?
5. When should renal ultrasonography and voiding cystourethrography be done in the child with a urinary tract infection?
6. If the workup is positive for vesicoureteral reflux, how should the child be treated in the long term?

Urinary tract infection (UTI) is among the most common bacterial infections affecting infants and children. Children with UTI frequently present with urinary symptoms such as dysuria, frequency, and urgency. Young infants and toddlers may present with nonspecific symptoms, as with other types of bacterial infection. Further, because of the subtle nature of the symptoms at the early stages of disease, medical intervention may be delayed, resulting in overwhelming sepsis. In most children, UTIs resolve completely with appropriate antibiotic therapy. In the child with an underlying anatomic or functional abnormality of the genitourinary system, such as vesicoureteral reflux (VUR) or bowel-bladder elimination dysfunction, respectively, or with delayed or inadequate antibiotic treatment, however, UTI may result in renal scarring that can sometimes cause hypertension or, rarely, end-stage renal disease.

Urinary tract infection is a nonspecific, generic term implying significant bacteriuria, irrespective of the site of bacterial growth in the urinary tract. In many young children with bacteriuria, clinical findings overlap, and precise classification is not easily made. Some commonly used terms are clarified as follows.

Asymptomatic, covert, and screening bacteriuria are synonymous terms usually used when bacteriuria is detected during surveys of healthy children. The pediatrician should be aware, however, that some affected children, particularly those who are at high risk for developing UTIs, may have subtle urinary symptoms on close questioning. Those children should be treated for UTI using the same principles as used for children who present with obvious symptoms.

Cystitis implies infection of the bladder only. Main features of cystitis are voiding symptoms, such as dysuria, frequency, urgency, enuresis, and foul-smelling urine. Fever, if present, is usually low grade, and the patient may present with lower abdominal pain as well.

Acute pyelonephritis is infection of renal parenchyma characterized by systemic symptoms, such as high fever, chills, flank pain, and vomiting along with voiding symptoms.

Chronic pyelonephritis is a term that has been used in various ways. Ideally, it should be used only to refer to renal scarring resulting from repeated infections as diagnosed based on histologic analysis of renal biopsy specimens. Practically, the term often refers to scarred kidneys as demonstrated by nuclear medicine studies or reduced kidney function.

Urethritis implies infection of the urethra and usually occurs in the setting of sexually transmitted infections. The usual symptoms are dysuria and urethral discharge.

Epidemiology

Bacteriuria is detected in approximately 1% of girls and 2% of boys during routine screening of healthy newborns and young infants in the United States. Approximately 1% of girls continue to have asymptomatic bacteriuria throughout childhood. Bacteriuria in boys older than 1 year is very uncommon. In most affected infants and children, bacteriuria resolves spontaneously with time and does not cause renal damage.

Symptomatic UTI occurs in approximately 2.5% of children annually and accounts for more than 1 million office visits per year. Up to approximately 7% of girls and 2% of boys have culture-proven symptomatic UTI by age 6 years. Before the age of 1 year, UTI recurs in 75% of infants. After 1 year of age, 40% of girls and 30% of boys develop recurrent UTIs following the first episode. In early infancy, UTI is approximately twice as common in boys as in girls and approximately 10 times more common in uncircumcised boys than circumcised boys. After the first 6 months of age, the prevalence of symptomatic UTI becomes considerably higher in females than males, and the difference between circumcised and uncircumcised males disappears. Among vaccinated febrile infants, UTI is the source of fever in approximately 4% to 8% of patients, even in those with symptoms of upper respiratory infection.

Clinical Presentation

Signs and symptoms of UTI in neonates and young infants are usually nonspecific and include fever, irritability, poor weight gain (or weight loss), diarrhea, vomiting, and jaundice. Occasionally, bacteremia or sepsis with temperature instability, cyanosis, and disseminated intravascular coagulation may occur. Older children often have similar signs and symptoms, and often they are able to describe abdominal or flank pain, dysuria, frequency, urgency, enuresis, foul-smelling or cloudy urine, and occasionally gross hematuria (Box 112.1).

Pathophysiology

The pathogenesis of UTI involves interaction between various bacterial factors and protective host factors.

Bacterial Factors

Escherichia coli accounts for 80% to 90% of first infections. The remainder are caused by other gram-negative enteric bacilli (eg, *Proteus, Klebsiella, Enterobacter*) and gram-positive cocci (eg, enterococci, *Staphylococcus saprophyticus*). Rarely, *Morganella morganii, Proteus mirabilis, Providencia stuartii*, and *Serratia* species can cause infection in young children as well. Most organisms that cause UTI originate from the fecal flora. Infections caused by *S saprophyticus*, a coagulase-negative staphylococcus, occur mostly in adolescents with UTI. Nosocomial infection can be caused by *Citrobacter, Enterobacter, Enterococcus,* and *Pseudomonas.*

Box 112.1. Clinical Features of Urinary Tract Infection

- Abdominal pain
- Burning or pain on urination
- Urgency
- Frequency
- Fever
- Leukocyturia or positive nitrite on urinalysis
- Positive urine culture

Microorganisms that cause UTI usually enter the urinary tract by an ascending route. To initiate colonization and infect the urinary tract, these organisms must first adhere to uroepithelium to avoid being swept away during voiding. Bacterial adhesion in *E coli* is mediated by *fimbriae*, which are fine, hair-like proteins emanating from the bacterial cell wall. One important type of fimbriae, P fimbriae, adheres to receptors on the uroepithelium, and some studies have shown that women and children with recurrent UTI have increased numbers of these receptors. In most young children with normal anatomy, acute pyelonephritis is caused by *E coli* with P fimbriae. In most patients with VUR and scarred kidneys, however, the infection is caused by *E coli* without P fimbriae. Thus, the role of P fimbriae in the pathogenesis of renal scarring is uncertain. Additionally, many of these bacteria, which are typically extracellular organisms, can survive and flourish intracellularly by taking advantage of the nutrients of the host cell and evading immune defenses. Other bacterial virulence factors include K and H antigens, colicin, and hemolysin; however, their role in the pathogenesis of UTI is not clearly defined.

Host Factors

Many unalterable host factors contribute to the pathogenesis of UTI, including age, sex, genetics, anatomy, and immune response to infection. Females seem to be at increased risk for UTI because the female urethra is shorter than the male urethra and closer to the anus. As previously stated, the uroepithelium of older girls and adult women who develop recurrent UTI binds *E coli* more avidly than uroepithelium from nonsusceptible individuals. Additionally, individuals with certain P and Lewis blood groups develop more UTIs than others without these specific blood groups. Urinary obstruction or other anomalies may contribute to the development of UTIs in approximately 2% of girls and 5% of boys, especially infants.

Vesicoureteral reflux is the retrograde passage of urine from the bladder to the ureter. After passage through the bladder wall, the normal ureter tunnels under the bladder mucosa for approximately 2 cm before it opens into the bladder lumen. Under normal circumstances, the submucosal segment is compressed when the bladder is filled and during voiding, thus preventing urine backing up into the ureter. Most VUR is primary and caused by a congenital abnormality of the ureterovesical junction, with the ureter having a short submucosal segment and more laterally placed openings. Reflux also may occur in the presence of normal ureteral anatomy when bladder pressures exceed 40 cm of water, as seen in patients with posterior urethral valves or neurogenic bladders resulting from inadequate emptying of bladder creating high pressure inside the bladder and causing leakage of urine back into the ureter. Vesicoureteral reflux is graded on a scale of 1 through 5, with stage 5 being the most severe based on radiologic imaging (Figure 112.1). However, nuclear voiding cystourethrography (VCUG), an alternative study that involves reduced radiation exposure but poor resolution, has been recommended for screening in girls. Because of the poor resolution, however, staging is less precise than with radiologic grading of VUR. Therefore, nuclear VCUG grading has only 3 stages: mild, moderate, and severe.

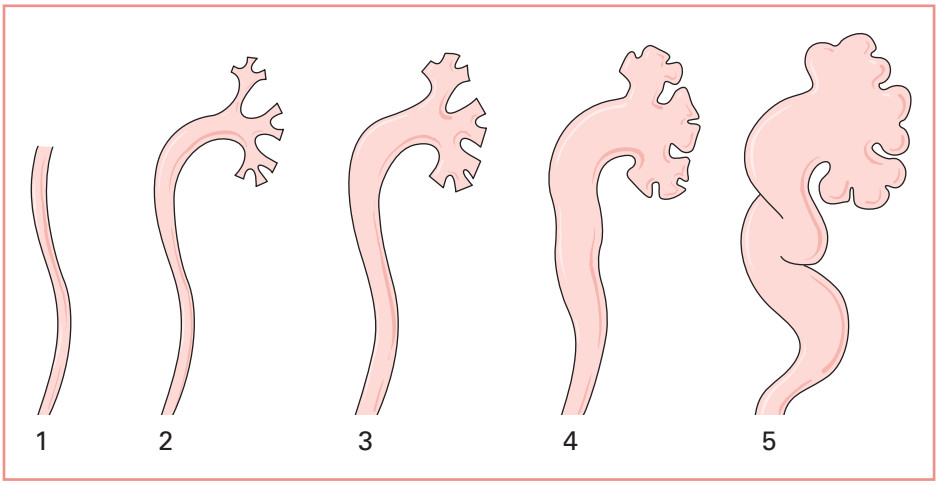

Figure 112.1. Grading of vesicoureteral reflux by vesicoureterography based on international classification. 1, Ureter only. 2, Ureter, pelvis, and calyces, but without dilatation. 3, Mild or moderate dilatation of ureter and mild or moderate dilatation of renal pelvis, but no or slight blunting of fornices. 4, Moderate dilatation or tortuosity of the ureter with moderate dilatation of renal pelvis and calyces and complete obliteration of the sharp angles of fornices, but maintenance of papillary impressions in most calyces. 5, Gross dilatation and tortuosity of ureters, renal pelvis, and calyces; papillary impressions are no longer visible in most calyces.

The incidence of VUR in normal infants is generally stated to be less than 2%; however, recent studies suggest that the incidence of low-grade VUR is much higher, particularly in preterm infants, than previously thought and may be similar to that in older children with UTI. In infants with UTI, the prevalence of VUR is approximately 25% to 50%; in school-age children, approximately 25% to 30%; and in adolescents, approximately 10% to 15%. These findings suggest that VUR often spontaneously resolves with increasing age and maturation of the bladder wall. Vesicoureteral reflux may be a familial disorder and has been reported in 10% to 30% of siblings of index cases. The incidence of UTI is increased in the presence of VUR, likely because of bladder and bowel dysfunction (BBD) or bladder elimination dysfunction resulting in a high amount of residual urine, which refluxes into the ureters or kidneys. This also provides infected urine direct access to the kidneys, which can result in pyelonephritis and, potentially, renal scarring.

It would seem that the greater the severity of VUR in the child with UTI, the greater the likelihood of renal scarring. Recently, however, it has been clearly recognized that many neonates (especially boys) with antenatal VUR, even in the absence of UTI, have congenital dysplastic renal parenchymal defects that had been misidentified as infective scars. Therefore, it is now presumed that the progression of renal scarring in such patients occurs as a result of the natural course of the congenital defect, with or without UTI.

Although many predisposing host factors cannot be changed, several potentially modifiable behaviors related to elimination are associated with UTI in older children. The school-age child with frequent reports of dysuria or recurrent UTIs with no history of UTI as an infant should be questioned for symptoms of *dysfunctional voiding,* a term often applied in the setting of children (especially girls) with no neurologic or anatomic abnormalities but who exhibit abnormal voiding behavior. Such girls often hold their urine for so long that they need to rush to the bathroom, only to incompletely empty their bladder, resulting in urinary stasis and the potential for infection. Additionally, the constipation and abnormal stooling patterns that frequently are associated with dysfunctional voiding are characteristic of BBD. In children between the ages of 6 and 12 years, recent data reveal BBD resulting in diurnal urinary incontinence in 30.7%, holding maneuvers in 19.1%, and urinary urgency in 13.7%, all of which can predispose to UTI.

Differential Diagnosis

In infants and young children, symptoms of UTI are often nonspecific. Thus, a high degree of suspicion for UTI must be maintained. An acute abdomen may rarely be confused with UTI. Some children with dysuria may have chemical irritation from exposure to materials such as bubble baths. A girl with overweight may retain urine in the labial folds, which can cause maceration, urethral irritation, vulvitis, and/or nonspecific vaginitis. Similarly, some young girls do not sit with their legs spread wide enough on the toilet, which can result in reflux into the vagina and cause post-void dribbling with subsequent urethral irritation or vulvitis and/or nonspecific vaginitis. In these patients, urinalysis may be positive for blood or sometimes leukocytes; however, urine culture findings usually help differentiate UTI from perineal flora contamination or vulvitis and/or nonspecific vaginitis or urethral irritation.

Evaluation

History

In all infants and young children with fever without an apparent source, urinalysis, urine Gram stain, and urine culture should be obtained to evaluate for UTI before initiating antibiotic treatment.

If the febrile child younger than 2 years does not appear to be ill, workup should be based on risk assessment. In the older child, a history of fever, dysuria, frequency, abdominal pain, and nausea and vomiting is suggestive of UTI (Box 112.2). The physician should also inquire about any history of previous UTI, abnormal voiding, and constipation.

Bladder and bowel dysfunction is a common risk factor for constipation, urinary incontinence, or enuresis, which can predispose to UTI among school-age children. Lower urinary tract symptoms must be investigated carefully at routine pediatric visits.

Recurrent UTI generally refers to reinfection with a new organism, whether the same or a different species. This is a common problem, especially in the first year after initial UTI. Reinfection with the same organism is infrequent; however, if intermittent symptoms of UTI persist during administration of antibiotics and repeat urine culture is positive after 14 days, the initial infection is characterized as persistent. Persistence is the result of medication noncompliance or inappropriate choice of antibiotic (ie, the pediatrician has not followed up on the sensitivity results and changed the antibiotic accordingly). If symptoms relapse within 2 months even after a negative culture was obtained at 14 days after completion of antibiotic treatment, the condition is characterized as a *relapse* of the previous infection; that is, the infection remained latent and flared after completion of antibiotic treatment. Relapse may be indicative of underlying structural or functional problems of the urinary tract, kidney stones/hypercalciuria, or often, inappropriate antibiotic therapy. If an underlying structural or functional problem is suspected by the pediatrician, appropriate workup should be initiated, and nephrology or urology referral should be made based on those results.

Physical Examination

Weight and height measurements are important to determine whether a patient has a chronic renal condition that may be predisposing to infections, such as obstructive uropathy or neurogenic or nonneurogenic bladder with secondary or primary VUR. The physician should check all vital signs to help determine whether the UTI involves the lower or upper tracts and to assess the severity of infection. An elevated blood pressure and temperature are consistent with an upper tract infection. The abdomen should be examined for masses and tenderness, the genitalia for local lesions, and the lumbosacral area for anomalies (eg, deep sacral dimples, tuft of hair, lipoma, hyperpigmentation, hemangiomas).

Box 112.2. What to Ask

Urinary Tract Infection

Children Age 2–24 Months

- Does it hurt when the child urinates?
- Does the child void with increased frequency?
- Does the urine have an unusual odor?
- Has the child had previous urinary tract infections?
- Does the child have a good urinary stream or urine dribbles?

Children Older Than 24 Months

- Does the child have burning on urination?
- Is the child's urine red or brown?
- Has the child started to wet the bed again?
- Does the child have increased urinary frequency?
- Does the child report abdominal pain?
- Does the child report flank pain?
- Does the child have a fever?
- Does the child have low appetite, or nausea or vomiting?

Laboratory Tests

The diagnosis of UTI is established by documenting significant bacteria in a urine specimen sent for culture. The decision to obtain a urine culture is influenced by the age of the child and the child's symptoms. The factors that influence the likelihood of UTI and the need for a urine study in infants between 2 and 23 months of age are as follows: younger than 12 months, maximum temperature of greater than or equal to 39°C (≥102.2°F), race other than black, female sex or uncircumcised male, and no other fever source. A calculator for more specifically determining the likelihood that an infant in this age group has a UTI can be found at https://uticalc.pitt.edu.

In the young infant, the specimen always should be obtained by bladder puncture or catheterization. Because of the risk of contamination in infants and children, a bag urine sample is not reliable. In the older child with bladder control, a midstream urine collection is satisfactory. The diagnosis of UTI should never be based on the presence or absence of white blood cells alone. Although most older children with symptomatic UTI have pyuria, many neonates and young infants with UTI (25%–50%) may not manifest this finding. Furthermore, leukocyturia may occur in other renal disorders in the absence of UTI. A positive urinary nitrite test is suggestive of UTI; however, the false-negative rate is nearly 50%.

Most patients with UTI (≥85%) have urine bacterial counts greater than 100,000/mL on a voided specimen (ie, significant bacteriuria), although some adult women and teenage girls with symptomatic recurrent UTI have catheterized or "clean catch" urine colony counts less than 1,000/mL. Generally, colony counts of less than 1,000/mL have not been observed in young children with UTIs. Colony counts between 10,000 and 100,000/mL obtained via clean catch are generally unlikely to be significant unless the child has symptoms of UTI, associated leukocyturia, or cultures that are pure growths of a single organism. Any growth of an organism from a suprapubic tap is considered significant. A colony count of at least 10,000/mL in a sample obtained by catheterization is usually necessary to diagnose a UTI. In most children with UTI, however, urine collected by either of these techniques grows more than 50,000 organisms/mL.

The C-reactive protein level usually is increased in the infant or child with high fever and clinical findings suggestive of acute pyelonephritis. Several other laboratory studies, including erythrocyte sedimentation rate, urinary lactic acid dehydrogenase isoenzymes, urinary concentrating ability, and antibody-coated bacteria, have been used with varying success to differentiate upper (ie, renal) from lower (ie, bladder) UTI in older children and adults. Overall,

the reliability of these studies in pediatric patients, especially infants and young children, is not adequate to recommend their routine use. More recently, testing of serum procalcitonin levels has been tried, and preliminary studies suggest that an elevated serum procalcitonin level may have some predictive value in diagnosing pyelonephritis and VUR.

Imaging Studies

Although controversy exists concerning the recommendations, the most recent position statement from the American Academy of Pediatrics (AAP), which was published in 2016, recommends that children younger than 2 years should undergo renal and bladder ultrasonography after the first UTI. Routine VCUG should not be performed unless evidence exists of hydronephrosis, scarring, other anomalies suggestive of obstructive uropathy or high-grade reflux, other atypical complex situations, or recurrent UTIs. If renal or bladder ultrasonography reveal hydronephrosis suggestive of VUR or obstruction, further studies (eg, VCUG, nuclear scan [MAG III], or both) are warranted (Box 112.3).

When febrile UTI recurs and the decision is made to obtain a VCUG, nuclear VCUG rather than contrast VCUG is an acceptable alternative for girls. If indicated, VCUG may be performed after the UTI has resolved; if resolution has not occurred, the study should be delayed 4 to 6 weeks depending on the clinical circumstances. According to the AAP guidelines, antibiotic prophylaxis must be administered until completion of the studies. Excretory urography (ie, intravenous pyelography) is no longer recommended.

Because of a shortage of the technetium Tc 99m succimer (DMSA) in the United States, renal scanning is no longer used to differentiate upper from lower tract UTI or to identify renal scarring. To rule out renal scarring in a child with recurrent UTI, high-resolution Doppler renal ultrasonography or power Doppler renal ultrasonography can be done; these studies detect scarring by delineating the area with poor blood flow.

Management

Per the 2016 AAP reaffirmation of the guideline on diagnosis and management of UTI in febrile infants and young children age 2 to 24 months, for girls the risk factors associated with UTI are white race, age younger than 12 months, temperature at or above 39°C (≥102.2°F), fever for more than 2 days, and no source of infection, and for boys the risk factors are uncircumcised status, race other than black, temperature at or above 39°C (≥102.2°F), fever for more than 24 hours, and no other evident source of infection.

After UTI is confirmed or if the level of suspicion for UTI is high, based on the previously described risk assessment by the pediatrician, all newborns and infants younger than 2 months with a UTI should be treated with parenteral antibiotics, starting with broad-spectrum antibiotic coverage, such as ceftriaxone, cefotaxime, or ampicillin and gentamicin, pending results of sensitivity studies. Infants and children 2 months and older who appear well and can tolerate liquids may receive oral antibiotics on an outpatient basis. Most physicians recommend cephalexin for the first infection until the results of bacterial sensitivity tests are available; treatment is continued for 10 days. For the older child with a high likelihood of UTI based on the risk assessment, antibiotics can be initiated after obtaining a urine culture; otherwise, observation is acceptable until the culture results are available.

In the adolescent with a clear-cut lower UTI, a shorter course of combination trimethoprim and sulfamethoxazole is also effective. The physician should be aware of the local *E coli* resistance patterns, because some communities have a high incidence of *E coli* resistant to this combination. The child who appears toxic or is vomiting should be admitted to the hospital and started on parenteral antibiotics until clinical improvement is evident, at which time the child can be sent home on oral therapy. In the child with a complicated UTI, an infectious disease specialist should be consulted about any questions of the susceptibility and resistance pattern of the urinary pathogen; this specialist also can be consulted about selecting the appropriate antibiotic. A pediatric nephrologist or urologist ultimately should decide on the treatment plan, particularly concerning duration of therapy and follow up (Box 112.4).

Recent studies indicate that continuous antibiotic prophylaxis (CAP) is not necessarily preventive for infection or renal scarring and may cause increased risk for resistant infections with resistant bacteria. However, the physician may decide to treat the child with recurrent UTI (with or without VUR) with low-dose antibiotics (ie,

Box 112.3. Indications for Voiding Cystourethrography

- Prenatal ultrasonography demonstrates moderate to severe hydronephrosis that is confirmed on postnatal ultrasonography
- Detection of bilateral hydronephrosis, in newborn boys
- Child with a history of recurrent urinary tract infection and elevated serum creatinine level with no obvious predisposing factor detected on renal and bladder ultrasonography
- History of severe pyelonephritis in a patient with bladder elimination defect or bladder and bowel dysfunction
- The older child with a long history of recurrent urinary tract infections and bed-wetting

Box 112.4. Indications for Hospitalization for Urinary Tract Infection

- Not tolerating intake orally
- Failed outpatient management
- Impending septic shock
- Dehydration
- Abnormal kidney (ie, single kidney, polycystic kidney disease, chronic glomerulonephritis)
- Immune disorder
- Marked elevation of inflammatory markers (ie, white blood cell count, C-reactive protein level, procalcitonin level)
- Concern about ability of the parent or guardian to follow outpatient management recommendations

trimethoprim and sulfamethoxazole, cephalexin, or nitrofurantoin) for 12 to 18 months after treatment for an acute infection. A recent study examined the outcome between early discontinuation of CAP versus a traditional 2-year course of antibiotics until a child achieves 5 years of age and found early discontinuation to be equally beneficial as the earlier recommendation of long-term CAP. If breakthrough infections occur during the short course of CAP, however, that treatment can be continued for a longer period. Sometimes, the parent or guardian prefers to continue prophylaxis until the child is mature enough to understand the consequences. Provided these children receive close surveillance and follow both physician recommendations and parental guidance, many begin to consume more water (≥1–2 L/day for young children and 2–4 L/day for teenagers), practice proper bladder and bowel habits, and ultimately become infection free for years or stop developing further infections. For the child who develops UTI despite close surveillance and monitoring, it is important for the physician to reevaluate the child for renal scarring and monitor blood pressure closely for developing hypertension.

Indications for referral to subspecialty services, such as pediatric nephrology or urology, depend on the type of practice, type of insurance coverage, and, more frequently, whether the child has complicated or recurrent UTI without an obvious predisposing factor.

Surgery is not necessary in most infants with VUR, including many with severe disease (grades 4 and 5), because most cases of grade 1 through 3 and some cases of grade 4 and 5 reflux in infants resolve with increasing age. In the child older than 5 years with grade 4 or 5 reflux, the rate of resolution with medical treatment is much lower (approximately 20%–25%). The results of the Randomized Intervention in Children with Vesicoureteral Reflux (RIVUR) study show no difference in the rate of renal scarring between prophylactic medical treatment and surgery. Therefore, surgical reimplantation of the ureter is usually recommended only for those patients with poor adherence to antibiotic prophylaxis or with breakthrough infections, especially if the upper tract is involved. This latter group seems to have benefited the most from surgery. If diagnosis of correctable anatomic genitourinary anomaly, such as ureteropelvic junction obstruction or ureterovesical junction obstruction, is made, however, pediatric urology and nephrology specialists should be consulted.

An alternative to surgical reimplantation is dextranomer microspheres (eg, Deflux), a gel composed of dextranomer and hyaluronic acid that can be injected endoscopically into the ureter. It was approved by the US Food and Drug Administration in September 2001 after having been used extensively throughout Europe with great success.

Prognosis

In most children, UTI is a minor illness with few long-term or serious consequences. However, UTI commonly reoccurs, especially during the first year after the initial UTI. For all children, repeat urine cultures should be obtained during follow-up assessments at the completion of antibiotic treatment to avoid inadequate treatment, because some children may require more than the typically prescribed 10- to 14-day course of antibiotics.

Risk factors for the development of renal scarring and eventual hypertension or, rarely, renal failure, include young age (<1 year), recurrent episodes of acute pyelonephritis, delay in starting effective antibiotic therapy, high-grade VUR, BBD, and neurogenic bladder. Increased vigilance in recognizing UTI and provision of appropriate treatment, including follow-up care, would substantially reduce or even obviate these devastating consequences in children with the particular risk factors. Compared with children age 5 years and older, infants and children younger than 2 years with recurrent UTI and high-grade VUR are more likely to develop calyceal clubbing and renal scarring. Renal scarring following UTI may be mitigated by CAP, especially in children with low-grade VUR. However, despite the findings of the RIVUR study that showed a decrease in the number of recurrent infections using CAP compared to placebo, renal scarring was not prevented at 2-year follow up. Because of this, children with recurrent UTIs should be referred to subspecialty services, either pediatric nephrology or urology, for closer surveillance and management (Box 112.5).

Box 112.5. Indications for Subspecialty Referral of the Pediatric Patient With Urinary Tract Infection

- >2 new febrile urinary tract infections in 6 months or >3 new febrile urinary tract infections in 12 months
- A history of urinary tract anomaly or newly diagnosed urinary tract anomaly (eg, severe hydronephrosis, bilateral vesicoureteral reflux, kidney stone disease)
- Single kidney
- Cystic kidney disease
- Spina bifida or neurogenic bladder of any etiology

CASE RESOLUTION

The girl is hospitalized because of the vomiting. She is started on intravenous ceftriaxone and improves in 48 hours. Inpatient renal ultrasonography is normal, and she is discharged home with oral antibiotics. Because this is her first episode of UTI and because ultrasonography was normal, VCUG is not indicated. No consideration is given to prophylactic antibiotics because of her history and normal results on renal ultrasonography.

PART 10

Orthopedic Disorders

CHAPTER 113

Developmental Dysplasia of the Hip

Kier Maddox Blevins, MD, and Andrew K. Battenberg, MD

CASE STUDY

A 4-month-old girl is seen for her routine health maintenance visit. She is doing well and has no complaints. The results of the entire examination are within normal limits except for limited external rotation and abduction of the left hip, which is approximately 45°, in comparison to that of the right hip, which is almost 90°.

Questions

1. What factors are responsible for normal growth and development of the hip joint?
2. What specific physical maneuvers help in the evaluation of infants with decreased range of motion of the hip?
3. What are the clinical findings of hip dislocation during and after the neonatal period?
4. What are some conditions associated with hip dysplasia that may be noted on physical examination?
5. What is the appropriate diagnostic workup of infants with suspected hip dysplasia?

Developmental dysplasia of the hip (DDH) is a common pediatric orthopedic concern that requires a thorough understanding of normal development, pathoanatomy, natural history, and management. Although historically referred to as "congenital dislocation of the hip," the term was changed because *developmental dysplasia of the hip* defines a spectrum of hip pathology, from congenital dysplasia of the hip, to partial dislocation of the femoral head (ie, hip subluxation), to acetabular dysplasia, to complete dislocation of the femoral head from the true acetabulum. Developmental dysplasia of the hip may exist at birth or manifest during infancy. In a newborn with true congenital dislocation of the hip, the femoral head dislocates into and out of the acetabulum. In an older child, the femoral head remains dislocated, resulting in secondary changes in the femoral head, the acetabulum, and the lateral pelvic wall where the displaced femoral head articulates with it. When DDH is recognized and managed appropriately, the affected child has the potential for normal development. If the diagnosis is missed or delayed, however, the child may suffer significant morbidity, including severe degenerative hip disease.

Epidemiology

The prevalence of DDH is 1% to 7% of all live births. Ethnic variations exist; the incidence in Native American and black individuals is 76 and 0.06 per 1,000 live births, respectively. The literature indicates that pediatricians and orthopedic surgeons diagnose DDH in 8.6 per 1,000 live births and 1.5 in 1,000 live births, respectively. The use of ultrasonography in the evaluation of an infant with suspected DDH has resulted in the diagnosis of DDH in 25 in 1,000 live births. Hip instability in the neonate is estimated to range from 11.5 to 17 per 1,000 live births. Approximately 60% of these cases resolve by 1 week of age, and 90% resolve by 2 months of age. Approximately 60% of infants affected by DDH are firstborn.

Females are affected up to 7 times more frequently than males as result of estrogen-induced ligamentous laxity in utero. The prevalence of DHH is greater in infants with higher birth weights and those who are postmature. Approximately 20% of all DDH occurs in infants born in the breech position. A positive family history of DDH increases the risk by 10%. A female born in the breech position has a 1 in 35 chance of having DDH.

The left hip is involved in 60% of children with DDH and the right hip in 20%, and bilateral involvement occurs in 20% of such children. Developmental dysplasia of the hip has an increased association with lesions of mechanical molding, such as congenital torticollis (approximately 8% of affected children may have DDH), metatarsus adductus (approximately 2%–10% of these children may have DDH), and talipes calcaneovalgus.

Clinical Presentation

The clinical presentation and signs of DDH in children vary with age. In neonates, diagnosis is made primarily by the physical examination (eg, Ortolani maneuver, Barlow maneuver). Classic signs of DDH in older infants are asymmetric skin folds, limitations demonstrated in hip abduction, and a positive *Galeazzi sign*, that is, unequal knee height when the patient is supine with both the hips and the knees flexed. Physical signs, which become more obvious after children are walking, include waddling gait, limping, and toe walking (Box 113.1).

Box 113.1. Diagnosis of Developmental Dysplasia of the Hip

- Breech presentation
- Oligohydramnios
- Female sex
- Positive family history or ethnicity
- Persistent hip asymmetry (eg, asymmetric skin folds, abduction of 1 hip and adduction of the other hip)
- Lower limb deformity (eg, limp, toe walking)
- Torticollis

Pathophysiology

Developmental dysplasia of the hip encompasses a wide variety of conditions ranging from hip instability to dislocation. Normal growth and development of the hip joint is dependent on a genetically determined balance of growth of the acetabular and triradiate cartilages and a well-located and centered femoral head. In a normal hip at birth, a tight articulation exists between the femoral head and acetabulum; however, in DDH or dislocation, this tight articulation is absent. Dysplasia refers to either a hip that is dislocated but can be relocated, or a hip with a positive Ortolani sign (ie, it can be dislocated on provocation). The term *dislocation* refers to any hip with a negative Ortolani sign, that is, the hip is not reducible and is associated with secondary adaptive changes, such as shortening, decreased abduction, and asymmetric skin folds.

Dysplasia of the acetabulum is also associated with hip instability. The dysplastic acetabular cavity is more shallow, with a more vertical inclination angle (Figure 113.1). Although most dislocations occur at or near the time of delivery, this abnormal development of the acetabular cavity helps explain why dislocations can also occur later in infancy. Late hip dislocations are reported in 3% to 8% of affected infants.

The etiology of DDH is poorly defined but is thought to be multifactorial, involving genetic and intrauterine environmental factors. Newborns with a first-degree relative with a history of DDH have a 12-fold increased risk of DDH. The primary intrauterine environmental factors are tight maternal abdominal and uterine musculature; breech presentation, which causes abnormal hip flexion and resulting dislocation of the femoral head; and positioning of the fetal hip against the mother's sacrum, causing increased femoral adduction and resulting in dislocation of the femoral head. In utero mechanical factors relate to molding and restriction of fetal movement. It is believed that the tight, unstretched maternal abdomen and uterine musculature of the primigravida may restrict fetal movement, thereby predisposing firstborn infants to DDH. The increased occurrence of other conditions thought to be secondary to molding (eg, congenital muscular torticollis) with DDH supports this theory of space restriction. Physiologic factors are related to ligamentous laxity and inherent instability of the hip at birth. In utero, a growth rate discrepancy exists between the femoral head and the acetabulum. The femoral head grows more rapidly, and at birth only 50% of the femoral head is covered by the acetabulum. Additionally, diffuse ligamentous laxity exists in the final 4 weeks of gestation in preparation for birth, including laxity of the hip capsule. Female infants may be even more sensitive to maternal hormones, such as estrogen and relaxin, which are thought to be responsible for this generalized physiologic laxity. Environmental factors that may predispose infants to DDH include swaddling with the legs in extension and adduction, which is still practiced in some societies (eg, use of cradleboards by Navajo individuals in North America). Such swaddling was also practiced in Japan until 1975, and after teaching proper swaddling methods, the incidence of DDH decreased fivefold. Other factors include muscle contractures resulting from neuromuscular disease, such as cerebral palsy.

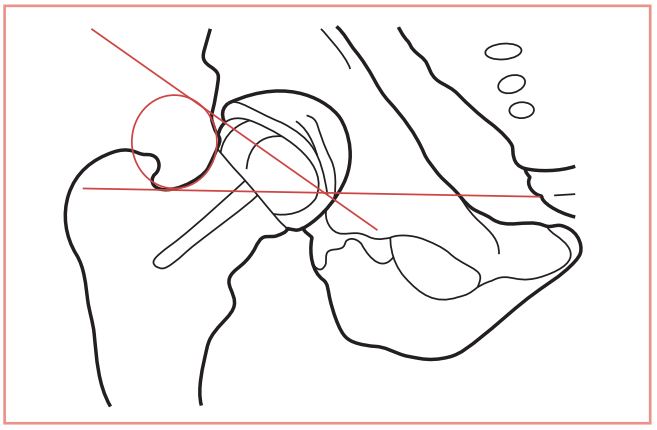

Figure 113.1. Illustration shows the increased inclination angle characteristic of developmental dysplasia of the hip. The more vertical orientation of the acetabulum (compared with normal) results in a less stable hip articulation.

Differential Diagnosis

The differential diagnosis of hip dysplasia depends on the age of the child and the presenting complaint. An infant may have a "click" on abduction of the hip that represents the snapping of a ligament rather than the reduction of the dislocated hip into the joint. An infant with limited abduction may have a neuromuscular disorder, such as spastic diplegia, a form of cerebral palsy that affects the lower extremities. The older child who presents with a gait disturbance, such as limp, waddling gait, or toe walking, may have a neuromuscular condition, fracture, or infection (eg, osteomyelitis, septic arthritis).

Evaluation

History

Family history of DDH should be reviewed, and a careful neonatal history should be obtained, including presentation (eg, breech versus vertex), type of delivery, history of prenatal problems (eg, oligohydramnios), history of neuromuscular disorders (eg, cerebral palsy) and presence of congenital torticollis or metatarsus adductus (Box 113.2).

Box 113.2. What to Ask

Developmental Dysplasia of the Hip

- Was the infant in a breech presentation?
- Does the child have any muscular problems, such as torticollis?
- When did the gait disturbance begin?
- Does anything make the child's gait better or worse?
- Is the child in any pain?
- Did any member of the family have hip dysplasia?

Physical Examination

It is important to evaluate the hip joint for instability or dislocation throughout the first year after birth or until the child begins to walk. It is important to assess the patient for other causes of hip instability as well, because a diagnosis other than DDH may require a different treatment approach and prognosis. For example, a neurologic examination should be performed to assess for spasticity associated with cerebral palsy, a spine examination to assess for torticollis, a cutaneous examination to assess for changes associated with spinal disorders (eg, spina bifida), and a foot examination to assess for conditions such as metatarsus adductus. The Ortolani maneuver and the Barlow maneuver may be used in the neonatal period to evaluate for DDH (Figure 113.2). Both tests are performed with the infant positioned supine and the hips and knees flexed to 90°. The infant should be quiet and relaxed, because both tests require a cooperative child for adequate results.

The Ortolani maneuver, also referred to as the "click of entry," is a diagnostic test used to detect reduction of a dislocated femoral head. To perform the test, the examiner gently abducts the hip and lifts the femoral head anteriorly. A positive sign is a palpable "clunk," felt when a dislocated femoral head is reduced. This "clunk" differs from the audible hip click, which is the result of nonpathologic processes, such as ligamentous snapping. Each leg should be examined separately, not simultaneously.

The Barlow maneuver, also referred to as the "click of exit," is a diagnostic test that is used to identify a dislocatable femoral head in an unstable or dysplastic acetabulum. To perform the maneuver, the hips are adducted, and a posterior force is placed along the longitudinal axis of the femur. Subluxations or dislocations are readily palpable. The Ortolani and Barlow maneuvers are rarely used after 6 to 8 weeks of age because the surrounding soft tissues and muscles adapt to the dislocated hip, making it more difficult to reduce.

If the diagnosis of DDH or dislocation is not made shortly after birth, a different set of physical findings exists, including asymmetry of hip abduction secondary to adductor muscle shortening as well as contracture on the affected side. Limited hip abduction is the most reliable late diagnostic sign of DDH.

As the femoral head dislocates posteriorly, the thigh is shortened on the affected side, producing relative limb shortening and asymmetry of the gluteal, thigh, and labial folds. Asymmetric gluteal folds may result from bunching of skin and subcutaneous tissue on the affected side; however, asymmetric skin folds have not been shown to be uniformly predictive of DDH and assessment for DDH requires further evaluation. The *Galeazzi sign* is noted when the femoral head displaces laterally and proximally, causing apparent shortening of the femur on the affected side. On examination, a positive Galeazzi sign may be observed with discrepancy in knee heights noted when infants are supine, with the sacrum flat on the examination table and the hips and knees flexed (Figure 113.3).

In the child of walking age, the physician may notice a limp because of the relative leg length discrepancy. A child may try to disguise the limp by toe walking. A Trendelenburg test may be positive. Normally, when a child stands on 1 leg, the hip abductors straighten

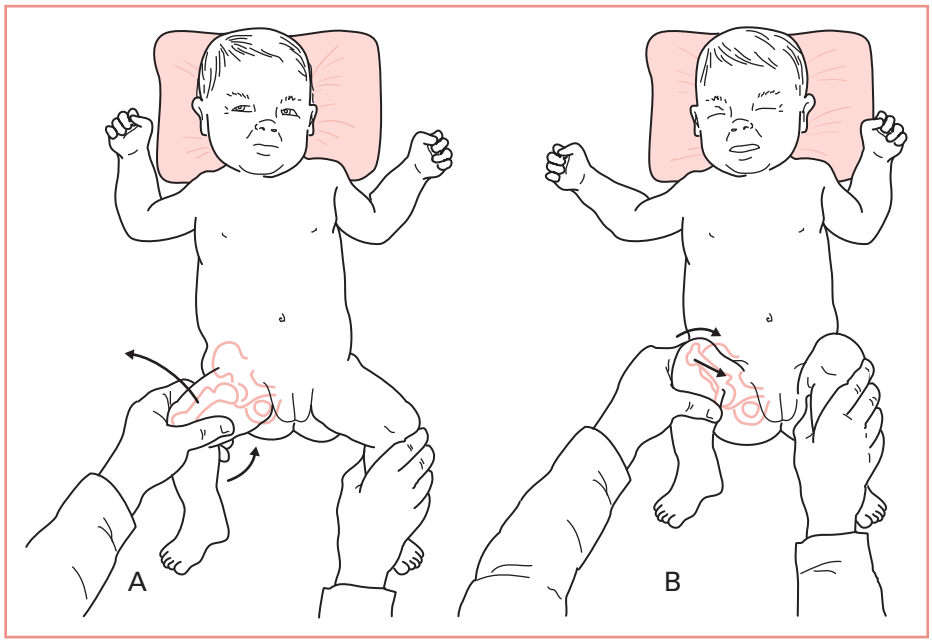

Figure 113.2. Illustration of the Ortolani and Barlow maneuvers. A, Ortolani (reduction) maneuver. B, Barlow (dislocation) maneuver.

the pelvis and keep the center of gravity over the femoral head. If the abductors are weak, the weight shifts to the opposite side, causing it to droop. The gait abnormality classically associated with unilateral hip dislocation in a child of walking age is called the Trendelenburg gait. In contrast, a child with bilateral hip involvement may display hyperlordosis and a waddling gait.

Imaging Studies

Radiologic and ultrasonographic evaluations may aid in the diagnosis. Hip ultrasonography is helpful to confirm the diagnosis and identify more subtle forms of the disorder. In some European countries, ultrasonography is used as a primary screening modality; however, in the United States the recommendation is to restrict its use to the high-risk infant (ie, female born breech) or an infant with a click that has not resolved after 2 weeks of observation. Dynamic ultrasonography is the only diagnostic test that allows real-time evaluation and a 3-dimensional view of the neonate's hip as it is being manipulated. Reliable radiographic changes begin to become evident by 4 to 6 months of age when the ossific nucleus of the femoral head appears in most infants (Figure 113.4). A flat, shallow acetabulum and delayed ossification of the femoral head are the simplest and most easily recognizable findings. Ultrasonography is primarily used before 6 months of age and radiography at age 6 months and older because 80% of infants have adequate femoral head ossification after 6 months of age. It is recommended that dynamic ultrasonography be used only during the initial and final evaluations, because interobserver differences may result in unnecessary or potentially harmful changes in treatment.

Classification

A primary means of classifying dysplasia of the hip is the Graf classification system, which combines many factors, including age as well as the cartilaginous/boney roof and rim angles of the

Figure 113.4. Illustration of radiographic findings associated with developmental dysplasia of the hip. The left hip is dislocated. The femur is lateral and proximal, the acetabulum is shallow and flat, and the absence of the ossific nucleus on the left is evidence of delayed ossification of the femoral head.

acetabulum and femoral head by ultrasonography measurements to establish the level of dysplasia present in infants. Another of the most commonly used classification systems for severity of persistent DDH into adulthood was developed by Crowe in the late 1970s. The Crowe classification assumes that the ratio of femoral head diameter to pelvic height is 1:5 (Table 113.1). Using this assumption, any proximal migration of the femoral head can be noted based on its relationship to 3 major landmarks identified on an AP radiograph of the pelvis: inferior margin of the acetabulum (ie, teardrop),

Table 113.1. Crowe Classification of Developmental Dysplasia of the Hip in Adults

Group	*Description*
I	Subluxation <50% or proximal dislocation <0.1% of the pelvic height
II	Subluxation 50%–75% or proximal dislocation of 0.1%–0.15% of pelvic height
III	Subluxation 75%–100% or proximal dislocation of 0.15%–0.20% of pelvic height
IV	Subluxation >100% or proximal dislocation of >0.20% of pelvic height

Reprinted with permission from Jawad MU, Scully SP. In brief: Crowe's classification. Arthroplasty in developmental dysplasia of the hip. *Clin Orthop Relat Res*. 2011;469(1):306–308.

pelvic height (ie, distance from iliac crest to ischial tuberosity); and the medial head-neck junction (ie, distance from the head-neck junction to the teardrop). The amount of migration of the femoral head is directly related to the severity of the hip dysplasia, and this amount guides both prognosis and management.

Management

The need for repeat examinations of the hips during the first year after birth cannot be overemphasized. The children with any suspected hip instability or any child with less than 60° of hip abduction should be evaluated with appropriate imaging studies and referred to an orthopedic surgeon for further evaluation. An orthopedic surgeon can aid the primary care physician in the diagnosis and management of DDH. The identification of newborns who truly require intervention is currently under debate, because only 20% of newborns with some form of hip instability require intervention and the remainder spontaneously resolve by 2 months of age.

The goal of management is to return the femoral head to its normal position within the acetabulum and restore normal hip functioning. The common practice of triple diapering should be discouraged because it is unreliable, often delays definitive therapy, and may produce complications, such as osteonecrosis of the femoral head.

The management of DDH is divided into 5 different treatment groups (Box 113.3).

The Pavlik harness is the primary method of managing DDH during infancy. This device has become the clear method of choice for treatment of infants with DDH and is accepted as the standard of treatment worldwide. The *Pavlik harness* consists of a chest strap, shoulder straps, and anterior and posterior stirrup straps that maintain the hips in flexion and abduction while restricting extension and adduction (Figure 113.5). Used properly, the harness holds the hips in a flexed and abducted position while allowing infants to move their legs within safe limits of abduction and adduction until stability is achieved. In the newborn with DDH, the harness should be worn for 23 hours a day until the clinical and radiographic examinations are normal. The harness must be worn for a minimum of 3 months by children 3 months and younger, whereas children 4 months or older usually wear the harness for a period of double their age. A newborn with a diagnosis of true dislocation must wear the harness full time until the dislocatable hip has stabilized in the acetabulum.

The harness should be applied and monitored by an orthopedic surgeon, because inappropriate application may result in adverse outcomes, such as inferior dislocation and, the most serious, osteonecrosis of the femoral head. Parents and guardians play a key role in the successful use of the harness and must be educated on the disease process and the proper use of the harness. Overall, the Pavlik harness has an 85% to 95% success rate; however, it loses efficacy as the child ages because of soft tissue contractures that manifest in previously untreated individuals.

If this treatment method is ineffective or if the diagnosis is not made until after 6 months of age, traction followed by either open or closed reduction and spica cast immobilization may be used. Closed reduction should immediately follow failure of any conservative bracing or treatment method, because good results are more difficult to obtain with increasing age, especially after a child is walking. As children age, chronic dislocation results in more permanent pathologic changes to femoral, acetabular, and soft tissue anatomy. A failure rate of approximately 10% has been reported after closed reduction, and by 2 to 3 years of age nearly 25% of patients may

Box 113.3. The Five Treatment Groups for Developmental Dysplasia of the Hip

1. Newborn to 6 months
2. Infant (6–18 months)
3. Toddler (18–36 months)
4. Child and juvenile (3–8 years)
5. Adolescent to young adult (>8 years)

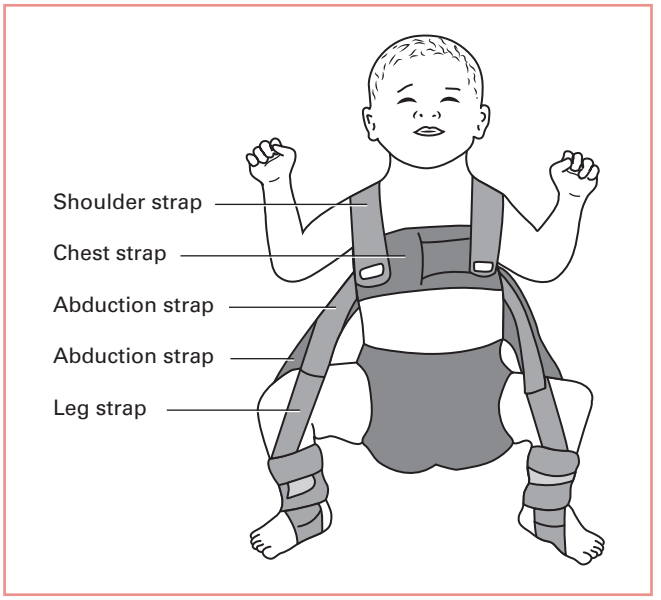

Figure 113.5. Illustration of the Pavlik harness.

develop the severe complication of osteonecrosis; thus, it is critically important to observe these children carefully for an extended period of time postoperatively. Surgical treatment is required in children older than 18 months to safely reduce the dislocated hip and to surgically re-create normal anatomy. These procedures include femoral shortening, acetabuloplasty to correct acetabular dysplasia, and *capsulorrhaphy* (ie, suturing the joint capsule).

Prognosis

The prognosis of DDH depends on age at the time of diagnosis and severity of the deformity. In children, the long-term prognosis for satisfactory hip function is good when DDH is recognized early and managed appropriately. Generally, children with DDH that is diagnosed after age 1 year have a poorer prognosis for satisfactory hip function than those with DDH that is diagnosed during infancy. The prognosis of untreated DDH differs based on the type of DDH. Generally, a patient with unilateral dislocation will have a worse prognosis than a patient with bilateral dislocation because of the associated limb-length discrepancy, asymmetric motion and strength, gait abnormalities, and subsequent degeneration of the ipsilateral knee. Although this belief is controversial, it is generally accepted that patients with chronic subluxation have the worst prognosis because of femoral point loading in the subluxated hip; this point loading results in early arthritis. Regardless of a patient's position along the spectrum of DDH, left untreated, the patient will experience disability ranging from limp to pain and stiffness of the hip as well as early onset degenerative joint disease in adult life.

CASE RESOLUTION

The infant has less than 60° of abduction of the left hip, which is a sign of DDH. An anteroposterior radiograph of the pelvis may be ordered to confirm the diagnosis. Regardless of the radiographic findings, the infant should be referred to an orthopedic surgeon for further evaluation and treatment. If hip dislocation is confirmed, the initial treatment will involve bracing with a Pavlik harness.

CHAPTER 114

In-toeing and Out-toeing: Rotational Problems of the Lower Extremity

Kier Maddox Blevins, MD, and Andrew K. Battenberg, MD

CASE STUDY

A 3-year-old girl is brought to the office. Her mother is concerned because beginning a few months prior to this visit her daughter's feet appeared to "turn in" when she walked. The girl has never walked like this before, and she has no history of trauma, fever, pain, or swelling in the joints. The physical examination is within normal limits except for the in-toeing gait.

Questions

1. How can observation of a child's gait help determine the etiology of in-toeing and out-toeing (ie, rotational problems)?
2. What are the common causes of in-toeing and out-toeing?
3. Does evaluation of in-toeing and out-toeing require any laboratory or radiologic studies?
4. What is the natural history of most rotational problems?

Benign rotational variations of the lower extremities, such as in-toeing and out-toeing, occur in many healthy children. Although rotational problems that produce in-toeing and out-toeing may initially be physically alarming, spontaneous resolution occurs in most cases. Such problems are a common cause of parental or caregiver concern during infancy and childhood, but they rarely result in physical limitation. Most of these children can be managed adequately by primary care physicians and do not need orthopedic referral. A thorough understanding of the normal rotational variations that occur in children younger than 10 years of age is essential to proper treatment as well as patient and parent or caregiver education. More importantly, a general understanding is imperative to identify more serious underlying structural problems.

Specific terminology is used to describe limb positioning. *Version* is normal variation in limb rotation, whereas *torsion* refers to abnormal conditions (ie, >2 standard deviations above or below the mean). *Adduction* is movement toward the midline, whereas *abduction* is movement away from the midline. *Varus angulation* is deviation toward the midline, whereas *valgus angulation* is deviation away from the midline. An *inverted foot* is one turned toward the midline on its long axis. An *everted foot* is one turned away from the midline on its long axis.

Epidemiology

In neonates or young infants, in-toeing is most likely the result of clubfoot (ie, talipes equinovarus), isolated metatarsus adductus, or metatarsus primus varus. The prevalence of clubfoot is 1 in 1,000 live births, with a male to female ratio of 2:1. The condition is bilateral in approximately 50% of patients. Metatarsus adductus, which is much more common than clubfoot, occurs in approximately 1 in 500 live births. It is often bilateral. Internal tibial torsion is the primary cause of in-toeing in the second year after birth, and femoral torsion accounts for most cases of this condition during early childhood.

Physiologic out-toeing is classically evident in infants who have not yet begun to walk and is the most common cause of bilateral out-toeing. In older infants and children, however, lateral tibial torsion is believed to be the most common cause of out-toeing.

Clinical Presentation

Children with congenital clubfoot, metatarsus adductus, and metatarsus primus varus present with in-toeing during infancy. Typically, congenital clubfoot is evident at birth. A severe medial, midline, plantar crease is present, and the foot appears C-shaped, with both the heel and forefront turned inward (Figure 114.1). The affected foot

Figure 114.1. Congenital clubfoot.

is small, wide, and stiff, and the lower leg appears small because of hypoplasia of the calf muscles. In contrast to clubfoot, in metatarsus adductus and varus only the forefoot turns inward.

Tibial torsion is apparent during the second year after birth. In affected children, the feet turn inward during ambulation, but the knees are straight because the deformity is distal to the knee. Medial femoral torsion is evident at 3 to 4 years of age and usually affects girls. Affected children can sit in the "W" position with both legs behind them. As these children walk, both the knees and the feet appear to turn inward because the deformity is proximal to the knee.

Physiologic out-toeing is seen in infancy. Classically, parents or caregivers note that when they hold their child in a standing position, both feet turn outward. Approximately 5° of out-toeing is normal after age 3 years. Further degrees of out-toeing may be the result of lateral tibial torsion.

Pathophysiology

Several factors are involved in the etiology of rotational conditions. Most of these deformations are caused by intrauterine positioning. Genetics are also believed to play a role in the development of rotational problems, because parents may often have the same rotational deformity as their children. Other contributing factors include bony and neuromuscular abnormalities in clubfoot and certain sleeping and sitting positions in metatarsus adductus and medial tibial torsion. For example, sleeping in the prone position with the legs internally rotated may worsen internal tibial torsion or metatarsus adductus.

During the early intrauterine period, internal rotation of the lower extremity brings the big toe to the midline. During the later intrauterine period, infancy, and childhood, however, external rotation predominates. Alterations in this normal lateral process are caused by genetic and environmental factors, including intrauterine molding and sleep positions. Conditions influenced by intrauterine position, such as metatarsus adductus and developmental dysplasia of the hip, sometimes occur in the same child. Additionally, children with rotational deformity should undergo careful screening for other anomalies associated with intrauterine positioning as well, such as torticollis.

Typically, congenital clubfoot is an isolated birth defect and is considered idiopathic. Two major etiologies have been proposed: (1) a germline defect in the talus results in abnormal bony development, resulting in plantar flexion, inversion, soft tissue contractures, and hypoplasia of the calf muscles and the bones of the foot and (2) clubfoot represents the final common pathway of disruption anywhere along the neuromuscular unit, including the central nervous system, peripheral nerves, and muscles. Additionally, genetics are believed to play a major role because 25% of all cases are familial and there is 33% concordance of identical twins. Environmental factors, including intrauterine position and molding, are also thought to contribute.

In-toeing is usually caused by benign conditions, such as metatarsus adductus, excessive internal tibial torsion, and excessive femoral torsion. Less frequently, patients have pathologic conditions such as clubfoot, skewfoot, hip disorders, and neuromuscular diseases. Typically, out-toeing is caused by external rotation contracture of the hip, external tibial torsion, or external femoral torsion.

Conditions Associated With Rotational Variations in Children

In-toeing

Metatarsus Adductus, Metatarsus Primus Varus, and Skewfoot

Metatarsus adductus, with or without internal tibial torsion, is the most common cause of in-toeing from birth to 1 year of age. It is a functional deformity in which the forefoot is adducted with respect to the hindfoot with a neutral or slightly valgus heel. It is the most common pediatric foot problem referred to orthopedic surgeons and occurs in 1 in 500 live births and in 1 in 20 siblings of patients with metatarsus adductus. The rate is higher in males than females, twin births than singleton births, and preterm babies than term infants. Numerous theories exist as to the cause of metatarsus adductus, including in utero positioning, sleeping position of the baby, muscle imbalance, and medial cuneiform abnormality.

Presenting symptoms include cosmesis, in-toeing gait, and excessive shoe wear. On physical examination, the foot appears C-shaped with a concave medial border and convex lateral border. The forefoot can be brought into the neutral position either by stroking the lateral border of the foot or by gently straightening it. Metatarsus adductus can be classified as flexible or inflexible based on physical examination. Flexible metatarsus adductus typically resolves spontaneously and does not require splinting, bracing, or special shoes. However, the patient with rigid metatarsus adductus should undergo early casting; surgery is rarely necessary, and then only to manage resistant cases.

Congenital *metatarsus primus varus* is a bony abnormality that is characterized by an isolated adducted first metatarsal. Unlike flexible metatarsus adductus, metatarsus primus varus is a fixed deformity.

The foot cannot be brought into the neutral position, and a deep vertical skin crease is evident along the medial border of the tarsometatarsal joints. Because it is a more rigid deformity, early casting is recommended; surgery is necessary to address persistent deformity.

Skewfoot, also known as *serpentine metatarsus adductus,* is characterized by adducted metatarsals combined with a valgus deformity of the heel and plantar flexion of the talus. It is theorized that improper casting of metatarsus adductus or clubfoot may result in a skewfoot; however, most cases are idiopathic. Patients present with pain or callus formation under the head of the talus and base of the fifth metatarsal. Some feet undergo spontaneous correction, but surgery is indicated for the persistently symptomatic foot.

Dynamic Abductor Hallucis

Dynamic abductor hallucis (ie, searching toe), also known as "wandering toe" or "atavistic toe," can cause in-toeing. Children with a searching toe have a big toe that points medially when they walk. Unlike the other causes of in-toeing, which are structural and present at rest, this condition is a dynamic deformity. Searching toe results from the contraction of the abductors of the big toe during the stance phase of gait, which pulls the toe toward the midline. Typically, it resolves with age and subsequent development of fine motor coordination.

Clubfoot

Congenital clubfoot is a pathologic deformity of the foot that may be identified at birth (Figure 114.1). Clubfoot may be an isolated deformity or may occur in association with other neuromuscular anomalies, such as arthrogryposis, myelomeningocele, amniotic band syndrome, cerebral palsy, and poliomyelitis.

The diagnosis of congenital clubfoot is made at birth based on 3 conditions: forefoot varus, heel varus, and ankle equinus. Clubfoot can range in severity from a rigid deformity, in which the forefoot cannot be passively abducted into a neutral position, to nonrigid deformities, in which the forefoot can be gently brought toward the midline. Normal dorsiflexion of the ankle helps distinguish severe forms of metatarsus varus from clubfoot.

Internal Tibial Torsion

Internal tibial torsion is the most common cause of in-toeing from ages 1 to 3 years, is thought to be caused by intrauterine positioning, and is usually first noticed by parents or caregivers when their child begins to walk. Parents or caregivers often report that the child is clumsy and trips frequently. Internal tibial torsion is bilateral in two-thirds of affected children; when unilateral, the left leg is most commonly affected. Observation of gait reveals that the knees point forward but the feet turn inward. Because the knees are straight, the site of the rotational deformity lies below this joint. If the feet are normal and no metatarsus adductus or varus is present, the rotational deformity can be isolated to the lower leg. It is important to measure the thigh-foot axis and transmalleolar axis in the physical examination. Expectant observation is recommended, because the natural history of internal tibial torsion strongly favors spontaneous resolution by 4 years of age.

Internal Femoral Torsion

Internal femoral torsion is the most common cause of in-toeing in children, presenting between 3 and 6 years of age; it tends to occur in females and is usually bilateral. Typically, a child is brought to a pediatrician for evaluation after a parent or caregiver notices worsening in-toeing in a child with no history of in-toeing. Although excessive medial femoral torsion may be present at birth, it is often masked by the external rotatory forces present during infancy. Children with excessive internal femoral torsion characteristically sit with their legs in the "W" position and run with an eggbeater-type motion. Although no association has been shown between internal femoral torsion and degenerative joint disease, some studies suggest an increased association between internal femoral torsion and knee pain. This knee pain is referred to as "miserable malalignment syndrome," which results from a combination of internal femoral torsion and external tibial torsion. No treatment is necessary for most cases of femoral torsion, which usually resolves by 8 years of age.

Out-toeing

Physiologic Out-toeing

Out-toeing of infancy, which most commonly occurs in children who are just learning to walk, is caused by intrauterine positioning that results in external rotatory contractures of the soft tissues surrounding the hip. This condition may be perpetuated in children who sleep in the prone, frog-leg position, which holds the hips in external rotation and prevents normal stretching of the external rotators of the hip. Although both feet turn outward when the infant stands, the lateral rotation of both hips is normal on examination (Figure 114.2). More serious conditions, such as slipped capital femoral epiphysis, hip dysplasia, or coxa vara, are less common but should be considered.

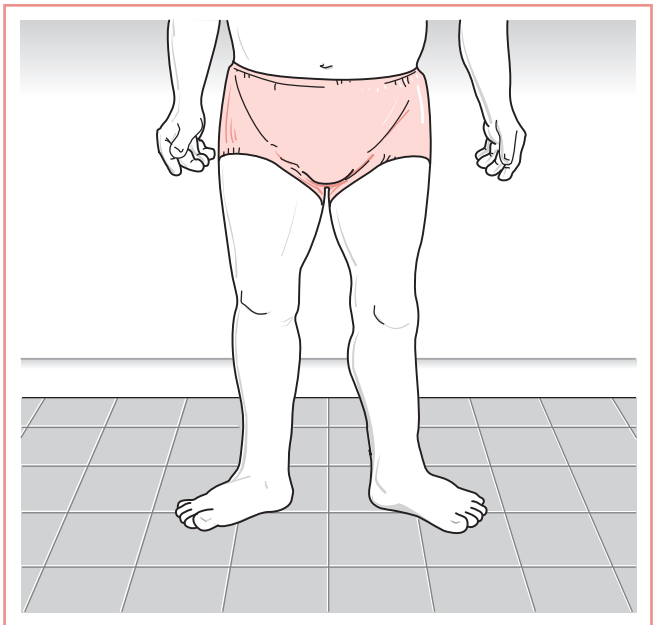

Figure 114.2. Physiologic out-toeing of infancy.

External Tibial Torsion

This condition may be suspected in children 3 to 5 years of age, but detection often is delayed until late childhood or adolescence. External tibial torsion tends to be unilateral, most often affects the right side, and generally worsens over time. Increased external tibial torsion often is associated with neuromuscular conditions, such as myelodysplasia and poliomyelitis. As the condition progresses, patients can develop disability and pain in the form of patellofemoral pain and instability. Some studies have even shown an association between external tibial torsion and degenerative joint disease of the knee.

Adolescent Hallux Valgus

Hallux valgus is well-described in the adult population but is beginning to be seen more often in the adolescent population. It is far more common in females than males, and studies have shown that up to 75% of affected patients have an affected mother. Adolescent hallux valgus is thought to be the result of a triad of deformities: abnormal bone growth, or exostosis, over the medial side of the first metatarsal head; valgus deformity of the hallux; and associated metatarsus primus varus. The etiologic factors for development of this deformity are similar to those for adults. The main contributing intrinsic factor is increased ligamentous laxity of the foot. The most common extrinsic factor is improper shoe wear. It has long been accepted that shoes with a narrow toe box, especially shoes with high heels, are strongly associated with hallux valgus. Other extrinsic factors commonly associated with hallux valgus are neuromuscular disorders, such as cerebral palsy.

The most common presenting symptom is pain over the medial aspect of the great toe metatarsal head. This is usually the result of pressure and chronic friction over the area. This pain can result in gait abnormalities and limit the patient's ability to participate in regular activity.

Differential Diagnosis

In-toeing and out-toeing may be classified according to anatomic level and usual age at presentation (Table 114.1). These conditions may be localized to 1 of 5 areas: toe, foot, tibia, femur, and hip. If in-toeing problems are placed in chronologic order by age of presentation, the affected area follows a toe-to-femur sequence.

Table 114.1. Site and Age of Onset of Rotational Problems of the Lower Extremity in Children

Rotational Variation	*Condition*	*Anatomic Site*	*Age of Onset*
In-toeing	Searching toe	Toe	Infancy
	Clubfoot	Foot	Birth
	Metatarsus adductus	Foot	Birth/infancy
	Metatarsus primus varus	Foot	Birth/infancy
	Medial tibial torsion	Tibia	Toddler stage (12–24 months)
	Medial femoral torsion	Femur	Early childhood (3–5 years)
Out-toeing	Physiologic out-toeing	Hips	Infancy
	Lateral tibial torsion	Tibia	Childhood

Evaluation

History

The clinical history must delineate the onset, duration, and progression of any structural problems. The typical natural history of benign rotational conditions is one of improvement over time, whereas a more serious condition is marked by a more progressive deformity. Relevant family and birth history, including gestational age, length of labor, complications, Apgar scores, birth weight, and length of hospital stay, should be noted. These details may heighten suspicion for cerebral palsy or the presence of hereditary disorders, such as vitamin D-resistant rickets, mucopolysaccharidoses, achondroplasia, epiphyseal dysplasia, or metaphyseal dysplasia that may affect rotational profiles. A thorough developmental history is important, because developmental delays may be a sign of underlying neuromuscular or neurologic disorders (Box 114.1). It is also important to determine whether the rotational problems cause marked functional impairment in the patient; this includes problems with tripping or pain difficulties with shoe wear.

Physical Examination

Normal variability in the lower extremities of young children must be differentiated from more serious structural problems. A detailed physical examination, including assessment of gait and neurologic and musculoskeletal function, is essential for making the correct diagnosis. This evaluation should include examination of the hips for signs of hip dysplasia, which may be associated with metatarsus adductus (see Chapter 113). Observation of the child's stature and leg-to-body ratio is also useful because short stature or disproportionate leg-to-body ratio may suggest a skeletal dysplasia.

Evaluation of postural conditions requires both static and dynamic physical examination. Static examination includes an overall evaluation of the patient and a rotational profile. The child's rotational profile, as described by Staheli, consists of

Box 114.1. What to Ask

In-toeing and Out-toeing

- Is there a family history of in-toeing or out-toeing?
- What is the birth history? Was the child a breech presentation?
- At what age did the child begin walking?
- When did the rotational deformity appear? Is it getting better or worse?
- Does the rotational problem produce any disability (eg, tripping or falling a great deal when walking or running)?
- Has any previous treatment been tried?
- In what position does the child sleep? In what position does the child sit?

5 components: internal and external hip rotation, thigh-foot axis, transmalleolar axis, heel-bisector angle, and foot progression angle during gait (Figure 114.3 and Figure 114.4).

Hip rotation in infants averages 40° of internal rotation and 70° of external rotation. By 10 years of age, internal hip rotation averages 50° and external hip rotation averages 45°. Internal rotation of between 70° and 90° is evidence of femoral torsion.

The *thigh-foot axis* consists of the rotation of the tibia and hindfoot in relation to the longitudinal axis of the thigh and indicates the degree of tibial torsion. In infants, the thigh-foot angle averages

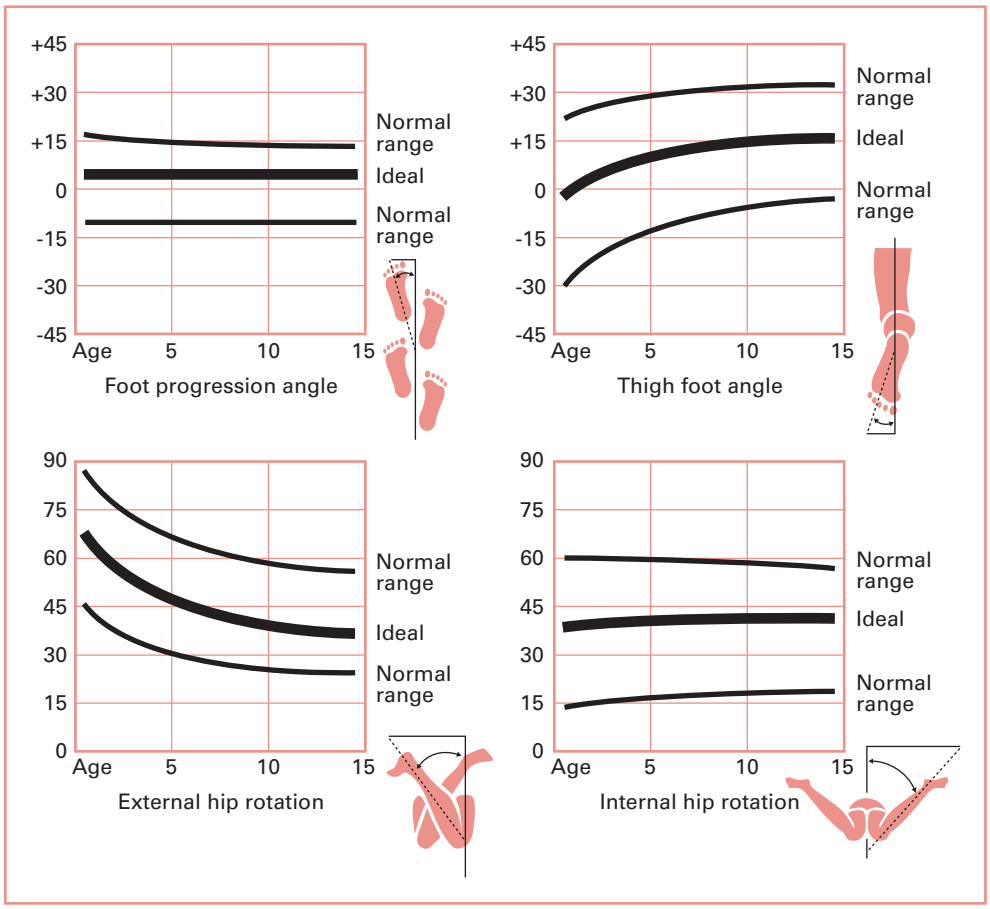

Figure 114.3. Three components of the rotational profile: foot progression angle during gait, thigh-foot angle, and external and internal hip rotation. The values along the y axis represent degrees and those on the x axis represent age in years.

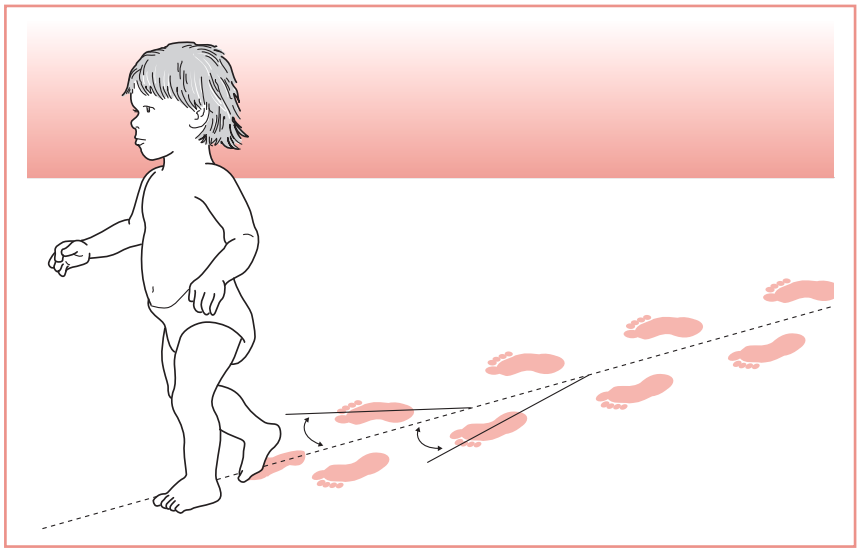

Figure 114.4. Evaluation of foot progression angle while walking.

5° internal (range: −30° to +20°). Excessive internal tibial torsion spontaneously resolves by 3 to 4 years of age, and by 8 years of age the thigh-foot axis averages 10° of external rotation.

The transmalleolar axis also aids in determining the amount of tibial torsion. It is formed by the angle at the intersection of an imaginary line from the lateral to medial malleolus and a second line from the lateral to medial femoral condyles. At gestational age 5 months, the fetus has an average of 20° of internal tibial torsion. During development, the tibia externally rotates to an average final adult position of 23° of external rotation.

The heel-bisector method is used in examination of the foot. The *heel-bisector line* is a line drawn through the midline axis of the hindfoot and forefoot. In the neutral foot, the heel-bisector line passes through the second web space.

The *foot progression angle during gait* is the angle of the foot relative to an imaginary straight line in the patient's path (Figure 114.4). Patients who in-toe are assigned a negative value, and patients who out-toe are assigned a positive value. This value represents the sum total effect of the child's structural alignment and dynamic torsion forces resulting from muscle forces.

The examination of the infant with clubfoot should include a careful examination of the back for signs of possible spinal dysraphism (eg, skin dimples and hairy patches) as well as a thorough neurologic examination.

To diagnose internal tibial torsion, the child sits at the end of the examination table with both knees flexed to 90° and the physician palpates the medial and lateral malleoli with the thumb and index finger. Normally, the medial malleolus lies anterior to the lateral malleolus (approximately 1 fingerbreadth). If the lateral malleolus is on the same plane or anterior to the medial malleolus, internal tibial torsion is indicated.

Alternatively, the diagnosis of tibial torsion can be made by measuring the thigh-foot angle (Figure 114.5). To measure the thigh-foot angle, with the child lying prone on the examination table the physician observes the relationship of the long axis of the foot compared with the axis of the thigh as viewed from above. The shape of the foot itself can also be assessed with the child in this position. Slight internal rotation is normal as children first learn to walk.

Diagnosis of medial femoral torsion can be made by observing the child's gait and measuring hip rotation. For example, when a child with medial femoral torsion ambulates, the knees and feet appear to turn inward. Internal and external hip rotation are evaluated with the child in a prone position, the pelvis flat, and the knees flexed to 90° (Figure 114.6). The degrees of normal rotation vary with age (Figure 114.3). During childhood, internal hip rotation greater than 70° is indicative of medial femoral torsion.

Imaging Studies

Routine imaging studies are not necessary for diagnosing rotational deformities. Imaging studies may be considered by the orthopedic surgeon to evaluate severe deformities in cases in which surgical correction is being considered. In the patient with clubfoot, radiography is used to assess the relationship between and development of the bones as well as to monitor cast correction.

Management

In-toeing

Metatarsus adductus generally resolves spontaneously, but stretching exercises for the foot may be advisable, particularly if the parent or guardian is anxious to "do something." Parents are instructed to manipulate the foot with each diaper change. This practice, however,

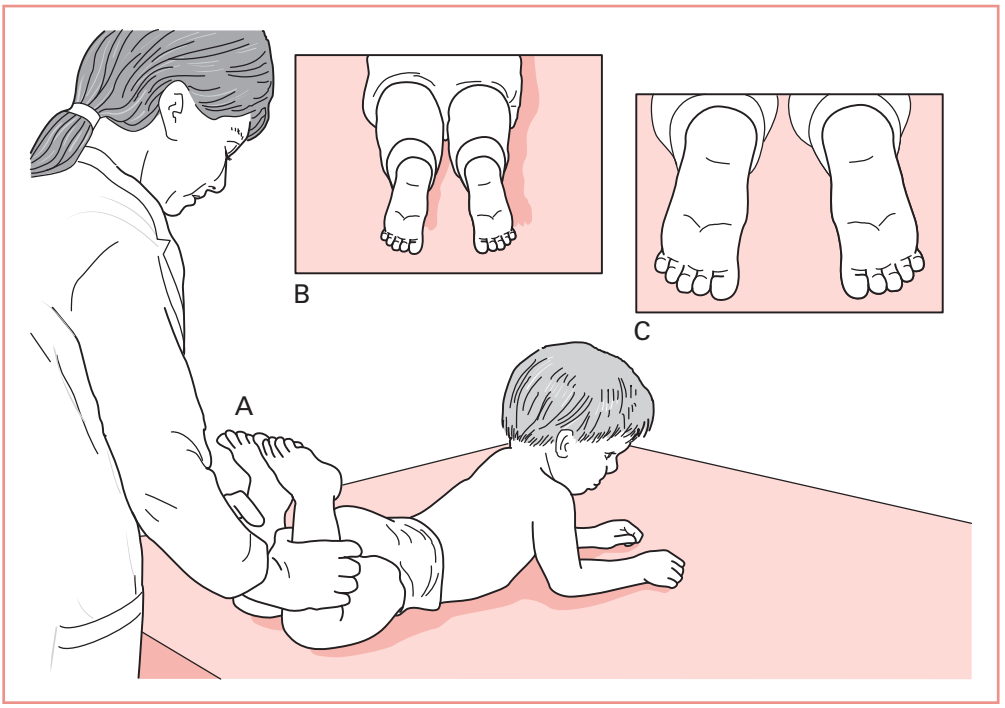

Figure 114.5. Evaluation of the thigh-foot axis. A, Observation with the child in the prone position is best. B, Determination of the thigh-foot axis. C, Assessment of the shape of the foot.

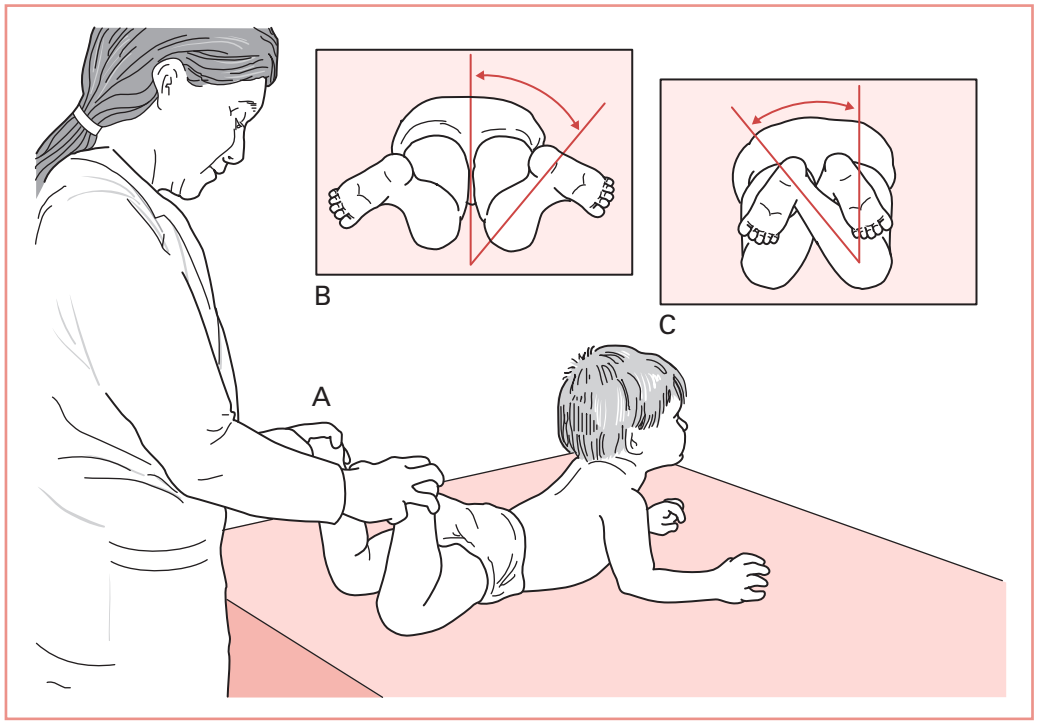

Figure 114.6. Evaluation of hip rotation. A, The child is prone, and the knees are flexed to 90°. B, Medial rotation is measured. C, Lateral rotation is measured.

should be used with discretion, because recent evidence has shown no benefit with stretching exercises when compared with no parental or caregiver intervention. Because most cases resolve within the first 3 months after birth, referral to an orthopedic surgeon should be made if the deformity persists at 3 to 4 months of age. Cast correction may be required for rigid deformities or deformities that persist beyond 3 to 4 months. Shoe modifications (eg, putting shoes on the wrong foot) should be avoided, because they have not been shown to have any long-term benefits.

Because metatarsus varus may progress when a child begins walking, referral to an orthopedic surgeon should be made as soon as the condition is detected. Serial casting followed by corrective shoes or inserts is the first line of treatment, and surgery is rarely required. Treatment for medial tibial torsion is rarely required, because this problem generally corrects with time when a child learns to walk. Night splinting, although still occasionally instituted, has not been shown to affect the natural history of this condition. If the deformity is severe, persists without improvement beyond the age of 18 months, or persists after the child has been walking for 1 year, the child should be referred to an orthopedic surgeon. Surgical correction (eg, tibial rotational osteotomy) may be required if the deformity is severe or persists beyond 8 to 10 years of age.

As with other conditions that produce in-toeing, medial femoral torsion generally does not require treatment. Even if it persists into adulthood, it usually produces no disability, nor does it increase the risk for degenerative arthritis in the involved joint. Nonsurgical treatment is ineffective. Surgical correction may be required for the patient with a history of repeated falls, severe gait problems, marked cosmetic deformity, anterior anteversion greater than 50°, or internal hip rotation greater than 80°. Derotational femoral osteotomy is the only effective method of treatment. However, it should not be performed until the child is at least 8 to 10 years of age.

Clubfoot, unlike other problems, is a pathologic deformity that requires treatment. Treatment should begin during the first week after birth and consists of serial manipulations of the foot and casting. Several months of casting may be required to attain full correction. Surgery is often required for resistant or recurrent cases. As many as 50% to 75% of patients with clubfoot may eventually require surgery. Surgery is usually delayed until an infant is 6 to 12 months of age.

Out-toeing

Physiologic out-toeing of infancy is a rotational problem that spontaneously resolves when a child learns to walk. Most cases resolve by 18 months of age. Severe lateral tibial torsion may require surgical correction with tibial derotational osteotomy.

In hallux valgus, the main concern often is cosmesis. Encouraging proper shoe wear or use of orthoses will result in improvement in the deformity; however, it can be difficult for adolescents to adhere to these recommendations. If nonsurgical treatment is unsuccessful or the patient is noncompliant, the patient should be referred to an orthopedic surgeon to discuss surgical correction.

Prognosis

Because the lower extremity rotates laterally with growth, the natural history of internal rotational problems, such as internal tibial torsion and medial femoral torsion, is one of resolution with time. In contrast, lateral tibial torsion may become worse with time.

The prognosis is excellent for most rotational problems. Parental or caregiver reassurance and education about the natural history of

these deformities may decrease anxiety and prevent unnecessary visits to specialists. Functional disability or degenerative arthritis is not commonly associated with persistence of these conditions.

Left untreated, clubfoot often results in considerable pain and disability. The affected foot can be difficult to fit with shoes. Additionally, clubfoot can be unsightly and cause children significant emotional distress.

CASE RESOLUTION

The girl seems to have medial femoral torsion because she has no history of rotational problems. Her entire leg turns in when she walks. Internal hip rotation greater than 70° confirms the diagnosis. The mother can be reassured that this is a normal, age-related phenomenon that most likely will resolve in time. The child can be reevaluated in 4 to 6 months. Orthopedic referral is not required at this time.

CHAPTER 115

Angular Deformities of the Lower Extremity: Bowlegs and Knock-Knees

Kier Maddox Blevins, MD; Andrew K. Battenberg, MD; and Carol D. Berkowitz, MD, FAAP

CASE STUDY

During the routine health maintenance examination of a 2-year-old boy, you observe moderate to severe bilateral bowing of both legs. The child's mother reports that her son began walking at 10 months. She has not noticed problems with his gait and says he does not trip or fall excessively. On examination, the boy's weight is greater than the 95th percentile for age, but otherwise he appears to be a healthy black child.

Questions

1. What types of angular deformity affect the lower extremities in children?
2. How does age help determine whether a child has a physiologic or pathologic angular deformity?
3. What clinical measurements can help distinguish physiologic from pathologic angular deformities?
4. To what extent are radiographs used in the routine assessment of angular deformities?

With normal growth and development, the angular alignment of children's legs progresses through a series of developmental stages, from relative bowlegs to knock-knees and eventually straight legs. Rotational problems, such as in-toeing and out-toeing, are deformities in the transverse plane that occur when a bone rotates internally or externally, respectively, along its long axis (Figure 115.1). Angular deformities, such as bowlegs and knock-knees, are deformities in the frontal plane. In *bowleg deformity* (ie, *genu varum*), the lower extremity distal to the knee joint is angled or tilted toward the midline of the body (tibial varus). In contrast, in *knock-knee deformity* (ie, *genu valgum*), the lower extremity distal to the knee is tilted away from the midline of the body (Figure 115.2). Variations in the knee angle that fall outside the normal range (eg, more than ±2 standard deviations of the mean) are referred to as genu varum for bowlegs and genu valgum for knock-knees (Box 115.1). Appreciation of the normal developmental sequence in conjunction with a careful history and physical examination can help pediatricians identify pathologic cases of bowlegs and knock-knees and initiate prompt management.

Epidemiology

Bowlegs and knock-knees are common in infants and children. Although all babies are born bowlegged, parents and guardians usually do not appreciate this finding until infants begin to walk. Knock-knees occur less frequently than bowlegs, occur more often in females than males, and are commonly associated with generalized ligamentous laxity. Although the frequency of these conditions is generally unknown, a study of more than 3,000 children aged 7 through 11 years found a prevalence of 7.9% for bowlegs and 2% for knock-knees. Other literature has shown that males are up to 4 times more likely than females to have bowlegs, whereas females were 3 times as likely to have knock-knees. Weight has also been shown to be an important associated factor in prevalence of these conditions. Bowlegs are more prevalent among underweight populations than in overweight individuals. In contrast, knock-knees are more common in overweight individuals compared with individuals with normal body weight. Pathologic cases of bowlegs and knock-knees are uncommon and are defined by the degree of angulation.

Clinical Presentation

Children with bowlegs have a characteristic wide-based stance with increased distance between the knees. They may walk with a waddling gait. In-toeing may be noted as a result of associated internal tibial torsion. Evaluation for pathologic bowlegs is required in cases in which the intercondylar distance (ie, distance between the knees) is more than 10 cm with the child lying supine with the medial malleoli touching.

Severe knock-knees may produce an awkward gait with the knees rubbing. Children may walk with the feet apart in an effort to avoid

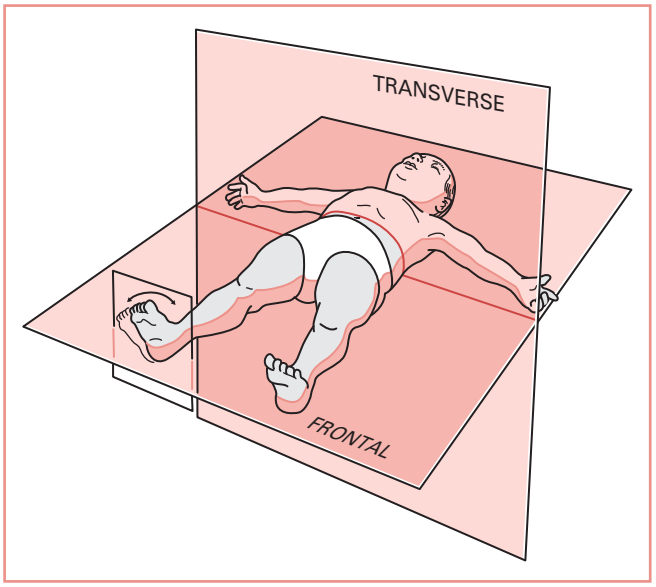

Figure 115.1. Select anatomic reference and rotational planes. Rotational problems (double-sided arrow) are deformities in the transverse plane. Angular deformities are assessed in the frontal plane.

Box 115.1. Diagnosis of Pathologic Bowlegs and Knock-Knees in the Pediatric Patient

- Asymmetric deformity
- Inconsistency with the normal sequence of angular development
- Stature less than the fifth percentile for age
- Severe deformity (>10 cm intermalleolar or intercondylar distance)
- History of rapid progression
- Presence of other musculoskeletal abnormalities

knee-to-knee contact. They may need to place 1 knee behind the other to stand with both feet together. Evaluation for pathologic knock-knees is warranted in cases in which the intermalleolar distance (ie, distance between the ankles) is more than 10 cm with the child lying supine with the knees touching.

Pathophysiology

The normal variation in the angular alignment of the lower extremities changes with age. During the first 2 years of age, relative bowing of the legs is common. Although physiologic bowing of the lower leg may be appreciated at birth, it is most prominent during the second year after birth, when it most commonly involves both the tibia and the femur. In patients in whom the deformity is associated with internal tibial torsion, it may appear more striking. Physiologic knock-knees manifest between 3 and 4 years of age. The knock-knee stage resolves between 5 and 7 years of age, when normal adult alignment develops. A slight knock-knee appearance remains in normal adults. Bowlegs or knock-knees that do not follow the normal variation in angular alignment of the lower extremities require further evaluation for pathologic causes.

The *tibiofemoral angle*, that is, the angle between the long axis of the femur and the long axis of the tibia, is used to assess the angular alignment of the leg. At birth, the tibiofemoral angle is approximately 15° varus, and it decreases to 0° between ages 18 and 24 months. By age 3 to 4 years, the angle peaks at approximately 10° degrees of valgus angulation. Between 5 and 7 years of age it decreases to the normal range of approximately 7° to 9° in girls and 4° to 6° in boys (Figure 115.3).

Recent evidence has shown that weight-bearing activity may affect the alignment of lower extremity alignment at the knee in adolescent children. An association exists between normal, healthy, active adolescents who participate in weight-bearing field sports and some degree of genu varum. This small degree of bowlegs is not pathologic, although it is noted in older adolescent children who have displayed increased weekly activity levels and more years of participation in weight-bearing sports than their counterparts of the same age.

Differential Diagnosis

The most common causes of genu varum and genu valgum are presented in Box 115.2. Typically, physiologic bowlegs and knock-knees are usually bilateral, and they occur in a sequence that follows the normal developmental pattern. Lateral bowing of the tibia is commonly noted during the first year after birth. Bowleg, involving both the femur and the tibia, are pronounced during the second year after birth, and knock-knees become prominent between 3 and 4 years of age. This is the normal sequence of angular development. Typically, bowlegs is the result of normal physiologic processes, Blount disease (ie, tibia vara), or rickets. Common causes of pathologic knock-knees are severe renal rickets and a history of proximal tibia fracture.

Blount disease, a growth disturbance involving the posteromedial aspect of the proximal tibia (ie, physis, epiphysis, and metaphysis), is the most common cause of pathologic bowlegs and is the result of idiopathic undergrowth of the medial side of the tibia. The 2 forms

Box 115.2. Common Causes of Genu Varum and Genu Valgum

Genu Varum

- Physiologic bowlegs
- Rickets resulting from vitamin D deficiency (nutritional) or vitamin D resistance (hereditary)
- Blount disease (ie, tibia vara)
- Achondroplasia
- Metaphyseal dysplasia
- Trauma, infection, or tumor of the proximal tibia (resulting in malunion or partial physeal arrest)
- Excessive prenatal fluoride ingestion

Genu Valgum

- Physiologic knock-knees
- Rickets (ie, renal osteodystrophy)
- Trauma, infection, or tumor of the distal femur or proximal tibia resulting in malunion or partial physeal arrest
- Paralytic conditions (eg, myelodysplasia, polio, cerebral palsy) resulting in contracture of the iliotibial band
- Osteogenesis imperfecta
- Rheumatoid arthritis of the knee

of the disease are early-onset (ie, infantile) and late-onset and are defined by disease development before or after 4 years of age. The late-onset form is further subdivided into juvenile (4–10 years of age) and adolescent (>10 years of age). At all ages, Blount disease is more common in black individuals than those of other ethnicities.

The infantile form of Blount disease, which initially was classified by Langenskiöld, is bilateral in 80% of patients and is associated with internal tibial torsion. The etiology is believed to involve mechanical stress on the growth plate, thus converting physiologic bowlegs to pathologic varus. Affected children often have obesity, are in the upper growth percentiles, and are early walkers, which puts early stress on the growth plate. Blount disease produces a sharp angulation at the proximal tibia, whereas physiologic bowlegs results in a gradual curvature of the legs involving both the femur and the tibia. Six stages of radiographic progression have been identified based on the degree of epiphyseal depression and metaphyseal fragmentation at the proximal tibia (ie, Langenskiöld classification). It may be difficult to distinguish between early stage Blount disease and physiologic bowlegs, although criteria have been established to help predict infantile Blount disease in children presenting with idiopathic bowlegs, that is, a body mass index greater than or equal to 22 and a tibial metaphyseal-diaphyseal angle greater than or equal to 10° degrees. These criteria have been shown to have a sensitivity of 95%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 98%.

The late-onset form of Blount disease is less common than the juvenile form and usually is unilateral. Knee pain, rather than deformity, is the most common presenting sign. It is more common in males than females, and affected children generally have obesity but are of normal height. Although the etiology is unclear, it is believed that in predisposed adolescents with obesity, repetitive trauma caused by excess weight results in decreased growth of the medial tibial physis.

Rickets, a disease of the growing skeleton, is a disorder caused by abnormal calcium and phosphorus metabolism that produces

inadequate bone mineralization. Rickets takes several forms, including vitamin D-deficient (ie, nutritional) rickets; vitamin D-resistant (ie, hereditary) rickets, which is the most common form; and severe renal osteodystrophy. Signs of rickets include short stature, poor muscle tone, joint pain, and angular deformities of the lower extremities. Nutritional rickets may occur in infants who are exclusively breastfed and do not receive vitamin D supplementation. The alignment at the time of onset of disease determines the direction of angulation. For example, vitamin D-deficient or -resistant rickets generally has an early onset and is more often associated with bowlegs. Children with rickets and bowlegs, unlike those with Blount disease, are late walkers and often have evidence of growth impairment. Renal osteodystrophy, which usually has a later onset, results in valgus deformity (ie, knock-knees).

Pathologic processes involving the proximal tibia, including trauma (eg, fractures), infection, and tumor, are additional potential causes of bowlegs and knock-knees. Overgrowth or malunion after fracture of the proximal tibial metaphysis most commonly results in genu valgum rather than genu varum.

Evaluation

History

The physician should obtain from the parents or caregivers the family history; an assessment of the child's growth and nutritional history; and a description of the deformity, its progression over time, its effect on function, and prior treatment (Box 115.3). A dietary history is also important, particularly whether the infant has been exclusively breastfed (because of the risk for vitamin D deficiency).

Physical Examination

The physical examination begins with a general screening of the child's nutritional growth and developmental status. The child's growth parameters (ie, height, weight, head circumference) should be measured and plotted on standard growth curves. Limb length should be measured bilaterally, using the distance from the anterior superior iliac spine of the pelvis to the medial malleolus of the ankle as a direct measurement of "true" leg length. The rotational status of the lower limb should be assessed, because internal tibial torsion is often associated with bowleg deformity (see Chapter 114). The child should be observed both standing and ambulating to determine the alignment of the legs in the coronal and sagittal planes. The intercondylar and intermalleolar distances can be measured with the child supine to determine the presence of excessive bowlegs or knock-knees (see the Clinical Presentation section earlier in this chapter). The intercondylar and intermalleolar distances should be measured every 6 months to monitor the progression of the deformity.

Box 115.3. What to Ask

Pathologic Bowlegs or Knock-Knees

- When was the deformity first noticed?
- Has it changed? If so, how fast?
- Has the problem been treated in any way?
- Does the problem seem to affect how the child walks?
- Has the child had any recent illness or trauma in the affected leg?
- Does anyone else in the family have a similar problem?
- Aside from this condition, is the child growing and developing normally?
- Has the infant been exclusively breastfed?
- Does the child eat a well-balanced diet?
- Does the child have any chronic medical problems, such as kidney disease?

Laboratory Tests

Most children with physiologic angulation do not require any laboratory studies. A general metabolic screening, including levels of hemoglobin, calcium, phosphorus, vitamin D, creatinine, and alkaline phosphatase, may be ordered if a systemic or metabolic abnormality is suspected.

Imaging Studies

Radiographs are usually obtained in the evaluation of bowlegs or knock-knees if pathology is suspected. True pathology is more likely if the deformity is unilateral, painful, markedly asymmetric, or progressing at an accelerated rate. If obtained, radiographs should include the entire lower extremity to allow assessment of alignment of the femur and tibia. The child should be standing, and a single weight-bearing radiograph of both legs should be obtained that includes the hip and the ankle. Radiographs centered on the knee or ankle are also helpful in determining if the physeal plate is open. Pathologic conditions such as rickets (osteoporosis, metaphyseal fraying, cortical thinning, widening of the growth plates), Blount disease (beaking of the medial metaphysis of the proximal tibia), various bone dysplasias, and forms of dwarfism can usually be ruled out by radiographs. An increased uptake of the proximal medial aspect of the tibia on bone scanning may help differentiate early infantile Blount disease from extreme physiologic bowlegs. If pathology within the joint or premature arrest of physes is suspected, computed tomography or magnetic resonance imaging can detect minor defects that may not be apparent on conventional radiographs.

Management

Angular deformities within normal developmental limits should be managed with continual observation and reassessment. The severity of the deformity should be documented, and the child should be followed at 3- to 6-month intervals until the condition resolves. Physicians should reassure parents and caregivers that bowlegs and knock-knees are normal developmental variations that resolve spontaneously with time. Generally, it is best to avoid special diets, braces or shoe wedges, arch supports, and bars, because they have not been shown to affect the normal developmental sequence.

The child with physiologic varus may be followed clinically until 18 to 24 months of age. Pathology should be suspected if correction has not begun by this time or if the angulation is progressive. The child with more than 10° of valgus or with an intermalleolar distance greater than 10 cm after 8 to 9 years of age may require further evaluation. The child with suspected pathologic bowlegs

or knock-knees should be referred to an orthopedic surgeon for further evaluation.

Although treatment of Blount disease in children younger than 3 to 4 years may consist of bracing if the deformity is mild and identified early, surgery is often necessary. Surgery involves an osteotomy to realign the tibia. Failure to do so may result in damage to the medial aspect of the knee over time. Medical management, such as administration of vitamin D for nutritional rickets, is of primary importance in the treatment of the various forms of rickets. Surgical correction, such as osteotomies to correct varus or valgus deformities, should be avoided until medical management has been maximized, because even severe deformities may resolve with conservative management.

Additionally, guided growth by the less invasive means of epiphyseal stapling (ie, hemiepiphysiodesis) can be used to restrict growth on one-half of the physis while allowing unrestricted growth on the other one-half of the physis. This results in eventual correction of the angular deformity. The ideal patient for this intervention is a child with a severe, pathologic angular deformity with open physes.

Prognosis

Physiologic bowlegs and knock-knees spontaneously resolve without further sequelae. Although knock-knees are primarily a cosmetic problem, in rare cases degenerative arthritis is a late complication. No evidence exists of a causal relationship between malalignment of the knee and the development of osteoarthritis. However, biomechanical and gait studies show an association between poor alignment in the distal lower extremity at the knee joint and the potential for osteoarthritis. Increased load occurs in the medial compartment and lateral compartment of the knee in genu varum and genu valgum, respectively. In adolescents with severe deformity, surgical correction may be necessary to prevent the acceleration of potential late complications.

CASE RESOLUTION

The boy should be evaluated for pathologic causes of genu varum, especially Blount disease, for the following reasons: his age is at the upper limit of normal for bowlegs and his deformity is severe, he is black, he has a history of early walking, and he has obesity. A standing radiograph of the lower extremities should be obtained, and the boy should be referred to an orthopedic surgeon for further evaluation and management.

CHAPTER 116

Orthopedic Injuries and Growing Pains

Sara T. Stewart, MD, MPH, FAAP

CASE STUDY

A 6-year-old boy has a 1-week history of leg pains. He wakes up at night and cries because his legs hurt; however, during the day he is fine, with no pain and no movement limitations. He has no history of trauma, fever, or joint swelling. The family history is negative for rheumatic or collagen vascular disease. The boy's height and weight are at the 50th percentile for age, he is afebrile, and the physical examination is unremarkable.

Questions

1. What is the differential diagnosis of leg pains in school-age children?
2. What laboratory or radiographic studies are appropriate for children with leg pains?
3. How do musculoskeletal injuries in children differ from those in adults (eg, injury type, injury location)?
4. How does the physician decide the extent of the diagnostic workup in a child with extremity pain?
5. What fractures are commonly seen at different ages?

Children by nature are active and explorative. They routinely experience cuts, scrapes, minor injuries, and pain. Because primary care physicians are often the first to examine children with injuries, they play an important role in making the preliminary diagnosis and assessing the need for further evaluation and treatment. The more common complaints and injuries seen in pediatricians' offices are discussed in this chapter: growing pains, radial head subluxation (ie, nursemaid's elbow), and fractures, including growth plate injuries. Evaluation of children with limp is discussed in Chapter 118.

Epidemiology

The term "growing pains" is somewhat misleading, because no evidence exists that these pains are associated with growth. The period of middle childhood, when growing pains are diagnosed, is not the period of most rapid growth in the child. "Leg aches" or "idiopathic leg pain" may be better terms for the pains, but growing pains is the most widely used term.

The prevalence of growing pains is not well defined, but it is estimated to be between 15% and 30% of all children. These pains most commonly occur in children between 4 and 14 years of age, and girls are affected more frequently than boys.

Nursemaid's elbow, or radial head subluxation, is the most common joint injury in childhood. It occurs most commonly in children 1 to 4 years of age, with a peak incidence between 2 and 3 years of age. Other ligament and tendon injuries are relatively uncommon in prepubertal children because of the relative strength of these structures in comparison to the growth plate of the adjacent developing bone. Most commonly, fractures involving the growth plate occur before ligamentous injury. With the exception of pulled elbow, joint dislocations and ligamentous injury in children usually are the result of significant trauma.

Trauma and injury are significant causes of morbidity and mortality in childhood. Injuries are the most common reason for hospitalization in children and adolescents younger than 18 years and are the leading cause of death after age 1 year. Musculoskeletal problems account for 15% of all injuries and most commonly occur in the upper extremity. Fractures are perhaps the most common significant form of musculoskeletal injury in children who present to physicians for evaluation and treatment.

Clinical Presentation

Children with growing pains typically present with a history of intermittent, poorly localized pain in the bilateral lower extremities that occurs at night over a long period. The pain most commonly involves the calves and anterior thighs, never the joints. Symptoms usually resolve within several minutes, and in the morning the child has normal activity.

Subluxation of the radial head is characterized by a sudden onset of elbow pain associated with the traumatic event and subsequent decreased use of the arm. At the time of presentation for medical care, a child with this injury typically appears well, aside from a refusal to use the affected arm. The child typically holds the arm

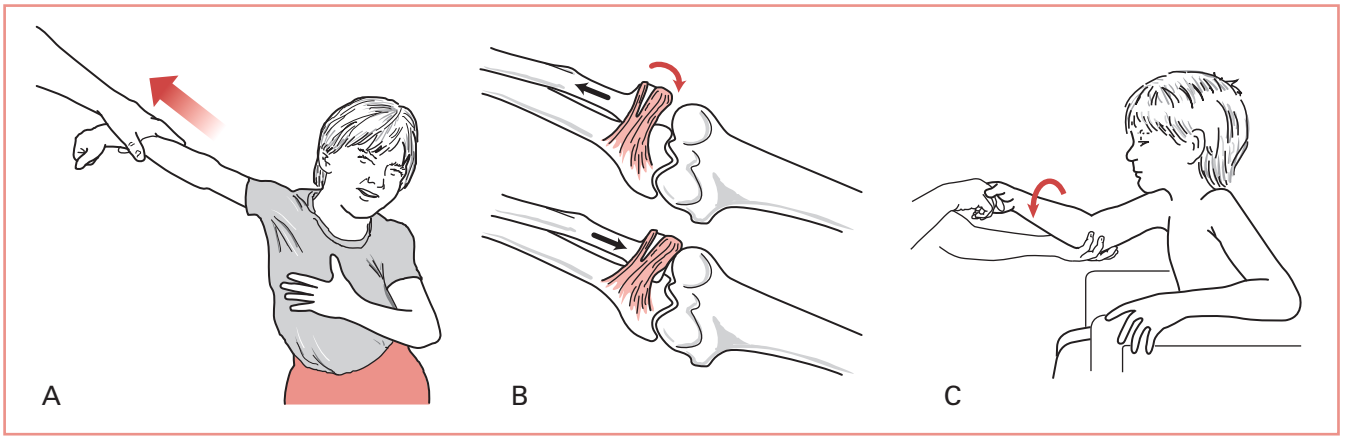

Figure 116.1. Nursemaid's elbow. The sudden traction on the outstretched arm pulls the radius distally, causing a tear in the annular ligament at its attachment to the radius. A portion of the ligament becomes trapped within the joint as the traction is released and the arm recoils. A, Mechanism of injury. B, Pathology. C, Method of reduction (ie, hyperpronation).

close to the body with the elbow in slight flexion and the forearm pronated. Usually, no gross deformity, swelling, or overlying skin trauma is evident, and the child typically refuses to supinate the forearm during examination. Point tenderness may be elicited laterally over the radial head.

Obvious deformity or lack of spontaneous movement in the extremity in question is strongly indicative of an underlying fracture. Localized swelling, tenderness, and limited range of motion all may be signs of a fracture.

Pathophysiology

Growing pains are recurrent aches or pains localized most commonly to the muscles of the legs and occasionally to the muscles of the arms of children. The pain is located deep within the extremity and not in the joints. Etiology remains unclear. Emotional and psychological stress, a low pain threshold, bone fatigue, and myalgia secondary to exercise or physical activity all have been implicated as possible contributory factors. Approximately one-third of patients also report recurrent headaches or abdominal pain.

Nursemaid's elbow is subluxation of the radial head caused by rapid and forceful extension and pronation of the forearm. This mechanism most commonly occurs when caregivers pull a child toward themselves and the child resists, wanting to go in the other direction. As illustrated in Figure 116.1, the subluxation occurs as the result of tearing of the annular ligament, with trapping of the ligament between the radius and the capitulum humeri. This injury occurs primarily in young children, because the ligamentous attachment to the bone becomes thicker with age and growth.

Because of anatomic and physiologic differences between children and adults, such as the presence of a cartilaginous growth plate, thicker periosteum, and increased plasticity of the skeleton in children, fracture patterns in children often are different from those in adults. Additionally, fractures may influence long-term growth and development of the affected limb in a growing child.

Fractures are classified based on anatomic location, type of fracture, and degree of angulation or displacement. Fracture location may be described as diaphyseal, metaphyseal, or epiphyseal/growth plate depending on the portion of the bone involved (Figures 116.2 and 116.3). Fractures may be open or closed. In closed fractures, the skin over the fracture site is intact, whereas in open fractures, the skin is broken. In cases in which 2 bone fragments are displaced relative to each other, the direction and degree of displacement are based on the distal fragment.

The Salter-Harris classification is used most commonly to classify growth plate injury (Table 116.1, Figure 116.4). Approximately 15% of all fractures in children involve the growth plate. Type 1 and 2 fractures are the most common fractures involving the growth plate. Type 3 and 4 fractures involve the epiphysis and are considered to be intra-articular. Type 5 fractures are uncommon and are caused by a crush injury to the growth plate. With type 1 and 5 fractures

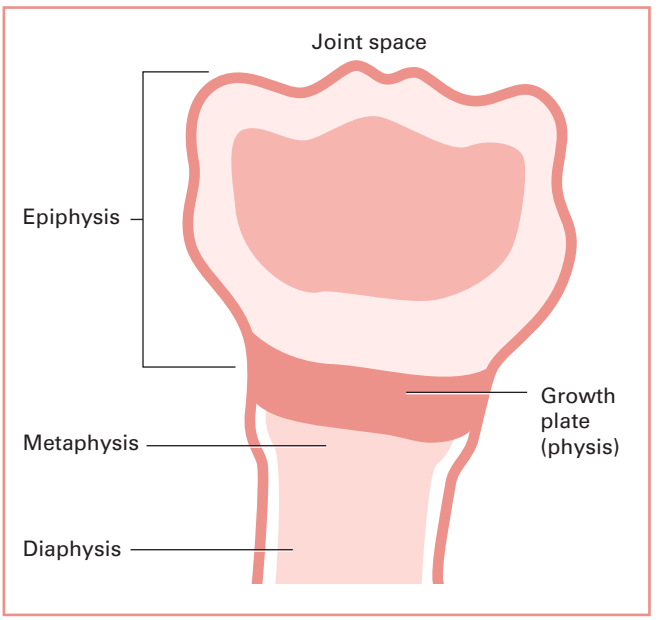

Figure 116.2. Anatomy of a long bone.

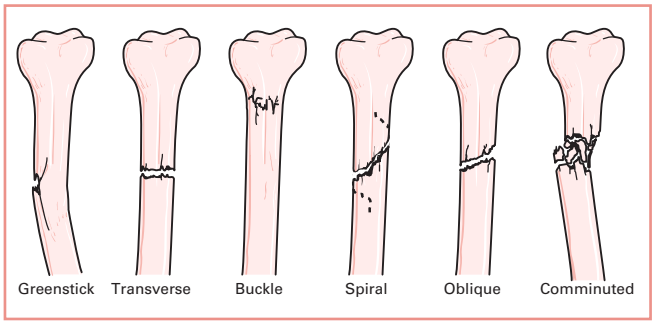

Figure 116.3. Non-epiphyseal plate fractures.

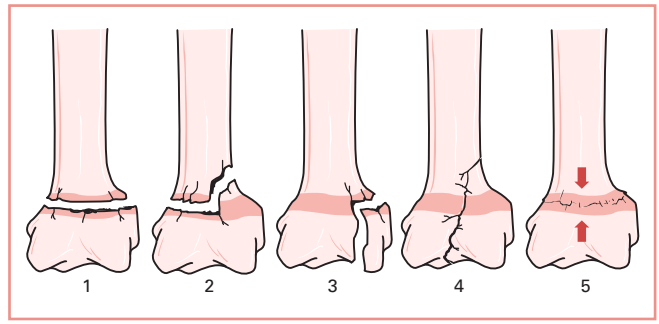

Figure 116.4. Salter-Harris classification of epiphyseal plate fractures.

Table 116.1. Long Bone Fracture Patterns That Occur in Children

Type	*Description*
	Nonepiphyseal Plate Fractures
Complete	Both sides of the bone fractured; type depends on direction of fracture line
Transverse	Perpendicular to long axis of the bone
Oblique	At an angle to long axis of the bone
Spiral	Zigzag course around the bone
Comminuted	Fractures with ≥3 fragments (rare in children)
Buckle or torus	Bone compression causes it to bend or buckle rather than break; occurs at junction of metaphysis and diaphysis
Greenstick	Cortex broken on tension side but intact on compression side
Bowing	Deformation of bone caused by bending without fracturing
Classic metaphyseal lesion	Fracture of distal, poorly mineralized metaphysis, perpendicular to long axis of bone; previously termed bucket-handle or chip fracture
	Epiphyseal Plate Fractures (Salter-Harris Classification)
Type 1	Horizontal fracture through the physis
Type 2	Fracture through the physis, extending into the metaphysis
Type 3	Fracture through the epiphysis, extending into the physis
Type 4	Fracture through the epiphysis, physis, and metaphysis
Type 5	Crush injury of the physis

Box 116.1. Common Causes of Leg Pain in Children

Growing Pains
- Leg aches
- Idiopathic leg pains

Trauma
- Fracture
- Compartment syndromes
- Soft tissue injury
- Muscle strain/sprain

Infection
- Cellulitis
- Soft tissue abscess
- Myositis
- Osteomyelitis
- Septic arthritis

Neoplasia
- Malignant bone tumors (eg, osteosarcoma, Ewing sarcoma)
- Leukemia
- Metastatic disease (eg, lymphoma, neuroblastoma)

Benign Bone Lesions
- Osteoid osteoma
- Bone cysts
- Langerhans cell histiocytosis

Collagen Disease
- Juvenile rheumatoid arthritis
- Dermatomyositis
- Fibromyalgia
- Rheumatic fever

Other Musculoskeletal Causes
- Legg-Calvé-Perthes disease
- Slipped capital femoral epiphysis
- Osgood-Schlatter disease
- Transient synovitis of the hip
- Osteochondritis dissecans
- Patellofemoral stress/chondromalacia patellae
- Generalized ligamentous laxity and joint hypermobility

Miscellaneous Causes
- Sickle cell disease pain crisis
- Psychosomatic conditions

initial radiographs may appear normal because bone fragments are not displaced. Because of involvement of the growth plate, any injury of the physis is associated with risk of growth arrest. The risk is variable, however, depending on the type of injury.

Differential Diagnosis

The diagnosis of growing pains is one of exclusion. Leg pain in children has many causes (Box 116.1). If the pain is limited to vague pains in the legs at night with no associated limp or signs of inflammation, the differential diagnosis may be limited to growing pains, restless legs syndrome, general systemic diseases (eg, leukemia), benign bone tumors (eg, osteoid osteoma), or possibly fibromyalgia.

Leukemic infiltration of the bones may cause leg pain before systemic signs such as fever, weight loss, and adenopathy are present. Osteoid osteoma, a benign bone tumor that most commonly occurs in adolescent boys, characteristically causes pain that is worse at night and is usually relieved by nonsteroidal anti-inflammatory medications. Unlike with growing pains, however, the pain may be localized to 1 place. Fibromyalgia likely is underdiagnosed in the pediatric population; in adults, this condition is a well-recognized cause of chronic, generalized limb pain without a clear, organic source. It occurs more commonly in adolescents than in younger children. This benign, intermittent musculoskeletal pain syndrome is associated with multiple tender "trigger points," stiffness, fatigue, and a nonrestorative sleep pattern.

When evaluating for nursemaid's elbow, an elbow fracture should be ruled out. Certain fractures and specific features of fractures deserve mention (Figure 116.3). Fractures that often occur during childhood include clavicular fracture, which is the most common childhood fracture and most commonly fractured bone from birth trauma, and spiral fractures of the distal tibia, that is, the "toddler's fracture" or childhood accidental spiral tibial fracture. This fracture typically occurs in children who have not been walking long, such as those between 9 months and 3 years of age. It is thought to be caused by a rotational force on the lower leg, which could occur as an ambulatory child falls in a twisting motion. Often, when the child presents for medical care, the parents or guardians are unaware of a history of trauma and the chief symptom is that the child refuses to bear weight on the affected leg. Elbow fractures, including supracondylar humerus fractures as well as lateral and medial condyle fractures, commonly occur as the result of a fall directly on the elbow or on an outstretched hand. These fractures require careful attention to neurovascular status because of the risk of associated injury to the median or radial nerve or brachial artery, which could result in Volkmann contracture. A *Monteggia fracture* is a dislocation of the radial head in association with an ulnar shaft fracture. Long bone fractures in preambulatory children, rib fractures, classic metaphyseal lesions, and the presence of multiple fractures in a child are all concerning for nonaccidental trauma and should prompt a more thorough evaluation of possible physical abuse (see Chapter 144).

Because of the relative weakness of the physis compared with the surrounding ligaments, trauma sustained near joints may be more likely to cause a type 1 Salter-Harris growth plate fracture rather than ligamentous injury (eg, sprain, strain). Therefore, it is important to include this type of fracture in the differential diagnosis of children with point tenderness near the end of a long bone because this injury requires cast immobilization.

Box 116.2. What to Ask

Growing Pains

- When (ie, what time of day) does the pain typically occur?
- How long has the pain been occurring?
- Does the pain resolve and then recur in any predictable manner?
- Where is the pain? Does it change location?
- Does anything make the pain better or worse?
- Is the child sick in any other way?
- Does the pain interfere with the child's activities or with sleep?
- Does the parent notice any changes, such as swelling or redness in the child's legs?

Orthopedic Injuries

- How did the injury occur?
- How long ago was the injury sustained? When did the symptoms begin?
- Was the incident witnessed by an adult?
- How strong was the injuring force? From what direction did it come?
- What was the position of the affected extremity at the time of the injury?
- Did the child experience any head trauma or loss of consciousness?
- What, if any, first aid was administered at the scene?
- Has the child been able to move the affected extremity since the injury occurred?

Evaluation

Accurate diagnosis of orthopedic injuries in pediatric patients often is challenging, because children may be not only poor "historians" but also uncooperative with examinations, especially if they are experiencing pain.

History

A thorough history is essential for the accurate diagnosis of growing pains and orthopedic injuries (Box 116.2). A complete history of the events related to the injury should be obtained, including what happened after the injury was sustained.

Physical Examination

The physical examination of the child with suspected growing pains should include evaluation for signs of systemic disease, such as fever, lymphadenopathy, hepatosplenomegaly, abnormal growth, and generalized weakness or fatigue. Leg length and circumference should be measured. The legs should be palpated and range of motion assessed in the hip, knee, and ankle. Gait should be assessed as well.

The child with suspected nursemaid's elbow should be observed for how the child holds the affected arm compared with the unaffected arm. The child should be evaluated for limited active motion at the elbow and resistance to attempts at passive movement, especially supination. No swelling should be present, but tenderness over the radial head may be elicited. Additionally, the shoulder and wrist should be thoroughly examined.

It is important to perform a complete physical examination in the presence of the parent, guardian, or other chaperone after first having the child disrobe. Examining only the involved extremity is insufficient. The presence of a deformity, point tenderness, or limitation of motion supports the diagnosis of a fracture. All long bones should be palpated, and the presence of bruises and scars should be noted, because these may indicate child abuse. Examination of the involved extremity includes inspection of the overlying skin for swelling, lacerations, or punctures. The degree of active and passive motion and strength compared with the uninvolved side should be noted. In cases of suspected leg injuries, the child's gait should be observed, if possible. Assessment of neurovascular function distal to the injury includes evaluation of capillary refill, peripheral pulses, and motor and sensory function.

Laboratory Tests

A complete blood cell count and erythrocyte sedimentation rate may be considered for the child with leg pains that do not resolve or for the child with symptoms that are atypical for growing pains.

Rheumatologic screening tests can be ordered based on abnormal findings (eg, elevated erythrocyte sedimentation rate, elevated white blood cell count). A diagnosis of growing pains requires normal results on all laboratory tests. Routine laboratory studies are not necessary in the evaluation of nursemaid's elbow or fractures. Because femoral fractures often are associated with significant blood loss, however, it is important to monitor hematocrit in these patients.

Imaging Studies

If leg pains persist and interfere with routine activity, radiography or bone scanning of the legs may be considered. Radiographic evaluation is not required for the child with nursemaid's elbow if presentation is typical and reduction is successful. Radiographs, if obtained, usually are negative because often the dislocation is corrected during positioning for the x-ray itself. Radiographs should be obtained in children with suspected fractures, however. Fractures involving the growth plate, especially Salter-Harris type 1 and 5 fractures, may be particularly difficult to diagnose radiographically because the growth plate is primarily cartilaginous and, thus, radiolucent. Bone scanning or follow-up radiography may be done to diagnose suspected fractures when initial radiographs are negative.

Management

Parental/guardian education and reassurance about the benign nature of growing pains are important. The pains themselves usually respond to supportive measures, such as heat, massage, and analgesia. Stretching exercises for the legs also have been recommended. Referral to an orthopedic surgeon should be considered if the pain is severe and persistent and a specific diagnosis cannot be made based on physical examination and laboratory workup.

Subluxation of the radial head is among the few medical conditions with a dramatic, immediate cure. To manage the elbow, the annular ligament must be reduced back to its anatomic position. In both common methods of reduction, the elbow is stabilized with application of pressure laterally over the radial head with the thumb of the medical professional. The first method involves rapid, firm hyperpronation of the forearm. In the second method, the forearm is firmly supinated, after which the elbow is flexed. Although success rates are high with both methods of reduction, several studies suggest superiority of the hyperpronation method. A click may be heard or felt as the radial head is reduced, and pain relief usually is immediate for children who are treated shortly after their injury. Return of function may require up to 30 minutes, however. If treatment is delayed, such rapid relief of symptoms may not occur. After reduction, the parent or guardian should be advised that the child may need mild pain medication. Some physicians recommend short-term immobilization in a sling or splint to facilitate soft tissue healing. If reduction is unsuccessful, the physician should consider obtaining radiographs and referring the patient for orthopedic consultation.

Most fractures should be referred to an orthopedic surgeon for evaluation and management unless the primary care physician is experienced in reducing and casting fractures. Several techniques are used in fracture management. Closed reduction is the nonsurgical reduction or realignment of fracture fragments. Open reduction implies that an incision has been made to expose the fracture and proceed with manipulating the bone fragments into place. Fixation, or stabilization of the fracture with any type of device, may be required following the reduction. *Internal fixation* is that in which the device is placed under the skin, and *external fixation* is that in which the device begins outside the skin but passes through the skin to bone. Indications for open reduction include failure of closed reduction, the necessity for precise anatomic reduction, and complex multisystem trauma.

Certain fractures are common in pediatrics. Most clavicular fractures do not require reduction and can be managed with immobilization in a sling for 4 to 8 weeks. Elbow fractures (eg, lateral condyle fracture, supracondylar humeral fracture) are at particular risk for neurovascular compromise and often necessitate open reduction to achieve anatomic reduction. Typically, distal forearm fractures are managed with closed reduction and casting; however, forearm fractures in the middle and proximal thirds of the bone may be more difficult to reduce in the office setting. Stable metacarpal and phalangeal fractures can be splinted in an aluminum splint or taped to an adjacent finger (ie, buddy taping). The metacarpophalangeal joints should be maintained in 50° to 90° of flexion, and the interphalangeal joints should be maintained in approximately 20° of flexion to minimize stiffness. Unstable finger fractures may require open reduction and pin fixation.

Femoral shaft fractures in infants and children can be managed with closed reduction and spica casting. As the child ages, a fixation device may be required in addition to the closed reduction. Open reduction is rarely necessary. Closed reduction and cast immobilization usually are used in the management of tibial shaft fractures. Short cast immobilization may be required for metatarsal fractures, and buddy taping is used for stable toe fractures.

Because of the potential for infection, open fractures are orthopedic emergencies that require immediate attention and orthopedic consultation. Careful wound débridement is required. Antibiotics should be administered, and tetanus immunization may be given based on a review of the immunization history.

Prognosis

Growing pains resolve over time without sequelae. Recurrence of nursemaid's elbow is common, occurring again in up to one-third of patients. Thus, parents and guardians should be cautioned about pulling a child's arms or lifting a child by 1 hand. Remodeling is the spontaneous correction of deformity. Fractures in children generally heal faster and remodel better than equivalent fractures in adults. Vascular and nerve injuries and growth disturbances are potential complications of fracture and fracture management. Compartment syndrome, a potentially serious vascular injury, may also occur.

Growth plate injuries require special attention because of the potential for subsequent growth abnormalities of the affected bone. Prognosis of growth plate fractures depends on the type of injury sustained. Generally, Salter-Harris type 1 and 2 fractures are associated with a good prognosis for long-term healing and growth. The severity of injury and accuracy of reduction determine the prognosis

of type 3 and 4 fractures. Growth arrest is common after type 5 fractures because the physis itself is injured.

CASE RESOLUTION

The child has the benign condition commonly referred to as growing pains. Management involves parental education and reassurance. Local heat, massage, and analgesia (ie, ibuprofen) may be recommended.

CHAPTER 117

Sports-Related Acute Injuries

Monica Sifuentes, MD; Kier Maddox Blevins, MD; and Andrew K. Battenberg, MD

CASE STUDY

A 15-year-old female basketball player reports 6 months of intermittent pain in her left knee. Occasionally the knee gives out while she is playing ball. The patient denies any associated swelling or erythema over the joint. She can walk with no problem and reports no history of direct trauma to the area. She is otherwise healthy.

Physical examination shows the patient to be a well-developed, well-nourished adolescent girl in no acute distress. The examination is normal, with the exception of mild pain to direct palpation of the left patella. No swelling, erythema, or effusion of the knee joint is evident, and full range of motion is noted in the left hip, knee, and ankle. The back is straight.

Question

1. What are some of the most common orthopedic findings in adolescent patients, and why do they occur in this age group?
2. What is the pathophysiology of overuse syndromes?
3. What is the purpose of the preparticipation physical evaluation?
4. What criteria help determine if an adolescent should be disqualified from participation in a competitive sport?
5. What are the current recommendations for the management and rehabilitation of acute soft tissue injuries?

Many adolescents with varying degrees of athletic ability participate in sports during their middle school/junior high school and high school years. Some participate in sports at the college level as well. Regardless of the reason for participating, team sports are an important means by which children and adolescents can experience both winning and losing. Individuals learn the importance of group participation and develop interactive skills with other team members. They are exposed to the concept of physical fitness, which can improve body image as well as self-esteem.

Participation in athletics carries significant risks, however. Injuries, inappropriate coaching, and aggressive training sessions are not uncommon occurrences that may have long-term sequelae for young athletes. Primary care physicians are responsible not only for the evaluation of children prior to their participation in sports but also for the prevention, diagnosis, and management of athletic injuries.

Epidemiology

Recent estimates indicate that approximately 38 million young athletes participate in organized sports in the United States each year. Of these, 4 million athletes younger than age 14 years and 2 million high school–age athletes are treated for a sports injury. These numbers have increased dramatically in the past 20 years. This increase is thought to be multifactorial, including an increase in the number of female athletes in the United States following the passage of Title IX of the Education Amendments of 1972, a new emphasis on year-round competition, single-sport focus, and increased training intensity. Several studies have attempted to quantify the overall injury rate associated with athletic participation. In general, the rate of injury for individuals 13 through 19 years of age is 7% to 11%. Approximately 20% of those injured sustain a significant injury. For boys, the sports with the highest injury rate in all age groups are football, basketball, and soccer. In girls, gymnastics, cheerleading, and roller skating account for the most injuries. Sex-related differences have been found in some studies, depending on the sport. Overall, boys tend to have more shoulder-related injuries, whereas girls tend to have more knee and ankle injuries as well as more problems with overuse syndromes. Reports indicate that the severity of sports-related injuries increases with age. Along with the increased incidence of injuries, sports-related injuries previously thought to be rare in the pediatric population are on the rise. For example, anterior cruciate ligament (ACL) ruptures are occurring with increased frequency in this demographic, especially among high school–age females. Management of such injuries is complicated in skeletally immature individuals because of the need to preserve growth potential.

Preparticipation Physical Evaluation

The goal of the preparticipation physical evaluation (PPE) is to identify any physical conditions or abnormalities that may predispose the young athlete to injury. Examples include a history of concussion with head trauma or an incompletely healed sprain.

The PPE consists of 2 parts: a review of the patient's current health and medical history, including sports injuries and family history relating to participation in strenuous exercise, and a complete physical examination with a focus on the musculoskeletal system.

Known as a "2-minute orthopedic examination," the musculoskeletal examination is a detailed assessment of all muscle groups, assessing their strength, tone, and function. Congenital or acquired deformities should also be noted. The American Academy of Pediatrics has developed a form specifically for the PPE visit (see Chapter 38).

Disqualification from participation in specific sports is appropriate in certain situations. Competitive sports are classified according to their degree of contact or impact and their strenuousness. Recommendations differ depending on the adolescent's medical condition and the type of sport the athlete desires to play. For details of these recommendations, see Selected References at the end of this chapter. Fortunately, many young athletes are healthy and rarely need to be restricted from sports participation.

Clinical Presentation

Older children and adolescents with sports-related injuries usually present with specific reports of pain or swelling in a particular joint (Box 117.1). Additionally, they may report nonspecific musculoskeletal pain occurring in certain areas, such as the lower back or shoulder, or they may report a limp, decreased range of motion of an extremity, or an inability to participate in a desired activity without pain.

Pathophysiology

Unlike adults, adolescents are particularly susceptible to injury because their bones and joints are not fully mature. Most injuries that occur during adolescence involve the epiphysis, which is the weakest point of the musculoskeletal system. Additionally, the presence of congenital anomalies, such as leg length discrepancy and hip rotation abnormalities, puts the young athlete at further risk for injury. Biomechanical and neuromuscular factors, hormonal influences, and anatomic differences have also been proposed as reasons for higher rates of some injuries in young female athletes compared with young male athletes. For example, patellofemoral pain syndrome, which presents as knee pain exacerbated by activity, is a common problem in adolescent females, affecting nearly 1 in 10 of those who are active. Contributing biomechanical factors include tight iliotibial bands, weak gluteal strength, and a relative genu valgum resulting from increased hip width in female individuals. This combination causes valgus stresses at the knee, internal femoral rotation, and abnormal patellar tracking, which places the athlete at increased risk for patellofemoral syndrome.

Most orthopedic injuries are the result of either macrotrauma or microtrauma. Sprains are an example of macrotrauma, whereas overuse syndromes can be considered microtrauma. *Macrotrauma* is the result of complete or partial tearing of muscle, ligaments, or tendons and often is associated with acute injuries. In contrast, *microtrauma* usually is caused by chronic repetitive trauma to a particular area, resulting in inflammation and ultimately, pain. Such injury most commonly occurs in soft tissues, such as muscle and tendon, but can occur in bone as well.

Box 117.1. Diagnosis of Orthopedic Injury in the Older Child or Adolescent Patient

- Joint pain or swelling
- Tenderness to palpation of the affected joint
- Decreased range of motion of the affected joint or extremity
- May or may not have associated bruising of the skin overlying the injury

Definitions

A *sprain* is a stretching injury of a ligament or the connective tissue that attaches bone to bone. A *strain* is a stretching injury of a muscle or its tendon, which is the connective tissue that attaches muscle to bone. *Tendinitis* is an inflammation of the tendon. *Apophysitis* is an inflammation of the apophysis, which is the site of ligamentous or tendinous attachment to growth cartilage (eg, Osgood-Schlatter disease [ie, apophysitis of the tibial tubercle], Sever disease [ie, calcaneal apophysitis]). A *stress fracture* is an incomplete fracture often occurring in the bones of the legs and feet from repetitive trauma to the area. It is believed that the pain associated with shin splints may result in part from atypical stress fractures of the distal tibia.

Overuse syndromes occur from repetitive microtrauma to the musculoskeletal system secondary to excessive or biomechanically incorrect activity. Typically, they are the result of training errors in which athletes are "trying to do too much too fast." Common syndromes in adolescents include Osgood-Schlatter disease, shin splints (ie, medial tibial stress syndrome), and patellofemoral syndrome (ie, chondromalacia patellae).

Grading of Sports Injuries

Sprains most commonly occur in the knee or ankle, and they can be classified according to the degree of injury. Assigning a grade that describes the injury is useful when considering the prognosis of a particular injury. Grading an injury is helpful when referring patients to sports medicine specialists (eg, orthopedists). Typically, sprains are classified as grade I, II, or III (Table 117.1). Grade I generally refers to stretching of the ligament, grade II is a partial tear of the ligament, and grade III is a complete tear of the ligament. Joint stability, range of motion, and degree of pain and swelling determine the grade of the sprain. The grading system for strains, however, is based on an assessment of strength. Because strains typically do not cause joint instability, criteria for grading strains are different from those for sprains and may be more subjective (Table 117.2).

Table 117.1. General Classification of Sprains

Grade	Joint	Range of Motion	Weight Bearing	Pain	Swelling
I	Stable	Normal	Normal	+	+
II	Stable	↓	↓	++	++
III	Unstable	↓↓	↓↓	+++	+++

Abbreviations: ↓, reduced; ↓↓, markedly reduced; +, mild; ++, moderate; +++, severe.

Table 117.2. General Classification of Strains

Grade	Strength	Palpable Defect	Pain
I	>4	–	+
II	3–4	±	++
III	<3	±	+++

Abbreviations: –, none; ±, variable; +, mild; ++, moderate; +++, severe.

Differential Diagnosis

The differential diagnosis of orthopedic conditions depends on the anatomic site of the injury or symptom and the mechanism of injury. Box 117.2 lists some of the more common orthopedic conditions by location. Anomalies of skeletal development, such as congenital angular deformities of long bones, and soft tissue abnormalities, such as Ehlers-Danlos syndrome, should be considered as possible etiologies for overuse syndromes. Other nonorthopedic conditions, such as collagen vascular diseases, infections, and tumors, may present with joint or bone symptomatology.

Evaluation

History

The history should focus on the musculoskeletal system and the mechanism of injury (Box 117.3). Other pertinent information about the activity level and competition level of the sport should be ascertained as well, because it can help the physician determine any underlying factors that may have precipitated the injury, such as a chronic overuse mechanism. It is also important to note the increased numbers of children engaging in early single-sport specialization, because these children may be prone to overuse injury and should be evaluated for signs of burnout.

Box 117.2. Differential Diagnosis Based on the Site of Injury

Back
- Epiphyseal injury
- Herniated disk
- Muscle strain
- Spondylolysis

Upper Extremity
- Acromioclavicular sprain
- Acute elbow injury
- Finger injury
- Flexor-pronator tendinitis
- Glenohumeral dislocation
- Glenohumeral subluxation
- Hamate fracture
- Impingement syndrome
- Lateral epicondylitis
- Olecranon bursitis
- Scaphoid fracture
- Sternoclavicular sprain
- Wrist sprain

Lower Extremity
- Achilles tendinitis
- Ankle sprain
- Anterior cruciate ligament sprain
- Calcaneal apophysitis
- Femoral stress fracture
- Iliac apophysitis
- Iliac crest contusion
- Medial/lateral ligament sprain
- Osgood-Schlatter disease
- Patellar dislocation/subluxation
- Patellar tendinitis
- Patellofemoral stress syndrome
- Plantar fasciitis
- Posterior cruciate ligament sprain
- Prepatellar bursitis
- Quadriceps contusion
- Shin splint syndrome

Box 117.3. What to Ask

Sports-Related Injuries
- What is the acuity of the injury?
- What activity or sport was the patient engaged in at the time of the injury?
- How often has the patient engaged in this sport or particular activity in the past?
- Were there any new additions to the routine in this instance?
- Did the pain begin after a single injury or after repetitive activity?
- If the injury is related to a repetitive activity, does the pain occur at a specific time during this activity?
- What was the mechanism of injury?
- Is the pain incapacitating?
- Has a similar injury ever occurred in the past?
- How was the injury treated?
- Was there any pain following the previous injury?
- Does the patient feel as if he or she has completely recovered?
- How was this current injury managed acutely?
- Has the patient altered daily activity in any way to compensate for this problem?

Physical Examination

The physical examination should focus on the musculoskeletal system. Any adolescent who has not undergone a physical examination within the past year, however, should first undergo a complete physical examination to exclude any systemic condition that might manifest initially as musculoskeletal pain. This is especially important in adolescents with chronic or systemic symptoms, such as intermittent extremity pain, swelling of an affected joint, and fever.

Any pain or swelling of an affected joint or muscle should be noted. In the patient with a history of acute trauma, an area of ecchymosis or joint effusion may be seen. The affected joint should be tested for range of motion and joint laxity to determine the degree of sprain. Special testing for ligamentous laxity should be performed (Figure 117.1). For the knee, the most common methods are the anterior drawer test and the posterior drawer test to evaluate anterior and posterior movement of the knee joint, respectively. However, the Lachman test has gained considerable popularity because it has been shown to be a more sensitive and specific test for ACL injury. The patient is examined in a supine position on an examining table, and the knee, ligaments, and tibia are assessed. It is important to note that in the setting of a recent injury, soft tissue swelling and guarding because of pain can limit the efficacy of these tests. Additionally, a large knee effusion is evidence of significant intra-articular pathology, such as a fracture or ligament rupture.

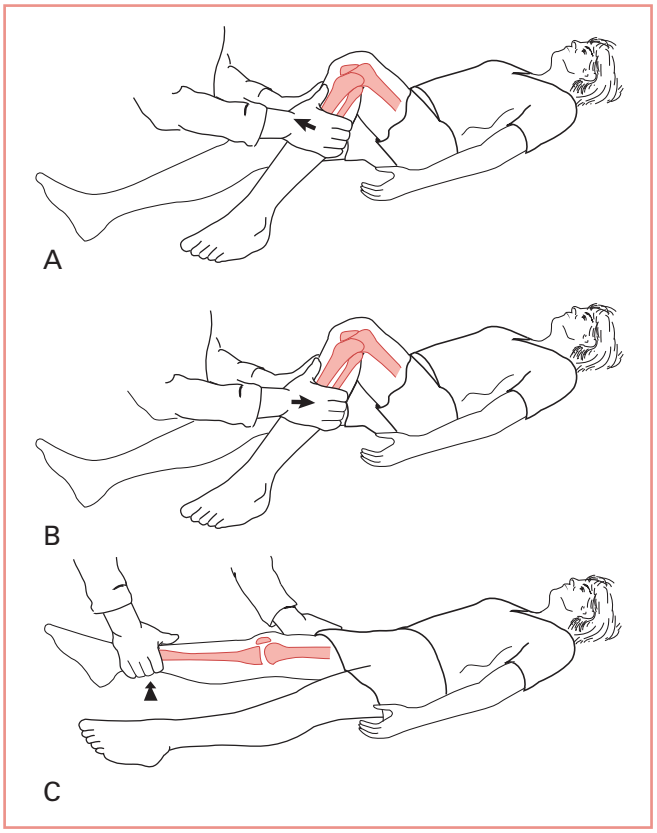

Figure 117.1. Maneuvers used to determine stability of the knee joint. A, Anterior drawer test, in which anterior force is applied (arrow). B, Posterior drawer test, in which posterior force is applied (arrow). C, Medial ligament stability, in which lateral force is applied (arrow).

Muscle spasms and diminished range of motion in an adjacent joint should be noted because these may be signs of a strain injury. Strength of the strained muscle or muscles should be assessed, and any pain with palpation or range of motion should be noted. A palpable defect of the muscle is suggestive of complete rupture of the muscle, whereas muscular contusions are associated with localized pain, soft tissue swelling, or hematoma. Pinpoint tenderness over a particular bone may be indicative of a fracture or, if the tenderness is elicited at the site of a tendon insertion, inflammation. Reviewing the mechanism of injury and the timing of the symptoms often is helpful in differentiating between a fracture and tendinitis.

Laboratory Tests

A complete blood cell count and erythrocyte sedimentation rate may be helpful in adolescents with a history of chronic joint pain or swelling. If the results are abnormal, further workup is indicated to distinguish between a collagen vascular disease (eg, systemic lupus erythematosus), an infection (eg, osteomyelitis), or, rarely, an arthritic disorder (eg, juvenile idiopathic arthritis). In adolescent populations, in which individuals may be sexually active, the physician should consider the possibility of gonococcal arthritis.

Imaging Studies

Often, a plain radiograph of the involved joint or bone is the only necessary diagnostic study. Because ankle sprain is such a common occurrence, it is important to understand when a radiograph is necessary to rule out fracture. The Ottawa Ankle Rules are guidelines for obtaining radiographs in acute ankle injury; they are approximately 100% sensitive and have been validated for use in children older than 6 years (Box 117.4). Plain radiographs of joints above and below the symptomatic area are also sometimes indicated. For example, the Maisonneuve fracture, which is a fracture of the proximal fibula near the knee that can occur with serious ankle injury, can be missed if a knee radiograph is not obtained in addition to ankle views. Advanced diagnostic tests, such as computed tomography, have limited value in the evaluation of an acute soft tissue injury. Magnetic resonance imaging may be indicated for injuries that do not improve despite adequate treatment and rehabilitation. See Chapter 118 for a discussion of imaging studies used to evaluate a child presenting with limp.

Management

With soft tissue injuries, the aim of acute management is to limit the extent of bleeding and inflammation that occur in the first 48 to 72 hours after injury. The mnemonic RICE (rest, ice, compression, elevation) is helpful. Rest should be explained as "relative rest," because the athletes should be allowed to do as they wish as long as they are pain-free during or within 24 hours of the activity. Ice should be placed in a plastic bag and applied directly to the skin for a continuous 20 minutes. Longer periods of icing are discouraged because this can result in peripheral nerve palsy caused by cryoinjury. Patients should ice the injury 3 to 4 times a day for the first 48 hours, after which icing should be done at least once daily until the swelling or pain is gone. Compression is especially important and should be started as quickly as possible after injury. When applying compression bandages, wrapping should begin distal to the injury and should proceed proximally; this prevents trapping of edema and swelling distal to the compression wrap, allowing proper drainage of injured tissue. The injured extremity

Box 117.4. Ottawa Ankle Rules

- Obtain an ankle radiograph if ANY of the following:
  - — Bone tenderness at the posterior edge or tip of the lateral malleolus
  - — Bone tenderness at the posterior edge or tip of the medial malleolus
  - — Bone tenderness along the distal 6 cm of the tibia or fibula
  - — Inability to bear weight both immediately after injury AND in the emergency department for 4 steps
- Obtain a foot radiograph if ANY of the following:
  - — Bone tenderness at the base of the fifth metatarsal
  - — Bone tenderness at the navicular bone
  - — Inability to bear weight both immediately after injury AND in the emergency department for 4 steps

should be elevated as often as possible. The use of this plan for soft tissue injuries facilitates early healing and allows rehabilitation to proceed more quickly.

Anti-inflammatory or analgesic medications, such as ibuprofen, aspirin, and naproxen, are useful in controlling pain and swelling. For adolescent patients, dosages are similar to those used in adults: aspirin, 650 to 1,000 mg every 6 hours; ibuprofen, 400 to 800 mg every 6 to 8 hours; or naproxen, 500 mg twice daily. To minimize gastrointestinal side effects, the medication should be administered with a snack or milk. Ideally, these drugs should be used for 7 to 10 days. Neither oral nor parenteral corticosteroids are indicated in the management of overuse injuries or acute trauma to the extremities.

After the acute phase, therapy is aimed at rehabilitation and resolution of any edema or hematoma (Box 117.5). Athletes should slowly begin range-of-motion exercises as tolerated. Although complete tissue healing may take 6 to 8 weeks, most young athletes may return to athletic activity sooner.

Depending on the degree of tissue damage, modified activity should be recommended initially in athletes who have suffered from overuse syndromes. Complete rest is rarely indicated. Participation in another sport, such as swimming or cycling, often is preferable to complete immobilization. In addition to the use of anti-inflammatory agents, physical therapy is another important therapeutic modality. Cryotherapy, whirlpool baths, or alternating heat and ice treatments can be helpful. Reconditioning should be continued after 3 to 12 weeks of modified activity, depending on the extent of recovery. This entails gradual strengthening and flexibility training as well as reevaluation of previous modes of training to minimize the risk of reinjury (Box 117.6). Additional aspects to consider are strength imbalances and biomechanics, such as those that occur in patellofemoral syndrome. By identifying specific musculoskeletal imbalances, the physician can suggest stretches and strengthening exercises specific to the patient's deficits.

Some sports injuries may require surgical management because of severe trauma to key anatomic structures requiring ligamentous repair or fracture fixation. Tibial spine fractures, ACL reconstruction, and other injuries necessitating hardware, such as osteochondritis dissecans, may result in malunion, deformity, and arthrofibrosis in skeletally immature patients. The closer adolescent patients are to skeletal maturity, the lesser their risk for such sequelae. Orthopedic surgeons and pediatricians must effectively communicate management plans and options to patients and parents or guardians of patients with these injuries so they are prepared for the outcomes and associated complications that may arise.

Box 117.5. Principles of Rehabilitation Following Sports-Related Injury

- Resolution of hematoma
- Resolution of edema
- Regain full range of motion or flexibility
- Regain full muscle strength and endurance
- Regain agility and coordination
- Regain cardiovascular endurance

Box 117.6. Rehabilitation of Musculoskeletal Injuries: The Four Phases[a]

- Limit additional injury and control pain and swelling (RICE mnemonic).
- Improve strength and flexibility (ie, range of motion) of the injured structures.
