The American Academy of Pediatrics is an organization of 67,000 primary care pediatricians, pediatric medical subspecialists, and pediatric surgical specialists dedicated to the health, safety, and well-being of infants, children, adolescents, and young adults.

The recommendations in this publication do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

Statements and opinions expressed are those of the authors and not necessarily those of the American Academy of Pediatrics.

Any websites, brand names, products, or manufacturers are mentioned for informational and identification purposes only and do not imply an endorsement by the American Academy of Pediatrics (AAP). The AAP is not responsible for the content of external resources. Information was current at the time of publication.

The persons whose photographs are depicted in this publication are professional models. They have no relation to the issues discussed. Any characters they are portraying are fictional.

The publishers have made every effort to trace the copyright holders for borrowed materials. If they have inadvertently overlooked any, they will be pleased to make the necessary arrangements at the first opportunity.

This publication has been developed by the American Academy of Pediatrics. The contributors are expert authorities in the field of pediatrics. No commercial involvement of any kind has been solicited or accepted in development of the content of this publication. Disclosures: Dr Allen disclosed a grant relationship with Wisconsin Partnership Program. Dr Greenbaum disclosed a family safety monitory board relationship with Retrophin and with Relypsa, and a family consulting relationship with Vifor and with Bristol-Myers Squibb. Dr Kwong disclosed an independent contractor relationship with Thermo-Fisher Scientific. Dr Ramers disclosed a research relationship with Gilead Sciences.

Every effort has been made to ensure that the drug selection and dosages set forth in this text are in accordance with the current recommendations and practice at the time of publication. It is the responsibility of the health care professional to check the package insert of each drug for any change in indications or dosage and for added warnings and precautions.

Every effort is made to keep *Berkowitz's Pediatrics: A Primary Care Approach* consistent with the most recent advice and information available from the American Academy of Pediatrics.

Special discounts are available for bulk purchases of this publication. Email Special Sales at aapsales@aap.org for more information.

Part 15: Chronic Diseases of Childhood and Adolescence

Preface

It has been nearly 25 years since the publication of the first edition of what was then simply *Pediatrics: A Primary Care Approach*. That book contained 113 chapters and 500 pages. The section titled Chronic Diseases included HIV, chronic lung disease, and chronic osteomyelitis, conditions no longer included in this current edition. The impetus for the book came from a series of noontime lectures I had given to the residents at Harbor-UCLA Medical Center on topics I wish I learned about during my pediatric residency but only acquired by having my own children and in practice. Most of the authors for the first edition were my fellow faculty.

As we move into the sixth edition, the landscape of pediatrics has continued to change and the book has expanded significantly, with 157 chapters, more than 1,000 pages, and authors from around the United States.

While we have conquered many diseases, particularly infectious ones, other problems have befallen our children. These problems, such as poverty, violence, and exploitation, were no doubt present when the first edition was written, but they certainly weren't center stage on our radars. I am pleased with how we have been able to remain in the forefront of pediatrics, expanding to cover the key issues confronting children, their parents, and their communities in the 21st century and recognizing the changing face of the practice of medicine, be it health systems science or population medicine.

I want to thank all our contributors for the quality of their work and for the recommendations for additional chapters. I also want to acknowledge the suggestions we have received from doctors in other disciplines, including family and emergency medicine and the nurse practitioner community.

The Publishing staff members at the American Academy of Pediatrics are outstanding. Mary Kelly, senior editor, professional and clinical publishing, was a particularly patient editor with the reassuring phrase, "It's all good." Thanks also to Laura Underhile, editor, professional/clinical publishing, and Alain Park for their work on the companion instructor's guide. And to Claudette Hoskins, thanks for your help, patience, and the ability to figure out what was wrong with my computer!

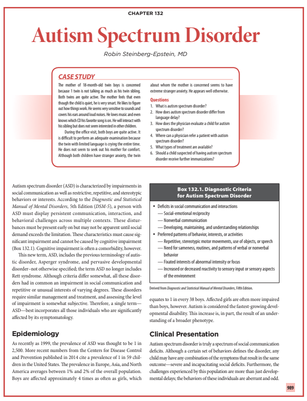
Carol D. Berkowitz, MD, FAAP

Using This Book

For the first time, *Berkowitz's Pediatrics: A Primary Care Approach* has been expanded to a 3-part system that further reinforces the key messages found in the text. The 3 components of this system are

- A *textbook* for use by students and instructors
- An *instructor's guide*
- *Student worksheets*

Together, they form a comprehensive program for students, pediatric residents, pediatric nurse practitioners, pediatric physician assistants, and other health care professionals.

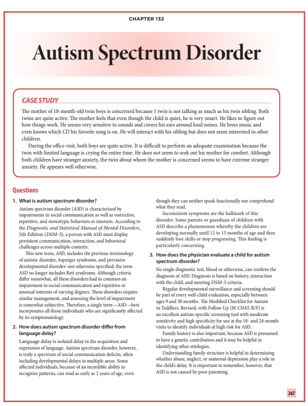


Textbook

The sixth edition of *Berkowitz's Pediatrics: A Primary Care Approach* continues its tradition of providing clear, practice-oriented guidance on the core knowledge in pediatrics. This patient-focused, practical text strives to present users with the situations and challenges they are most likely to encounter in their careers.

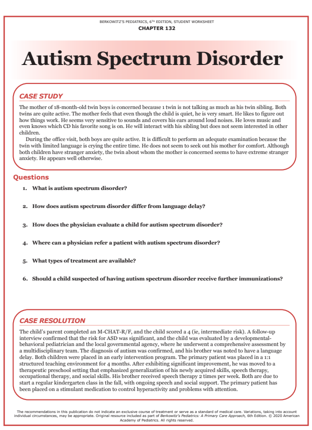
Five new chapters have been added to this edition of the text:

- Health Systems Science
- Population Health for Pediatricians
- Social Determinants of Health: Principles
- Adverse Childhood Experiences: Trauma-Informed Care
- Commercially Exploited Children and Human Trafficking



Instructor's Guide

The newly created *Berkowitz's Pediatrics Instructor's Guide* is designed to help facilitate learner-initiated discussion about core pediatric principles and common pediatric conditions. It also provides answers to the case study questions presented in each chapter of the textbook. The instructor's guide allows for instructor and program flexibility as to how the book and the accompanying questions are used.



Student Worksheets

Student worksheets corresponding to each chapter's case study questions are available online at https://services.aap.org/en/publications/berkowitz/ in a user-friendly format that users can download, complete, and print or email to prepare for discussions. The case study questions contained in the worksheets are designed to help users critically apply the theories presented throughout the textbook. Students will be able to answer all case study questions by reading the corresponding chapter in the text. It is also appropriate to access some of the resources referenced in the chapters.

PART 1

Primary Care: Skills and Concepts

CHAPTER 1

Primary Care: Introduction

Niloufar Tehrani, MD

CASE STUDY

As a primary care physician, you evaluate a 2-year-old boy who is presenting to the office for the first time. The mother states he has always been small; he was born at term but weighed only 2,272 g (5 lb). She is a single mother, and he is her only child. He speaks only 5 words and is quite active. The physical examination is normal, but the boy's height and weight are less than the fifth percentile. The mother reports her son is immunized, but she does not have his immunization records with her at this visit.

Questions

1. What are the 4 components of primary care?
2. What are the main characteristics of a medical home? What are the eligibility criteria for designating a practice as a medical home?
3. What is the difference between a consultation and a referral?
4. Why are laboratory tests done during a routine health maintenance visit?

Primary care is defined as the comprehensive health care a patient receives from the same health professional over a longitudinal period. The term was first used in the 1960s to designate the role of the primary care physician in response to the abundance of subspecialists and lack of generalists among practicing physicians. It is generally accepted that primary care physicians include pediatricians, family physicians, and internists. In 1966, *The Graduate Education of Physicians: The Report of the Citizens Commission on Graduate Medical Education* (the Millis Committee Report) to the American Medical Association recognized the importance of primary care and recommended a national commitment to educating primary care physicians. Primary care was further defined in 1974 by Charney and Alpert, who separated it into component parts: first contact, longitudinal care, family orientation, and integration of comprehensive care. To comprehend the depth of primary care, it is necessary to understand its component parts.

First contact occurs when a patient arrives for medical care at the office of a primary care physician. The visit includes an intake history, complete physical examination, screenings appropriate for age, and an assessment of problems with treatment, if indicated. Of great importance is the establishment of the physician-patient relationship. Physicians become the primary medical resource and counselors to these patients and their families and the first contacts when successive medical problems arise.

Longitudinal care, the second component of primary care, implies continuity of care over time. Physicians assume responsibility for issues concerning health and illness. In pediatrics, such care involves monitoring growth and development, following school progress, screening for commonly found disorders, conducting psychosocial assessments, promoting health, preventing illness with immunizations, and providing safety counseling programs.

Family orientation, the third component of primary care, is a recognition that the provision of adequate care is dependent on viewing patients in the context of their environment and family. In pediatrics, a child's problems become the family's, and the family's problems become the child's. This has become increasingly apparent with the recognition that the social determinants of health (eg, problems of poverty, drug use, obesity, teenage pregnancy, and gang involvement), directly affect a child's health and quality of life (see Chapter 141). The psychosocial forces in a particular child's life are intricately interwoven into that child's health care, and the assessment of these forces is an essential component of the primary care of that child. Environmental exposures (eg, lead contamination of the water supply) have a direct effect on a child's health, and the primary care physician must have knowledge of those environmental threats.

The fourth component of primary care, *integration of comprehensive care*, involves the use of health and educational resources in the community to supplement care as a means of addressing the increased complexity of pediatric medical problems. Primary care physicians integrate and coordinate these services in the best interest of patients. Working with social service agencies, home care providers, educational agencies, and government agencies, physicians can use multiple resources for the benefit of patients. Understanding the available community resources is an important part of a primary care physician's education.

Medical Home

When patients select a primary care physician, they have identified a medical home. The *medical home* incorporates the physical, psychological, and social aspects of individual patients into comprehensive health care services, thus meeting the needs of the whole person. This concept of the medical home was first documented by the American Academy of Pediatrics (AAP) in 1967 in the book *Standards of Child Health Care,* which noted that a medical home should be a central source of all the child's medical records. The

idea of a medical home developed into a method of providing comprehensive primary care and was successfully implemented in the 1980s by Calvin Sia, MD, FAAP, in Hawaii. He is considered to be the "father" of the medical home. In policy statements published in 1992 and 2002 (the latter reaffirmed in 2008), the AAP defined the characteristics of a medical home to be "accessible, continuous, comprehensive, family-centered, coordinated, compassionate, and culturally effective." Geographic and financial accessibility are key elements in making that home work for patients. The most important aspect of a home, however, is that it be a place in which patients feel cared for.

Since its implementation in pediatrics in 2004, the medical home model was adopted by the American Academy of Family Physicians and the American College of Physicians. The definition of the medical home was expanded to include use of electronic information services, population-based management of chronic illness, and continuous quality improvement. The concept has been accepted as a form of high-quality health care. Cost and quality of benefits have been well documented. Recognizing these benefits, large corporations in collaboration with health professionals formed the Patient-Centered Primary Care Collaborative to promote the idea of designated medical homes. As part of that collaborative, the National Committee for Quality Assurance adopted eligibility criteria for a practice to define itself as a medical home. Requirements for the designation include the adoption of health information technology and decision-support systems, modification of clinical practice patterns, and ensuring continuity of care.

With the advent of health care reform in the United States, as part of the effort to control the rising cost of health care, the federal government has endorsed the concept of the medical home model. The Academic Pediatric Association has defined the *family-centered medical home* to delineate the dependency of the child to the family and community in the medical home model. This principle was highlighted in a consensus statement that was developed and jointly endorsed by the AAP, American College of Physicians, American Academy of Family Physicians, and the American Osteopathic Association.

Role of the Primary Care Pediatrician

As a primary care physician, the pediatrician has a role that has included not only the management of acute illness and injury but also the preventive aspects of well-child care with its focus on immunizations, tracking growth and development, and anticipatory guidance. Currently, there exists a renewed emphasis on the importance of the role of the pediatric primary care physician in assessing the psychosocial aspects of pediatric patients. Evaluation of social issues such as family dysfunction, developmental problems (including learning disabilities) and behavioral problems (including emotional disorders), termed the *new morbidity* by Robert Haggerty, MD, in the 1970s, has become a significant part of the role of the physician. In 1993, the AAP stated that pediatricians are obliged to have knowledge of physical and environmental factors and behaviors affecting health, normal variations of behavior and emotional development, risk factors and behaviors affecting physical health, and behavior problems. The focus of the pediatrician should be detection, evaluation, and management, with referrals if necessary. Newer morbidities secondary to the increasing complexity of our society were outlined in 2001 by the AAP. These include school problems, mood and anxiety disorders, adolescent suicide and homicide, firearms, school violence, drug and alcohol abuse, HIV, obesity, and the effects of the media on children. Other psychosocial factors, such as poverty, homelessness, single-parent families, divorce, working parents, and child care, necessitate that pediatricians work with social service agencies to deliver appropriate care to their patients. The role of the primary care physician is continually expanding in an effort to deliver comprehensive care to each patient in a medical home. This care is often rendered by physician-led teams that include other health professionals.

Subspecialist Care

Considerable advancement has been made in medical knowledge and technology in the past several decades. Total knowledge of all fields is impossible for any individual physician. As a result, the role of the subspecialist physician has developed as an adjunct to that of the primary care physician. New fields of subspecialties, such as child abuse pediatrics, have arisen as a response to increased knowledge. The primary care physician should seek subspecialist consultation when the suspected or known disease process is unusual or complicated, in cases that require the use of specialized technology, and in situations in which the primary care physician has little experience with the disease. Generally, subspecialists evaluate patients and concentrate on the organ system or disease process in their area of expertise.

Use of a subspecialist is termed *secondary care*. The primary care physician can elicit the help of a subspecialist in the form of a consultation or a referral. When initiating a *consultation*, the primary care physician seeks advice from the consultant on workup or management of the patient. The consulting physician assesses the patient with a history and physical examination, focusing on the particular specialty. The consultant recommends possible additional laboratory tests and offers a diagnosis and treatment plan, after which the patient returns to the primary care physician for coordination of further care.

Electronic, abbreviated consultations can now be conducted using an e-consultation system. These consultations give the primary care physician a treatment plan, which may also include 1 or more visits to the subspecialist. For example, an 8-year-old girl with weight loss and persistent abdominal pain has an upper gastrointestinal radiograph series that reveals a duodenal ulcer. Her primary care physician requests a consultation from a pediatric gastroenterologist for an endoscopy to allow definitive diagnosis and up-to-date management guidelines. After the procedure, the girl returns to the primary care physician with recommendations for treatment and further care.

Primary care physicians can also generate a referral to a subspecialist, which differs from a consultation. A *referral* requests that the subspecialist assume complete care of the patient. This transfer of

care may be to a tertiary care site where a subspecialist provides care and assumes responsibility for coordinating further patient care. For example, a 4-year-old boy with recurrent fever, hepatosplenomegaly, and blasts on peripheral blood smear is referred to a pediatric oncologist for diagnosis, treatment, and ongoing medical care.

When requesting advice from subspecialists, whether on a consultative or referral basis, the primary care physician should outline specific questions with a probable diagnosis to be addressed by the subspecialist. For example, a consultation requesting evaluation of a child with hematuria is inappropriate. The primary care physician should perform a basic diagnostic evaluation and suggest the most likely diagnosis, after which the child can be referred appropriately. For example, a child with a diagnosis of nephritis should be sent to a pediatric nephrologist, whereas a child with a diagnosis of Wilms tumor should be sent to a pediatric oncologist.

When primary care physicians and subspecialists function cooperatively and offer 3 levels of care (ie, primary, referral, consultative), patients receive the highest quality medical care. Generally, care provided by subspecialists is characterized as being more expensive and procedure driven. Subspecialists order more laboratory studies than primary care physicians, which further inflates the cost of medical care. Additionally, if a patient lacks longitudinal health care and sees multiple practitioners, often repeat laboratory studies are ordered. Compared with subspecialty care, primary care is believed to deliver more cost-effective medical care. The spiraling cost of medical care has resulted in continued nationwide emphasis on producing more primary care physicians. It should be remembered, however, that the subspecialist plays an essential supplementary role to the primary care physician when managing complicated diseases. A balance between generalists and subspecialists must be maintained in the education process.

Laboratory Tests

For most conditions, the diagnosis is revealed by the history and physical examination in more than 95% of cases. Thus, good communication skills are a basic tenet of primary care. Patients frequently complain about unnecessary laboratory tests, which increase the cost of medical care, and the prescription of unnecessary medications. To lessen these problems, the primary care physician should be discriminating when ordering laboratory tests and prescribing medications, recognizing their value as well as their potential iatrogenic effects.

In primary care, laboratory tests are used to help confirm a condition suspected on the basis of the history or physical examination or diagnose a condition that may not be apparent after a thorough history and physical assessment. In pediatrics especially, the value of each test result should be weighed against the inconvenience, discomfort, and possible side effects in children. Tests in at-risk children can also be used as screening tools to prevent disease or identify a disease early so that treatment can begin and symptoms can be minimized. Laboratory studies can provide a host of other information, including data to establish a diagnosis, knowledge necessary to select therapy or monitor a disease, and information about the risk of future disease. Organ function, metabolic activity, and nutritional status also can be assessed, and evidence of neoplastic or infectious disease can be provided. Additionally, laboratory studies can be used to identify infectious and therapeutic agents or poisons.

Screening laboratory tests are used when the incidence of an unsuspected condition is sufficiently high in a general population to justify the expense of the test (see Chapter 13). Subclinical conditions, such as anemia, lead poisoning, and hypercholesterolemia, are part of some health maintenance assessments.

Physicians must remember that variability exists in test results and that laboratory error can occur. Laboratory results should always be viewed in the context of the patient. The sensitivity of a test, the ability of the test to detect low levels, and the specificity of a test for the substance being measured must also be considered by the physician when evaluating a test result.

Challenges for the Future

The role of the primary care physician in health care delivery has increased in importance. In 2010, the Patient Protection and Affordable Care Act was signed into law. This law emphasizes the importance of the medical home and promotes its implementation. Two of the basic tenets of primary care—accessibility and an ongoing relationship with the primary care physician, both of which are reported by patients to be very important—are recognized as essential components of the medical home. The challenge continues to ensure continuity in health care funding to preserve the continuity of the medical home. Payment reform promises to improve payment to primary care practices and rewards high performance. As proposed in health care reform, through accountable care organizations, primary care physicians would be the foundation of the organization whose mission is management of the continuum of care and cost as well as ensuring quality of care.

Access to same-day care, which is part of the obligation of the medical home and essential to pediatric patients, can be difficult in the busy schedule of primary care physicians. Practices must accommodate these visits. Community health centers can provide excellent medical homes for children in families with low income; however, these centers can have challenges with accessibility and adequate referral sources. Walk-in immediate medical care clinics and retail clinics have arisen, but episodic visits in a variety of settings do not deliver comprehensive care for the patient, and these short visits may not take into account the entirety of the patient's medical history. This creates a challenge for the primary care physician and medical home to develop a system to integrate the information from these encounters into the comprehensive medical record.

With the advent of hospitalists providing inpatient care, primary care physicians may not be included in inpatient management, which can make it challenging for primary care physicians to retrieve important information about the care of their patients.

Medical care reform incorporates accountability, demonstration of quality of care, and standards of medical practice into the medical home model, which has resulted in an exponential increase in the

oversight and bureaucracy of medical care. This business of medicine with redundant oversight of medical care has placed a tremendous burden of administrative activities on the primary care physician. Physicians face a significant challenge in providing care while answering to administrative structures. Additionally, although the use of electronic medical records decreases some of the challenges of information retrieval and communication among medical providers, it poses other challenges in a potential lack of pediatric functionality and loss of productivity.

The biggest challenge for pediatric primary care physicians has always been to ensure the future of health care funding to provide all children access to and availability of a medical home. The Patient Protection and Affordable Care Act aims to provide health coverage for nearly all children, but in a multipayer, market-driven health care system, significant challenges will remain. A multitude of programs exist to pay for children's health care, and these programs vary by state. Families move among payers, which disrupts continuity of care. Universal health care for children is being advocated. Without a secure national plan for financing, children's health care will continue to be variable, resulting in disparities in children's health.

CASE RESOLUTION

You ask the mother about her son's former physician and obtain signed permission to get the prior medical records, including immunizations. You attempt a hearing assessment as the initial step in evaluating his speech delay, but the patient does not cooperate. You ask the mother about access to food and complete a referral to the Special Supplemental Nutrition Program for Women, Infants, and Children and provide her with information about the Supplemental Nutrition Assurance Program (ie, food stamps). You provide the patient with an age-appropriate book from Reach Out and Read and make a return appointment for 1 month hence to continue care and determine whether the patient needs any immunizations.

CHAPTER 2

Talking With Parents

Geeta Grover, MD, FAAP

CASE STUDY

An 8-month-old boy with a 1-week history of cough and runny nose; a 2-day history of vomiting, diarrhea, and fever; and a temperature of 38.3°C (101°F) is evaluated in the emergency department (ED). The mother is very concerned because her son's appetite has decreased, and he has been waking up several times at night for the past 2 days.

A nurse interrupts and says that paramedics are bringing a 5-year-old trauma victim to the ED. The appearance of the 8-month-old child is quickly assessed; he seems active and alert. Bilateral otitis media is diagnosed. Before leaving the examination room the physician says to the mother, "Your son has a viral syndrome and infection in his ears. I am going to prescribe an antibiotic that you can begin giving him today. Give him ibuprofen as needed for the fever. Don't worry about his vomiting and diarrhea; just make sure that he drinks plenty of liquids and don't give him milk or milk products for a few days. Bring him back here or to his regular doctor if his fever persists, he doesn't eat, he has too much vomiting or diarrhea, he looks lethargic, or if he isn't better in 2 days."

Questions

1. How much information can most parents absorb at one time? Did this mother receive more information than she can reasonably be expected to remember?
2. How do you assess parental concerns? Did the physician sufficiently address the mother's worries?
3. How do you know whether a parent has understood all the information? Was this mother given a chance to clarify any questions she had?
4. What are some barriers to effective doctor-parent communication?
5. How does the setting itself influence communication?

Communication is the foundation of the therapeutic relationship between physicians, patients, and patients' families. Effective communication in the pediatric setting involves the exchange of information between physicians, parents, and children. In addition, observing the interaction between parents and children gives physicians an opportunity to assess parenting skills and the dynamics of the parent-child relationship. The communication needs of parents and children are quite different, which makes the exchange of information challenging. Parental concerns should be addressed in a sensitive, empathetic, and nonjudgmental manner. A nonthreatening, pleasant demeanor and age-appropriate language help facilitate communication with children (see Chapter 3).

Pediatrics encompasses not only the traditional medical model of diagnosis and treatment of disease but also maintenance of the health and well-being of children through longitudinal care and the establishment of ongoing relationships between physicians and families. Personal relationships between physicians and families create an atmosphere in which information can be exchanged openly. The pediatrician's role in such relationships is to not only diagnose and treat but also to listen, advise, guide, and teach.

The doctor-patient relationship is truly a privilege. Patients entrust physicians with their innermost thoughts and feelings, allow them to touch private parts of their bodies, and trust them to perform invasive procedures or administer medications. Mutual respect is essential for the development of a healthy relationship between physicians, parents, and children. Through practice and continued awareness of interpersonal abilities, the physician can develop good communication skills. All physicians eventually develop their own personal interviewing and examination style. What seems awkward and difficult at first soon becomes routine and even enjoyable as the physician becomes more comfortable with patients and their families.

Parental Concerns

Parents' preconceived ideas and concerns about their children's illnesses can greatly influence the exchange of information between physicians and parents. At health maintenance or well-child visits, it is important for the pediatrician to address parents' nonmedical and psychosocial concerns, such as their children's development, nutrition, and growth. Often these questions stem from discussions with other parents or, increasingly, from information received from various online and media resources (see Chapter 7). Although such concerns may seem trivial to the pediatrician, they may be extremely important to parents. In addition to addressing the needs of the child, the health maintenance visit also affords the pediatrician an opportunity to assess and address parental needs. Parental depression, substance abuse, family violence, or marital discord all can have profound effects on children's health and development. Similarly, the conditions in which children and their families live,

learn, work, and play can affect both physical and emotional health. Collectively, these conditions are known as the *social determinants of health* (see Chapter 141).

When evaluating children brought in for illness, it is important to ask parents what concerns them most. Parental fears may be much different from medical concerns. Failure to give parents the opportunity to ask questions or to address these concerns in a sensitive manner may result in dissatisfaction and poor communication.

The Pediatric Interview

Pediatric interviews are conducted in a variety of settings for many different reasons. The first interaction between the physician and parent or parents may be during the prenatal interview before the birth of the child, in the hospital following the delivery, or in the doctor's office during the well-baby visit. Later, the physician may see a child in the office for regular health maintenance visits or in the office, emergency department (ED), or hospital for an acute illness.

The specific clinical situation dictates the information that must be gathered and the appropriate interviewing techniques. During the prenatal visit, the physician should discuss common concerns and anxieties about the new baby with the prospective parent or parents. In addition, the prenatal visit affords the parent or parents an opportunity to interview physicians and evaluate their offices and staff.

In the emergency setting, the physician must elicit pertinent information necessary to make decisions about management within a short period. Lack of a long-term relationship can make communication in the ED particularly challenging. The physician should mostly use focused, closed-ended questions in this setting. For the periodic health maintenance visit, however, the use of broad, open-ended questions is more appropriate, and closed-ended questions should be used only as necessary for clarification.

Communication Guidelines

Professionalism encompasses technical, intellectual, and humanistic competencies. Clinicians are increasingly seeing conditions that may not be treatable; however, that does not mean the clinician cannot provide healing. Whereas "treatment" focuses on cure, "healing" is about building relationships with patients and helping them optimize emotional and physical health so that they may continue to pursue what has meaning and value for them.

Overall principles that are applicable regardless of the setting include interacting with the child and family in a professional yet sensitive and nonjudgmental manner. Common courtesies, such as knocking before entering the room, dressing and behaving in a professional manner, introducing oneself, and addressing parents and children by their preferred names, are always appreciated and welcomed. Taking a few moments to socialize with families develops a more personal relationship that may allow more open conversation about sensitive and emotional issues.

Family-centered care is an approach to health care in which the physician realizes the vital role that families play in ensuring the health and well-being of children. Physicians who practice family-centered care convey respect for parents' insight into and understanding of their children's behavior and needs, and actively seek out their observations and incorporate their family preferences into the care plan as much as possible. Benefits of family-centered care include a stronger alliance between the physician and family; increased patient, family, and professional satisfaction; and decreased health care costs. Since the passage of the Health Information Technology for Economic and Clinical Health (HITECH) Act in 2009, the electronic medical record (EMR) is increasingly affecting the practice of medicine (see Chapter 6). Although the EMR has the potential to improve patient understanding of health information as well as to improve sharing of medical information, without conscious effort to adjust clinical speaking and documentation practices, this new model of practice may also negatively affect patient-centered communication. Some behaviors that facilitate patient-centered communication with the EMR include screen-sharing, cessation of typing during sensitive discussions, and maintaining eye contact or continuing to speak while typing. In this digital age, physicians are learning to listen, talk, think, and type simultaneously.

The medical visit may be divided into 3 parts: the interview, physical examination, and concluding remarks. Examples of doctor-parent and doctor-child communications for each of these components are provided in Table 2.1.

Interview

The goal of the interview is to ascertain the chief concern, determine appropriate medical history, and gain an understanding of the family's perspective of the illness or its specific concerns. It is important to address cognitive (ie, informational) and affective (ie, emotional) needs of the family during the interview. The interview usually begins with open-ended questions to give parent and child an opportunity to discuss their concerns and outline their agenda for the visit. Often, the real reason for the visit is not disclosed until the family believes the physician to be trustworthy and honest. Rachel Naomi Remen, MD, coined the term *generous listening* to describe a technique of receiving and respecting information without judgment or any agenda to analyze it and determine what to do next. Generous listening creates a space of safety that allows parents and children to say what they perceive to be true. After issues have been laid out, closed-ended questions can be used to clarify and further define the information presented. It often becomes necessary to guide the interview, especially when parents have several broad issues on their agenda for that visit and time does not permit discussion of them.

The physician should gently acknowledge parental concerns and define time limitations. These actions allow the physician to focus on the most salient issues of that visit. Additionally, the physician should limit the use of medical jargon (ie, scientific terms) and be aware of nonverbal communication. A sincere, empathic, and compassionate communication style helps parents feel truly understood even if the physician can do little to help the situation. Pauses and periods of silence should be used, especially when discussing emotionally difficult issues, to convey to parents and children

Table 2.1. Communication Guidelines and Techniques for the Pediatric Medical Visit

Component of Medical Visit	*Technique*	*Examples*
Interview	Open-ended questions.	"How is Susie?"
	Closed-ended questions.	"Does she have a cough?"
	Repetition of important phrases.	"She has had a high fever for 4 days now?"
	Reflective listening.	"It sounds like you are concerned that this may be serious."
	Clarification.	"What do you mean by, 'Susie was acting funny'?"
	Pauses and periods of silence.	"I see that it is difficult for you to talk about this. Take your time."
	Limit medical jargon.	"Susie has an ear infection" vs "Susie has otitis media."
	Guide the interview.	"Right now, I am most interested in hearing about the symptoms of this illness."
	Be aware of nonverbal communication.	Use eye contact and phrases such as "I see."
	Acknowledge parental concerns.	"Worrying about hearing loss is understandable."
	Empathize.	"A temperature of 104°F can be very frightening."
	Remember common courtesies.	Knock before entering.
	Recognize personal limitations.	"I am not an expert in this area. I would like to consult with a colleague."
	Summarize.	"So, she has had fever for 4 days, but the rash and cough began 1 week ago?"
Physical Examination	Show consideration for the child.	"It's OK to be afraid."
	Inform.	"That took me some time, but her heart sounds normal."
	Explain procedures.	"You may feel a little uncomfortable during the rectal examination."
	Avoid exclamations.	"Wow! I have never seen anything like this!"
Concluding Remarks	Provide closure.	"Our time is over today. May we discuss this at the next visit?"
	Minimize discharge instructions.	"Call me if her rash recurs."
	Be specific.	"I am going to treat her with amoxicillin" vs "I'll prescribe an antibiotic."
	Praise and positive feedback.	"You're doing a great job."
	Confirm parental understanding.	"Please repeat for me Susie's diagnosis and treatment instructions so I'm sure I've been clear in explaining them to you."
	Give the parent or parents permission to ask questions.	"Please feel free to ask me about anything that concerns you."
	Reassurance.	"I know you are worried about her high fever, but I can reassure you that the fact she is playful and hungry are both good signs."

that their physician cares enough to listen. Physicians should not underrate their own knowledge; however, they should recognize their limitations and use consultants appropriately. Finally, the physician's understanding of the chief concern and history should be summarized so that the parent or parents have an opportunity to clarify points of disagreement.

The primary care physician faces increasing demands to address not only the physical but also the psychosocial health needs of patients. *Patient-centered care* is a comprehensive approach to medical care that encourages communication between the physician, patient, and family. The clinician addresses the immediate pressing medical concerns in the context of each patient's unique environmental circumstances and underlying psychosocial concerns, both of which may directly or indirectly affect health-related outcomes. Empathy, unconditional positive regard, and genuineness are essential physician characteristics in this collaborative approach.

Motivational interviewing is one such patient-centered, collaborative, and directive interaction style that offers an effective means of addressing these developmental, behavioral, and social concerns within the context of a primary care setting. *Motivational interviewing* addresses the ambivalence and discrepancies between a person's current values and behaviors and the person's future goals. In contrast to more traditional medical approaches that rely primarily on authority and education, motivational interviewing is a collaborative approach that relies on eliciting the patient's ideas about change. The physician who practices motivational interviewing understands that trying to move beyond a patient's readiness to change is likely to increase that patient's resistance to treatment; for example, lecturing to an adolescent who is not yet ready to quit smoking about the dangers of smoking is unlikely to be effective and may even produce more resistance. Motivational interviewing requires that the physician follow the 4 principles listed in Table 2.2.

Table 2.2. Principles of Motivational Interviewing

Principle	*Example*
Express empathy.	Use reflective listening.
Identify discrepancy between patient's current behavior and treatment goal.	Patient, not physician, presents arguments for change.
Decrease the likelihood of evoking patient resistance.	Avoid arguing for change.
Support the patient's self-efficacy.	Patient's own belief in the possibility of change is an important motivator.

Derived from Miller WR, Rollnick S. *Motivational Interviewing: Helping People Change.* 3rd ed. New York, NY: Guilford Press; 2013.

Operationally, open-ended questions (eg, "How do you feel about smoking?"), affirmations (eg, "You are tired of having to monitor your blood sugar every day and stick to your diet."), and reflective listening (eg, "You are worried about your daughter's behavior and are concerned that if it persists, she may be expelled from school.") are important tools of motivational interviewing. In addition, physicians who practice motivational interviewing ask permission before giving advice (eg, "Would it be OK if I shared some information with you?"). Alternatively, the physician may state the facts but let the parent interpret the information (eg, "What does this mean to you?"). Research has also shown motivational interviewing to be an effective tool for use with adolescent patients to increase self-efficacy to enact change (eg, adolescent smoking cessation).

Physical Examination

Parents keenly observe physicians' interactions with their children during the examination. It is an important time for the physician to build a therapeutic relationship with the child (see Chapter 3). The transition between the history and physical examination can be made by briefly telling the child and parent what to expect during the examination. The physician should show consideration for the child's fears. In general, physicians often find it helpful to speak with families at periodic intervals during the examination about their observations. Prolonged periods of silence as the physician listens or palpates may be anxiety provoking for the family. Physicians should explain any procedures that they or their staff are going to perform at a level that is appropriate for parents and children. In addition, the physician should try to avoid exclamations or comments to self during the examination (eg, "Wow, that's some murmur!"), which may be alarming to the family.

Concluding Remarks

The conclusion of the visit, which is all too easy to rush through, is extremely important. Closure can be provided by summarizing the diagnosis or outlining plans for a follow-up visit. The parent or parent should be asked to participate by acknowledging closure and helping to develop a management plan. Shared decision making and a consumer model are replacing the traditional paternalistic medical model in which the physician decided what should be done and the patient accepted the recommendations without question. In this shared decision making model, it is important to assess parental readiness for knowledge (especially in emotionally difficult situations) and keep family resources and limitations in mind. Discharge instructions should be minimized, the physician should be specific, and the number of diagnoses, medications, and "as needed" instructions (ie, indications for seeking medical advice, such as "return as needed for high fever") should be limited. When complicated discharge instructions are given, additional physician time may be required to ensure parental understanding. Praising parents on care of their children can boost their self-esteem and confidence and may minimize calls and questions. Parental understanding should be confirmed; parents should be asked to repeat the diagnosis and treatment plan. Simply asking parents if they have understood is not enough because they often say "yes" out of respect for the physician's time or embarrassment that they have not understood what has been said. For example, the physician could say, "I want to be sure that I've spoken clearly enough. Please repeat for me [child's name] diagnosis and treatment instructions."

Barriers to Effective Communication

Barriers to effective communication can be divided into systems-related barriers and interpersonal barriers (Table 2.3). The primary systems barriers are the setting itself and lack of continuity of care. Because of access problems within the health care system (ie, lack of health insurance coverage), many children receive only episodic care from different physicians in acute care clinics or EDs. Without the benefit of long-term relationships, doctor-patient communication may suffer.

Interpersonal barriers include physician time constraints, frequent interruptions, and cultural insensitivity. Frequent interruptions or apparent impatience on the part of the physician conveys to parents and children that the physician does not care or is too busy for them. Language differences may pose

Table 2.3. Barriers to Effective Communication

Barrier Category	*Specific Type of Barrier*	*Example*
Systems	Lack of continuity of care	Episodic care that is primarily illness driven
	The setting itself	Emergency departments and acute care clinics
Interpersonal	Physician time constraints	Appearing impatient or preoccupied
	Frequent interruptions	Pager goes off or asked to come to the telephone
	Cultural insensitivity	Suggesting treatments that are not acceptable within the family's belief systems

a significant barrier, depending on the region in which the physician practices. Ideally, physicians themselves should be able to speak directly with parents and children. If translators are needed, children must not play this role because doing so places them in an awkward situation. Parents of other patients must not be used either, because doing so would violate the patient's privacy. Only professional translators are recommended. Physicians should be sensitive to cultural differences (eg, issues about sex and gender, views on illness, folk remedies, beliefs). Suggesting treatments that are not culturally acceptable or are contrary to folk wisdom simply decreases compliance with prescribed treatment plans. For example, many Eastern cultures believe in the concept of "hot" and "cold" foods and illnesses. Suggesting to a mother that she feed primarily "hot" foods to a child she believes to have an illness that is also "hot" may not be acceptable to her. Such information is rarely volunteered and must be elicited through culturally sensitive patient interviewing.

Not only is effective communication essential for accurate diagnosis, but it is also correlated with improved patient recall of instructions and adherence to prescribed courses of treatment. Poor communication can have negative consequences for the patient (eg, compromised care) and physician (eg, medicolegal consequences). Effective communication enhances medical outcomes and patient satisfaction.

CASE RESOLUTION

The doctor-patient interaction presented in the case study illustrates several of the "not to" points discussed herein. The physician did not acknowledge parental concerns or make sure that the mother had understood the diagnosis and treatment plan. The mother was presented with more information than she could have reasonably been asked to remember. This interaction could have been improved had the physician conveyed to the mother that her concerns were appreciated and reassured her that her child was going to be all right. Furthermore, the physician should have told the mother the name and dosage schedule of the antibiotic to be prescribed and limited the number of "as needed" instructions.

CHAPTER 3

Talking With Children

Geeta Grover, MD, FAAP

CASE STUDY

The moment you walk into the examination room, the 2-year-old girl begins to cry and scream uncontrollably. She clings to her mother and turns her face away. The mother appears embarrassed and states that her daughter reacts to all physicians this way. After reassuring the mother that you have received such welcomes before, you sit down at a comfortable distance from the girl and her mother. You smile at the girl and compliment her on her dress, but she does not seem to be interested in interacting with you at this point. You place an age-appropriate book on the examination table, indicating to the child that the book is for her. You begin your interview with the mother and try not to look at the girl. Out of the corner of your eye, you see that her crying is easing and she has begun to examine the book you had placed on the table.

Questions

1. How does the age of children influence their understanding of health and illness?
2. Should physicians speak directly with children about their illnesses?
3. At what age can children begin to communicate with physicians about their illnesses?
4. How can older children be involved in the management of their health?
5. How can positioning and placement of children in the examination room affect the overall tone and quality of the visit?

Effective communication is essential in developing a meaningful and trusting relationship with children. In pediatrics, interviewing involves balancing the needs of parents and children. Whereas parents may be more focused on issues pertaining to disease, treatment, or aspects of parenting, children look to physicians with different needs and concerns, depending on their age. Developmental maturity, cognitive level, language ability, and sociocultural factors all play a role in a child's ability to communicate and affect their concepts of health and illness. As children grow and develop, their understanding of health and illness matures and develops as well. Developmentally sensitive communication helps build a trusting relationship that allows pediatricians to guide children as they grow to make appropriate decisions about their own health as well as assume responsibility for behaviors that may affect their health and well-being. The American Academy of Pediatrics advises that physicians have both a moral and an ethical obligation to discuss health and illness with children, and further, in keeping with their developmental capacities, allow them to be active participants in their own care.

Developmental Approach to Communicating With Children

Childhood is a time not only of considerable physical growth but also of tremendous social, emotional, and cognitive maturation. An appreciation of the cognitive stages of development helps pediatricians develop a healthy relationship with their patients by allowing them to communicate with children in an age-appropriate manner. Piaget defined 4 stages of cognitive development, which occur in the same sequence but not at the same rate in all children (Table 3.1).

In the *sensorimotor stage* (birth–2 years of age), children experience the world and act through sensations and motor acts. They are developing the concepts of object permanence, causality, and spatial relationships. In the *preoperational stage*, (2–6 years of age), children understand the world only from their own viewpoint. As egocentric thinkers, they are unable to separate internal from external reality, and fantasy play is important. School-age children (6–11 years of age) are capable of *concrete operational thinking*. These children can reason through problems that relate to real objects. Older children (>11 years of age) have the capacity for abstract thought, which defines the *formal operations* stage.

Table 3.1. The Four Stages of Cognitive Development According to Piaget

Age[a]	Stage	Characteristics
Birth–2 years	Sensorimotor	Experiences the world through sensations and motor acts
2–6 years	Preoperational	Egocentric thinking Imitation and fantasy play
6–11 years	Concrete operational	Mental processes only as they relate to real objects
>11 years	Formal operations	Capacity for abstract thought

[a] Approximate ages.

An appreciation of how children's cognitive development affects their understanding of illness and pain aids physicians in developing therapeutic relationships with their patients. When using a developmental approach to children's understanding of illness, children's explanations of illness are classified into 6 categories that are consistent with Piaget's cognitive developmental stages (Table 3.2). Children 2 to 6 years of age view illness as being caused by external factors near the body (ie, phenomenalism, contagion). Young children engage in so-called magical thinking; proximity alone provides the link between cause and illness. Children 7 to 10 years of age should be able to differentiate between self and nonself. At this stage, they begin to understand that although illness may be caused by some factor outside the body, illness itself is located inside the body (ie, contamination, internalization). Children 11 years of age and older understand physiologic and psychophysiologic explanations of illness.

A similar developmental sequence applies to children's understanding of pain. Younger children may attribute pain to punishment for some transgression or wrongdoing on their part. They may not understand the relationship between pain and illness (eg, "Pain is something in my tummy."). Children with concrete operational thought can appreciate that pain and illness are related, but they may not have a clear understanding of the causation of pain (eg, "Pain is a feeling you get when you are sick."). Older children and adolescents begin to understand the complex physical and psychologic components of pain. For example, they realize that although the bone in the arm is broken, pain is ultimately felt in the head (eg, "Pain goes up some nerves from the broken bone in my arm to my head.").

Guidelines for Doctor-Child Communication

A developmental framework that accounts for children's language skills and causal reasoning abilities is essential in providing appropriate health care to children. Successful communication with children depends not only on spoken words but also on nonverbal cues and the environment itself. A pleasant, child-friendly environment with bright colors, age-appropriate wall decorations, and toys helps make children feel more comfortable. Health professionals should be sincere, because children are extremely sensitive to nonverbal cues. The pediatrician should take a few minutes to enjoy time with the child; this not only gives the child a chance to evaluate the physician but also allows the clinician to begin assessing areas of development. A general principle of the pediatric examination is to begin with the least invasive portions of the examination (eg, heart, lungs, abdomen) and save the most invasive for last (eg, oropharynx, ears). Pediatricians should maintain their self-control in difficult situations. If they approach their limit, they should step outside for a few minutes or ask someone for assistance. Guidelines for physician-child communication are provided in Box 3.1. Age-specific guidelines exist for children from birth to 6 months of age, 7 months to 3 years of age, 3 to 6 years of age, 7 to 11 years of age, and 12 years and older.

Birth to 6 Months of Age

Newborns and infants through 6 months of age have not yet developed a fear of strangers and can therefore usually be easily examined in a parent's arms or on the examination table. Although verbal interaction is limited, it is important to play with newborns and infants, hold them, and talk to them. By watching physicians interact with their infants, new parents have an opportunity to learn how to behave with their infants.

Seven Months to 3 Years of Age

Infants and children 7 months through 3 years of age are perhaps the most challenging with whom to develop rapport and on whom to perform examinations. After entering the examination room, pediatricians should take a few moments to converse or play with these infants and children. Such actions help put children at ease and allow them to get to know their doctor. Children 1 to 2 years of age

Table 3.2. Children's Concepts of Illness

Stage of Cognitive Development	*Age*	*Concept of Illness*	*Question*	*Example of Child's Answer*
Preoperational	2–6 years	Phenomenism	How do people get colds?	"From the sun."
		Contagion	How do people get colds?	"When someone else gets near them."
Concrete Operational	7–10 years	Contamination	How do people get colds?	"You're outside without a hat and you start sneezing. Your head would get cold—the cold would touch it—and then it would go all over your body."
		Internalization	How do people get colds?	"In winter, people breathe in too much air into their nose and it blocks up the nose."
Formal Operations	≥11 years	Physiologic/psychophysiologic	How do people get colds?	"They come from viruses, I guess."
			How do people get a heart attack?	"It can come from being all nerve-racked. You worry too much, and the tension can affect your heart."

Box 3.1. Physician-Child Communication

Do

- Provide a pleasant environment.
- Pay attention to nonverbal cues.
- Be sincere and honest.
- Enjoy interacting with the child.
- Speak to the child in an age-appropriate manner.
- Get down to the child's eye level.
- Examine from least to most invasive.
- Respect the child's privacy.
- Maintain self-control.
- Have a sense of humor.

Don't

- Limit the child's participation.
- Threaten the child.
- Compare the child to others.
- Engage in power struggles.

will likely busy themselves exploring the room during the history taking. By acknowledging them periodically, physicians build rapport that will help later during the examination. Children 2 to 3 years of age are usually very apprehensive of the examination. The physician should get down to children's eye level when speaking to them. If applicable and true, reassurances such as, "You're not going to get any shots today," can help alleviate their fears. Making false promises, however, can be detrimental to developing a trusting relationship. Because stranger anxiety has developed, the physician should try to do as much of the examination as possible with the child in the parent's lap. Distractions such as stethoscope toys, flashing penlights, or keys may be helpful.

Three to 6 Years of Age

Children's expressive capabilities are growing at tremendous rates during this period. Children can usually be engaged in conversation. Although they should be given repeated opportunities for participation, they should not feel pressured to take part. Children may doubt the physician's true intentions and will likely speak only after their comfort level has been achieved. One way to involve children in the examination is to ask simple questions about their illness (eg, "Where does it hurt?"). In addition, children should be given some control during the examination (eg, "Should I look in your mouth next or your ears?"), and they may be allowed to handle or inspect physicians' equipment when possible. Knowing what to expect next and having some control over the examination can help decrease children's fear and increase their cooperation.

Seven to 11 Years of Age

Making a conscious effort to involve children in this age group in all phases of their care, from gathering data to developing a care plan, can be rewarding because children in this age group are increasingly able to be partners in their care. The physician should make a point of speaking directly with children and not just with parents concerning the chief symptom and history. Pediatric encounters are usually dominated by parents, but the clinician can encourage children to speak by addressing them by name or directing eye gaze toward them. Children can usually provide a good history of their illness, although their concept of time may be misleading. For example, a "long, long time" may mean hours, days, or months, and parents need to clarify this. Children should be asked about school, friends, and favorite activities. Answers to such questions give the physician an idea of children's social and emotional well-being, which may be affecting their physical health. Physicians sometimes overlook children's need for privacy at this age. Drapes should be used appropriately during the examination, and the physician should be sensitive to the presence of other children or adults in the room.

Physicians should begin to involve older children in the management of their illness. Children's understanding of their illness and its management should be assessed (eg, children with asthma could be asked, "What is this inhaler for? When are you going to use it? Show me how."). Children should be given an opportunity to express their fears and anxieties, and these concerns should be discussed (eg, "Asthma can be scary, especially when you can't catch your breath. Have you ever felt like that? Tell me about it."). Children should be involved in the management of their illness, which allows them to develop a sense of responsibility for their own health and medical care. Active participation in their health care visits results in greater visit satisfaction, knowledge, and competence of prescribed medical therapies.

Age 12 Years and Older

Communication with adolescents is discussed in detail in Chapter 4.

Children and Health Literacy

Health literacy (see Chapter 34) is a person's ability to receive, understand, and use information to make appropriate health decisions. At what age does an individual become responsible for his or her own health? Although in the medical setting children often have limited involvement in medical decision making about their own health, in the community children are routinely making decisions that affect their well-being. For example, a 4-year-old chooses water instead of a soda at a friend's birthday party; a 6-year-old runs home to put on her helmet before she rides her neighbor's new bike; an 8-year-old recognizes that her cough is the first sign of an impending asthmatic attack and goes to the school nurse to use her inhaler; or a 12-year-old refuses the cigarette she is being offered. Health attitudes and behaviors learned during childhood affect adult lifestyle choices and thereby health. Health literacy skills should be encouraged from a young age. If information is presented in an age-appropriate manner, children between ages 3 and 18 years are capable of understanding and using health information. In today's world of patient-centered care and ever-increasing accessibility to health information through new technologies, it is imperative that physicians encourage patients to be knowledgeable consumers beginning at a young age.

Barriers to Effective Communication With Children

The manner in which adults speak to children is influenced by what they think children can understand. Physicians tend to overestimate the understanding capabilities of younger children and underestimate those of older children. Lack of appreciation for the cognitive sophistication of children may result in frustration for all involved. Younger children are presented with information they may not be able to comprehend, and older children may feel frustrated because they are being spoken to as though they are much younger.

Overestimating children's receptivity to medical information can be particularly problematic in the case of children with chronic illness. It is easy to assume that children with chronic medical conditions or those with more hospitalizations would have more sophisticated understanding of illness causation. Although these children may seem more savvy and knowledgeable about medical procedures, little research exists to support the assumption that they have more sophisticated understanding of illness causation than would be expected based on their age or developmental level, or that they are better able than their peers without chronic medical concerns to understand and retain medical information.

Another potential barrier in communicating with children is limiting their participation. Physicians tend to elicit information from children but exclude them from diagnostic and management information. Especially when dealing with chronic or serious illness, children should be asked about their desired level of involvement. Children want to know about their illness and will use whatever information is available to them to make sense of their situation. Developmentally sensitive communication allows children access to usable information, improves their understanding of their situation, decreases fear, and contributes positively to their ability to participate in management.

Providing pediatric care can be both rewarding and enjoyable, but many physicians have been frustrated or pushed to the limit at some point when working with children. On the part of the child, crying or lack of cooperation generally stems from fear or a sense of lack of control over the situation. On the part of the physician, engaging in power struggles or making threatening remarks (eg, "If you're not good, I'll have to give you a shot.") or comparisons between siblings (eg, "Your brother is younger than you and he didn't cry.") are not only ineffective but may make the situation worse. A clear perspective, mindful consideration of developmental level, empathy, and a sense of humor are much more useful.

CASE RESOLUTION

You learn from the mother that her daughter has been in good health. The mother has brought in the child for a routine health maintenance visit. You assess that the child's development is normal and her immunizations are up-to-date. As you and the mother talk, the child appears more relaxed and less frightened. You use the book to engage and distract the child during the examination. She begins to respond to your questions and cooperate with the examination, but she chooses to remain on her mother's lap. Praising a child who is cooperative helps reinforce preferred behavior.

CHAPTER 4

Talking With Adolescents

Monica Sifuentes, MD

CASE STUDY

This is a first-time visit for a 15-year-old girl who is accompanied by her mother. The mother is concerned because her daughter's grades have been dropping since beginning high school, and she appears fatigued and irritable. The mother reports no new activities or recent changes in the home situation and no new stressors in the family. Both parents are employed, the girl has most of the same friends she has always had, and her siblings currently are doing well academically. The girl is healthy and has never been hospitalized. After the mother leaves the room, the girl is interviewed alone.

Questions

1. When interviewing adolescents, what is the significance of identifying their stage of development?
2. What are important areas to cover in the adolescent interview?
3. What issues of confidentiality and competence need to be discussed with adolescents before conducting the interview?
4. When should information be disclosed to others, despite issues of confidentiality?

Adolescence is a time of unique change from a cognitive, physical, and neurobiological standpoint. Unlike other periods in life in which individuals have at least some knowledge or experience to guide them, adolescence can be characterized by feelings of physical awkwardness, emotional turmoil, and social isolation. In addition, the teenage years are dreaded by most parents, who often feel ill-equipped to handle the unpredictability of their children's responses to puberty and daily social interactions. Rather than directly approach their adolescent, some parents choose to engage in quiet observation. They fully intend to support their children but wait to be approached. Thus, many adolescents do not have the active guidance or timely advice of parents during the teenage years and prefer to spend their time alone or in the company of friends or acquaintances. Fortunately, most adolescents pass through this period uneventfully. In fact, many individuals go through this period gladly and appreciate finally being permitted to drive a car, gain employment, or start dating.

The physician should approach interviews with adolescents differently from interviews with younger children, because with adolescents information comes directly from the teenager rather than a parent (Box 4.1). Unlike an interview with a younger pediatric patient, the adolescent interview should focus on several psychosocial issues that may be uncomfortable to discuss in the presence of a parent. Thus, each teenager should be interviewed alone. The goal of the interview is to help adolescents become more comfortable discussing issues related to physical and mental health with the physician, give adolescents the opportunity to become more responsible for their health care, and discover any psychosocial issues that might interfere with a relatively smooth passage through adolescence.

Box 4.1. Keys to Successful Interviews With Adolescents

- Listen attentively, with minimal interruptions.
- Respect privacy.
- Explain confidentiality.
- Use open-ended, nonjudgmental questions; start with general observations of concern and follow up with specific questions.
- Define medical terms clearly.
- Invite the adolescent to ask questions.
- Help empower the teenager to address health issues.
- Reinforce the teenager's own positive support systems.

Adapted with permission from Sacks D, Westwood M. An approach to interviewing adolescents. *Paediatr Child Health.* 2003;8(9):554–556.

Stages of Adolescence

Adolescents are stereotypically labeled as difficult, complex, and time-consuming patients with complicated concerns that result in nonmedical diagnoses. In addition, they can be accompanied by overbearing, demanding parents, or sometimes no parent.

The quality and quantity of information obtained from the adolescent during the medical and psychosocial interview can be greatly enhanced by taking developmental milestones into consideration. Adolescence can be divided into 3 developmental stages: early, middle, and late (Table 4.1). For example, interest in discussing long-term educational goals varies depending on the age of the adolescent. Most 18-year-olds are prepared to discuss college plans, specific vocational interests, and employment opportunities. In

Table 4.1. Developmental Milestones During Adolescence

Early Adolescence (11–13 years)	*Middle Adolescence (14–16 years)*	*Late Adolescence (17–21 years)*
Concrete, egocentric thought processes	± Abstract thought processes emerge	Abstract thought processes well formed
Parental supervision prominent	± Parental supervision	Limited or no parental supervision
± Risk-taking behavior with feelings of invulnerability	± Risk-taking behavior	Risk-taking behavior diminishes; vocational objectives formalized
± Peer pressure	Peer pressure prominent	Impact of peer pressure decreasing

Reprinted with permission from March CA, Jay MS. Adolescents in the emergency department: an overview. *Adolescent Medicine*. 1993;4(1):1–10.

contrast, 12-year-olds are still anchored in the concreteness of early adolescence and often are ill-prepared to discuss detailed plans for higher education. Current middle school experiences are much more important to this age group and therefore should be the focus of discussion. Peer pressure is most prominent during middle adolescence; thus, 16-year-olds with friends who smoke cigarettes and drink alcohol likely have tried or use the same illicit substances.

Knowledge of these developmental differences allows the interviewer to more effectively explain instructions and diagnoses to teenagers. For example, compared with 14-year-olds, 19-year-olds can better understand the effects of untreated or recurrent chlamydial cervicitis on long-term fertility. This is not to say that physicians should not discuss these possible consequences with a sexually active 14-year-old with chlamydia; rather, they should use more concrete descriptive wording and repeat the information at future visits. Age guidelines are not rigid, however, and each interview should be individualized to the particular adolescent and the circumstances surrounding the visit.

Issues of Confidentiality and Competence

A discussion about confidentiality is essential and can be approached in 1 of 2 ways. Each method has distinct advantages and disadvantages. To allow conversation to flow more naturally, interviewers should use the approach with which they themselves are most comfortable.

The first approach involves informing adolescents at the beginning of the interview that most issues discussed are held in strict confidence and will not be repeated to anyone. Exceptions are suicidal or homicidal behavior and a history of or ongoing sexual or physical abuse. In any of these instances, other professionals are told of the disclosed information, and parents or guardians ultimately are informed of the disclosure. The advantages of this approach are that discussion of such logistics at the beginning of the interview is less awkward, and the ground rules are clear from the start. This contributes to an atmosphere of trust and honesty. The disadvantage is possible inhibition by adolescents who are unsure about disclosing particular incidents (eg, those concerning sexual abuse) for fear of involving other professionals or family members. Interviewers should be nonjudgmental, reassuring, and empathetic to reduce the possibility of such an occurrence.

The second, less popular approach to the discussion of confidentiality involves informing adolescents at the end of the interview or when and if an exception to maintaining confidentiality arises. Proponents of this approach argue that adolescents tend to respond more honestly to questions when they do not believe physicians will inform others, including their parents or legal guardians. As mandated reporters, however, physicians have a legal responsibility to report sexual and physical abuse; in cases of suicidal or homicidal behavior, it is in the patient's best interest to inform other professionals of this disclosure. The disadvantage to this method is that these issues often arise at very emotional times during the interview, and it is difficult to interrupt the patient to discuss mandated reporting. If physicians wait until the end of the interview to inform adolescents about mandated reporting, however, patients may leave the office feeling deceived and may not return for future visits. For this reason, most health professionals prefer to inform adolescents at the onset of the interview about confidentiality with the hope that it contributes to the development of a trusting relationship.

An assessment of the adolescent's ability to make health-related decisions is another important aspect of the interview. *Competence* is the ability both to understand the significance of information and to assess alternatives and consequences to sufficiently identify a preference. Various factors other than age must be considered, such as maturity level, intelligence, degree of independence, and presence of any chronic illness. This last factor is included because adolescents with chronic conditions may have already participated in decisions about their health care. Regardless, it can be difficult to assess competence from just 1 visit. It may not even be necessary to make an assessment emergently, except in certain cases, such as with an unplanned pregnancy.

Although it is imperative to interview adolescents alone, every attempt should be made to involve parents or guardians in physical and mental health decisions. Although specific state laws allow physicians to treat minors in emergent situations and in cases of suspected sexually transmitted infections without the consent of a parent or guardian, physicians should urge adolescents to inform their parents or guardians of any ongoing problems disclosed during the interview. The ultimate decision, however, rests with the adolescent. Physicians can assist adolescents in discussing delicate issues with their parents by role-playing with teenagers or by sitting in on the conversation between the adolescents and their parents when disclosing sensitive information. Health professionals should become familiar with the specific consent laws related to minors in the state in which they practice medicine to confirm the legal abilities of minors to consent to sensitive health care services.

Psychosocial Review of Systems

A major part of the adolescent interview involves obtaining a thorough psychosocial history, which typically can be completed in 20 to 30 minutes. The approach, which is known by the acronym *HEADSS* (home, employment and education, activities, drugs, sexuality, suicide/depression), allows interviewers to evaluate the critical areas in adolescents' lives that may contribute to a less than optimal environment for normal growth and development (Box 4.2). Questions about sexuality, sexual orientation, and gender identity must be asked in a nondirected, open-ended, nonjudgmental fashion, giving adolescents time to respond. This information is imperative to adequately assess risks for conditions such as social isolation, unintended pregnancy, and sexually transmitted infections, including HIV. In addition, an inquiry about sexual, physical, and emotional/verbal abuse is indicated during this part of the interview.

Because most adolescents now have access to the internet 24/7 via their cell phone, home computer, or other electronic device, it is important to discuss screen time with them and their parents to obtain a more accurate picture of their online activities, connectedness with peers and family, and sleep hygiene practices. In addition to reviewing the amount of time spent on an electronic device each day, physicians also should inquire about texting, sexting, and whether the patient is a victim or perpetrator of cyberbullying.

Issues That Need Immediate Attention

Many issues discussed during the psychosocial interview can be a source of significant stress and anxiety for adolescents. Evidence of psychological or adaptive difficulties must be taken seriously and should be reassessed at future visits. Certain disclosures, however, demand immediate attention. Suicidal ideation, with or without a previous attempt, requires a more in-depth analysis of the gravity of the problem. Mental health professionals should be involved emergently in the clinical assessment of these precarious situations. Other issues that require immediate attention include possible danger to others and a history of or ongoing sexual or physical abuse. Depending on the specific circumstance, issues such as a possible or confirmed unplanned pregnancy, bullying, substance use, and sexual orientation may not necessarily require the emergent

Box 4.2. What to Ask

HEADSS

H: Home

- With whom does the adolescent live?
- Have there been any recent changes in the living situation?
- How are things between parents/other adults living in the home?
- Are the parents or guardians employed?
- How does the adolescent get along with the parents and siblings?
- Does the adolescent feel safe at home? In the neighborhood?
- Is there a firearm in the adolescent's home? If so, what does the adolescent know about firearm safety?

E: Employment and education

- Is the adolescent currently in school?
- What does the adolescent enjoy about school? Dislike?
- How is the adolescent performing academically?
- Has the adolescent ever been truant or expelled from school?
- Are the adolescent's friends attending school?
- Is the adolescent currently employed? How many hours does the adolescent work each week?
- What are the adolescent's future education/employment/vocational goals?

A: Activities

- What does the adolescent do in his or her spare time?
- How much time is spent on technology (the computer, cell phone, other electronic devices) during the day and at night?
- What does the adolescent do for fun? Is the adolescent ever bored?
- With whom does the adolescent spend most of his or her time?

D: Drugs

- Do any of the adolescent's friends smoke tobacco, use electronic cigarettes, vape, or use illicit drugs or alcohol?
- Is the adolescent currently using, or has he or she ever used, tobacco, electronic cigarettes, or vaporizer?
- Is the adolescent currently using, or has he or she ever used, any illicit drugs? What about steroids? Alcohol?
- Does the adolescent ever feel pressured by friends to use drugs or alcohol?

S: Sexuality

- What is the adolescent's sexual orientation and/or gender identity or expression?
- Is the adolescent currently in a relationship?
- Is the adolescent sexually active?
- If so, what was the age of the adolescent's first sexual experience?
- What types of sexual experiences has he or she had?
- How many sexual partners has the adolescent had in his or her lifetime?
- Does the adolescent have a history of sexually transmitted infections?
- Does the adolescent (or the partner) use condoms or another method of protection?
- Does the adolescent (or the partner) use any methods of contraception?
- Does the adolescent have a history of sexual or physical abuse?

S: Suicide/depression

- Is the adolescent bored all the time? Ever sad or tearful? Tired and unmotivated?
- Has the adolescent ever felt that life is not worth living or ever thought of or tried to hurt their self? More importantly, does the adolescent have a suicide plan or access to a firearm?

involvement of other providers initially; however, close follow up must be assured and arranged by the physician or other health professional regardless of consent by a parent or guardian.

Concluding the Interview

The adolescent interview should be conducted at a time when the adolescent is relatively healthy and the interviewer has set aside ample time for a thorough, uninterrupted discussion. However, all topics need not be addressed during the initial interview if time does not permit and the adolescent appears relatively stable based on initial screening. Issues that are not covered in depth at this visit can be addressed at the next one. The number of appointments needed to discuss or work through a particular problem or concern is unlimited.

At the end of each visit, the interview should be summarized, any difficult topics identified, and the issue of confidentiality reviewed once again. Adolescents should then be asked to identify a person whom they can trust or confide in should any problems arise before the next visit. In some instances, this issue may already have been discussed during the interview. Adolescents also should be given the opportunity to express any other concerns that were not addressed in the interview and ask additional questions.

The physician should clearly point out to the adolescent any significant risk factors or risk-taking behaviors that have been identified during the interview and assess the teenager's readiness to change this behavior. For those adolescents who are not engaging in high-risk behaviors, the physician should acknowledge that things seem to be going well, praise them with sincere positive feedback, and review their individual strengths and accomplishments. Available resources, such as teen hotlines and popular websites, should be given to the adolescent prior to inviting the parent or guardian back into the examination room. General concerns should then be reviewed with the parent or guardian while maintaining the adolescent's confidentiality. The parent or guardian also should be given appropriate written or electronic resources to review, particularly if a sensitive subject has been discussed, and invited to call the physician if any additional questions or concerns arise. The follow-up appointment should be arranged with the adolescent before the conclusion of the visit.

CASE RESOLUTION

The adolescent should be informed about confidentiality and the specific exceptions to maintaining it. Nonthreatening topics, such as home life, school, employment, and other outside activities should be explored first, followed by questions about sexuality, gender, sexual orientation, sexual activity, and illicit drug use. Suicidal behavior or depression and safety issues should also be reviewed with the teenager alone and again with the parent if there is a need for a more formal or immediate mental health evaluation. In addition, computer and cell phone use as well as sleep hygiene should be evaluated. Identified high-risk behaviors and their consequences should be discussed with the adolescent at the end of the interview, and a plan for future visits should be arranged. The mother should then be invited back into the examination room prior to the conclusion of the visit to discuss nonsensitive issues unless permission has been obtained from the teenager to disclose and discuss confidential topics.

CHAPTER 5

Telephone Management and E-medicine

Emily Borman-Shoap, MD, FAAP, and Iris Wagman Borowsky, MD, PhD, FAAP

CASE STUDY

The mother of an otherwise healthy 10-month-old girl calls and tells you that her daughter has a fever. The girl's rectal temperature has been 39.4°C to 40.0°C (103°F to 104°F) for the past 2 days. Although she is fussy with the fever, she plays normally after receiving acetaminophen. The girl is eating well and has no runny nose, cough, vomiting, diarrhea, or rash.

Mother also mentions 2 other concerns that she has been meaning to bring up with you. The first involves questions about feeding and how to introduce table foods; the other is sleep problems. Her daughter has been waking up several times a night for the past month, and mother feels exhausted.

Questions

1. How do telephone and face-to-face encounters between physicians and patients differ?
2. What are some general guidelines for effective doctor-patient communication via telephone?
3. What historical information is necessary for appropriate telephone management?
4. What points are important to cover in home treatment advice?
5. For nonurgent issues, what are the possible roles of telephone encounters or e-medicine in patient care?

Parents and guardians are increasingly accessing their children's health professional through avenues other than a typical office visit. Telephone management and electronic communications make up a substantial portion of a primary care physician's time. It is estimated that pediatricians spend more than 25% of their total practice time engaged in telephone medicine. Telephone management includes triage of acute illness symptoms as well as ongoing preventive care and management of chronic conditions. Electronic communication also plays an increasing role in acute, chronic, and preventive care.

Telephone Management for Acute Illness

The main components of a telephone management encounter for acute illness mirror those of an office visit: establish rapport, gather a complete history, formulate an assessment and plan, ensure adequate follow-up, and document the encounter. The key difference is that often a telephone call offers no opportunity for a physical examination or direct observation of the child; however, video conferencing and the ability to send photographs electronically is beginning to minimize this difference. Obtaining a thorough history remains the critical component of telephone management, however. Closed-loop communication, with the parent/guardian or patient repeating back to the physician the plan of care, is also an important component of the telephone consultation.

Telephone Communication Skills: Establishing Rapport

Parents and guardians commonly call their pediatric health professional because they are worried about their child. The friendly voice of a staff member in the health professional's office has a substantial role in reassuring an anxious parent. Each call should begin with a "verbal handshake." Staff should identify themselves and the place in which the call is received and offer to help. They should learn the caller's name, the caller's relationship to the child, and the child's name. Using the child's name in conversation helps establish rapport and creates a more personal atmosphere.

Telephone calls for medical advice are often received in busy environments, such as emergency departments (EDs) or clinics, in which other patients are waiting to be seen. It is easy to be abrupt under these circumstances and not give complete attention to a caller. If a call is not an emergency, staff members can take the caller's telephone number and return the call as soon as possible. The health professional who is returning a call to a patient should ensure it is a good time for the patient to receive a return call. Unsafe

practices, such as talking while driving, should be avoided by both the health professional and the patient.

Studies show that the length of a patient visit does not correlate with patient satisfaction. Telephone encounters need not be lengthy; the average length of a call is reported to be 3 to 5 minutes, depending on the setting. Each call must be pleasant, however, and address the caller's concerns. Open-ended statements and questions, such as, "Tell me about your child's illness," or "Are there any other symptoms?" are useful at the beginning of a call because they give the caller an opportunity to explain the situation without interruption.

Establishing rapport is more difficult on the telephone than in person because on the telephone the health professional is limited to verbal communication. In face-to-face encounters, the health professional can use words as well as means of nonverbal communication, such as facial expressions, eye contact, gesturing, and touch, to convey warmth and empathy. The health professional should use various aspects of verbal communication to convey sincere interest in a caller's concerns and should pay attention to these verbal cues from the caller. Many components of verbal communication, including vocal expression, pace, articulation, tone, volume, and pauses, affect telephone interactions. The health professional should speak clearly and use vocabulary that the caller understands. Medical jargon should be avoided. A friendly yet respectful tone and a calm, professional manner should be maintained.

Careful listening is crucial to obtaining the information necessary to make medical decisions over the telephone. One of the major goals of the health professional is to recognize and respond to the caller's main concerns and expectations. Researchers have found the following questions useful in the identification of parents' chief concerns: "What worries you the most about [use child's name] illness?" and "Why does that worry you?"

In interacting with a caller who rambles, it may be necessary for the health professional to focus the conversation. Asking the question, "What can I do to help?" should clarify the reason for the call. If it is necessary to verify information, the professional can summarize what has been heard and ask if they have understood correctly. Using a triage protocol book or similar resource can help the health professional streamline questions and aid in correct disposition of the patient.

The angry caller may elicit defensive or confrontational behavior from the health professional. Responding to anger with arguments is time-consuming, stressful, and pointless. The health professional should be warm and understanding to create an environment in which a caller who wishes to discuss his or her feelings is comfortable. Acknowledging anger may encourage open discussion and problem-solving (eg, "You sound upset. I am ready to help you. What can I do?"). Empathizing with the caller (eg, "I don't blame you for being upset"; "That must have been very frustrating.") and apologizing if the caller has experienced delays or barriers in accessing care is also helpful.

The health professional can build confidence in the caller by validating the steps that individual has already taken, such as, "You did the right thing by giving your child acetaminophen for the fever. That is exactly what I would have done." "I'm glad that you called about this." The health professional may even be able to offer reassurance to a parent or guardian who is not managing the child's illness correctly by commenting that many parents and guardians try the same treatment. After providing that reassurance, a different treatment approach can be suggested.

Before the end of the conversation, the caller should be asked to "teach back" or summarize what the health professional has recommended and encouraged to call again if additional problems occur. For example, the physician might say, "I want to be sure I explained myself clearly. Can you tell me what you are planning to do now for your child?" Giving clear guidance about reasons to seek emergency care is particularly important.

Telephone History Taking

Most calls for triage of an acute problem are about upper respiratory symptoms, fever, rash, trauma, or gastrointestinal symptoms, that is, the same problems most commonly encountered in the office. With standardized history taking and home care advice, many patients with these chief concerns can be safely managed at home. Several excellent published telephone management protocols can aid the health care team in advising patients efficiently and appropriately. Many practices use nurses as the first point of contact for telephone triage, with the pediatrician serving as second-tier triage for more complex or worrisome concerns.

For the history obtained via telephone, it is necessary to gather sufficient information to make an appropriate decision. Questions should be asked with the aim of determining whether an emergency exists and making a diagnosis. The health professional should follow the same organized approach that would be used in the office setting (Box 5.1). Key features, such as patient age and past medical history, should guide questioning. For example, if the mother of a 20-day-old girl reports that the neonate has a temperature of 38.9°C (102°F), it is necessary to see the newborn in person immediately. An older child with the same chief report of fever may be safely managed at home, however, depending on the answers to other questions about additional symptoms. Similarly, knowledge that a child who has been exposed to chickenpox has a compromised immune system is crucial in providing appropriate telephone advice.

Additional specific questions should be asked to clarify the child's condition and obtain all the information necessary to make a good decision. Many physicians can access electronic medical records (EMRs)

Box 5.1. What to Ask

- How old is the child?
- What is the child's chief problem? What are the child's symptoms?
- How long has the child had these symptoms?
- How is the child acting?
- Does the child have any chronic illnesses?
- Is the child taking any medications?
- What are you most worried about?

remotely to review the child's record, which can greatly aid in obtaining a thorough history. If review of the medical record is possible, it is reassuring for the health professional to share that information with the child's caregiver by stating, for example, "I am reviewing your child's medical record in the computer so that I can be sure I have all the information I need to give you good advice."

The physician should focus on the critical features that will affect disposition of the patient (ie, ED vs office visit vs home care). For example, for the child who is vomiting or has diarrhea, the state of hydration is critical; for the child with a cough, the occurrence of breathing difficulty is critical; and for the child with head trauma, loss of consciousness is critical. Methods of teaching telephone management skills include role-playing, listening to mock parent calls, and reviewing tapes of actual calls.

Telephone Advice: Communicating the Assessment and Management Plan

In an emergency situation, that fact should be explained to the caller and appropriate follow-up plans made, such as advising the parent or guardian to call 911 for life-threatening conditions such as respiratory depression or uncontrollable bleeding. If the condition is potentially serious but non–life-threatening (eg, right lower quadrant pain or possible fracture), the caller should be advised to bring the child by car to the ED or physician's office within a specified amount of time. For other types of calls, the health professional must decide if and when the child should be seen by a physician and the appropriate course of home treatment.

Because most childhood illnesses are mild and self-limited, evaluation of the safety of medical advice obtained by telephone requires large samples to detect poor outcomes associated with mismanagement. Research has described a "wellness bias" in which health professionals, who primarily see patients with mild, self-limited illnesses, may downplay the severity of reported symptoms and choose the most benign diagnostic possibility. This bias may be more pronounced in a telephone encounter, in which the physician cannot see the child. One study reported telephone encounters in which physicians seemed to make a decision early in the conversation and then "shut out" additional information that should have led to the consideration of more serious diagnoses. The safest approach is to always have a high index of suspicion for a serious condition and to ask questions to confirm or dispel those suspicions. Research shows that parents expect to receive an explanation of their child's illness. The health professional should clearly state what the child's illness seems to be, the likely cause, and what the parent or guardian can anticipate (eg, length of time that the child is likely to be sick, additional symptoms that may appear).

Before giving any treatment advice, the health professional should ask the caller the following questions: "What have you done so far?"; "Have you given the child any medications?"; and "How is this treatment working?". If the therapy seems appropriate, the caller should be encouraged to continue the treatment. Alternatively, the regimen should be modified as indicated. Instructions for home treatment should be clear and as easy as possible to implement. If the instructions are complicated or lengthy, the health professional may ask the caller to write them down. When prescribing medication, the physician should ask if the child has any known drug allergies; for the prescribed medication the physician should give the dose, frequency of administration, and information about possible side effects. The health professional should verify that the caller can follow the telephone advice (eg, a parent has a thermometer and knows how to use it).

Closing the Encounter: Ensuring Appropriate Follow-up

The health professional should confirm that the caller understands the information and instructions and agrees with the plan. Asking questions such as, "What questions do you have?" encourages callers to raise uncertainties and ask for needed clarification. Most important, if the decision is to manage at home, the caller should always receive specific instructions about when to call back. The caregiver should call if the child's symptoms change, persist, worsen, or cause anxiety to the parent or guardian. Additionally, symptoms specific to the child's condition should be followed and the caregiver advised on when to call back or come in (eg, fever of >2 days' duration, irritability, decreased urination). If the physician plans to check up on the child by telephone, the physician should confirm and record the appropriate callback number or numbers. The caregiver who seems unduly anxious or uncomfortable with home treatment should be given the opportunity to have the child seen in person by a health professional.

Documentation

All calls for medical advice should be documented in the child's medical record for medical reasons (eg, better follow-up, improved continuity of care) and legal purposes. The form used for documentation should include the date and time of the call; the name, identity, and telephone number of the caller; the name and age of the child; the chief symptom; other symptoms; possible diagnoses; advice given; and the name of the person who took the call.

Privacy and Technology Considerations

Many calls take place over cell phones. The caller may be able to see the telephone number from which the physician is calling. The caller should be given clear instructions as to the appropriate avenue for calling the physician, for example, "Please call back to the nurse triage line if you need to talk to me again." Clinic staff may wish to give their patients access to a "direct line" to call back to the clinic so that patients do not have to go through an automated telephone triage with each return call. Some health professionals may choose to block their numbers so they are not visible by caller identification. Others may feel comfortable having a parent call directly to their cell phone but should give clear guidelines about doing so.

Many cell phones have the capacity for taking and sending photographs. A photograph can be a valuable additional piece of information when evaluating symptoms, such as rash. However, it is important for the physician to educate or remind the caller that data sent by cell phone is not secure. Many EMRs now include the option for patients to upload their own photographs or for health professionals to use a secure application to capture photographs for documentation in the medical record. The latter method is preferred.

Telephone Management: Preventive Care and Care Coordination

Telephone encounters can provide an excellent opportunity for preventive care and anticipatory guidance. Issues such as sleep problems or behavioral issues may be difficult to discuss during an office visit with the child present. Telephone follow-up provides an opportunity to minimize distraction during conversation between parent or guardian and physician. Some pediatric offices develop protocols and charge a fee for prolonged telephone consultation.

Telephone follow-up can also help facilitate care coordination for children with chronic health conditions. For example, a physician who recommends medication changes for a child who presents with poorly controlled asthma can have a follow-up call with the parents 1 month later to assess asthma symptoms. Using telephone follow-up when appropriate allows the health professional to provide patient-centered care (ie, individualize care to the patient's needs) and minimize missed work and school for patients and families.

E-medicine

Virtual medicine, or e-medicine, is an increasing avenue for communicating with patients. Studies suggest that up to 75% of patients would like to communicate with their physician through email. Patients and parents who choose electronic communication as a means of interacting with their physician report high rates of satisfaction and tend to have higher levels of education.

Email communication can be convenient for patients and families and may increase patient-centered care. Specific American Academy of Pediatrics, American Medical Association, and American Medical Informatics Association guidelines exist for the use of email with patients. Traditional email poses a variety of data security concerns, however. Therefore, many EMRs incorporate the ability for patients and their parents or guardians to interact directly with the EMR. This includes the ability to view laboratory test results, immunization records, growth charts, and patient problem lists. Additionally, it may be possible for a parent or guardian to send a secure message with a health question to the health care team. Clinic staff should create guidelines for patients and parents or guardians about appropriate issues to be addressed through electronic messaging, expected response time, and who will provide a response (ie, nurse or physician).

Communication through the EMR should be professional, concise, and to the point. Written communication has the benefit of eliminating sequential missed calls back and forth (ie, "telephone tag") when attempting to reach a parent or guardian by telephone. The physician should remember, however, that written communication is interpreted through the lens of the reader. Delicate or complex conversations should first be broached by telephone or in person. Similar guiding principles apply with telephone and email communications; the physician must establish rapport, give clear advice, and provide guidance for follow-up. Attention should be paid to correct grammar and spelling in emails, because errors may decrease confidence in the physician. Electronic communication can also be a useful method to provide patient education materials, such as a link to a helpful website.

Physicians should work with their health care system to clarify types of communication that are best transmitted electronically. For example, straightforward questions may be answered with a simple email message, but more complex care needs may be appropriate for a formal e-visit that can be billed to insurance. Research suggests that insurance plans may influence how patients choose to use e-medicine. For example, the patient with a high deductible insurance plan may prefer to first contact the health professional through an e-visit to determine if an in-person office visit is necessary.

Health Care Disparities

When developing telephone and e-medicine options, it is necessary to pay particular attention to meeting the needs of patients with limited English proficiency. Studies have shown that patients with limited English proficiency use e-medicine less frequently than patients with English proficiency, particularly for tasks such as requesting medication refills. Additionally, 1 study showed that in telephone encounters, patients with limited English proficiency disagreed with the care recommendation and tended to receive advice to seek higher acuity care more often than patients with English proficiency. Recommendations to promote health equity include continuing to explore ways to ensure that telephone and e-medicine are being delivered in a manner that is equitable and patient-centered for all patients.

Conclusions

Telephone management and e-medicine represent the changing face of medical practice. The health professional should be prepared to deliver care that meets the needs of the patient, which may necessitate being creative with how and where care is delivered. The approach must be tailored to each patient scenario, and physicians should continually strive to adapt their approach so that they can provide effective and appropriate patient-centered care both in and out of the office.

CASE RESOLUTION

The physician learns several facts that result in the recommendation that the child be seen that day. (Had the call been received at night, a visit the next day would have been advised.) These facts include the child's age, the height and duration of the fever, and lack of any symptoms of localized infection.

The other concerns of feeding questions and sleep issues present excellent opportunities for management through a follow-up telephone call, electronic communication, or office visit, depending on parent preference and clinic resources.

CHAPTER 6

Informatics

Alan Tomines, MD

CASE STUDY

You are a physician in a small pediatric practice. Your hospital implemented an electronic health record system, which has been made available within the hospital and in the offices of its affiliated practices. The hospital chief of staff asks you to participate on the hospital's informatics committee. You have served in the past on other clinically oriented steering committees, but you do not consider yourself a technology expert and you express your trepidation to the chief of staff, who asks you to speak with the head of the informatics committee.

Questions

1. What are the important informatics concepts to understand?
2. What are the important drivers of health information technology?
3. What are the challenges to physician acceptance of electronic health records?
4. What are the special pediatric considerations in electronic health records?

To make optimum clinical decisions, physicians must have information about their patients' health that is current, accurate, reliable, and complete. The physician should be able to access this information wherever and whenever necessary. To the extent possible, the physician should be presented with information that fosters an evidence-based approach to decision making, and the decisions made should be communicated to other health professionals in a manner that is clear and error-free. The physician should be able to review measures of the quality of care provided. Health information technology (HIT) holds the promise of increased access to patient health information, improved patient safety, reporting of desired health outcomes, and improved health care efficiency with the potential for decreased health care expenditures. The implementation and acceptance of HIT is not without challenges, however.

Basic Concepts

Although the terms "data," "information," and "knowledge" are sometimes used interchangeably, these are distinct concepts. *Data* are mere observations or facts (eg, hemoglobin equal to 9 g/dL). *Information* is data placed in meaningful context (eg, hemoglobin equal to 9 g/dL in a 3-month-old who is breastfed). *Knowledge* is the understanding of information, including an assessment of its completeness (eg, hemoglobin equal to 9 g/dL in a 3-month-old infant who is breastfed may represent a physiologic nadir but may also represent blood loss, increased destruction of red blood cells, or decreased production of red blood cells).

Information technology refers to any hardware or software that supports the management of data, including how the data are acquired, stored, retrieved, transformed, interpreted, and disseminated. For example, a *database* is an organized collection of data that facilitates the storage and retrieval of those data. An *information system* is the sum of the people, work processes, and information technology that supports an activity. Depending on the degree to which technology is applied, the processes of an information system may be automated, manual, or a combination of both.

Informatics Defined

Medical informatics is the science of the appropriate application of information technology to health care work processes. Specialists in informatics (referred to as *informaticians* or *informaticists*) serve as liaisons between clinical and technology staff to ensure that HIT is optimally applied to address clinical information and workflow needs. Medical informatics places great emphasis on nontechnologic considerations that can affect the successful implementation and acceptance of health information systems, including information science, cognitive psychology, project management, organizational and change management, health care policy, and ethics.

The field of medical informatics can itself be subdivided into specific clinical domains, such as nursing, pharmacy, veterinary medicine, dentistry, and imaging. *Biomedical informatics* is a term of broader scope that encompasses medical informatics; bioinformatics, in which the primary domain is genomics and bioengineering; and public health informatics.

Electronic Health Information Systems

All electronic health information systems ultimately are used in managing some aspect of patient care, and for ease of discussion in this chapter these systems are presented in 4 broad categories: electronic records of patient care, ancillary clinical systems, administrative systems, and telemedicine. Table 6.1 lists several common abbreviations used in electronic health information systems and informatics.

Table 6.1. Abbreviations Used in Informatics

Abbreviation	*Expansion*
ARRA	American Recovery and Reinvestment Act of 2009
CDR	Clinical data repository
CDSS	Clinical decision support system
CPOE	Computerized physician order entry
EHR	Electronic health record
EMR	Electronic medical record
eRx	Electronic prescribing
HIE	Health information exchange
HIPAA	Health Insurance Portability and Accountability Act of 1996
HIS	Hospital information system
HIT	Health information technology
HITECH	Health Information Technology for Economic and Clinical Health Act
IIS	Immunization information system (also known as an immunization information registry)
LIS	Laboratory information system
P4P	Pay for performance
PACS	Picture archiving and communication system
PHI	Protected health information
PHR	Personal health record
RIS	Radiology information system

Electronic Records of Patient Care

A *medical record* serves as the legal record of care provided to a patient by a health professional or health care organization. An *electronic medical record* (EMR) is an information technology that supports the traditional role of the medical record, including serving as an archive for clinical documentation, such as physician orders, progress notes, and laboratory and imaging results. A full-fledged EMR is more than an electronic version of the traditional paper-based record, however. It provides capabilities that support the enhanced delivery of care.

Important components of an EMR include a clinical data repository, a clinical decision support system, and computerized physician order entry. A *clinical data repository* (CDR) is a real-time database containing the clinically relevant patient data of an institution. It supports timely access of patient information for physician decision making and provides information used by other EMR components. A *clinical decision support system* (CDSS) is a special computer program that applies medical knowledge to data from a CDR to produce patient-specific care recommendations. A *computerized physician order entry* (CPOE) is a specialized computer program that allows health professionals to write electronic orders that are directed to the appropriate clinical staff or ancillary department. A CPOE can decrease errors resulting from illegible handwriting, decrease delays in the receipt and execution of orders, and allow entry of orders away from the care setting. Additionally, a CPOE paired with a CDSS can leverage patient-specific information in a CDR to prevent harm resulting from drug-drug interactions, drug-allergy interactions, or errors in age- or weight-based dosing.

Although an EMR generally operates within the functional boundary of a hospital or practice, the history of a patient's health care is not limited to these settings. The *personal health record* (PHR) is a summary of an individual's health history—usually self-maintained—that contains information collected from encounters with different health professionals, medicolegal documents (eg, living wills, advance directives), and other health information that may be relevant to patients (eg, regimens for nontraditional remedies, logs of home testing for blood pressure or glucose). The concept of a PHR is not new; patients with multiple medical problems have long maintained paper-based PHRs out of necessity to ensure they have at least 1 reliable and portable source containing a complete medical history. The electronic PHR is an evolving entity, ranging from scanned paper documents stored on portable devices to web-based applications that connect with EMRs and capture data from medical devices. The PHR is not considered a legal record of care.

The next stage in the evolution of the EMR is the *electronic health record* (EHR), which has the functionality of a full-fledged EMR with the additional capability for exchanging data among multiple different EMRs to provide the entire longitudinal history of the patient. With this data exchange capability, an EHR may also support the needs of population health, such as identification of patient-applicable clinical trials, mandatory reporting of notifiable disease, and provision of anonymized clinical data to support clinical and public health research. (The term EHR has been used interchangeably with and has largely supplanted the term EMR.)

A *health information exchange* (HIE) is an enabling technology that acts as a hub for the secure exchange of data between EHRs. Via an *interface* (a program that allows 1 information system to communicate with another), an EHR can connect to an HIE and exchange health information with other EHRs that are connected to that HIE. Although an HIE generally serves a specific geographic region, in future the interconnection of HIEs may allow an EHR in 1 region to share data with an EHR in another region, thereby providing nationwide or worldwide access to a patient's entire history of episodic care.

Ancillary Clinical Systems

Ancillary clinical systems provide information management and automation for specific health care services or domains, including pharmacy, laboratory, imaging, and immunizations.

A *pharmacy information system* tracks patients' prescription and payment information and can improve patient safety by checking for medication interactions and appropriate dosing. A related concept is *electronic prescribing* (*e-prescribing* or *eRx*), which is a specialized type of CPOE that allows physicians to prepare and transmit prescriptions electronically to a pharmacy information system.

When connected to an EHR, a pharmacy information system can receive and process prescriptions, and send back dispensing information to support medication reconciliation.

Laboratory information systems (LISs) are used to manage the receipt of laboratory orders, track specimens, capture data from automated analyzers, and present laboratory results to the ordering health professional via direct access to the LIS, or via an interface that transfers the results to an EHR. An LIS can support patient safety through timelier access to laboratory results and data for use in making individualized patient care decisions.

A *picture archiving and communication system* manages the storage and distribution of patients' electronic medical images, which often are captured directly from computerized or digital radiography devices, as well as other imaging modalities (eg, computed tomography, magnetic resonance imaging, ultrasonography). A *radiology information system* incorporates the functionality of a picture archiving and communication system while managing other service activities, such as reporting, scheduling, and billing.

An *immunization information system* (IIS, also referred to as an *immunization registry*) is used to document and track patient vaccinations. An IIS can send reminder or recall notices, as appropriate, to physicians and parents or guardians when vaccinations are due or when administered vaccines are determined to be ineffective or unsafe. An IIS usually is maintained regionally by public health entities; thus, it also collects reports on adverse vaccine events and provides summaries of regional vaccination prevalence. These systems usually have the capability to exchange data with capable EHRs.

Administrative Systems

A *hospital information system* comprises all the clinical and nonclinical information systems of an institution. A hospital information system may be a single integrated information system or may represent multiple interconnected information systems. Hospitals and large practices often have separate information systems to manage individual administrative functions, such as appointment scheduling, insurance eligibility, and billing and payment. A *practice management system* is an information system designed to manage administrative tasks for small- and medium-sized clinical practices.

Telemedicine

Telemedicine is not an information system per se but a related concept of interest in informatics. *Telemedicine* is the use of information and communication technologies to deliver health care over a distance, often to support patient care in rural or underserved areas. Many specialties exist within telemedicine, and they roughly correspond to distinct medical specialties, such as *teleradiology* (ie, the transmission of radiologic images electronically for interpretation) and *telesurgery* (ie, the use of video and robotic technology to perform surgery). The use of email and websites to consult with patients is also a form of telemedicine.

Key Drivers for Adoption of Informatics

The key drivers for the adoption of HIT are improved patient safety, the ability to measure health care outcomes, increased efficiency of work flow in the patient care setting, and reduced health care expenditures.

Improved patient safety through the reduction of preventable errors is the primary driver of information technology adoption in many health care organizations. In the report *To Err Is Human: Building a Safer Health System,* the Institute of Medicine (now known as the Health and Medicine division of the National Academies) estimated that up to 98,000 deaths annually in the United States are attributable to medical errors. Most errors were noted to be preventable and caused by systems and processes that increase or fail to prevent human errors. Computerized physician order entry is an EHR technology with the potential to improve patient safety by alerting a physician to errors before an order is submitted in an EHR.

Changes in the health care marketplace are driving the measurement of health care outcomes. *Pay for performance*, which relates payment to measures of quality of care provided; medical "report cards" that permit comparison of health care plans and professionals; and accountable care organizations are examples of market drivers. Electronic health records are critical to collecting and analyzing data to calculate these measures. Additionally, the decision support system of an EHR may improve health care outcomes through guideline adherence, such as by reminding both physicians and patients about care options that may have been overlooked.

Improvements in efficiency are another driver in the adoption of information technology. For example, efficiency can be gained by automating highly repetitive, data-intensive activities such as billing and scheduling. The introduction of information technology into a clinical setting without thorough consideration of effects on work flow, however, may introduce unanticipated workflow consequences that decrease efficiency or result in the creation of workarounds that reduce the effectiveness of the newly implemented technology.

In 2016, health care spending represented nearly 18% of the gross domestic product of the United States and increased at a rate nearly twice that of inflation. Information technology is considered to be a possible source of cost savings because its use has the potential to reduce duplication of diagnostic studies as well as the time spent on administrative tasks. As predicted in the 2001 report *Crossing the Quality Chasm: A New Health System for the 21st Century,* the use of email has served to meet the needs of patients more quickly and at lower cost than a traditional visit.

Challenges

Despite the existence of significant health care drivers for the adoption of informatics, several challenges prevent the easy implementation and acceptance of HIT, including information security, technology costs, organizational change, system usability, and the effect on physician-patient interaction.

The ease with which information systems can exchange data should not belie the care required to protect electronic patient data. *Protected health information* (PHI) is any information about a patient (eg, name, medical record number) that may be used to identify that patient. Patients have the expectation that their PHI will be kept private; health professionals' assurance that private information will not be revealed is referred to as *confidentiality*; the policies and technologies that support confidentiality are called *security*. The Health Insurance Portability and Accountability Act of 1996 defines the measures that must be taken to ensure that PHI is kept secure and is made available only to authorized individuals or organizations participating in a patient's health care. Although health information systems often use sophisticated technical barriers to protect patient data, recent instances have occurred in which hospitals' EHRs have been accessed and control of them gained by unauthorized parties who sought ransoms to restore control of the EHR. Generally, such data breaches are the result of failure to adhere to security safeguards, such as sharing passwords or failing to update security software. Educating health professionals is critical to ensuring the confidentiality of patient data.

The cost of implementing health information systems can be prohibitive for health care delivery organizations, particularly small practices. To address this barrier, the Health Information Technology for Economic and Clinical Health (HITECH) Act was included in the American Recovery and Reinvestment Act of 2009. The HITECH Act authorized the provision of Medicare and Medicaid incentives to physicians and hospitals that adopt EHRs and demonstrate "meaningful use" of EHRs by meeting specific objectives toward improved health care delivery and outcomes. These objectives include using EHRs for basic activities, such as recording patient demographics and vital signs; maintaining active problem, medication, and allergy lists; providing patients with summaries of outpatient visits and inpatient discharge instructions; electronic prescriptions and CPOE; and providing drug-drug and drug-allergy checks. The objectives also include more complex functions, such as providing data to public health agencies for disease surveillance as well as immunization and cancer registries; generating lists of patients with specific conditions for quality improvement and research; identifying and providing patient-specific education resources; and supporting medication reconciliation and care summaries across health care settings. To assure physicians and hospitals that they are adopting EHRs that allow them to meet meaningful use regulations, the US Department of Health and Human Services developed criteria for certifying EHRs. By 2016, more than 95% of eligible hospitals and 60% of office-based physicians had demonstrated meaningful use of certified EHRs.

Management of organizational change is an important part of successful information system implementations. Introduction of technology inevitably results in workflow changes for physicians and nurses and may result in repurposing of administrative staff. Resistance to these changes should be anticipated, and strategies to mitigate resistance should be instituted, including involvement of health professionals in the selection and ongoing enhancement or optimization of EHRs.

It is also important to consider the effect of technology on the patient-physician interaction. Physicians increasingly engage in electronic documentation and ordering during patient visits. Although some patients have a favorable opinion on the use of HIT, physicians should be sensitive to patients who feel that technology is intrusive; as appropriate, physicians should acknowledge the intrusion and identify potential benefits to the patient, including efficiency of access to information and more efficient communication of prescriptions to pharmacies or orders to ancillary services. Additionally, physicians should remain vigilant and not allow the EHR to detract attention from their patients during the office visit.

Human-computer interaction is the study of the interactions between people and information technology. It is important for users to perceive that the technology is both useful (ie, supports the work being done) and usable (ie, readily learned, efficient, helps in avoiding and correcting errors). Perception by the physician that an EHR is difficult to use or interferes with patient care or patient interaction may impede the acceptance of EHRs as supportive tools. The topic of usability of HIT is an emerging area of research in the field of informatics.

Pediatric Considerations

Although certified EHRs are present in more than 95% of hospitals, only 3 in 4 children's hospitals have successfully demonstrated their meaningful use; similarly, pediatricians trail other primary care specialists in demonstrating the meaningful use of EHRs. Although pediatric patients represent approximately 25% of the US population, pediatric EHR functionality often is underdeveloped. When considering these systems for pediatric settings, particular attention should be focused on the highly specific data, task, and policy needs of pediatric practice.

The presence of functionality to support clinical tasks that are generally, if not uniquely, related to pediatrics should always be examined. Immunization management, including the ability to assess a patient's status or exchange data with an IIS, is highly desirable. Weight-based dosing and tracking of specialized growth parameters (eg, for Down syndrome, for preterm infants) are other functions that are often overlooked. Age-specific documentation and educational materials may be lacking or may require customization.

The data and terminology of an information system should suit the highly specific needs of pediatric practice. For example, units of measure should reflect the requisite data precision needs of pediatric patients. Options to display patient age in hours rather than years, months, or even days and weight in grams is critical to appropriate care in the neonatal period. Laboratory values should be accompanied by normative ranges for age. Patient identification must account for the frequent changes in names and numeric identifiers that may occur in infancy or during change of custody. Pediatric terminology, such as developmental milestones, type of cry, or characterization of stool, are often overlooked in information systems designed for adults.

Pediatric policy issues should also be reflected in the design of an information system. Authorization for the child or the child's parent(s), guardian(s), or other legal authority to view all, none, or

portions of a child's medical record should be enforced electronically as it would be for the paper medical record. This is particularly true for adolescent records, in which the need for granular awareness of EHR data elements by the pediatrician as well as privacy controls to restrict what a parent, guardian, or other legal authority may see, should be consistent with the relevant statute. Likewise, secondary use of patient data for public health, research, or commercial purposes should be allowed or restricted as appropriate.

Currently, no electronic medical home for the care of children exists. The electronic history of a child's care may be distributed across EHR systems, immunization registries, school health information systems, and specialty registries for rare conditions, trauma, or foster care. With the promise of HIEs as a conduit for data exchange, it may be possible to create a virtual medical home in the future. It is important that pediatricians work toward reducing the legislative, technologic, and cultural barriers to linking child health information systems without compromising the security or confidentiality of PHI.

Pediatricians should be actively involved in the acquisition and development of information technology to ensure that child-specific data and policy needs are addressed. Pediatricians should also be involved in national policy initiatives to ensure that health information systems are certified for pediatric use and integrated to support care that is child-centered.

CASE RESOLUTION

You speak with the head of the informatics committee. You learn that you have been asked to participate because of your understanding of physician workflow in the office setting and that you are intended to advocate for the highly specific data needs and policies associated with the pediatric population. You are expected to use your pediatric expertise and draw on your leadership experience to obtain stakeholder buy-in of information systems. Additionally, in collaboration with other pediatricians and physicians, you will work to improve the efficiency, effectiveness, and relevance of the EHR in supporting the physicians' work and working to achieve improved patient outcomes.

CHAPTER 7

Counseling Families About Internet Use

Alan Tomines, MD

CASE STUDY

A 16-year-old girl is accompanied by her mother for a routine visit. The girl is doing well in school, is active in team sports, and has a small circle of friends who are well-known to her mother. The mother describes no new problems at home and no changes in behavior. However, the mother is concerned that her daughter "spends too much time on the computer."

Questions

1. What are the commonly used internet services?
2. What are the benefits and risks of the internet?
3. What strategies may be used to make the internet safer to use?
4. What signs may indicate that an adolescent is engaging in risky online behaviors?

The *internet* is a worldwide system of interconnected computer networks. At its inception, it was the exclusive domain of the military and academia; currently, the internet is a public gateway to electronic information, communication, and commercial services. The internet has profoundly changed the way we learn, work, play, and interact with others. It has become an integral part of the education and socialization of children, making it an influence of interest for parents, physicians, and researchers. The physician can provide pragmatic counsel to families that focuses on the benefits and risks of the internet, strategies for safer use, and assessment of online behavior in adolescents. The physician should also be prepared to discuss health information that families find on the internet.

A Brief History of the Internet

The internet began in the 1960s as the Advanced Research Projects Agency Network (ARPANET), a US Department of Defense project to share government-funded, university-based computer resources across a reliable communications network. Through the 1970s, ARPANET found acceptance with academics and researchers as a conduit for the exchange of scientific information, in large part because of the newly developed email technology for sending and receiving messages.

Recognizing the potential of the ARPANET, the National Science Foundation (NSF) began a parallel effort to connect the computer science departments at universities that were not affiliated with ARPANET. Initially called the Computer Science Network (CSNET) and later renamed NSF Network (NSFNET), this new network further expanded the exchange of scientific information. In 1990, ARPANET was retired, and many of its networks were absorbed into NSFNET. The resulting network, which was renamed the "Internet," extended its reach into the business sector and to international researchers but remained relatively inaccessible to the lay public.

During the early 1990s, the European Organization for Nuclear Research (known as CERN) developed protocols to facilitate the sharing of physics research data over the internet. These protocols allowed the sharing of computer files composed of text and images as documents that could be viewed using a special computer program called a "browser." This system of linked documents was collectively dubbed the World Wide Web or simply "the Web," with related collections of documents referred to as web pages or websites. In 1993, CERN made its work freely available, resulting in the rapid proliferation of publicly accessible commercial and personal websites—a model that has continued to the present day.

Internet Services and Concepts

Internet access usually is obtained through an *internet service provider* (ISP), a company that has an internet connection that it shares with consumers on a subscription basis. The most commonly used internet services are email and the Web. A person actively using an internet service is said to be "online." Use of the Web is sometimes referred to as *surfing* and is facilitated by *search engines*, such as Google and Bing, that use keywords or topics to find relevant documents, images, websites, or other services on the internet.

Internet services may be accessed by a wide range of computing devices, from traditional personal and laptop computers to mobile platforms, such as tablets and *smartphones* (cell phones that provide access to internet services). Smartphones and tablets access scaled-down versions of web-based content via specialized applications commonly referred to as "apps."

Because of their popularity in the pediatric age group, a few internet services are worthy of physicians' notice. *Web logs* (or *blogs*) are web-based journals. Like a traditional paper-based journal, a blog supports the written presentation of activities, thoughts, or feelings. A blog that is delivered using video usually is referred to as a *video blog* (or *vlog*). Blogs and vlogs may be public (available for anyone to read) or private (having restricted access).

Social networking websites, such as Facebook, Twitter, and Instagram, are similar in content to blogs and vlogs, with the added dimension that users are encouraged to create a network of online friends by establishing links to other users' social networking accounts. Blogs, vlogs, and social networking websites are examples of *asynchronous services* in which communication between users does not have to take place in real time and the content of which may be moderated and censored by the owner of the service for appropriateness.

By contrast, *chat rooms* are internet venues that permit the *synchronous* (ie, real-time) exchange of text messages between multiple simultaneous participants. Chat rooms as independent entities have largely been supplanted by other similar synchronous technologies, including direct messaging communication offered through social networking websites as well as instant messaging, a popular premium service often offered with smartphones. Although sometimes referred to as "text messaging," *instant messaging* (IM) is a more inclusive term that reflects the immediacy of interaction as well as the expansion of content exchanged to include multimedia, such as images or audio and video files.

The aggregate of synchronous and asynchronous social networking internet services is collectively referred to as *social media*. The ready accessibility of internet access, the portability of internet-ready devices, and the convenience of social media apps makes it possible to have a continuous online presence.

Internet Benefits and Access

The physician should be able to identify the benefits of internet use. The internet provides access to a wealth of educational resources and cultural experiences. Access to these resources allows children to exercise their reading, writing, information-seeking, and technology skills. The internet also provides the opportunity to easily communicate with family and friends. Additionally, children with common interests can use internet services to commiserate with and encourage other children. For example, the social networking websites Ben's Friends (www.bensfriends.org) and Rareshare (https://rareshare.org) connect patients with uncommon medical conditions to help them share their collective experiences.

The physician may also actively participate in reducing disparities in internet access. Internet use and access is correlated with socioeconomic status. Although currently most households have access to a computer with access to the internet, millions of individuals do not have access. The pediatrician may help families gain access to the internet by identifying institutions that provide safe online environments, such as libraries, community centers, and schools. As patient-centered internet-based health interventions are increasingly being studied as a supplement to traditional health care delivery, addressing disparities in internet access may help bridge gaps in care in underserved communities.

The physician should also be aware that children with disabilities may have difficulty using the internet without *assistive technology*, that is, hardware or software designed to improve the accessibility of computers. Children with visual impairment or blindness may be aided by the use of special software, including screen magnifiers, braille embossers, or *screen readers* (ie, software that uses a computer-generated voice to read email and web pages), although many websites are not compatible with screen readers. Children with hearing impairment or deafness may be aided by ensuring that their computers are set to provide visual cues rather than audio prompts; typically, such functionality is built into operating systems. Children with mobility or dexterity challenges may have difficulty using a traditional keyboard and mouse; alternative keyboards and pointing devices, computer touch screens, and tablet devices can be suggested as supporting technologies. Pointing devices that use sound or infrared beams, as well as software that responds to the spoken word, may be viable alternatives in cases in which manual control is not possible.

Internet Threats

Although the internet has many benefits, being online entails some risks. The physician should be able to inform parents and guardians about the threats posed by the internet.

To understand internet threats, it is helpful to recognize that the internet has neutral properties that do not cause threats but that allow them to exist. First, the internet is anonymous: People may not be who they represent themselves to be. Second, the internet is interactive: Unlike traditional media (eg, newspapers, radio, television), the internet user may have real-time interactions with another person, or with sophisticated computer programs that respond as if human. Third, the internet has few restrictions: Anyone can put almost anything on the internet, without regard to credibility or appropriateness. Finally, the internet is public and permanent: Although information on a website may be removed, it is possible for anyone who visits a website to make an electronic copy of what is there, and many websites are archived and may be retrievable from websites, such as the Internet Archive (http://archive.org), long after their removal from internet search engines.

Although these properties of the internet are neutral, they enable some of the most common internet threats: exposure to strangers and/or predators; interpersonal victimization; exposure to pornography; and participation in online gaming, gambling, and shopping.

The anonymity and interactivity of the internet enables online predators. More than one-third of adolescents online have "friends"

whom they have never met in person. Approximately three-fifths of adolescents active online have received an instant message or email from a stranger, and approximately 1 in 6 has been contacted by someone who made them feel scared or uncomfortable. More than 90% of teenagers have shared personal information about themselves online, including name, birth date, interests, and contact information.

Online interpersonal victimization is the receipt of harassment or unwanted sexual attention over the internet. One-fifth of children have reported being victimized; 1 factor that places individuals at high risk for victimization is talking about sex with someone online. *Cyberbullying* is a specific type of online interpersonal victimization consisting of receipt of electronic communications that are harmful or threatening. Cyberbullying may be as prevalent online as "traditional" bullying, with nearly one-fifth of middle school–age children reporting that they had been cyberbullied at least once in the previous 12 months. Approximately 88% of teenagers have witnessed other people being mean or cruel online, with 21% saying that they have joined in.

Although children may be individually targeted by strangers or cyberbullies, they may also passively encounter undesired internet content. More than 40% of children reported having been exposed to pornography online, and nearly two-thirds of those children described this exposure as unwanted. In adolescents between the ages of 15 and 17 years, more than 70% reported accidentally being exposed to online pornography, with a risk factor for exposure being the downloading of images.

Sexting is the exchange of sexually explicit text, images, or multimedia, generally via IM. Sexting sits at the convergence of pornography and cyberbullying, with the added danger that some adolescents may not perceive sexting as harmful or threatening. In some jurisdictions, minors who have participated in sexting have been charged with possessing child pornography.

In addition to the aforementioned threats, recent studies point to the internet and digital media use as having a role in addictive behavior and attention-deficit/hyperactivity disorder as well as in detracting from healthy behaviors, such as physical activity and adequate sleep. With the wide variety of benefits of and threats posed by the internet, the physician should be prepared to provide parents and guardians with strategies for appropriate and safe internet use.

Strategies for Appropriate Internet Use

The physician may assist parents and guardians with promoting appropriate internet use by informing them of the benefits and threats, helping them set guidelines for screen time and content, and encouraging them to be active participants with their children online. Parents or guardians who may not be technically savvy or may require basic instruction on internet use may be advised of the availability of classes offered by libraries, schools, and community groups.

The American Academy of Pediatrics (AAP) has provided age-specific guidance for the use of digital media, including the internet. These recommendations include the avoidance of most screen media for children younger than 18 months; limiting screen use to 1 hour per day for children ages 2 through 5 years; and consistent time limits for children age 6 years and older, specifically identifying activities that are not allowed. The AAP offers a Family Media Plan tool (www.healthychildren.org/English/media/Pages/default.aspx) to assist parents and guardians in creating developmentally appropriate plans for managing digital media use.

By sharing time online, parents and guardians can promote and model responsible internet behavior. These adults should talk with their children about what they see together on the internet and encourage children to share what they have experienced when online alone, whether good or bad. Placing the computer or other internet-enabled device shared by the family in a public location in the home will encourage the idea that the internet is a shared experience; however, caregivers should be aware that mobile devices allow children to access the internet independently and covertly.

Parents and guardians should set and enforce house rules for internet behavior. Children should be encouraged to be good citizens, including not doing anything that may be hurtful to others and not plagiarizing information that they find freely on the internet. Children should not communicate with or plan to meet strangers known only to them through the internet, nor should they respond to messages that are unsolicited or that make them feel uncomfortable. Children should not share personal information or pictures with others on the internet, nor should they download files from the internet. For older children, safety pledges can be used as formal agreements of acceptable use.

To facilitate parental or other caregiver oversight of internet use, the physician should advise that computers and mobile devices may be configured to allow internet access only during certain hours of the day and to disable access to the internet after a specified amount of time has elapsed. As possible, children should be provided with a separate account to access devices and the internet. Having a separate account promotes autonomy for older children while allowing parents or guardians to restrict internet content. Monitoring software automates tracking of internet usage by creating a reviewable record of websites and images viewed, messages sent and received, and even individual keystrokes entered. The potential benefits of monitoring software should be weighed against the invasion of the child's privacy, and parents and guardians should understand that some children are savvy enough to erase their internet browsing history; consequently, the absence of a web browsing history may be a cause for suspicion. Parents and guardians should also regularly monitor IM activity on smartphones.

Strategies for Safer Internet Use

Although encouraging appropriate use and behavior is important to enjoying the benefits of the internet, the physician should also recommend the use of internet safety tools to protect against inappropriate use and external threats.

Software to protect malware is not directly targeted to children, but it is something about which parents and guardians should be

aware. Malware generally includes *viruses* and *worms* (ie, software programs that can corrupt the information saved on a computer), *spyware* (ie, software that tracks internet activity and sends this information to another person), and *pop-ups* (ie, a new browser window that may contain marketing or other undesired content). Viruses and worms are generally downloaded as attachments in email, whereas spyware and pop-ups are introduced by surfing the Web. Attempts should be made to protect against *spam* (ie, unsolicited email) as well, which may contain undesired content or solicitations.

Filters are special computer programs that allow the presentation of acceptable internet content and that block content deemed to be inappropriate. Filtering may use 1 or more of the following methods: "blacklists" of websites that are specifically blocked; "white lists" of websites that are specifically permitted; the blocking of specific words or terms; and the maturing technology of blocking suspicious image content. Filters are neither perfectly specific nor perfectly sensitive and may require adjustment by the parent or guardian to achieve an acceptable level of filtering. Parents and guardians may contact their ISP to enable *server-side filtering* (ie, filtering of content before it enters the home). If server-side filtering is too restrictive for some members of the household or not sufficiently restrictive for others, a *client-side filtering* approach may be considered, in which filtering software is installed directly on computers or mobile devices. Client-side filters work with standard web browsers, although special child-oriented web browsers may be acquired that have client-side filtering built in.

When a child encounters inappropriate internet content or messages that are hurtful or distressing, parents and guardians should alert their ISP as well as the owner of the website on which the content was or messages were discovered. As appropriate, the parent or guardian should also contact the appropriate legal authorities and the National Center for Missing & Exploited Children (www.missingkids.com). Commercial websites that collect personal information from children younger than 13 years are required to follow the Children's Online Privacy Protection Act of 1998, which is enforced by the Federal Trade Commission. According to this law, internet website operators must post their policy indicating what personal information is collected, how that information will be used, and if that information will be shared with a third party. Parents or guardians must consent to the collection and use of personal information and may revoke this consent at any time.

Additional internet safety information is available to families through reputable web-based resources, such as the Federal Trade Commission resource OnGuardOnline (www.onguardonline.gov), the National Center for Missing & Exploited Children's NetSmartz Workshop (www.netsmartz.org), iKeepSafe (www.ikeepsafe.org), and INOBTR ("I Know Better") (www.inobtr.org). Parents and guardians should also be aware of other venues in which their children may access the internet, such as schools, libraries, and friends' homes, and they should find out what internet safety policies and technologies have been instituted in these environments.

Adolescents on the Internet

Most adolescents have access to the internet from home, and many more may gain access to the internet at school or at a friend's house. Additionally, 95% of adolescents report that they have access to a smartphone, and 45% report that they have a nearly continuous online presence. Parents and guardians should be aware that adolescents who have excessively restrictive internet rules at home are more likely to attempt internet access outside the home, where it may be more difficult to monitor their activity.

Adolescents have mixed views on the effect of the internet, specifically social media, on their lives. Approximately 45% of adolescents believe that social media has neither a positive nor a negative effect, approximately 30% describe its effect as mostly positive, and nearly 25% describe its effect as mostly negative. Open parent-/guardian-child communication about internet use should be encouraged so that adolescents feel that they can discuss what they see on the internet with their parent or guardian without jeopardizing their internet access privileges.

Adolescents may engage in risky online behaviors, including communicating with and planning to meet strangers in person. Based on review of past cases, the Federal Bureau of Investigation has identified specific behaviors that may indicate a child is engaging in risky online behaviors, including spending several hours online, especially at night; having pornographic images on the computer; turning the monitor off or quickly changing the screen when a parent or other caregiver enters the room; and using unrecognized user names or accounts. Other offline behaviors that should arouse suspicion include telephone calls from unknown adults, outgoing calls to unrecognized telephone numbers, gifts or packages received, and unexplained credit card activity.

The physician should consider addressing online activities in the adolescent psychosocial review of systems. Asking adolescents about online activities may unveil risky online behaviors or provide an opportunity to discuss concerns about their health and well-being. Nearly one-third of adolescents have searched the internet for health information, often related to sex and sexually transmitted infections, nutrition, and exercise and fitness. Adolescent girls in particular have a tendency to search for information on physical abuse, sexual abuse, and dating violence as well. Online activities worthy of inquiry include health topics searched for on the internet, which social networking accounts the adolescent has, sharing personal information on the internet, communicating with strangers, meeting people known only via the internet, and engaging in (or being a victim of) cyberbullying or sexting. Adolescents should also be reminded that the internet is not private and that colleges and employers may discover information about the adolescent on what appear to be "private" social networking pages.

Health Information on the Internet

Patients regard physicians as the preferred and most trusted source for health information; however, patients increasingly seek out health information on the internet before, or sometimes in lieu of,

consulting with their physician. It is important to remind families that health information on the internet may be outdated, incomplete, incorrect, intentionally misleading, or easily misinterpreted. When a patient has questions about information found on the internet, the physician should take care not to disregard the information outright. These inquiries provide opportunities to educate the patient and address issues of concern, and the patient may value the physician's opinion of the information.

The physician may support patients by suggesting evidence-based health information resources on the internet, such as the AAP's official website for parents (www.HealthyChildren.org); the US National Library of Medicine website MedlinePlus (www.medlineplus.gov); the Centers for Disease Control and Prevention (www.cdc.gov); and the US Department of Health and Human Services (https://healthfinder.gov). The specialist should be prepared to identify online information sources and support groups, particularly for rare, chronic, or debilitating conditions. The physician should caution families caring for children with special medical conditions about the characteristics of less reliable online resources or support groups, which may include novel or alternative treatment regimens, advice to stop treatment, or charging of fees for participation or treatment.

CASE RESOLUTION

The pediatrician learns that the adolescent uses her laptop computer for 1 to 2 hours every afternoon to complete her homework assignments and is on the internet for an additional 2 to 3 hours every evening streaming videos on YouTube, posting images and thoughts to her Instagram and Snapchat accounts, and occasionally checking her Facebook page. The pediatrician advises the girl that, for safety reasons, personal information should never be shared over the internet, adding that colleges and employers often research prospective candidates online. The pediatrician also asks whether the patient has received, witnessed, or participated in hurtful or distressing communications or imagery online. With both the mother and daughter present, the pediatrician discusses the option of drafting a parent-child contract that clearly establishes the rules for acceptable internet use in and out of the home, including appropriate time limits. The pediatrician also directs the mother to internet-based resources for safeguarding the home environment and mobile devices, as well as a workshop at the local library on internet security.

CHAPTER 8

Cultural Competency Issues in Pediatrics

W. Suzanne Eidson-Ton, MD, MS; Hendry Ton, MD, MS; Blanca Solis, MD; and Jesse Joad, MD, MS, FAAP

CASE STUDY

You are seeing AJ, a 12-year-old Mexican American boy, for a well-child visit. His mother speaks Spanish and "a little" English, is single, and works full time in motel custodial services. After school and during summers, AJ is cared for by his 17-year-old brother and his maternal grandmother, who lives a block away. AJ's weight and body mass index are well above the 95th percentile for his age. When discussing his diet, you learn that his mother buys packaged foods that he can make for himself when she is away. She is concerned that he will not eat if she does not buy the processed, fatty foods he likes. Additionally, these types of foods are more plentiful than healthier options at the local market at which she shops. AJ sometimes eats at his grandmother's home, but she is elderly and does not cook much anymore. When discussing physical activity, AJ states that he wants to play soccer. His mother is concerned about this, however, because he often complains of headaches and stomachaches when it is time for practice, and she does not want to buy the equipment if he will quit after a few weeks, as has happened in the past.

As is your practice with all adolescents, you ask to speak with AJ alone. During your assessment, you learn that he is attracted to boys but has not shared this information with anyone. He is certain that his brother will not approve and that his mother will be heartbroken. He is sometimes teased at school because he is "not tough enough," and he fears some of the bigger bullies might try to jump him if he hangs around after school to participate in any after-school sports activities.

Questions

1. What is the definition of culture?
2. What is cultural competence? What is cultural destructiveness?
3. What is meant by unconscious bias?
4. Why is it important to use a certified interpreter when talking to the parent with limited English proficiency? When is it appropriate for the pediatric patient to interpret for their parent?
5. How does understanding the perspective of the patient and the parent affect medical decision making?

The provision of culturally competent care is no less important for pediatric patients than adult patients. Those who provide health care to children face many important issues concerning culturally competent care, including health disparities and health care disparities based on socioeconomic status, ethnicity and/or racial identity, sexual orientation, and gender identity. Many issues of cultural competency, health disparities, and approaches to cross-cultural care are similar across minority populations in the United States, including some rural white populations.

Definition of Culture

Culture is a set of meanings, norms, beliefs, and values shared by a group of people. It is dynamic and evolves over time and with each successive generation. Culture encompasses a body of learned behaviors and perspectives that serve as a template to shape and orient future behaviors and perspectives from generation to generation and as novel situations emerge. It shapes how and what symptoms are expressed and influences the meaning that individuals attribute to symptoms, including one's beliefs about the causes, effects, and potential remedies for these symptoms. Culture is a broad category that includes not only race and ethnicity but also sexual orientation, gender roles, gender identity, socioeconomic status, nationality, and other group affiliations. The interaction between the culture of the patient and family and that of the physician is often significant and can result in bias in both assessment and treatment. These biases, in turn, can contribute to health and health care disparities.

Health Disparities

Health disparities are differences in health outcomes across different groups. *Health care disparities*, as defined by the Institute of Medicine (now the Health and Medicine division of the National Academies) in the document *Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care,* are "racial or ethnic differences in the quality of health care that are not due to access-related factors or clinical needs, preferences, and appropriateness of intervention." Health disparities and health care disparities exist within the United States and particularly affect minority populations. Although health disparities may be caused by many social determinants of health, such as socioeconomic status and access to safe neighborhoods, healthy food, and health care, health care disparities are directly related to what happens to certain patients in the health care system after they have accessed care. Addressing health disparities moves medicine and society closer to *health equity,* which is achieved, as defined by Braveman et al, "when everyone has a fair and just opportunity to be as healthy as possible."

Latinx is a gender-neutral term that refers to individuals of Latin American heritage. Latinx children in the United States face significant health and health care disparities. (Throughout this chapter the term Hispanic is used for information reported from any study in which that term was used.) The Hispanic population has among the highest prevalence of overweight in children, but American Indian/Alaska Native children having the highest rates of overweight, at nearly one-third of that population. Additionally, in the United States Hispanic children also have a lower fitness level and watch more television than white children. The reasons behind these disparities are complex and multifactorial. Many ethnic minorities and limited English proficiency (LEP) groups also face disparities in the health care they receive. For example, for minority groups the duration of their routine well-child visits is shorter and Latinx children are less likely than white children to receive counseling at these visits.

In addition to these examples of lack of access to quality health care, many social, political, and cultural elements contribute to health disparities observed in certain ethnic groups. Evidence exists to indicate that these social determinants have a more significant effect on health than medical care does (see Chapter 141). Although physicians can effectively address the social determinants of health through activism and advocacy, it may be difficult to do so on an individual patient care level. Nevertheless, it is important to understand these issues and how they may contribute to patients' health outcomes. For example, lack of access to quality, low-cost foods in one's neighborhood, lack of transportation, advertising practices that target low-income communities, and lack of access to safe playgrounds are examples of social determinants that contribute to obesity. It is also essential to understand the influence of culture on patients' health beliefs, health behavior, and health status. Cultural issues are further discussed later in this chapter.

Finally, acculturation is also likely to affect health, health beliefs, and health behaviors. Second-generation Hispanic adolescents are twice as likely as first-generation Hispanic adolescents to have obesity or overweight. Similar findings have been observed in other populations (eg, Americans of Asian descent). Acculturation across generations in Hispanic communities has been associated with decreased fruit and vegetable consumption, increased soda consumption, and decreased physical activity. These effects of acculturation have been shown in other immigrant groups as well. Acculturation is a complex variable in relation to pediatric obesity, however. For example, in 1 study, Mexican American mothers who were less acculturated had children with higher body mass indices.

Cultural Competence

Physicians who strive for cultural competence attempt to minimize their bias and seek to incorporate cultural assets into their work with patients. Cultural competence is a continuum (Figure 8.1). *Cultural destructiveness*, the least developed state along that continuum, comprises attitudes and practices that are meant to be harmful to cultures and individuals within the particular culture. Physicians at this level may overtly discriminate against individuals based on their culture (eg, intentionally making homophobic, racist, or sexist remarks to colleagues). Physicians who have *cultural incapacity* do not overtly discriminate but lack the ability and willingness to recognize and intervene when discrimination happens. As a result, they ultimately reinforce culturally oppressive behaviors and policies. In the *cultural blindness* phase, an individual believes that culture makes no difference and that all people are the same. This viewpoint ignores cultural strengths, encourages assimilation, and often results in blaming the victims of racial injustices for their problems. Physicians at this stage may have difficulty believing in the validity of health disparities, despite the enormous body of evidence supporting the existence of such disparities. Although these physicians strive to give quality care to everyone, they do not recognize culture-specific experiences that affect patients' health, such as poverty or violence based on race, sexual orientation, or

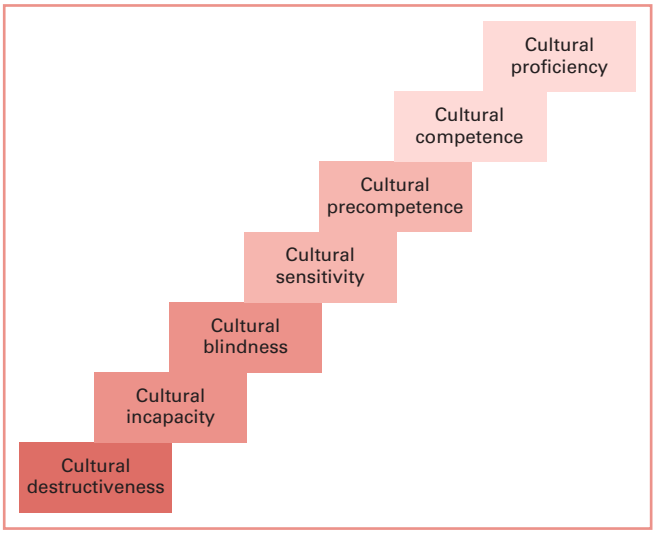

Figure 8.1. Steps in achieving cultural proficiency.

gender, and they miss opportunities to incorporate culturally relevant strengths into treatment, such as collaboration with traditional healers, extended family, or faith-based organizations. *Cultural precompetence* is characterized by a willingness to deliver quality services and a commitment to civil rights but a lack of knowledge and experience to implement culturally relevant services. Culturally pre-competent physicians often struggle with knowledge that disparities exist and that perhaps they continue to contribute to them but are at a loss as to what to do about it. In contrast, physicians at the stage of *cultural competence* seek to expand their cultural knowledge and resources, often in consultation with culturally diverse communities. They also continuously self-assess and adapt traditional service models to enhance care for culturally diverse patients. Using native culture-based talking circles with American Indian youth to improve their understanding of obesity is an example of working at this stage of cultural competence. Finally, physicians who exhibit *cultural proficiency* hold cultural diversity in highest esteem and continuously advocate for increased cultural competence throughout the system of care. It is important to recognize that physicians move back and forth along this continuum dynamically, influenced by their own experiences. For example, physicians who identify with being in the culturally competent phase when working with Latinx patients may find themselves having cultural incapacity when working with gay or lesbian patients.

Another helpful model is the concept of *cultural humility*, which is a process of self-reflection and commitment to a lifelong learning process, thereby engaging the physician in an ongoing courageous and honest process of self-critique and self-awareness. Both the cultural competence model and the cultural humility model reflect cultural competency as a process rather than an end result or a fixed state.

Communication

Initially, during every clinical visit, it is important to maximize communication with the patient and the parent (see Chapters 2, 3, and 4). Effective communication results in an improved physician-patient relationship, treatment adherence, and health outcomes. Poor communication may have negative consequences. Patients with LEP, in particular, have increased barriers to health care, decreased health quality, and decreased health status. In a Joint Commission study involving 6 hospitals, researchers found that patients with LEP were at increased risk for iatrogenic harm. In contrast, use of interpreters is associated with increased follow-up with preventive and primary care services. Ideally, a trained medical interpreter should be available to communicate with patients or parents who do not speak English. Although it happens often in clinical practice, it is inappropriate to rely on the patient to interpret for the parent. It is clearly a difficult position for a child or adolescent to interpret health information for a parent. It is not guaranteed that the patient understands what the physician is communicating or that the patient is interpreting correctly for the parent. It also disturbs the power balance between parent and child. Strategies for using interpreters are provided in Box 8.1.

Box 8.1. Strategies for Using an Interpreter in the Clinical Visit

- Talk with the interpreter briefly before the interview to discuss overall goals for the interview and ground rules (eg, use word-for-word interpretation). If using a certified medical interpreter via telephone, have a brief discussion about the goals for the interview.
- Give the interpreter and the patient permission to ask questions about terminology with which they may be unfamiliar.
- Use nonverbal behaviors, such as eye contact, nodding, and facial expressions, to signal to the patient that the physician understands what is being communicated.
- Speak directly to the patient and address the patient in the first person.
- Use short, simple statements and speak on 1 topic at a time.
- Avoid medical jargon and ambiguous statements.
- Meet briefly with the interpreter after the interview to confirm pertinent information, ask about cultural information, and discuss feedback. Do this with telephone interpreters as well.
- Remember that interpreters are not medical professionals. Therefore, consider information volunteered by interpreters as being reliable as collateral information provided by other individuals who are not health professionals.

Unconscious Bias

In addition to ensuring effective communication, it is important for the physician to address the unconscious biases that the physician may have about a patient. Although few health professionals intentionally discriminate based on culture, studies suggest that physicians are likely to have unconscious biases that can significantly affect patient care.

Physicians can take steps to manage unconscious bias. It is essential to first acknowledge that bias does exist in the health care system and within the lived experience of patients as well as physicians. It is good practice for health professionals to explore the Project Implicit website (https://implicit.harvard.edu/implicit) and take the online tests designed to detect bias across various cultural dimensions, including race, sex, gender, and sexual orientation. Most people who take these tests quickly realize that they carry biases they had no idea existed within themselves. For many, acknowledging their own biases may be the most difficult step. The next step is to work toward replacing one's own biases with positive and realistic associations about other groups. For example, seeking out dialogue and companionship with people culturally different from oneself can help replace one's negative assumptions with more positive associations. Finally, it is important to be mindful of the potential influence of unconscious bias on medical decision making, whether treating a patient of similar background to the physician or a patient of a quite different background. It is essential to consider cultural context; however, it is also important to be aware that each patient is a unique individual. In any situation in which bias may be present, the physician should speak less and listen more, striving to avoid assumptions.

Eliciting Patients' Perspectives

Optimization of clinical collaboration is dependent on each stakeholder—patient, family, and physician—having an opportunity to express their understanding of the health issue in question. Typically, however, the physician obtains the patient history with limited consideration of the patient's and family's beliefs about the health problem. Difficulties may arise if the patient or a family member disagrees with the physician's explanations of the illness. In many cultures, openly disagreeing with a physician's assessment and treatment recommendations is considered disrespectful. Instead, the patient and family may acknowledge the physician's status by expressing agreement but maintain their own ideas about how to address the issue. For example, although a parent may report the intention to follow through with the physician's recommendation to change to a healthier diet to improve the health of the child, the parent may continue to purchase less healthy ready-made foods because of real or perceived difficulties getting healthier foods given the parent's long work hours and the lack of healthy food in the family's neighborhood. The physician may characterize obesity as a primarily biologic problem, whereas the parent may view the condition primarily as a problem of access and time.

Furthermore, the parent may not perceive the child's overweight status as a problem at all. The relationship of pediatric obesity to cultural ideals and norms around food, eating, and parenting is complex. Some evidence in ethnographic studies shows that, in some Latinx cultures, feeding children and especially giving "treats" is a means of showing love. A parent or guardian with a child who is a so-called healthy eater may not want to limit the child's enjoyment of food. Additionally, body size ideals vary across communities, and some evidence indicates that in some Latinx communities children who meet criteria for overweight are considered more attractive and healthier than thinner children, who may be considered frail. Poverty and the experience of food scarcity can further exacerbate overeating during times when food is more accessible. Finally, particularly when other friends or family members offer food to a child, it may be considered socially unacceptable for the parent to refuse or criticize the type of food being offered. Understanding such cultural norms can be helpful in treating individual patients. It is important to remember, however, that particular individuals and families have their own cultural norms that may or may not be consistent with others in their ethnic group.

Conflicts in health beliefs between the physician and the patient and/or family may result in treatment nonadherence and dropout. It is important that the physician and the patient and/or family discuss their respective health perspectives. The better the physician's understanding of the health beliefs of the patient and family, the more effectively the physician can address differences and build on common ground. Likewise, patients and families may feel a greater level of comfort with a physician's recommendations if their questions and concerns about the physician's perspectives are addressed. The questions in Box 8.2 can help a physician further understand the health beliefs of the patient and family.

Decision Making

It is also important for the physician to understand how the patient or family makes medical decisions. Many physicians look to a child's parent or guardian as the primary decision maker. This process may be culturally influenced, however. Parents or guardians from strongly collectivistic cultures, in which the needs and priorities of the group supersede those of the individual, may wish to involve others (eg, senior family members, spiritual leaders, clan leaders) in health care decision making. Failure on the part of the physician to allow the inclusion of these persons in the decision making process may result in the parent or guardian feeling forced into a decision, may precipitate conflict within the family, and may result in the family or community blaming the parent or guardian should a bad outcome occur. Suggested questions for facilitating a discussion about decision making are presented in Box 8.2.

Sexual Orientation and Gender Identity

At any clinic visit, it is extremely important for the physician to remain nonjudgmental and be supportive of the patient's sexual orientation and gender identity development. (See

Box 8.2. What to Ask

General Questions

- About which problem or problems are you most concerned?
- What do you think has caused the problem?
- What are your concerns about this problem? How does it affect you and your child?
- What treatments do you think might work for it?
- What have you done in the past? How satisfied were you with the results?
- What are your goals for treatment?
- What is your understanding of the treatment offered? What are your concerns about it? What are the barriers for completing or carrying out the treatment?

Health Issues Identified by the Physician

- What do you think about the concerns that I have raised with you (ie, the problems the physician has identified [eg, obesity])?
- Have you been told about this concern before? If so, what is your understanding of it?

Decision Making

- How do you usually make decisions about health care?
- Do you involve anyone else in that process? Who? What are their roles?
- Who usually makes the final decision?
- How comfortable are you with using that process to make decisions about your child's current situation?

Chapters 57 and 150, respectively, for suggestions on providing culturally competent care around sexual orientation and gender identity and on addressing bullying.) Two helpful resources are the Fenway Institute National LGBT Health Education Center (www.lgbthealtheducation.org/lgbt-education/learning-modules/) and the Family Acceptance Project (https://family-project.sfsu.edu).

As the result of inequitable treatment, sexual minority individuals experience significant health disparities. Discrimination, bullying, and abuse can result in mental health issues, such as depressive disorders, posttraumatic stress disorder, suicidality, and substance use. Individuals who are lesbian, gay, bisexual, transgender, or questioning (LGBTQ+) also have more barriers to access health services than heterosexual cisgender individuals, resulting in lower rates of screening and preventive services. (A *cisgender* person is one whose gender identity or expression matches the cultural norm for the person's biologic sex.) Youth who are LGBTQ+ are also more likely to face family alienation and homelessness. Disclosure of sexual orientation and physician attitude are important mediating factors to heath care experiences of LGBTQ+ individuals; however, 90% of youth in 1 study reported having reservations about disclosing to their physician. This underscores the importance of physician training on facilitating these important conversations.

It is also important to examine the intersectionality of ethnicity, sexual orientation, and gender identity. For example, the National Longitudinal Study of Adolescent Health, in which 20,000 adolescents were surveyed, indicated that male and female Hispanic adolescents were more likely to report same-sex romantic attraction than their peers of other ethnic groups. This difference was significant compared with white and Asian peers. Additionally, male and female Latinx adolescents were more likely than their peers to be victims of violence. These findings show that issues of sexual minority groups and bullying are important to consider in addressing adolescent health disparities in culturally diverse communities in the United States.

It is also important to understand the patient's sexual orientation in the context of the patient's family and ethnic community. For example, in some traditional communities, such as some American Indian tribes, certain sexual minorities (eg, nonbinary or "two-spirit" individuals) are accepted in the community and considered to possess certain spiritual gifts. Although LGBTQ+ youth in Latinx families do face challenges, particularly in situations in which antigay religious views are of strong influence, strong cultural identity can serve as a grounding influence for LGBTQ+ individuals. For example, in 1 study, young urban Hispanic men who have sex with men were less likely to engage in risky sexual behavior if they were connected to their ethnic community.

CASE RESOLUTION

While speaking with AJ alone, you express support for his early sexual identity development, identify safe adults in his life with whom he can discuss his feelings and concerns, and identify community resources for LGBTQ+ individuals. When AJ's mother returns to the room, you also discuss AJ's and his mother's perspectives about food, his weight, and his activity level, using a medically trained interpreter to ensure clear communication with his mother. You identify some of this family's strengths: AJ's mother's desire to help him be healthier; AJ's relationship with his grandmother, who cooks healthy traditional foods; and AJ's supportive relationship with his older brother. After discussion, the patient decides that he would like to learn to cook from his grandmother and will commit to cooking a family dinner once a week, which delights his mother. His brother has also agreed to take him to soccer practice and games for a neighborhood soccer team. AJ likes this idea, because he feels safe from bullies with his brother present and feels that soccer will help him be stronger and more confident. You arrange for a follow-up visit in several months to check in with AJ and his mother about their progress and to brainstorm about further interventions. This will include 1-on-1 time with AJ and further discussion of his sexuality.

CHAPTER 9

Global Child Health

Suzinne Pak-Gorstein, MD, PhD, MPH, FAAP, and Maneesh Batra, MD, MPH

CASE STUDY

You are watching television when the programming is interrupted by breaking news that a severe earthquake has struck a developing country you have recently visited. You wonder if and how you could become involved in efforts to help the country respond to the disaster, prevent diseases, and rebuild its health care infrastructure.

Questions

1. What are the global trends in childhood disease and mortality? How does this compare with the United States?
2. What is global health?
3. What is the role of the pediatrician in global health?
4. What are the key organizations in global health with which pediatricians work?
5. How can the pediatrician carry out international work in an ethical and effective manner?
6. What are useful global health resources?

Background

Worldwide, an estimated 5.3 million children younger than 5 years of age died in 2018, for an average of nearly 15,000 children dying each day (Figure 9.1). This represents a 58% reduction from the 12.6 million deaths of children younger than 5 years of age estimated in 1990. Even so, significant disparities in child mortality persist and have become increasingly concentrated geographically, with specific regions of the world bearing a disproportionate burden. The continents of Africa and Asia combined account for 86% of all child deaths, with one-third of these deaths occurring in South Asia and half in sub-Saharan Africa. Less than 1% of deaths occur in high-income countries.

Nearly one-third of all child deaths worldwide were caused by 3 communicable diseases: pneumonia (16%), diarrhea (8%), and malaria (5%). Most of these lives could be saved through increased access to low-cost prevention and treatment measures, including

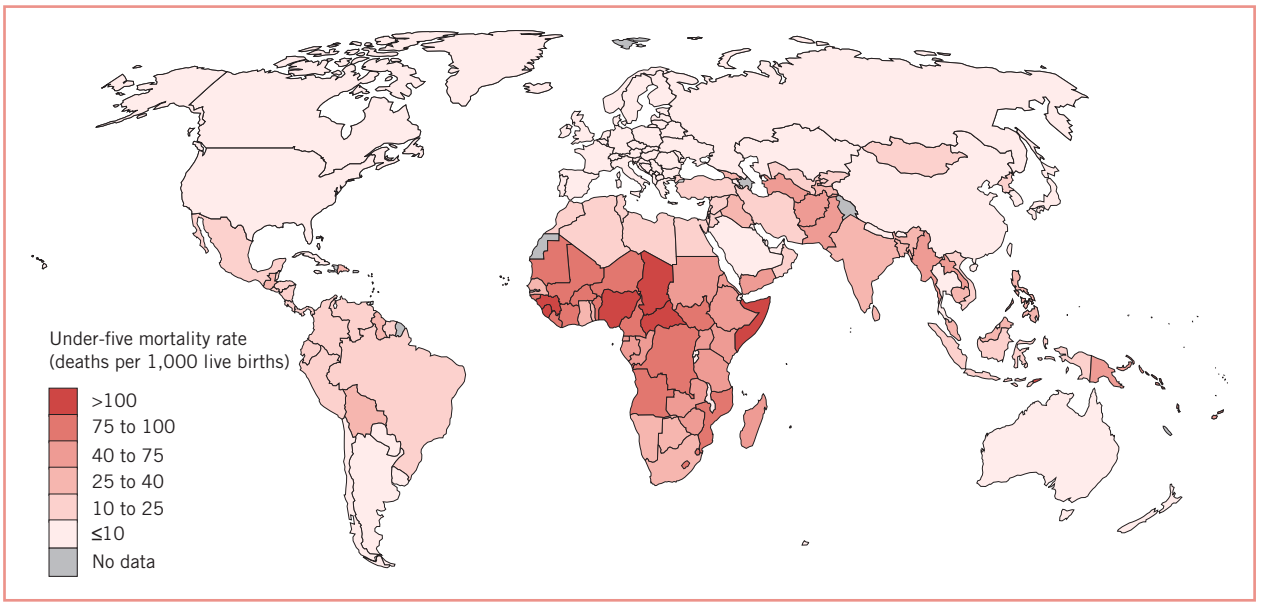

Figure 9.1. Mortality rates for children younger than 5 years in 2018.
Reprinted with permission from United Nations Inter-agency Group for Child Mortality Estimation (UN IGME). *Levels & Trends in Child Mortality: Report 2019. Estimates Developed by the UN Inter-agency Group for Child Mortality Estimation.* New York, NY: United Nations Children's Fund; 2019.

antibiotics for acute respiratory infections, oral rehydration therapy for diarrhea, immunizations to protect against pneumococcal pneumonia and diarrhea caused by rotavirus gastroenteritis, and the use of insecticide-treated mosquito nets and appropriate drugs for malaria.

Undernutrition is an underlying cause of at least one-third of all deaths in children younger than 5 years. Reducing chronic and acute undernutrition would have a substantial effect on reducing child mortality. Furthermore, improved coverage of specific nutritional interventions, such as early and exclusive breastfeeding, are cost-effective and reduce the prevalence of pneumonia and diarrhea.

The first month after birth is a perilous phase for a child's survival, with an estimated 47% of deaths in children younger than 5 years occurring during this period. Most of these deaths occur at home in the first postnatal week as the result of preterm birth (18%); intrapartum-related complications, such as birth asphyxia (12%); and neonatal sepsis (7%). Thus, improving neonatal care is essential to the goal of improving child health. Increased access to basic, inexpensive interventions is necessary to reduce neonatal mortality rates globally, including delivery by skilled birth attendants, hygienic umbilical cord care, and the training of community health workers to assess and begin early treatment for neonatal infections.

Mortality among young children aged 5 through 14 years is lower than that of children younger than 5 years (7.2 deaths per 1,000 live births and 39 deaths per 1,000 live births, respectively). Decreases in mortality for these older children and adolescents have slowed since the year 2000, however. In 2017 an estimated 0.9 million children 5 through 14 years died, which represents approximately 2,465 deaths each day. Most deaths among these children occurred in sub-Saharan Africa (54%) and Southern Asia (25%). Injuries accounted for a larger proportion of deaths (30%) among these older children than among children younger than 5 years, with drowning and road injuries causing 14% of deaths in the older age group. Leading causes of death among adolescents ages 10 through 19 years include road injury, HIV, suicide, lower respiratory infections, and interpersonal violence.

Box 9.1. United Nations Sustainable Development Goals[a]

1. End poverty in all its forms everywhere
2. End hunger, achieve food security and improved nutrition and promote sustainable agriculture
3. Ensure healthy lives and promote well-being for all at all ages
4. Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all
5. Achieve gender equality and empower all women and girls
6. Ensure availability and sustainable management of water and sanitation for all
7. Ensure access to affordable, reliable, sustainable and modern energy for all
8. Promote sustained, inclusive and sustainable economic growth, full and productive employment and decent work for all
9. Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation
10. Reduce inequality within and among countries
11. Make cities and human settlements inclusive, safe, resilient and sustainable
12. Ensure sustainable consumption and production patterns
13. Take urgent action to combat climate change and its impacts
14. Conserve and sustainably use the oceans, seas and marine resources for sustainable development
15. Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss
16. Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable and inclusive institutions at all levels
17. Strengthen the means of implementation and revitalize the global partnership for sustainable development

[a] These goals were developed and signed by all United Nations member countries in 2015. There are 17 goals with 169 targets (with 1 specific goal for health that includes 13 health goal targets) and a series of measurable indicators for each target.

Sustainable Development Goals

In 2015, world leaders agreed to the 17 Sustainable Development Goals (SDGs) for improving global well-being by 2030. The SDGs were built on lessons learned from the 8 Millennium Development Goals (MDGs), which were specific, measurable targets set by the United Nations in 2000 to eradicate poverty, hunger, illiteracy, and disease by 2015. Progress toward meeting the MDGs has been significant, although uneven, with the poorest and most disadvantaged countries as well as marginalized communities and social groups within developed countries not attaining these goals.

The SDGs aim to address the underlying determinants of poverty and poor health in a sustainable manner by expanding its goals to address the systems-based, underlying socioeconomic, political, and environmental factors. The 17 interconnected SDGs are comprehensive and apply universally to all nations, both developed and developing (Box 9.1).

The third SDG (SDG-3) specifically focuses on population health, to "ensure healthy lives and promote well-being for all at all ages." Although the MDGs included targeted relative reductions in mortality (eg, reduce under-5 mortality by two-thirds), the SDG-3 sets absolute targets to end preventable deaths of neonates in particular and other children younger than 5 years of age. Specifically, these more equitable goals call on all countries to reduce neonatal mortality to no more than 12 deaths per 1,000 live births and under-5 mortality to no more than 25 deaths per 1,000 live births by 2030.

Inequities in Health

Significant disparities exist in child health. Sub-Saharan Africa grapples with a high child mortality rate (ie, 76 per 1,000 live births in 2017); that is, 1 in 13 children in that region dies before 5 years of age. In comparison, Western European countries have an under-5-year mortality rate of 4 deaths per 1,000 live births, and in

high-income countries fewer than 5 per 1,000 children die before their fifth birthday.

In 2017, an estimated 82% of all the growth in global wealth went to the top 1%, whereas the bottom 50% saw no increase at all. The SDG-10 calls for reducing inequalities in income as well as those based on age, sex, disability, race, ethnicity, religion, or other status within a country. Large inequalities in child health exist between, as well as within, countries. For example, in Bolivia and Peru, the richest one-fifth of the population has almost universal access to a skilled attendant at birth, compared with only 10% to 15% among the poorest one-fifth. Women in poor rural households accounted for two-thirds of unattended births.

Although the United States spends more on health than any other country ($10,348 per capita), it ranks lower than other highly developed nations with respect to its under-5 mortality rate (7 deaths per 1,000 live births), which is greater than rates in most of Europe. Additionally, the United States lags behind other comparable countries with worse life expectancy and higher rates of disease burden as calculated in disability-adjusted life-years. Significant health inequities are also apparent within the United States. Black children age 1 to 4 years have the highest death rates (38.8 per 100,000), followed by Native American children (30.5 per 100,000); Asian/Pacific Islander children have the lowest death rates (16.5 per 100,000). Much of the differences in health outcome are the result of disparities in nonmedical social determinants, such as income and education. Compared with other Western countries, however, the United States spends disproportionately more on health care than on social services that could indirectly improve health outcomes.

To attain the SDGs of reducing child mortality, targeted interventions that focus on the poorest populations are needed that could close gaps in intranational health disparities. It has been projected that policy interventions aimed at reducing country-level inequities would have a major effect on the under-5 mortality rate. Worldwide, had the child mortality rates of all countries been reduced to that with the lowest rate (2.1 deaths per 1,000 live births), a total of 5.1 million deaths of under-5 children could have been prevented in the year 2017 alone, which would represent a 95% reduction of child deaths.

The Health and Medicine division of the National Academies (formerly the Institute of Medicine) definition of *global health* (GH) encompasses "health problems, issues, and concerns that transcend national boundaries, and may best be addressed by cooperative actions...." For the World Health Organization, GH involves health problems that affect global politics and economies and arise from disparities in sociopolitical and economic status. Inequalities in health within and between countries arise from inequalities within and between societies. Consequently, the emerging field of GH intersects medical and social science disciplines such as demographics, economics, epidemiology, political economy, and sociology.

Integrating Global Health Into Pediatric Careers

Children constitute the most vulnerable group in any society, and the strongest medical advocate for the health of children is the pediatrician. Consequently, pediatricians have been leaders in addressing global and local health disparities, and their collective voice has been powerful. Global health work varies widely in scope and extent. The duration of GH activities ranges from single short-term medical missions to long-term postings in resource-limited settings. Involvement in GH encompasses the direct provision of clinical services, technical assistance for program development, research, education and training of health workers, and governmental advocacy for policy changes. The goals of GH activities range from forging novel directions in areas of basic science and epidemiologic, clinical, and operations research to addressing the needs of the world's poorest communities. Ideally, GH experiences should be transformative for the health professionals who engage in these experiences and for the poor communities of the world that they serve.

By committing to a single international site (eg, hospital, rural clinic, community) and working with a partner based at that site, the pediatrician can engage in a longitudinal supportive relationship that is sustainable and effective. Pediatricians can also make a sustainable impression by empowering in-country partners through training of trainers, such as community health workers, supervisors, and clinicians responsible for health professional trainees.

Pediatricians may engage in GH activities in multiple domains, including patient care, teaching and training, research, and advocacy. Pediatricians have also played an important role in responding to humanitarian emergencies in the United States as well as in other countries, such as in the aftermath of devastating earthquakes and other natural disasters. Additionally, pediatricians with skills in research and evaluation may contribute to GH through clinical research and program evaluations.

Many GH opportunities do not require an overseas trip. Although vulnerable populations and health inequities certainly exist in low-income countries, significant inequities abound in the United States. Among developed countries, those with the highest health status have the lowest levels of health inequality. The United States ranks at the bottom of this list, with 1 of the poorest health rankings and the highest inequalities in health. Opportunities to engage in local GH work are plentiful and include supporting the care and resettlement of local refugee and immigrant families, supporting international adoptees, serving migrant farmworkers, and supporting Native American health issues.

The pediatrician may also work locally for GH by advocating for equity of health care at all levels domestically and globally, working in the home office of a US-based GH organization, and providing expertise to support international organizations dedicated to helping vulnerable children. Finally, pediatricians can make a significant impact in GH by lobbying the US government for more international relief funding or supporting corporations with ethical international trade practices.

Beyond the Hospitals: Global Health, Community Health, and Advocacy

Increasing numbers of medical students and residents in the United States seek training opportunities in developing countries, and most of these trips are spent in a foreign hospital on a pediatric

ward providing direct clinical care. In addition to observing and managing tropical diseases and more severe forms of commonly encountered pediatric conditions, visiting physicians and students learn and experience common themes in these low-resource settings: underpaid and under-trained health workers, hospital administration untrained in health management, dilapidated facilities, basic medicine shortage, lack of tools in testing and imaging, and higher mortality rates. Because the needs at such hospitals and clinics are glaring, the physician instinctively seeks to fill the gaps with what defines quality health care in the United States—more medicines, equipment, clinical staffing (in the form of visiting physicians), and perhaps training. However, the long-term effect of a brief visit, even repeated visits, may be further improved through efforts to prevent disease using public health approaches and focusing on communities.

With additional training in areas such as public and community health or health service management, the pediatrician may act as an "agent of change" by undertaking systems-based quality improvement approaches, public health measures, and community-based strategies to bring about lasting positive effects on child health.

Box 9.2 lists some key categories of GH organizations. In collaboration with community groups, the clinician or student can effectively empower community health workers and work within local community-based nongovernmental organizations (NGOs) to contribute to lasting and contextually appropriate change.

Getting a sense of how most of the world lives is a tremendous gift, honor, and burden that accompanies these experiences. Continuing to advocate for children living in poverty throughout the world after returning from a short-term medical experience is a great way to enact one's ongoing responsibility. Additionally, although perhaps less glamorous than traveling overseas, working within the US health care and political system to promote awareness for change has the potential to catalyze lasting and significant improvements in child health. Similarly, through work to empower local refugee communities in the United States or to advocate for more equitable access to health care for vulnerable immigrant children, pediatricians can make a significant and lasting difference in the efforts to close the gap in health disparities.

Ethical Issues in Global Health

The traditional model for medical experiences for US-based physicians presumes that individuals in the United States possess the knowledge, skills, and resources to improve the conditions of people living in developing countries. Most students and physicians who have participated in such an experience, however, report that they themselves derive the greatest benefit from such experiences.

Although the desire to improve the conditions of children by providing clinical care is well-intentioned and altruistic, the potential exists for short- and long-term harm. In the short term, caring for children in such settings with conditions that are unfamiliar to visiting students or physicians and out of the scope of their training can result in errors in diagnosis and management. Often, students have less supervision of their clinical work in these settings, which

Box 9.2. Examples of Global Health Organizations

International Health or Multilateral Organizations
- World Health Organization (WHO)
- United Nations Children's Fund (UNICEF)

Bilateral Government Organizations
- US Agency for International Development (USAID)
- Centers for Disease Control and Prevention (CDC)
- Peace Corps

International Donor Foundations
- Bill & Melinda Gates Foundation
- Wellcome Trust
- Children's Investment Fund Foundation (CIFF)

US-Based Nongovernmental Organizations
- Partners In Health
- Global Health Council
- Save the Children

International Nongovernmental Organizations

Specialized services or training
- Short-term service/training trips (eg, cleft palate repairs)

Emergency relief and rehabilitation
- Doctors Without Borders (Médecins Sans Frontières)
- International Committee of the Red Cross
- CARE International
- International Rescue Committee (IRC)

Consultant Organizations: For-profit and Not-for-profit

Global health consultant organizations may take government contracts to provide international support
- Seed Global Health (formerly Global Health Service Partnership)
- FHI 360 (formerly Family Health International)
- John Snow, Inc. (JSI)

Faith-Based Organizations
- World Vision
- Aga Khan Foundation
- American Friends Service Committee

Academic Institutions

An increasing number of academic institutions are developing global health programs in partnership with international groups, overseas academic institutions, or ministries of health
- Consortium of Universities for Global Health (CUGH)

Local and Domestic
- Global health advocacy organizations
- Refugee resettlement agencies
- Native American health services

- Physicians for Social Responsibility (PSR)

Table 9.1. Preparation for Working in Resource-Limited Settings: Themes, Subcategories, and Examples

Category Themes	*Subcategories*	*Example of Recommendations for Best Practices*
Logistics and safety	Personal health Safety Travel logistics Medical licensure Malpractice insurance	Create strategies for risk reduction, including for transportation, environment, food, risk-taking behaviors, and recreational activities, and emphasize that local laws (eg, seat belts, restricted areas) apply to all visitors
Knowledge and skills	Medical knowledge Health systems knowledge Procedural and practical skills (if applicable)	Familiarize oneself with local disease patterns, reference materials, on-site formularies, and clinical practice guidelines, including resources available through the World Health Organization
Attitudes and behaviors	Personal motivations Learner humility Cultural humility Understanding of culture shock and reentry shock Professionalism and behavior	Recognize that behaviors, skills, and competencies of local providers are culturally based and resource-dependent, and avoid comparison with home institutions, superior or judgmental attitudes, and denunciations of differences in clinical care
Local resources	Clinical resources Human resources Needs and assets	Familiarize oneself with the host site formulary, laboratory supplies, radiology capabilities, medical technology, medical transportation services, patient costs, and patient payment models before departure to best inform adaptations in diagnostic evaluations and management
People	History, politics, and economics Culture Religion Local health beliefs Language	Arrange plans for interpreter services during the visit, if necessary, and recognize the burdens imposed on local health professionals when assisting with interpretation
Ethics	Donations Research and projects Patient privacy Patient care with resource limitations Scope of practice Supervision Sustainability Effect on hosts	Follow host institution guidelines and accepted international guidelines about the donations of medications, technology, and supplies
Communication	Predeparture, on-site, and post-return communications	Schedule meeting with returning traveler to assess wellness, provide an opportunity for debriefing of the experience, obtain input on the program or partnership strengths and weaknesses, and determine the effect of the experience on clinical practice and career plans
Partnerships	Choosing opportunities Predeparture selection processes Clear expectations Evaluation	Provide transparent goals and objectives for both visitors and the sending institutions and ensure that the host institution has an opportunity to review them and modify them if necessary

can result in harm to patients and students' growth as physicians. In the long term, provision of clinical care by visiting students or physicians can undermine the existing health system infrastructure.

As the number of medical students, trainees, and physicians from the United States who visit developing countries for short-term training experiences continues to grow, concern for medical tourism and the long-term effect of these training experiences on the under-resourced hosts is rising. As indicated in Table 9.1, key factors for ensuring effective, sustainable, and ethical international collaborations include forethought, planning, and long-term partnership. Key guiding principles of effective and sustainable partnerships include equity, inclusivity, sustainability, mutual benefit, prevention of adverse effect, social justice, and humility. Although most partnerships in GH involve trainees and practitioners from a higher-income country visiting a facility in a low-income country, everyone may derive greater benefit from reciprocal exchanges; such bidirectional exchanges impart true parity within partnerships.

Proper predeparture preparation and education for any overseas medical experience is a critical first step and entails orientation about the country and its sociopolitical context and public health priorities. Knowledge of the key medical problems facing the communities as well as international and local treatment guidelines and strategies to deliver care within the confines of existing local resources are also important. Critical key minimal standards for preparation are described in Table 9.1.

The fundamentals for the creation of a meaningful international partnership with a community involve multiple steps. The first step is the development of a mission or an identified shared purpose with partners before visiting a new international site. Second, it is critical to establish a collaboration with a local agency, such as an NGO or a governmental agency, to promote sustainability and enhance effectiveness of the care delivered. A third important step for long-term effect and partnership is to ensure that the education of community members, other physicians, and trainees is a part of the mission and that appropriate educational experiences are structured into the trip and planning. Closely related to this is the appreciation of the reciprocal nature of any education: The visiting physician is in a position to learn just as much if not more than the local health workers about working in the local setting.

A fourth fundamental step for meaningful partnerships involves ensuring that service is truly being provided to the community by learning about the health priorities of the community from the NGO or other local agency. It is also important to encourage teamwork by working with appropriate supervision, including physicians from the host country. Effective international collaboration also requires sensitivity to the costs and burden that a visitor has on the host. Finally, assurance of partnership effectiveness requires building an evaluation process early on that incorporates the perspectives of all involved, including local officials, health professionals, and community members. This includes assessment of whether educational objectives are being met for all stakeholders, including the host site.

CASE RESOLUTION

You learn about a US-based NGO with a long history of partnership and work in the earthquake-stricken country. You research that NGO further and learn that it is a reputable group with long-term interests in the country. You speak to friends who have recently visited the country and learn more about what skills and resources are needed. You arrange to join a team of experienced health workers from the NGO by taking time from work and garnering support from your family to manage in your absence. You undergo an in-depth orientation of the site, people, sociopolitical situation, team roles, and expected activities through a series of discussions with all participants.

CHAPTER 10

Child Advocacy

Marni E. Shear, DO, FAAP, and Grant P. Christman, MD, FAAP

CASE STUDY

A 7-year-old boy is brought to the emergency department by his mother with acute onset of respiratory distress. He awoke from sleep with a coughing fit and has not been able to catch his breath since. His mother explains that her son was admitted to the hospital with similar symptoms 1 month previously and was diagnosed with asthma at that time. Although the boy was prescribed 2 inhalers during his hospital admission, his mother reports she no longer has these because her son has not needed them. She also explains that her child has a daily nighttime cough and frequent coughing with exercise. After administration of an oral steroid load and 3 doses of ipratropium bromide and albuterol sulfate, the child's breathing improves somewhat. He is admitted to the inpatient pediatric service for ongoing asthma management and care.

Questions

1. What does it mean to be a child advocate?
2. Aside from caring for individual patients, how can pediatricians promote the well-being of their communities?
3. What is the role of the pediatrician in child advocacy?
4. What are the levels of advocacy?
5. How does the pediatrician implement advocacy?

An *advocate* is someone who speaks on behalf of a person or cause. No group in our society has a greater need for advocates than children. Children are ill-equipped to face the many threats to their health; they cannot obtain their own health insurance, access available social services, or get themselves to the doctor when sick. Additionally, children have limited influence compared with adults in our society. They cannot vote, donate money to political campaigns, or speak publicly to advance their interests. The word "advocate" is derived from a Latin root meaning "one who has been called to another's aid." From the beginnings of pediatrics as an independent branch of medicine, pediatricians have answered this call to advocate for the health and well-being of children.

Abraham Jacobi, MD, who is often referred to as the father of pediatrics in the United States, spent his career in the late 1800s and early 1900s advocating for children through legislation in New York and the District of Columbia. He addressed issues such as breastfeeding, food and water contamination, and conditions in foundling homes. He urged physicians to be involved in public life and policy making, and he was the founder and first president of the American Medical Association (AMA) Section on Diseases of Children. Another founder of pediatrics in the United States, Job Lewis Smith, MD, recognized the need for a clean water supply and decent housing to decrease the high infant mortality rate of his time. He worked through public advocacy to improve living conditions for all children, and he was the founder of the American Pediatric Society, which was the first pediatric medical society.

In 1921, the US Congress passed the Sheppard-Towner Act, the first major federal program to specifically address maternal and child health. It provided matching funds to states for services for pregnant women and new mothers. The AMA, which was concerned about government interference in the practice of medicine, condemned the act, whereas the AMA's own Section on Diseases of Children supported it. Conflict related to the Sheppard-Towner Act ultimately resulted in the pediatric group leaving the AMA and founding the American Academy of Pediatrics in 1930. The American Academy of Pediatrics has been advocating for children ever since.

The New Morbidity

Advocacy remains important because the "new" morbidities in pediatric medicine, some of which are new and others of which are only newly recognized, are related to social and economic forces. Child health outcomes improved dramatically in the 1900s with the development of vaccines, antibiotics, and new and improved surgical care to manage the classic morbidities of infectious disease, infant mortality, poor nutrition, epidemics, overcrowding, and chronic disease. New morbidities that were recognized in the 1960s to 1980s, as described by Robert Haggerty, MD, included family dysfunction, learning disabilities, emotional disorders, and educational problems. In the 1980s to early 2000s, Judith Palfrey, MD, documented new challenges for pediatricians: social disarray, political ennui, the sequelae of high-tech care, and new epidemics of violence, AIDS, cocaine, and homelessness. The newest morbidities of the 21st century include the increased prevalence of childhood obesity, bullying, significant health disparities among cultural and socioeconomic groups, and the growing population of children with special health care needs. Mounting evidence, such as provided by the Adverse Childhood Experiences Study conducted from 1995

through 1997 by the Centers for Disease Control and Prevention and Kaiser Permanente, has demonstrated the critical need to identify and mitigate sources of toxic stress, which can pose a long-term threat to the developing brain.

Although improvement has occurred in recent years, many children in the United States continue to face challenges in obtaining access to quality health care. The 2015 National Health Interview Survey found that children without health insurance were less likely to have a usual source of care and were more likely to postpone seeking care than children with health insurance (Figure 10.1). In the past several decades, government programs such as Medicaid and the Children's Health Insurance Program have expanded the availability of health care coverage to children of limited financial means. The passage of the Patient Protection and Affordable Care Act in 2010 (PPACA) resulted in significant increases in access to health care for many pediatric populations. The number of children younger than 18 years with no health insurance coverage decreased from 6.6 million in 2012 to 3.9 million in 2016; however, 1 in every 20 children remained uninsured as of 2016. Among children in poverty, the uninsured rate was 7%, compared with a rate of 5% for children not in poverty. Racial and ethnic minorities were also more likely to be uninsured, with Hispanic children having the highest rate at 7.9%. As of 2016, approximately 40% of all children were receiving coverage from public insurance programs, an increase from 2010. With ongoing legislative efforts to either repeal PPACA or reduce benefits, the future of access to health care for children remains in jeopardy.

These significant issues affecting child health cannot be adequately addressed on an individual basis. Advocacy on a community or national scale is required to improve child health outcomes and quality of life for children.

Levels of Advocacy

Every pediatrician serves as a child advocate on a daily basis. With every patient encounter, the pediatrician advocates for care in the best interest of the patient. This first level of advocacy includes treating the individual's immediate medical needs, that is, performing screening tests, providing anticipatory guidance, and coordinating referrals as necessary. In addition to providing direct medical care, the pediatrician may advance the welfare of the child by, for example, writing letters to help a patient obtain social services, or visiting a patient's school for a meeting on creating or reviewing an Individualized Education Program.

The second level of advocacy is community advocacy. The AAP policy statement "The Pediatrician's Role in Community Pediatrics," describes "community pediatrics" as a perspective that broadens the perspective from a focus on the individual patient to all the children in the community; a recognition that family, education, society, culture, spirituality, economy, environment, and politics all affect the health of children; a synthesis of clinical practice and public health principles directed to providing health care to a child and promoting the health of all children; a commitment to collaborate with the community to optimize health care for all children, especially disadvantaged children; and recognition that community pediatrics is integral to the role of the pediatrician. The pediatrician has a responsibility to improve conditions in the community to benefit patient health. To do this, they must be familiar with the services that are available for children. They can develop relationships with child care centers, schools, community coalitions, city governments, and local organizations to advocate for the best interests of children. Examples of potential involvement in the community include serving as a board

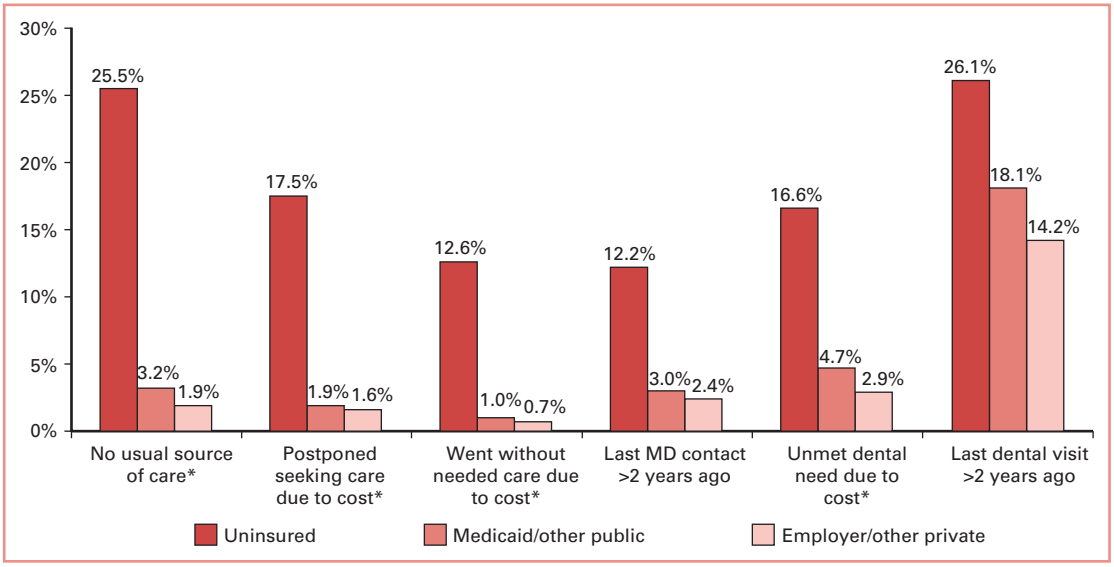

Figure 10.1. Children's access to care by health insurance status in the United States in 2014.

* In past 12 months. Questions about dental care were analyzed for children age 2–17 years. All other questions were analyzed for all children younger than age 18 years. MD contact includes other health professionals. Respondents who said usual source of care was the emergency department were included among those not having a usual source of care. All differences between the uninsured and the 2 insurance groups are statistically significant ($P < 0.05$). Adapted with permission from Kaiser Family Foundation analysis of 2015 National Health Insurance Survey (NHIS) data. https://www.kff.org/wp-content/uploads/2015/11/children_s-access-to-care-by-health-insurance-status.png

member of a community organization, developing health agendas, working with an existing organization to design and fund a community service project, and being a source of information for the community on child health issues.

On the state level (the third level), pediatricians can work to improve health care resources or develop policies to help and protect children. Opportunities for involvement include working on legislation, budgets, regulations, and initiatives or working with the executive branch of local and state government. The fourth level of advocacy is the federal level; at this level, pediatricians can educate their senators and congresspersons on child health issues. Pediatricians may also testify before a congressional subcommittee. The fifth and final level of advocacy is the international level. For example, a pediatrician may choose to work with the World Health Organization to improve immunizations for all children worldwide. Global child health is currently a focus of many advocacy training programs.

At the local, state, and national levels, voting remains a powerful tool for the pediatrician to advocate for child health and welfare. In addition to voting themselves, pediatricians can encourage their patients to register to vote when they reach the age of eligibility.

Becoming a Child Advocate

To become an effective child advocate, the pediatrician must first identify an issue that he or she wants to change or set a goal to improve the lives of children. The more specific the issue or goal, the easier it is to develop a solution. Ideas often arise from clinical practice, in which repeatedly engaging in individual advocacy efforts on behalf of patients with the same problems suggests the need for a larger solution. The first step in taking action is to obtain background information about the problem and collect objective data that support the need for change, then define the nature of the problem and the affected population in clear and precise terms. Child health data from public agencies and private organizations are increasingly accessible via the internet.

Community Projects

Alternatively, a pediatrician may find that an issue is best addressed through a community advocacy project. In developing such a project, the pediatrician's relationship with the community is of utmost importance, and the pediatrician should endeavor to become familiar with the community as a whole. Community exploration, which may be as simple as walking or driving through a community and observing, can reveal areas of need, such as dilapidated housing or unsafe streets. Equally important is the discovery of the community's assets, including institutions such as places of worship, schools, and banks, which strengthen a community and are potential sources of support for and counsel about the project. Pediatricians should view themselves as members of the community, acting from within and in collaboration with the community, rather than as outsiders bringing about change externally.

The next step is to develop an intervention. After the possible solutions are considered, the pediatrician should collaborate with community stakeholders to develop and implement the most practical solution. Having credibility in the community makes the task of collaboration much easier. Collaboration requires the ability to compromise and be flexible in developing and implementing plans. Larger projects may require funding, and grants may be sought from advocacy organizations, foundations, the government, or even local businesses. Data should be collected during the intervention to monitor the success of the project and then shared publicly with members of the community as well as with leaders who can shape policy (eg, legislators). If the project is successful, its methods may be adopted by child advocates in other communities.

Legislative Advocacy

Although involvement in the legislative process is initially daunting for the physician without political expertise, often it is the only means by which to effect a desired change for children's health. Information about the content and progress of existing bills is readily available online, and legislators can be contacted by letter, email, or telephone to offer a position. It is helpful to become familiar with the process by which a bill becomes a law, both at the state and the federal level; the identities of the important players change as a bill progresses through the various subcommittees and committees and ultimately proceeds to a floor vote.

Pediatricians may also arrange to meet with a legislator or staff member at a district or capital office to discuss their position personally. In the dual role of scientist and healer, the pediatrician is in a unique position to inspire both the heart and the mind. It is important to state the problem clearly and explain why a new law is the solution, present well-researched facts that support the position, and use clear language, avoiding medical jargon whenever possible. The pediatrician should minimize the appearance of self-interest by focusing on how the proposal will help children, rather than how it will benefit the profession. It may also help to connect with the legislator by sharing a story about a patient encountered in practice who has been affected by the problem, especially if the patient is a constituent of the legislator (although the patient's identity must never be discussed without the patient's consent). Providing the legislator a concise fact sheet summarizing the position and the pertinent background information helps ensure that the position is not forgotten when the legislator is considering the issue at a later date.

The pediatrician should be prepared to encounter opposition from some legislators and avoid responding with angry statements that would be alienating. Effective advocacy requires building relationships with legislators over the long-term, and a legislator who opposes a position 1 year may be a potential supporter the next year, when the political climate changes, or may be a potential ally on another important issue. Among the several other pitfalls to be avoided include making or agreeing with partisan statements or claiming to represent an organization (eg, AAP) or an institution (eg, a university) without authorization. When asked a question to which they pediatrician does not know the answer, it is best to avoid guessing and to instead offer to do further research and provide the requested information to the legislator at a later date.

When developing a new legislative proposal from scratch, it is necessary to remember that although the factors contributing to child health are numerous and complex, each legislative proposal must by nature be concrete and limited. It may be best to start small and work for incremental change. The first step is to identify a clear and, if possible, measurable, objective and define the target population. Other important information to know when drafting a proposal includes any potential funding sources (if applicable) and which government agencies might be involved in implementation or enforcement. The pediatrician should partner with 1 or more legislators early on, not only because a bill must be sponsored by a legislator to be considered for passage but because many of the finer points of the legislative process are outside the experience of the average pediatrician. Building a coalition of support within the community and involving important stakeholders such as politicians, business professionals, other health professionals, educators, and parents, will help the bill gain political support.

Opposition should be expected, and potential sources of opposition should be identified in advance. If opposition from a powerful interest group is anticipated, it may help to meet with a representative of that group to explain the proposal. Potential arguments might include ways in which the proposal is really in the group's best interest, the moral imperative to help children, or the potential for negative publicity by opposing an initiative to benefit children. Compromising on aspects of the proposal should be considered when doing so might turn a detractor into an ally. When facing intractable opposition from powerful interests, pediatricians and supporters should strive to recruit even stronger allies into their coalition.

The process of turning a policy idea into legislation may be lengthy. It may be necessary to reintroduce a bill repeatedly over several years before achieving passage. After a bill becomes a law, advocates must continue working to ensure that necessary funds are allocated during the budgeting process, that public agencies implement the law as intended, and that the law is reauthorized when necessary. Physicians who are recognized as experts in child health policy will be called on to testify before committees in Congress or the state legislature on policy issues affecting children.

Media Advocacy

The media, including newspapers, magazines, radio, television, and the internet, are extremely influential. News stories about child health and welfare may not always be written from a child-friendly point of view. The pediatrician plays an important role in providing the media with better information and a different angle on a story. For instance, a pediatrician reading a newspaper story about a child who exhibited signs of autism shortly after his 1-year-old physical examination might write a letter to the editor discussing the lack of scientific evidence for a connection between vaccinations and autism. Over time, a pediatrician can develop relationships with local journalists, who can then turn to the pediatrician for information when covering child health stories.

A directed media campaign may also be a key element in an advocacy project. At the community level, the media can help educate the public about child health practices, notify the public of events, and bring out potential allies and coalition members. When advocating for legislation, the pediatrician can use the media to reach legislators directly and, equally important, reach thousands of the legislators' constituents simultaneously, who may in turn help pressure their legislators for change. In such situations, it is essential to plan a media strategy in advance by determining the most important target audience, selecting the appropriate types of media to approach, crafting a message appropriate to those media, and preparing thoughtfully for encounters with journalists.

Getting Connected

The AAP is a vital resource for pediatricians interested in child advocacy, with opportunities for involvement offered through the AAP Department of Federal Affairs, as well as the various state chapters advocating at the state and local levels. The AAP has also established a network of pediatricians who advocate through social media, using Twitter as a communication platform on which Tweetiatricians can initiate and facilitate conversations on various topics related to child health. A social media toolkit is available through the AAP to help pediatricians choose the best platform for their specific outreach goals. In an effort to promote understanding of the effect of poverty and social determinants on child health, the Academic Pediatric Association has developed a robust curriculum to help deepen understanding of income disparities, social determinants of health, health care delivery systems in the United States, and opportunities for legislative advocacy. Other national organizations with which pediatricians may become involved and that provide advocacy toolkits include Docs For Tots (http://docsfortots.org), Children's Defense Fund (www.childrensdefense.org), Children Now (www.childrennow.org), the National Center for Children in Poverty (www.nccp.org), and the Child Welfare League of America (www.cwla.org).

Improving the health of all children through advocacy is considered to be the responsibility of pediatricians and can be a tremendously rewarding part of pediatric practice.

CASE RESOLUTION

Managing this child's asthma is only the first aspect of thorough pediatric care. For the pediatrician to advocate for this patient and prevent a third admission for a subsequent and potentially worse asthma exacerbation, it is necessary to obtain essential information, such as the patient's social history and the environment in which he lives. A thorough social history is obtained and reveals that the child lives with his mother and grandmother. The mother recently lost her job, and she and her son moved into a 1-bedroom apartment with the child's grandmother. The apartment has old carpeting, and the mother expresses concern about mold on the walls. The child's grandmother smokes cigarettes, but she avoids smoking in the apartment when the child is home. The patient and his family are counseled about his diagnosis of asthma and potential asthma triggers. The grandmother expresses interest in smoking cessation, and resources are provided. The family receives an asthma action plan and education on the use of a metered dose inhaler with a spacer, and the pediatrician uses the teach-back method to ensure understanding of the plan of care at discharge. The pediatrician becomes concerned about the high prevalence of asthma in the community and explores coalitions in the area that recognize similar concerns. He becomes a member of the coalition steering committee and works with the local health department and other community stakeholders to develop a home-based intervention program in which community health workers provide families with in-home environmental assessments, education, and support. As a result of the coalition's efforts, the child's home is 1 of many apartment complexes in the area assessed by the local housing authority, and resultant action is taken to bring the property up to health and safety standards.

PART 2

Principles of Health Care and Pediatric Management

CHAPTER 11

Health Systems Science

Stephanie R. Starr, MD, FAAP

CASE STUDY

You are seeing Sara, a 14-year-old girl with multiple health issues (ie, asthma, obesity, acanthosis nigricans, mood disorder, attention-deficit/hyperactivity disorder, posttraumatic stress disorder) for a follow-up visit for a recent concussion. You know her family (ie, mother and sister) well. She has frequent emergency department visits for abdominal pain, asthma exacerbations, and headaches. You frequently lack sufficient time during visits to address all her concerns and the health issues you want to discuss. The mother has been unemployed for several years. Your team has had some challenges reaching her family when visits are missed. You sincerely want to help Sara and her mother meet their health goals for Sara but feel that providing the best care during office visits is not making a significant difference in her health.

At today's visit, the mother asks for head imaging because she is concerned about Sara's ongoing dizziness and headaches; however, her neurologic examination is normal and she does not have any "red flag" symptoms or signs that warrant head imaging. You want to be patient- and family-centered, but you are concerned about the risks and costs of unnecessary testing.

Questions

1. How might you approach the conversation with Sara and her mother in response to their request for imaging?
2. How are evidence-based medicine, "less is more" conversations, and shared decision making related to high-value care?
3. What other health systems science-related issues do you recognize in Sara's story, and what systems strategies might be considered to improve her health and experience of care?
4. What microsystem-level actions could you and your care team use to improve the health care and outcomes of similar patients in your pediatric practice?
5. What macrosystem-level actions could you and your colleagues take to improve the health care and outcomes of similar children in your health system or community?

Introduction

Rapid Evolution of US Health Care and Persistence of Significant Gaps in Health

For decades, primary care pediatricians have focused on the individual needs of infants, children, adolescents, young adults, and their families, and have made every effort to provide the highest quality care to their patients. The components of primary care and the patient-centered medical home are ideally combined to optimize the care of children using a holistic approach (see Chapter 1). The role of the primary care pediatrician is changing from managing acute illness to preventing illness to diagnosing and treating new morbidities, such as mental health disorders, neurodevelopmental disabilities, chronic disease, and other disorders that often stem from socioeconomic determinants of health, including poverty, family dysfunction, abuse, and other adverse childhood experiences. Although advocacy (see Chapter 10), culturally competent care (see Chapters 8 and 57), and global child health (see Chapter 9) have long been emphasized in caring for pediatric patients, these new morbidities and other changes in the lives of patients and their families require an explicit focus on new topics. Social determinants of health are estimated to contribute more toward health outcomes than health behaviors, care via the health care system, or genetics. Advances in shared decision making and conversations with patients and families on choosing tests and treatments that are high value to patients, families, clinicians, and the system require new clinical skills not traditionally taught in caring for individual patients.

As children, their families, and their health issues have changed, so have pediatric practices and the broader US health care system. In 2007, the Institute for Healthcare Improvement proposed Triple Aim as the ultimate goal of health care, that is, optimal health of the population and best experience of care at the lowest cost. Health care stakeholders (ie, patients, families, payors, insurers, health professionals, health care systems, society) more commonly frame this as value, that is, the quality of care (ie, care that is safe, timely, effective, efficient, equitable, and patient-centered) divided by the cost of care over time. Health care spending does not correlate to health outcomes, and health care costs are the largest contributor to personal US bankruptcies. Substantial gaps in health care access, equity, affordability, safety, effectiveness, and efficiency persist despite significant advances in biomedical science. Primary care pediatricians and other health professionals are advancing child

health via health care improvement (ie, quality improvement [QI], patient safety [see Chapter 21]) initiatives locally, regionally, and nationally. Doing so requires the ability to see levels of the health care system beyond the individual patient alone and to espouse the professional responsibility to care for the system in addition to caring for individual patients. In current practice, some health professionals have added a fourth aim: wellness of the health professionals and others on the care team.

Many interactions and systems issues that affect health care and health underlie every physician-patient interaction (Figure 11.1). This complex health care system is rapidly changing, including but not limited to payment models and insurance reform, new care delivery models, population health strategies, and emerging technology. Medicine and health care have become a team sport, with less focus on the physician-patient interaction alone and increased incorporation of interprofessional health teams into the patient-centered medical home model. Although pediatric health issues have changed significantly and the health care system is constantly evolving, little has changed in the training of the primary care pediatric workforce. The American Academy of Pediatrics (AAP) "Agenda for Children 2017-2018" includes topics not traditionally learned in medical school or residency, including access, finance, and social determinants of health. Practicing pediatric health professionals enter the profession with a steadfast commitment to improving the health of children, and many identify additional learning that would help them practice in this rapidly evolving health care system.

Medical Education and the Needs of Society

Medical education has an obligation to improve quality of life, reduce the burden of disease, and help advance the Triple Aim to fulfill its contract with society. Despite gaps in health care quality and rising costs of care, little has changed in physician education since Abraham Flexner proposed reform in 1910. Accreditation and certification bodies have added requirements in some areas, such as the Accreditation Council for Graduate Medical Education Systems-Based Practice and Practice-Based Learning and Improvement competencies in residency and fellowship, but many changes are incremental and gaps persist. Because medical costs are the most common reason for personal bankruptcy filings in the United States and because of the desire to first do no financial harm, some health professionals have advocated for high-value care as the seventh competency required for graduate medical education.

Traditional physician training in basic and clinical science alone does not meet the current health needs. Many practicing health professionals identify additional learning that would help them practice in the rapidly evolving system and achieve the Triple Aim. To help medical education evolve to match the pace of change in practice, and in recognition that rigorous basic and clinical science training is insufficient to meet the Triple Aim, many medical educators are advocating for training physicians in a "third" science: health systems science (HSS; Figure 11.2).

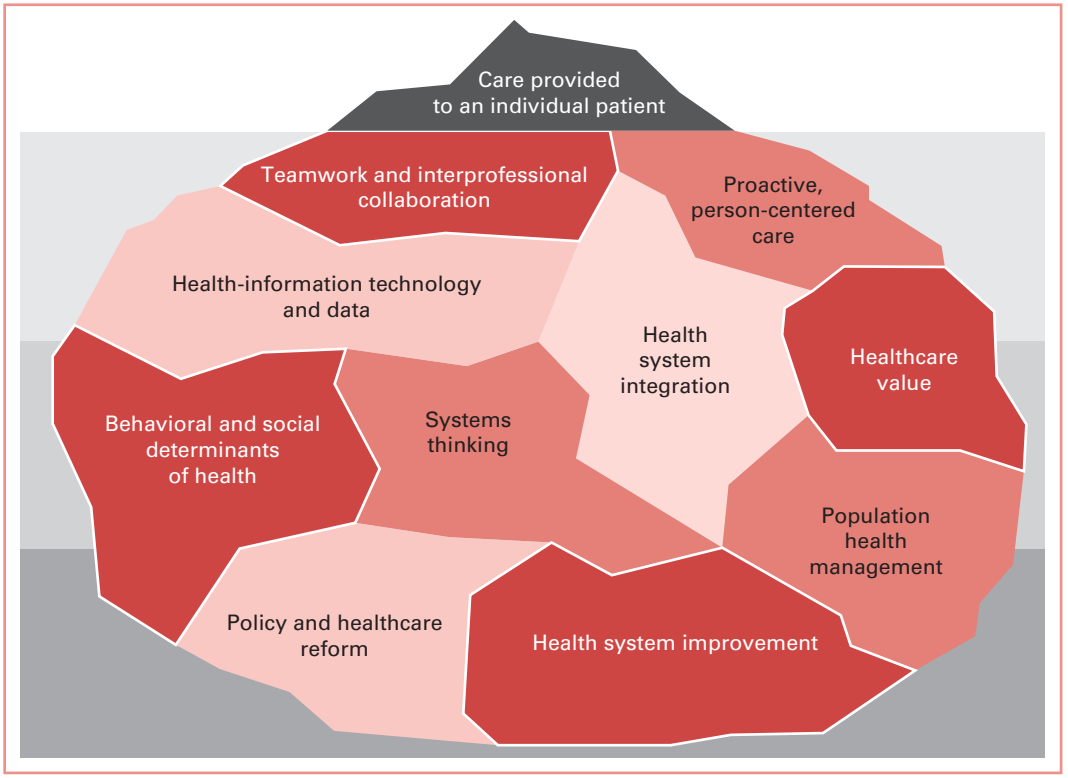

Figure 11.1. The "iceberg" of health care concepts affecting health.

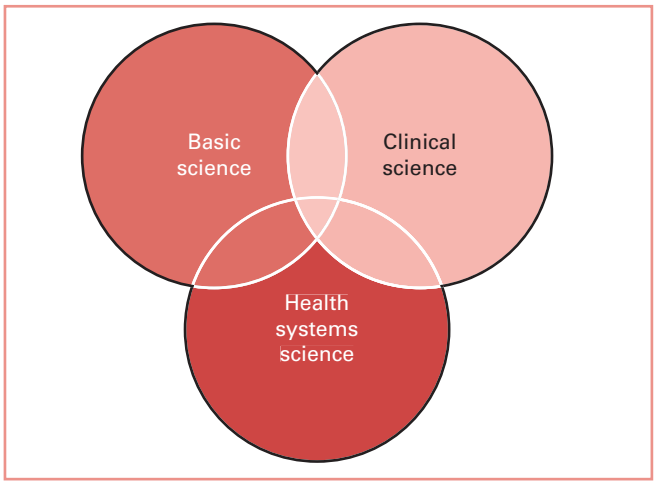

Figure 11.2. The 3-pillar model of medical education.

Health Systems Science in Medical Education

Health Systems Science Education: Definition, Framework, and Relevance to Primary Care Pediatricians

In 2017, experts from 11 medical schools published a curricular framework for HSS education to help address health and health care gaps. The curricular framework was proposed based on existing or planned systems-related curricula at their schools (Figure 11.3). *Health systems science* in medical education is defined as the principles, methods, and practice of improving quality, outcomes, and costs of health care delivery for patients and populations with systems of medical care. Stated another way, HSS can also be defined as the concepts and skills needed by health professionals to ensure that the basic and clinical sciences and the good intentions of health professionals have maximal effect on the Triple Aim.

The core content domains within HSS were described as health care structures and processes; health care policy, economics, and management; clinical informatics and health information technology; population and public health; value-based care, and health system improvement. Content areas (ie, cross-cutting domains) traditionally included in many schools but re-envisioned within HSS included scholarship; leadership and change agency; professionalism and ethics; teamwork and interprofessional education; and evidence-based medicine and practice. Systems thinking was described as the linking domain for the HSS framework.

Some schools use terms similar to HSS, such as "science of health care delivery," "health care delivery science," and "foundations of health care delivery" (Figure 11.4). Many medical schools in the United States and elsewhere are incorporating HSS-related curricula, with variation in scope and depth. The nomenclature related to this third science and the evidence for best methods to teach and assess it will continue to evolve. The old mantra "we are training students

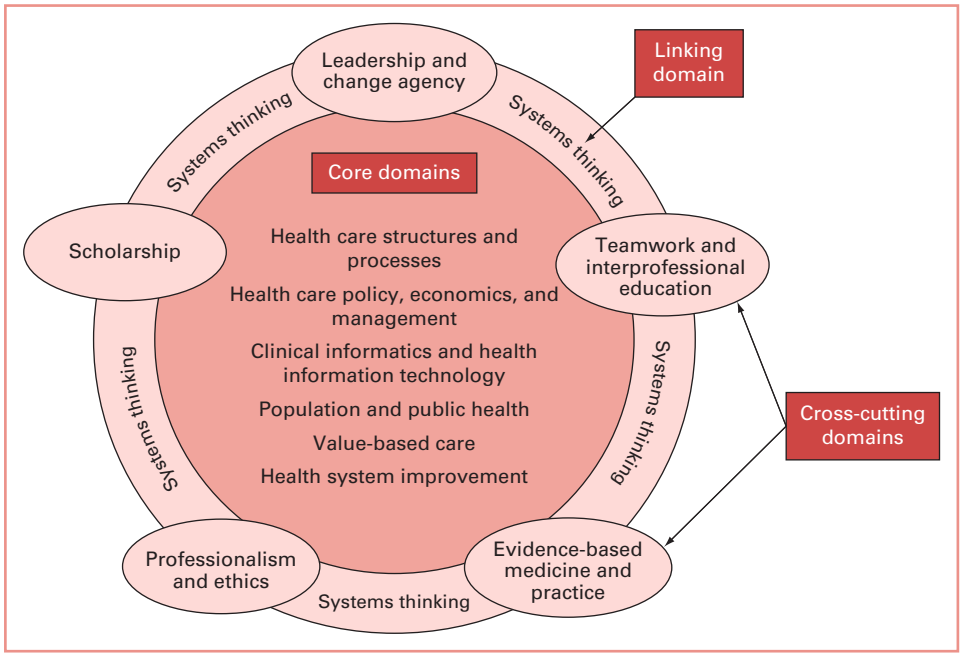

Figure 11.3. Core, cross-cutting, and linking domains for a health systems science (HSS) curricular framework. Core curricular domains are content areas that align directly with HSS. The cross-cutting domains are content areas that traditionally may have been included in undergraduate medical education curricula but that have a new context in the HSS. The 1 linking domain—systems thinking—unifies or links the core curricular or cross-cutting domains to other core curricular or cross-cutting domains (ie, internal linking, depicted in this figure) and to other areas of the curriculum, such as the basic and clinical sciences (ie, external linking, not depicted in this figure).

to care for tomorrow's patients" is no longer the ideal; schools are demonstrating that medical students can improve the care of today's patients as they learn about HSS.

Pediatricians in training and those in practice likely have significant variation in their understanding and practice of HSS-related concepts and skills based on their undergraduate medical education, graduate medical education, and/or their practice experiences. Although health professionals may have experience and expertise in some HSS-related areas, which for pediatricians includes a focus on advocacy and culturally competent care, they may not be able to easily explain relationships across HSS topics to team members and/or the students and residents they teach. Without a broad definition of the third science concepts that affect health and health care, pediatricians may miss opportunities to recognize and close gaps in care for children and their families. Pediatricians committed to caring for children can have great impact when they see their professional duty is both to doing their work (caring for individual patients) as they improve their work (caring for the health care system and for populations of patients). Envisioning HSS as a third science with a conceptual framework can foster systematic thinking and help pediatricians recognize the actions they can take (or "levers" they can pull) to meaningfully improve child and family health.

Systems Thinking: Components and Levels

Systems thinking is at the core of HSS. Pediatricians may recognize gaps in care that occur during office interactions with patients (eg, inability to identify a dentist who accepts the family's government health insurance) more easily than they can anticipate or see other gaps through the lens of the patients' and families' view as they experience care across a system. It can be difficult to really know what patients and families experience from the moment they call to try and schedule an office visit, to parking, to checking in to the front desk, to being led to a room by a nurse or other care team member, to being seen by the pediatrician, to going to the laboratory (on site or at a distance) for a blood test, to accessing test results and interpretation from the pediatrician.

Health professionals should ideally understand 3 essential concepts related to health care systems: systems thinking; the structures, processes, and outcomes comprising the building blocks of health care delivery; and effect on the patient of every level of the health care system.

Systems Thinking

The Waters Foundation has summarized 14 habits of systems thinkers that encourage health professionals to be flexible in their thinking, identify new insights, and appreciate other perspectives, including recognition that a system's structure generates its behavior. Stated another way, every process is perfectly designed to get the results it gets, so to get a different outcome, the structure and/or process must be changed as well. Systems thinkers can apply tools (many of which are used in QI training) to augment these 14 habits.

The Building Blocks of Health Care Delivery: Structures, Processes, and Outcomes

Avedis Donabedian, MD, MPH, considered by many to be the grandfather of US health care quality, explained the importance of improving health care quality by using structural, process, and outcomes measures. These measures provide a granular way of showing that health improvement efforts are "moving the needle" and having a positive effect (see Chapter 21). Examples of structure, process, and outcomes measures are given in Table 11.1.

Effect on Patients: Recognizing the Levels of the Health Care System

The effect—both positive and negative—on patients occurs at every level of the health care system, and clinicians must be able to recognize the levels of the health care system on behalf of patients and clinical team members. Patient- and family-centered pediatricians and their care teams consider the experience of care, disease, and treatment burden from the perspective of the patient and family. Pediatricians who think with a systems perspective are more likely to identify additional opportunities to improve care not only for their individual patients, but also for groups of similar patients. They can make or influence changes (ie, pull levers) not only at the patient-clinician level, but also at the microsystem, mesosystem, and macrosystem levels (Figure 11.5).

The *microsystem* is most familiar to pediatricians; it is the front-line clinical team that, in addition to physicians, may include nurses, nurse practitioners, clinical assistants, secretaries, and receptionists. Nurses on the team may have several specialized roles based on their scope of licensure, including clinic nurse, triage nurse,

Table 11.1. Examples of Measures to Assess the Quality of Pediatric Asthma Care

[a] Most important to patients and families.

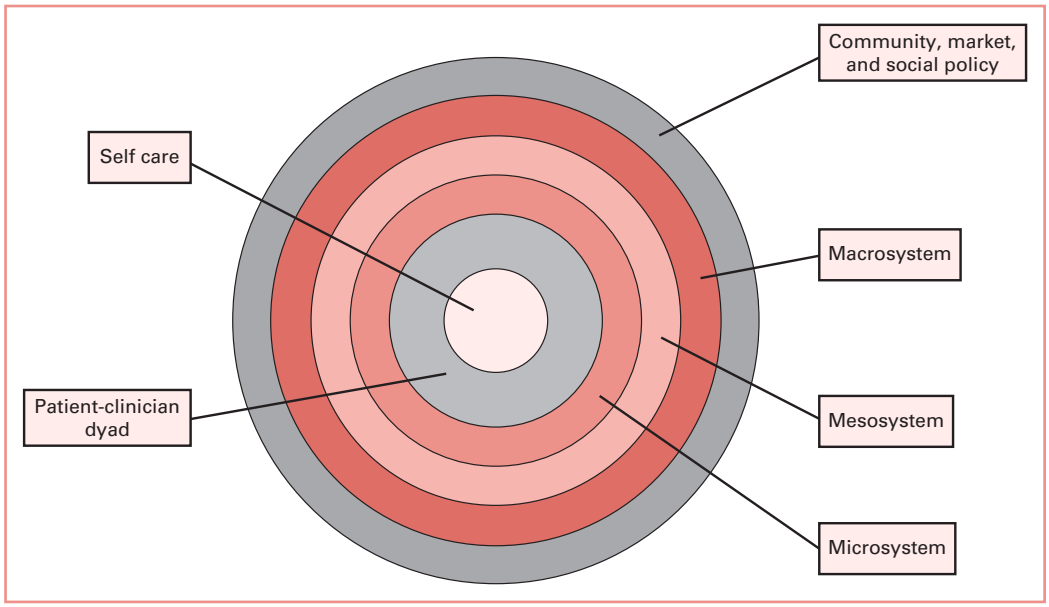

Figure 11.5. Levels of the health care system. Self care is care provided by patients and their families. Note that patients and/or families can obtain resources for their health directly from the community (outer circle). The microsystem is the front-line interprofessional clinical team with whom patients and/or families interface. In pediatric primary care, physicians, nurse practitioners, nurses, and secretaries are part of the primary care team/practice. The mesosystem comprises connected microsystems that patients and/or families traverse in their experience of care (eg, primary care team, inpatient care team, radiology team, pharmacy team, outpatient specialty care team, emergency department team). The macrosystem comprises mesosystems that patients and/or families traverse in their experience of care (eg, community health center, referral specialty health center, public health).

and care manager (eg, for complex patients). Ideally, every team member has a role that enables that person to work at the peak of that individual's experience and licensure, and all perspectives are leveraged to recognize gaps in care and contribute to closing gaps (eg, via QI initiatives).

Mesosystems are collections of microsystems that a patient may move across during an episode of care. For example, a large multispecialty group practice at 1 clinic may have multiple pediatric, family medicine, and internal medicine teams (ie, microsystems) as well as other microsystems (eg, laboratory, radiology, and pharmacy teams). During a visit for possible pneumonia, a patient may move across 3 microsystems (ie, pediatric, radiology, and pharmacy teams) before leaving the clinic. Opportunities to improve the care of other patients like that one may occur at the microsystem level (eg, improving wait times) or may require a coordinated effort across 2 microsystems. Quality improvement and advocacy are levers that can be pulled to make or influence change at this level.

Similarly, *macrosystems* are collections of mesosystems across which a patient may move during an episode of care. An ill child seen in a primary care mesosystem who is transported to the emergency department mesosystem (with, for example, emergency

medicine microsystem, laboratory microsystem, radiology microsystem) and is later admitted to the hospital (with similar mesosystem members) encounters an entire macrosystem. The quality of care this child receives is dependent in part on the strengths or weaknesses not only of each team, but on how the teams communicate during handoffs and how everyone is able to envision the patient's journey from the start of his or her experience (ie, in the primary care office) to the end (ie, hospitalization and eventually, discharge home). To reiterate, both QI and advocacy can occur at the macrosystem level.

Applying Health Systems Science to the Components of Pediatrics

Primary Care

The components of primary care as described by Charney and Alpert in 1974 include first contact, longitudinal care, family orientation, and integration of comprehensive care (see Chapter 1). For all pediatricians working in the current US health care system, these components remain critical and relevant, but the pediatrician with a systems view will recognize the need for additional components and will understand that it is necessary to evaluate each component at multiple levels of the system to maximize the health of all children. Examples of each component at multiple levels of the health care system are described in Table 11.2. These examples are opportunities for pediatricians and colleagues in their clinical (ie, microsystem) teams to see opportunities to promote high-value care and improve child health and, in doing so, advance the Triple Aim.

Pre–First Contact

The process or steps that patients and families encounter before having their first contact (ie, office visit) was not conceptualized when medicine and care delivery outside of public health was purely transactional, an interaction between the patient and the physician (or in the inpatient setting, a patient and a hospital team). Variation in access to care based on health insurance, geography, transportation, and other barriers now affect how a patient interacts with primary pediatric teams in primary care medical homes. Pediatricians and pediatric medical homes seeking to improve child health care and health must conceptualize their role in ensuring the patients in their care have access to care when they need it and to preventive care to maintain their health.

For example, in 2015 the National Academies of Sciences, Engineering, and Medicine (NASEM) published a white paper titled *Improving Diagnosis in Health Care*. The authors proposed a systems view of diagnostic errors, with the recognition that accurate and timely diagnosis cannot be made without access to the care team (Figure 11.6). Pediatricians must envision the health care system from the patients' and families' point of view and recognize opportunities to improve the likelihood that children who need the first contact are able to benefit from the team's care.

First Contact

A first contact in a pediatric medical home may be a visit for an acute or chronic health issue or for a well visit. Using a systems view, the pediatrician should consider how excellence in this first contact would be defined by patients and their families. In addition to the patient-physician relationship and cultural effectiveness (see Chapters 8 and 57), patients and families might prioritize a focus on needs, desires, and goals unique to the child and/or family. Pediatricians might also include screening for poverty and for financial harm from medical treatment. Currently, this first contact may be with another care team member via a nurse triage telephone call or via an online patient portal message.

Longitudinal Care

Longitudinal care requires providing optimal care over time to individual patients and to populations of patients, ideally within the medical home model. The Joint Principles of the Patient-Centered Medical Home (PCMH) were co-published in 2007 by the AAP, American Academy of Family Physicians, American College of Physicians, and the American Osteopathic Association. An emphasis on the Triple Aim and the change in payment models (from fee-for-service to payment for value) have helped fuel this population health approach. Care is no longer limited to face-to-face physician visits and phone triage with nurses; it includes nonvisit care via electronic patient portals between in-person visits to address simple new concerns, determine if a visit is necessary, provide test results, and follow up with patients and families on chronic health issues.

The AAP aptly describes the population health mindset as a change by health professionals from passivity to proactivity. Rather than waiting for patients to come to providers and care teams, the care teams reach out to patients and families. Not all patients in a given practice have the same level of need; thus, different systems approaches are necessary. Relatively healthy patients benefit from preventive interventions (eg, immunizations) and screenings (eg, review of growth at well visits, lead and developmental screenings). Children with a single chronic disease (eg, persistent asthma) may benefit from practice-level processes to improve their health outcomes by targeting identification of emergency department visits, monitoring oral steroid use, and regularly updating asthma action plans. For children with medical complexity, care management may be necessary to help families and the PCMH team optimize the value of care rendered (eg, assigning a primary nurse who knows the child well and who can triage concerns as they arise).

The National Resource Center for Patient/Family-Centered Medical Home (formerly the National Center for Medical Home Implementation), a collaboration between the AAP and the Maternal and Child Health Bureau of the Health Resources and Services Administration of the US Department of Health and Human Services, summarized a number of promising practices and their PCMH innovations, including family orientation and integration of comprehensive care.

Family Orientation

Children and their caregivers will not achieve optimal health or have an optimal experience of care unless pediatricians and their care teams are deliberate in their commitment to systematic culturally competent and effective care, both for individual patients and groups

Table 11.2. Examples of Opportunities to Increase Health Care Value for Patients and Families

Care Opportunity	*Individual Patient (and Family)*	*Microsystem*	*Mesosystem/Macrosystem*
Pre–first contact	Pre-visit contact (electronic or paper) soliciting the family's initial health concerns and the family's story that they want to share with the team in advance	Open access scheduling Expanded clinic hours Website or other electronic presence to welcome families and explain resources	Decrease barriers to transitioning new patients from inpatient settings (eg, neonatal intensive care unit, hospital) into the medical home model
First contact (ie, first clinic visit)	Culturally competent care (see Chapters 8 and 57) Routine inclusion of the question "What matters to you?" at the first visit[a]	Screening for mental health issues in pediatric patients (eg, PHQ-9M for patients age 12–17 years) and in mothers of infants (eg, postpartum depression screening) Adverse childhood experiences screening Food scarcity screening	Strategies to decrease wait times and increase efficiency of the visit from the family's perspective
Longitudinal care	Advocacy (eg, with school system for IEP) for health needs Health coaching Steps 1–4 in high value care framework (see Figure 11.6)[b]	Step 5 in high-value care framework (QI): Identify systems-level opportunities to improve value (see Figure 11.6)[b] Non-visit care (eg, online portal) Care management for patients such as those with complex presentations, asthma, or depression Identification of and contact with high-risk children needing the influenza vaccine	Strategies to improve transitions of care to adult providers for young adults with medical complexity across pediatric primary care, adult primary care, and specialty groups Strategies to collaborate on matters of school-related health, such as with coaches for concussion services, school staff about meals and nutrition, and in-school influenza vaccine clinics
Family orientation	Shared decision making that incorporates patient and family preferences, values, and context (ie, circumstances)[c]	Needs assessments of families in the practice in terms of issues such as preferred communication and extended hours	Advocate for needs assessments of families in other areas of multispecialty practices
Integration of comprehensive care	Use of handoff tool with accepting physician when a patient is admitted to the hospital or to another new care team	Registered nurse care management program with registry for medically complex children Electronic tool for communicating patient care goals between patient, family, and health care teams	Work with inpatient and outpatient specialty, emergency department, and hospital colleagues to improve transitions of care and patient safety when patients move from 1 setting to another

of patients. Care team members must have knowledge of the social determinants of health and their effect on health (see Chapter 141). This is particularly important when establishing a strong relationship with children and their caregivers at the first visit.

Integration of Comprehensive Care

Integration of comprehensive care requires pediatricians and their PCMH team members to integrate the care of patients within the PCMH and across other parts of each patient's health ecosystem to ensure that data are shared appropriately and handoffs occur effectively. This includes the interaction between primary and secondary (or specialty) care (see Chapter 1). Several new care delivery innovations include electronic specialty consults as well as integrated behavioral health and other specialty care models integrated within the PCMH. It also includes integration as part of ongoing care (eg, in conjunction with community partners, such as public health, schools, child care centers, home health and nursing agencies, and pharmacies).

To Err is Human, published in 1999 by the Institute of Medicine (now the Health and Medicine division of the National Academies), catalyzed the US patient safety movement. A critical component of safe care is the expert and deliberate process for communicating with teams and across teams at times of transition. This includes transitions across care settings during an episode of care (eg, emergency department to

hospital, hospital to PCMH, PCMH to specialty care). The Agency for Healthcare Research and Quality Team STEPPS program provides a model for training in interprofessional teams to improve patient safety. The I-PASS program is a framework studied in pediatric residencies to increase patient safety during provider handoffs. Common handoffs in integrated, comprehensive care include dismissal of patients with complex medical issues from an acute care hospital setting to the PCMH.

Pediatric Primary Care Examples of Health Systems Science Principles

Advocacy

Advocacy has long been a professional expectation of pediatricians on behalf of children, a segment of society without a legal voice. Advocacy occurs at the individual patient-pediatrician level (eg, working with schools to evaluate students who may qualify for special education services) or at a higher level (eg, the state legislature for effective booster seat laws). Carol Berkowitz, MD, has described advocacy for individual patients as advocacy with a "little a," and for groups of patients as advocacy with a "big A."

Systems thinking can help reveal opportunities to advance child health in the realm of advocacy. For example, pediatricians can use the AAP Oral Health Toolkit to advance oral health initiatives for children at multiple levels of the system, including the community. Alternatively, if during a face-to-face clinic visit a pediatrician notes findings that are suspicious for child abuse and maltreatment, the pediatrician is legally bound to advocate for the child by reporting to Child Protective Services. Pediatricians can work with their clinical (ie, microsystem) team to develop new strategies for making children more comfortable during visits when suspected abuse is the chief concern. They can work with community partners to ensure child-friendly handoffs to those conducting forensic interviews and to educate child caregivers on reporting requirements and parents on abuse prevention strategies (ie, macrosystem). Conceptualizing the system in this manner may also help pediatricians consider the stakeholders who can align with their efforts and/or inform their efforts to help ensure success.

Population Health

As mentioned previously, 1 intervention to improve pediatric health is care coordination of children with complex health needs. In 2014, the AAP published recommendations for care coordination of children with medical complexity, including features of care coordination excellence, such as use of health information technology and health outcomes tracking over time. This recommendation was reaffirmed in 2018. As with many population health strategies, the perspective focuses on the health of all patients empaneled to the PCMH, not just those who come in for face-to-face visits.

Recent years have seen several successful population health models within primary care settings, including collaborative care models for adolescent depression and other integrated behavioral health strategies. Primary care pediatricians have collaborated with pediatric subspecialists and nurse care managers using patient registries to proactively care for their population of children and adolescents with persistent asthma. Registries can also be helpful to proactively manage children with medical complexity and children with other chronic conditions, such as attention-deficit/hyperactivity disorder.

Social Determinants of Health

As previously noted, social determinants of health (see Chapter 141) are estimated to have a more significant effect on health than health behaviors, health care, or genetics. Pediatricians must

elicit information about social determinants of health to be successful in caring for individual patients. At the microsystem level and above within the health system, pediatricians and their care teams can use population health approaches to identify subpopulations of patients in their practice (eg, refugee families) and conduct a needs assessment to tailor the practice to meet the needs of these patients.

Beyond the health system, many opportunities exist for pediatricians and other child health advocates to influence change to minimize the negative effect of social determinants of health. The Centers for Disease Control and Prevention developed the "Health Impact in 5 Years" initiative, which highlights nonclinical, community-wide strategies (Figure 11.7). These evidence-based strategies report positive health impacts within 5 years, and cost effectiveness and/or cost savings over the lifetime of the population.

High-Value Care

The role and limitations of laboratory tests and other diagnostic studies in making an accurate diagnosis for patients and families has long been taught as part of the basic and clinical sciences. With a systems approach, the NASEM model for improving diagnoses emphasizes diagnoses as a series of hypothesis testing (see Figure 11.6). For example, the diagnosis of acute otitis media is made based on history and physical examination alone. A patient presenting with a limited diet and fatigue may require only 1 laboratory test (ie, complete blood count) to confirm iron deficiency anemia. Many diagnoses are made over time, however.

In 2012, the Alliance for Academic Internal Medicine and the American College of Physicians published a 5-step model for teaching high-value care to residents (Figure 11.8). These evidence-based strategies report positive health impacts within 5 years of implementation and are cost effective and/or cost saving over the lifetime of the population. They can help pediatricians see the relationships across the key HSS-related knowledge and concepts of evidence-based medicine, shared decision making, and health care improvement.

Steps 1 and 3 of the model are part of critical appraisal of the literature and evidence-based medicine. Step 2 provides an opportunity for pediatricians to stop medications or reconsider unnecessary testing if it does not provide value to the patient. Step 4, which is part of shared decision making, requires pediatricians to apply what they have learned from the evidence to the patient in front of them. More broadly, this is the stage at which shared decision making, whether formal or informal, is necessary to ensure that the patient (as age allows) and family are given adequate information to make a decision that reflects

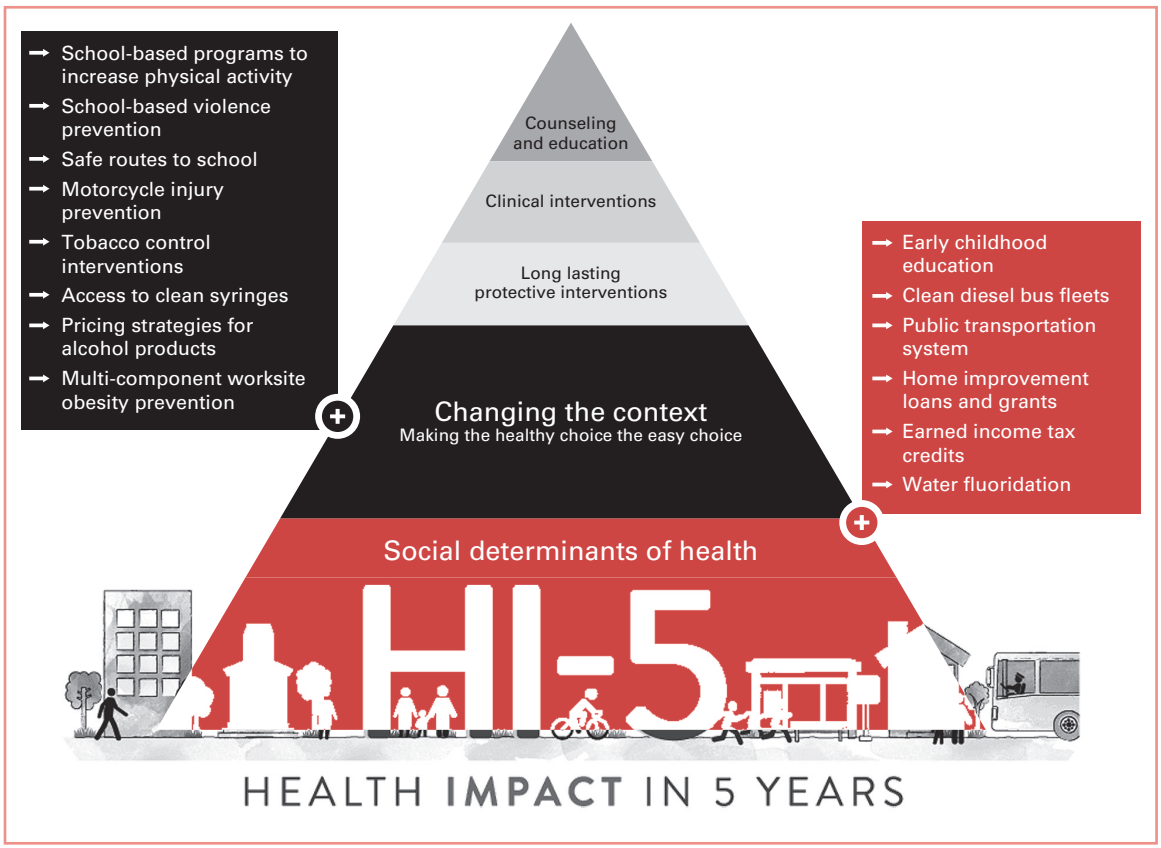

Figure 11.7. Public health impact pyramid. The pyramid depicts the potential impact of different types of public health interventions from greatest potential impact at the base (because they reach entire populations of people and require less individual effort) to least potential impact (because they target specific populations and require more individual effort).

their context (eg, other aspects of their lives they are balancing as a family, the work of being a patient), their preferences, and their values. Step 5 is health care improvement at the microsystem level or above, that is, QI or safety efforts to increase value for multiple patients.

Physicians may need help determining which tests to order using a high-value approach that reflects the individual considerations for each patient while also reflecting what is known to be effective care. Choosing Wisely collaborated with the AAP to identify 10 tests or treatments that pediatricians should question (Box 11.1).

Box 11.1. Ten Things Physicians and Patients Should Question

1. **Antibiotics should not be used for viral respiratory illnesses (sinusitis, pharyngitis, bronchitis and bronchiolitis).** Antibiotics should not be used for upper respiratory illnesses characterized by congestion, cough, or pharyngeal pain unless criteria for bacterial sinusitis or Group A streptococcal pharyngitis are met. The vast majority of these infections are caused by viruses.

   Respiratory infections account for the majority of antibiotic prescriptions for children, and it is estimated that 50% of antibiotic prescriptions for respiratory infections in children are unnecessary. Antibiotic use for viral respiratory illnesses not only leads to higher healthcare costs and more adverse events, but also can lead to antibiotic resistance.
2. **Cough and cold medicines should not be prescribed, recommended, or used for respiratory illness in young children.** Research has shown these products offer little benefit to young children and can have potentially serious side effects. Many cough and cold products for children have more than one ingredient, increasing the chance of accidental overdose if combined with another product.
3. **Computed tomography (CT) scans are not necessary in the immediate evaluation of minor head injuries; clinical observation/ Pediatric Emergency Care Applied Research Network (PECARN) criteria should be used to determine whether imaging indicated.**

   Minor head injuries occur commonly in children and adolescents. Approximately 50% of children who visit hospital emergency departments with a head injury are given a CT scan, many of which may be unnecessary. Unnecessary exposure to x-rays poses considerable danger to children including increasing the lifetime risk of cancer because a child's brain tissue is more sensitive to ionizing radiation. Unnecessary CT scans impose undue costs to the health care system. Clinical observation prior to CT decision-making for children with minor head injuries is an effective approach.
4. **Neuroimaging (CT, MRI) is not necessary in a child with simple febrile seizure.** Imaging, including head CT, brain MRI, and skull films are associated with some risk and do not help with diagnosis or treatment of simple febrile seizures. MRI is associated with risks from required sedation and high cost. Head CTs can slightly increase the long-term risk for cancer.
5. **Computed tomography (CT) scans are not always necessary in the routine evaluation of abdominal pain.** CT imaging in the emergency department evaluation of children with abdominal pain is frequent and can be inconsistently used, including overused. While radiation is necessary to perform a CT scan, there is both misunderstanding and often concern about the radiation necessary and the debate over the potential long-term development of cancer from this radiation. There also is the potential for

Box 11.1. Ten Things Physicians and Patients Should Question *(continued)*

an unnecessary amount of radiation from inappropriately performed CT examinations, as there are unique approaches and considerations with CT examinations in children that allow for lower radiation doses. CT can be very valuable in the setting of pediatric abdominal pain, but only when it is the correct test to do at the time (as opposed to waiting, or using another test that does not depend on ionizing radiation especially ultrasound), and performed in the right way (child-sized CT techniques).

6. **Don't prescribe high-dose dexamethasone (0.5 mg/kg per day) for the prevention or treatment of bronchopulmonary dysplasia in preterm infants.** High-dose dexamethasone (0.5 mg/kg day) does not appear to confer additional therapeutic benefit over lower doses and is not recommended. High doses also have been associated with numerous short- and long-term adverse outcomes, including neurodevelopmental impairment.
7. **Don't perform screening panels for food allergies without previous consideration of medical history.** Ordering screening panels (IgE tests) that test for a variety of food allergens without previous consideration of the medical history is not recommended. Sensitization (a positive test) without clinical allergy is common. For example, about 8% of the population tests positive to peanuts but only approximately 1% are truly allergic and exhibit symptoms upon ingestion. When symptoms suggest a food allergy, tests should be selected based upon a careful medical history.
8. **Avoid using acid blockers and motility agents such as metoclopramide (generic) for physiologic gastroesophageal reflux (GER) that is effortless, painless, and not affecting growth. Do not use medication in the so-called "happy-spitter."** There is scant evidence that gastroesophageal reflux (GER) is a causative agent in many conditions though reflux may be a common association. There is accumulating evidence that acid-blocking and motility agents such as metoclopramide (generic) are not effective in physiologic GER. Long-term sequelae of infant GER is rare, and there is little evidence that acid blockade reduces these sequelae. The routine performance of upper gastrointestinal (GI) tract radiographic imaging to diagnose GER or gastroesophageal disease (GERD) is not justified. Parents should be counseled that GER is normal in infants and not associated with anything but stained clothes. GER that is associated with poor growth or significant respiratory symptoms should be further evaluated.
9. **Avoid the use of surveillance cultures for the screening and treatment of asymptomatic bacteriuria.** There is no evidence that surveillance urine cultures or treatment of asymptomatic bacteriuria is beneficial. Surveillance cultures are costly and produce both false positive and false negative results. Treatment of asymptomatic bacteriuria is harmful and increases exposure to antibiotics, which is a risk factor for subsequent infections with a resistant organism. This also results in the overall use of antibiotics in the community and may lead to unnecessary imaging.
10. **Infant home apnea monitors should not be routinely used to prevent sudden infant death syndrome (SIDS).** There is no evidence that the use of infant home apnea monitors decreases the incidence of SIDS and should not be used routinely for this purpose; however, they might be of value for selected infants at risk for apnea or cardiovascular events after discharge.

Summary and Future Challenges in Health Systems Science

The knowledge, skills, and perspectives needed by pediatricians to effectively improve and maintain the health of children will continue to rapidly change in the coming decades, and health professionals must be able to envision the need for basic science, clinical science, and HSS to help all children realize their potential. The pace of change in pediatric trainee education and continuing professional development must align with that of the practice and society. The professional identity of pediatricians and other health professionals must focus on caring for patients and their families, for populations of patients, and for the system. Advancements in medical education concerning best practices in HSS education (for undergraduate medical education, graduate medical education, and continuing professional development) must evolve in a way that is authentic and meaningfully integrated with the work of interprofessional care teams. Finally, health services research, a topic that is beyond the scope of this chapter, must continue to elucidate best means of ensuring that high-value care occurs the first time, every time in a manner that complements the context, preferences, and values of the patient and family.

CASE RESOLUTION

You respond to the family's request for imaging using the guidance of the American College of Physicians for these conversations. You determine the perspectives of Sara and her mother ("What are you afraid we will find?" and "What do you think is going on, and what are you worried about?"); explain your reasoning for not recommending imaging ("The good news is that you do not have any worrisome symptoms."); make it clear that you are on Sara's side ("I wish more testing could help you, but it can actually make things worse."); and make a clear follow-up plan and review red flag signs and symptoms ("I want to see you in 2 weeks, but contact us sooner if there are changes that concern you.").

With your understanding of HSS-related concepts, such as social determinants of health and how system issues can negatively affect health, you work with your clinical (ie, microsystem) team to connect Sara's mother to a community health worker. The health worker meets with Sara and her family in their home to learn more about some of the challenges they are experiencing in accessing basic necessities as well as the health care system. The health worker connects Sara's mother to a primary care provider to help her address her own chronic illnesses and helps Sara's family access county services for housing and food. Your clinical team decides to initiate a QI project with the goal of reducing the number of missed follow-up visits for pediatric patients. In the course of the project, your team develops a care management approach for children with multiple chronic diseases. As part of your successful project, you begin screening for adverse childhood experiences to better recognize their effect on health, and several colleagues in your practice share what you have learned with the local health department and school system.

CHAPTER 12

Population Health for Pediatricians

Michael Weiss, DO, FAAP

CASE STUDY

You are preparing to see a patient familiar to your practice for an acute visit. You have not seen her for 11 months and, as you review the chart, you recall that the child is 5 years old and was born with a myelomeningocele at L4-5. She underwent surgery as an infant with placement of a ventriculoperitoneal shunt and gastrostomy tube. She has used a motorized wheelchair for 2 years and requires intermittent urinary bladder catheterization. Generally, she has done well and continues to see specialists in gastroenterology, neurosurgery, neurology, and urology. She attends public school, where she has an Individualized Education Program; receives occupational, speech, and physical therapy; and qualifies for in-class assistance. On further review, you note she is insured by your local Medicaid managed care plan and you receive a monthly capitation payment for her care in addition to potential value-based incentives around certain quality indicators.

Questions

1. What are the specific challenges associated with caring for this child?
2. How do you begin to organize her multiple special needs?
3. What are the clinical implications of the methodology by which you are paid for her care?
4. What strategies can you use to ensure this child receives the entirety of care required for her to thrive?
5. Who is your team?

Population Health: What and Why?

Population health has been defined in many ways. In simple terms, population health is about keeping a defined population healthy through proactive, preventive measures that minimize fragmented, inefficient care and improve clinical outcomes while reducing the overall cost of care.

During pediatric training and throughout their career, pediatricians appropriately spend most of their time developing and refining the knowledge and technical skills required to provide high-quality care to patients. Pediatricians learn about disease, enhance communication skills, and learn procedures, such as endotracheal intubation, lumbar puncture, and intravenous catheter placement techniques.

Over the past 3 to 4 decades, increasing emphasis has been placed on understanding how effective and efficient our delivery of health care is and how we measure these outcomes. This new focus filters down to frontline pediatricians, who must develop a clear understanding of much more than clinical care. Pediatricians need to understand health care payment methodologies, clinical quality metrics, care model design improvements, and care coordination programs. A fundamental understanding of these concepts is now a vital component of successfully caring and advocating for infants, children, adolescents, and young adults. This chapter reviews some of the main population health concepts and facilitates the successful navigation of the complex health care system, helping pediatricians provide improved care for their patients and families.

In the frequently quoted works, *To Err Is Human* and *Crossing the Quality Chasm,* the Institute of Medicine (now known as the Health and Medicine division of the National Academies) brought to light the prevalence of preventable medical errors and the disparity in quality of care across the United States. These reports estimated that 44,000 to 98,000 preventable deaths annually at a cost between $17 billion and $29 billion attributable to lost income and additional care necessitated by errors. Further, Institute of Medicine concluded that "The U.S. health care delivery system does not provide consistent, high-quality medical care to all people." In 2009, Atul Gawande, MD, MPH, a Boston-based surgeon and health policy researcher, published "The Cost Conundrum," in which he brought to light the wide variation in health care spending and outcomes across the United States. For 1 region in south Texas, he pointed to nearly double the national average per-capita spending on health care with no demonstrable improvements in quality versus the rest of the country. This, along with data from the Commonwealth Fund (Figures 12.1 and 12.2), brought to the public eye that the trajectory of health care spending in the United States was unsustainable and, more importantly, that patients were not receiving better-quality care

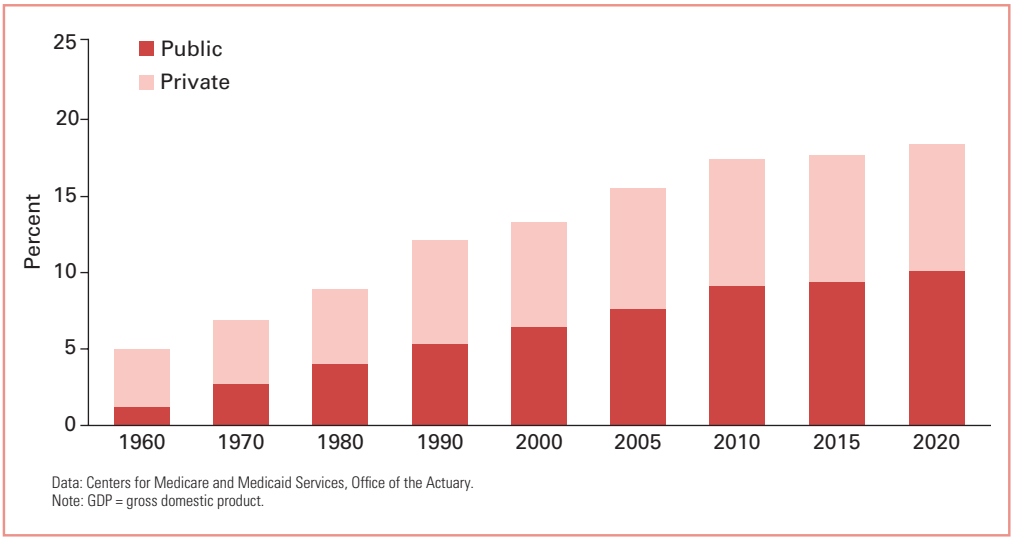

Figure 12.1. Growth in health spending as a share of the economy.

Accessed August 22, 2019.

as a result of the spending. Subsequently, the notion of the Triple Aim of better health for populations, better care experiences, and lower per-capita costs was introduced by the Institute for Healthcare Improvement (and more recently enhanced by others to become the Quadruple Aim by adding joy of practice). The concept of accountable care organizations then evolved from the Patient Protection and Affordable Care Act. This framework has served as the template for population health work across the country, in which the focus is on caring for populations of patients with proactive, team-based care, using accurate and timely data to effect positive clinical and service-based outcomes (see Chapter 21).

Health Care Payment Methodology and Practice

A basic understanding of the funding stream for the care patients receive is an important step toward improving quality, care coordination, and clinical outcomes. By far, the largest payers for children's health care in the United States are Medicaid and the Children's Health Insurance Program (CHIP), which cover nearly 30 million and 9 million children, respectively. Children qualify for the programs based on the income level and the number of members in their family. Qualifications vary by state and are usually based on a

percentage of the federal poverty level. CHIP serves as a supplement to assist those families who may not qualify for Medicaid. Coverage for basic care, called early and periodic screening, diagnosis, and treatment, or EPSDT, such as immunizations, developmental screening, and health maintenance visits, is mandated by these programs.

Private insurers make up most of the remaining payers. Private payment may occur through a preferred provider organization (PPO) or a health maintenance organization (HMO). With a PPO plan, patients are usually able to access any health professional covered by their insurance without the need for a specific referral that would be reviewed for clinical necessity in an HMO. High-level procedures and interventions may still require approval before they can be completed (eg, magnetic resonance imaging scans, surgeries). In an HMO plan, patients are encouraged to access their chosen or assigned primary care professional (PCP) for most conditions. If the PCP believes specialty care is required, an authorization request is generated and reviewed by the health plan for medical necessity before the patient can access the specialty care. Much debate exists over the preferred approach, as each has positive and negative components. The PPO provides more freedom of choice and ease of access, while the HMO creates an accountability and actionable data stream to the PCP of who serves as the medical home for patients. Data from regions where HMOs have been prevalent for some time show that quality and cost containment are enhanced in the HMO environment.

Within these insurance coverages there are also a variety of methods whereby payment to health professionals and hospitals can be made. In the traditional approach, known as fee for service, a health professional is paid based on a prearranged fee schedule for each encounter that occurs. Bundled payments, which are less common in pediatrics (particularly in the ambulatory setting), are set payments that are made for episodes of care. For example, for a joint replacement procedure, a bundled payment would include preoperative evaluation, surgery (including any required hardware), and postoperative care, including physical therapy and any durable medical equipment.

In the new accountable care paradigm, models involving population-based payment, also known as *capitation,* are much more prevalent. In these models, health professionals are paid a fixed per-member, per-month fee for caring for their patients. One advantage of this methodology is that patient attribution is very clear (addressed later in this chapter). Regardless of the number of times a patient is seen, the monthly payment for services is fixed. This model is aligned with population health principles in that prevention and proactive care are emphasized to create better quality and keep health care costs in check. In these models, services such as immunizations, mental health, and injectable medications are often carved out of the monthly payment and paid for on a fee-for-service basis due to the high cost involved.

As a complement to these payment methodologies, especially with a population-based payment approach, value-based care is being universally incorporated. This usually involves additional financial incentives for demonstrating clinical quality outcomes and appropriate resource use for a defined population for which the health professional is responsible. (Quality metrics are explored later in this chapter.)

The bottom line for pediatricians is to take the initiative to recognize the specifics of how their population of patients is being funded and implement strategies to ensure clinical and operational success. This understanding allows pediatricians to provide the best possible care for patients, advocate for appropriate and comprehensive pediatric-specific insurance coverage, and meet the business requirements of a practice.

Understanding Quality Metrics

Defining clinical quality in medicine has been a long-standing challenge. It has been defined as identifying the correct diagnosis and initiating appropriate treatment that results in resolution of the condition. It has also been defined as the receipt of a prompt appointment with the physician of choice in a friendly, welcoming environment, followed by timely communication and follow-up. Both outcomes are part of the quality spectrum because clinical success and service excellence are dually important.

The other challenge has been how to identify pediatric-specific metrics that are clinically meaningful and objectively measured, and which interventions by the physician responsible for the patient can effect positive change. Measures have evolved over time from process focused to outcome focused, with new emphasis on patient-reported outcome measures (Table 12.1). Clearly, the emphasis of various interventions is on the ultimate benefit to the patient, rather than completion of the intervention itself.

Table 12.1. Categories of Quality Metrics

Measure Type	*Description*	*Example*
Structure	Sufficiency of resources and proper system design	Proper use of a certified EHR
Process	Assesses the interaction between the patient/family and practitioner. Describes the means by which services are delivered	Completing a HbA_{1c} test for a patient with diabetes Completing a scheduled health supervision visit Use of evidence-based guidelines
Outcome	Assesses the effect the care delivered has on clinical outcomes	Number of hospitalizations for a specific condition (eg, asthma)
Patient-reported outcome	Status of a patient's health condition that comes directly from the patient or family	School absenteeism Ability to participate in typical social activities or sporting events
Patient experience	Patient or parent questionnaires addressing their experience with the care they received	CAHPS survey Can be hospital focused or ambulatory physician focused

Abbreviations: CAHPS, Consumer Assessment of Healthcare Providers and Systems; EHR, electronic health record; Hb, hemoglobin.

There are several evidence-based, nationally accepted pediatric Healthcare Effectiveness Data and Information Set (HEDIS) measures that are endorsed by the National Committee for Quality Assurance, National Quality Forum, Pediatric Quality Measure Program, and others. Each measure shares a similar format that includes a description of the clinical issue being addressed, patient inclusion and exclusion criteria, and documentation and coding requirements (Table 12.2). These measures are often part of value-based payment programs sponsored by health plans and organized medical groups and, in the information superhighway era, may be cited in the public domain to compare physicians, hospitals, and medical groups to national or local benchmarks.

Quality metrics are not without limitations. For almost every measure there are certain nuances that may pose potential challenges. For example, in the Appropriate Treatment of Children With Upper Respiratory Infection (URI) measure (see Table 12.2), a child may be seen by the primary care physician, diagnosed with a viral URI, and appropriately *not* given an antibiotic. Later the same day, the family may seek care by another primary care physician, who prescribes an antibiotic, and the child is now viewed as out of compliance with the measure. The physician with accountability acted appropriately but does not receive the correct credit for doing the right thing.

A second general category of quality metrics revolves around appropriate use of clinical resources. Measures in this domain typically include the frequency of emergency department (ED) visits, use of high-cost imaging studies (ie, magnetic resonance, computed tomography), or inpatient admissions for so-called ambulatory-sensitive conditions. For instance, ED visits for asthma may be preventable if a child is appropriately prescribed an inhaled corticosteroid, educated on proper spacer use, and given an asthma action plan. Appropriate resource metric results are typically compared with regional or national benchmarks.

Another category of quality metrics revolves entirely around patient and family experience (previously referred to as patient satisfaction). Typically, patients receive a written or telephone-based survey to assess the perceived level of care they received. The standardized Consumer Assessment of Healthcare Providers and Systems Clinician and Group (CG-CAHPS) survey is most commonly employed. Questions cover multiple domains that address service, timeliness of care, communication, and shared decision making. A representative CG-CAHPS question is: "Did your provider explain things in a way that was easy to understand?"

Greater emphasis in this area is demonstrated by the fact that most value-based programs include patient and family experience as up to 30% of the overall rating of a health professional.

Understanding these metrics, how they can be used to improve care, and how to address the technical and operational challenges associated with them is now an imperative for pediatricians in all disciplines. These metrics have additional utility, as they relate to office-based quality improvement activities and Maintenance of Certification.

Care Coordination Fundamentals

In 1967 the American Academy of Pediatrics first described the notion of the patient-centered medical home. Subsequently, in 2007, a joint statement endorsing the medical home concept was published by the American Academy of Pediatrics, American Osteopathic Association, American College of Physicians, and American Academy of Family Physicians. The patient-centered medical home concepts were updated in 2017 (Box 12.1). Cooley et al cited enhanced pediatric medical home capabilities as a harbinger of improved quality and lower cost of care. With the increasing demands of electronic health records (EHRs), quality metric performance, and other administrative duties, understanding and implementing appropriate care model design principles into one's practice is a necessity. Four such concepts are patient attribution, risk stratification, use of data and analytics, and the care team.

Table 12.2. Example Healthcare Effectiveness Data and Information Set Measure Specifications

HEDIS Measure	*Description*	*Specification*	*Definition*	ICD-10-CM *Codes*[a]
Appropriate Treatment of Children With Upper Respiratory Infection (URI)	Measure evaluates the percentage of children aged 3 months to 18 years who were given a diagnosis of URI and were *not* dispensed an antibiotic prescription.	• Patients with an outpatient or ED visit with a single diagnosis of URI and *not* prescribed an antibiotic on, or 3 days after, the date of the URI diagnosis. • Ensure any secondary diagnoses indicating the need for an antibiotic are submitted on the claim.	• Acute nasopharyngitis • Acute laryngopharyngitis • Acute URI	• **J00** • **J06.0** • **J06.9**
Well-Child Visit 3–6 Years (WC34)	Measure documents at least 1 well-child (health supervision) visit with the primary care physician during the measurement year.	Visit includes a health and developmental history, physical examination, health education, and anticipatory guidance.	Services specific to an acute or chronic condition do not count toward this measure.	• **Z00.110** • **Z00.01** • **Z00.121** • **Additional codes**

[a] Codes subject to change; current as of 2020.

Abbreviations: ED, emergency department; HEDIS, Healthcare Effectiveness Data and Information Set; *ICD-10-CM, International Classification of Diseases, 10th Revision, Clinical Modification*; URI, upper respiratory infection.

Box 12.1. 2017 National Committee for Quality Assurance Patient-Centered Medical Home Concepts

- Team-based care and practice organization
- Knowing and managing your patients
- Patient-centered access and continuity
- Care management and support
- Care coordination and care transitions
- Performance measurement and quality improvement

Patient Attribution

A foundational component of care coordination is knowing the patients a pediatrician is responsible for. This knowledge allows for proactive, rather than reactive, approaches to care. For example, knowing which children in the practice have not yet received an appropriate immunization or timely health supervision visit allows the pediatrician to reach out to schedule such care. Attribution is facilitated by the population-based payment paradigm, as compensation is tied to a defined population for which the pediatrician is clinically and financially responsible. In situations in which children are migrating among various physicians, attribution may be further complicated, and various methods have been devised to assist with this process. In such situations, most attribution models emphasize the frequency of primary care health supervision visits to a single pediatrician as the best predictor of responsibility for clinical outcomes for a given child. Attribution need not be dictated by the health plan; internal practice-based attribution can also be a successful approach. The important point is that a pediatrician must know their population to be effective.

Risk Stratification

Once a population is defined, the next step is to stratify the patients to focus efforts on the areas of greatest need. Patients can be stratified by age, medical condition, certain clinical gaps in care, or any other medical or psychosocial determinant. Multiple risk stratification tools have been identified, but their use is limited in the primary care office setting. More commonly, health risk assessment questionnaires are employed for this purpose. High-risk patients can be aggregated and assigned to care coordinators, where available, for close follow-up and care plan oversight. For example, patients in a practice with persistent asthma can be identified, and their care can be reviewed to ensure they are prescribed appropriate inhaled corticosteroids. This risk stratification process does not omit attention to the multiple well children in the practice who require ongoing proactive anticipatory guidance, immunizations, and education.

Use of Data and Analytics

Incorporating the use of data and analytics into practice is essential. These data sources may include health plans, government payers, such as Medicaid, hospitals, EHRs, regional health information exchanges, pharmacy benefit managers, or other sources of aggregated information. The health professional should be aware that these data are often claims based, and there may be a significant lag from the date of care to the actual report. Using this information facilitates proactive, preventive care and offers the ability to assess quality improvement activities. Examples of this type of data include HEDIS performance, ED and inpatient utilization by patients, and appropriate use of antibiotics. Accessing timely, accurate data can be very challenging. It is highly recommended that pediatricians develop partnerships with payers, hospitals, regional health information exchanges, and large physician groups to help aggregate data whenever possible. This approach also allows pediatricians to compare their performance with national and regional benchmarks.

The Care Team

The pediatrician should be focused on diagnostic skills, understanding and implementing appropriate therapies, and nurturing a strong and trusted relationship with patients and families. Unfortunately, the literature clearly demonstrates that physicians are spending more time in activities unrelated to these important competencies. Charting in complex EHRs, filling out forms, calling different clinicians to coordinate care, seeking medical records, and returning low-level calls are a few of the activities that dominate a pediatrician's day. How can this be adjusted to work for the patient and the physician?

In recent years, production improvement programs, such as Taiichi Ohno's Toyota production system, which inspired Lean Manufacturing in the United States, have been applied, very successfully, to medical care. The concept is to avoid waste in all its forms (eg, time), create standard work for all members of the team, and ensure each person is working to the height of their respective training and licensure. (An in-depth review of Lean methodology is beyond the scope of this chapter but highly recommended for additional reading.) For example, a medical assistant should be filling out certain forms under the direction of the medical team, rather than having licensed personnel performing that task. Likewise, a physician should not be searching for medical records or making copies.

The correct application of care team models creates a well-delineated set of roles with clear understanding of who the responsible team member is for each task. The team acts proactively and anticipates the needs of the patient. Approaches such as huddles and visual performance boards facilitate this proactive approach and highlight clinical and service goals and outcomes.

Putting It All Together

The role of the pediatrician has expanded in recent years. Pediatricians must provide the best clinical care possible and are now required to understand a multitude of payment models, quality metrics, and data sources that facilitate such care. A failure to incorporate this broader knowledge base into daily practice can adversely affect outcomes for patients. As advocates for children, the more pediatricians can understand about this new paradigm, the more successful they can be in ensuring that infants, children, adolescents, and young adults are provided the most efficient quality care possible.

CASE RESOLUTION

Your medical assistant performs a pre-visit chart review that includes identification of any potential gaps in care, recent hospitalizations or ED visits, review of specialty notes for updated medication doses, pending laboratory tests or diagnostic testing, and immunization records. The school Individualized Education Program is reviewed to ensure therapies are occurring at the appropriate frequency with associated progress reports demonstrating improvement. During your morning huddle with your care team, you determine that the child has seen 2 of her subspecialists since she last visited your office, so your team updates her medication list and overall care plan to reflect the latest information. You also determine that she is overdue for a health supervision visit, and your staff converts her acute visit today to a such a visit to include her annual influenza vaccine. You note that she has a registered nurse who acts as her case manager, who is provided by her Medicaid managed care program, and ensure that your team connects with the case manager and social worker to help coordinate care and address any social determinants of health that may pose a challenge. During her visit you include the family in all decision making about her care and provide a written summary of the visit and a specific action plan. Your office securely messages the family in 48 hours to reinforce the care plan and ask if there are any other questions.

CHAPTER 13

Principles of Pediatric Therapeutics

Bonnie R. Rachman, MD

CASE STUDY

An 18-month-old girl who has had a cough, runny nose, and fever for 2 days is brought to your office for evaluation. The previous night she awoke from sleep crying and pulling at her ear. The patient has no other symptoms. Her mother states she has had previous ear infections; the most recent occurred 2 months ago. The last time she took amoxicillin she broke out in hives. Otherwise, the patient has no significant medical history.

On physical examination, the patient is febrile with a temperature of 38.9°C (102°F) and has yellow rhinorrhea. The ear examination reveals a red, bulging, nonmobile tympanic membrane in 1 ear, while the other tympanic membrane appears normal. The remainder of the examination is benign.

Questions

1. What are the current clinical practice guidelines for antibiotic treatment of otitis media? How does treatment change with the age and symptoms of the patient?
2. How does the previous reaction to a medication influence the antibiotic choice?
3. How do factors (eg, parental work, child care) affect administration of the medication?
4. What role do over-the-counter medications have in the management of the patient's symptoms?

A *drug* or *therapeutic* can be defined as any substance that is ingested, absorbed, or injected that alters the body's function. Examples include prescription medications, over-the-counter (OTC) medications, homeopathic preparations, herbal remedies and teas, vitamin supplements, and illicit substances. Different drug categories have differing safety profiles and regulation levels. Prescription drugs are the most regulated. Homeopathic preparations, some vitamin formulations, and most herbal remedies may have little, if any, standardization, safety testing, or regulation. Illicit drugs have no quality testing.

The use of prescription and OTC medications is very common in pediatrics. The Slone Survey, a random digit-dial survey of medication use, found that families with children reported that more than 55% of children younger than 12 years had taken some medication preparation within the last 7 days. Of those taking a medication, 22% were taking at least 1 prescription medication. In a given month, more than 50% of preschool-age children had received some OTC medication. In 2011 to 2012, 7.5% of US children and teenagers aged 6 to 17 years took medication for emotional or behavioral difficulties. The number of children aged 12 years and younger being administered an OTC medication in a given period is more than twice that of a prescription medication. The most commonly used OTC medications are acetaminophen and ibuprofen. In the adolescent age group, aged 12 to 17 years, more OTC products are used for acne and less for allergies or pain relief. Given that the use of OTC medications is so prevalent and that many OTC medications contain multiple active ingredients, concerns about their safety profile for children is an issue that needs to be addressed by pediatricians with families at routinely scheduled office visits as well as by regulatory agencies.

Another concern is the use of prescription or OTC medications as drugs of abuse. Of particular concerns are adolescents who use alcohol, illicit drugs, and medications, including OTC cough medications containing dextromethorphan. In the 2017 Monitoring the Future survey of 8th, 10th, and 12th graders nationwide, approximately 3% of the survey participants reported using OTC cough medicine to "get high" in the past year. Also, in the past year, 49% reported use of alcohol, 28% reported use of marijuana, 61.3% reported use of Vicodin, and 1.9% reported use of oxycodone.

Furthermore, according to the Centers for Disease Control and Prevention, each year more than 60,000 children are brought to the emergency department (ED) for medication overdoses; OTC medications were implicated in more than 26,000 visits. Ninety percent of ED visits for medication overdoses resulted from unsupervised ingestions of prescription and OTC drugs, with peak incidence in the younger-than-5-year age group.

Most drugs prescribed for children have not been tested in children. Before the US Food and Drug Administration (FDA) initiated a pediatric program (Best Pharmaceuticals for Children

Act of 2002 [amended in 2007]), only about 20% of drugs approved by the FDA were labeled for pediatric use. Currently, about one-third of drugs prescribed to children have been studied for safety and efficacy in pediatric populations. The practice of prescribing drugs for off-label conditions is found in approximately 50% of all physician prescriptions. By necessity, doctors have routinely given drugs to children *off-label,* which means the drug has not been approved for use in children based on the demonstration of safety and efficacy in adequate, well-controlled clinical trials. It does not imply that the drugs are unsafe, improper, or illegal. The Pediatric Research Equity Act of 2003 (amended in 2007) requires pediatric studies and covers drugs and biologics. Under the Pediatric Research Equity Act, the FDA can require pediatric studies of a drug submitted in a new drug application if it determines the product is likely to be used in a substantial number of pediatric patients or if the product would provide a meaningful benefit in the pediatric population over existing treatments. In a systematic review of the frequency of off-label use of antibiotics in clinical pediatric practice, the percentage of off-label antibiotic prescriptions varied from 1% to 94%. Some of the wide variation observed in pediatric patients might be attributed to the heterogeneity among the study populations' ages of children.

Off-label use creates a liability for the physician. The burden of an adverse outcome is on the manufacturer or license holder when there is an on-label use of a medication and an iatrogenic injury is sustained. When the medication is prescribed off-label, legal liability is on the prescriber unless parents and/or guardians are appropriately informed and give their consent.

Differences in pharmacokinetics among infants, children, and adolescents can result in differences in drug efficacy and toxicity. To choose the most important therapeutic, health care professionals must consider a number of factors, including patient characteristics, disease epidemiology, safety profile, patient compliance, and cost-effectiveness (Box 13.1).

Box 13.1. Factors in Choosing Appropriate Therapeutics

Patient Characteristics
- Age
- Medical history
- Allergies
- Use of other medications

Disease Epidemiology
- Epidemiology
- Age-specific factors

Safety Profile
- Therapeutic index
- Black box warning

Patient Compliance
- Taste
- Purpose of treatment
- Storage
- Side effects

Cost-effectiveness
- Drug availability
- Formulary restrictions

Patient Characteristics

Infants and children have different physiological characteristics than adults, including immaturity of metabolic and organ function. Body weight and surface area are considerations in drug dosing for pediatrics. In addition, the therapeutic window for many drugs is smaller for children than adults. Pharmacological factors, including age-based variability in absorption, metabolism, and excretion of drugs in children compared with adults, as well as age-specific contraindications of certain medications, pose special vulnerabilities for children to the adverse effects of overdosing. Conversions of doses from ingredient amounts to volumes for liquids labeled for home use are also problematic.

The patient's medical history plays an important part in the choice of an appropriate therapeutic. Depending on the patient's condition and medical and surgical history, the absorption, metabolism, or usual effectiveness of a therapeutic may be altered. Children with short bowel syndrome can potentially have difficulty absorbing oral medications depending on which portion of the bowel was removed. Children with intellectual disability who are given central nervous system–altering medications can be difficult to monitor for changes in mental status seen with systemic infection. In addition, children with glucose-6-phosphate dehydrogenase deficiency can suffer from drug-induced hemolytic anemia when given certain drugs, such as sulfonamides. Children who are malnourished are at greater risk for drug toxicity because low serum albumin levels decrease the amount of bound drug and result in increased levels of unbound drug in circulation.

Allergies to medications and reactions to prior drugs are important pieces of information to glean from the patient and family. Specific information about symptoms or problems while taking a drug are of great significance because side effects can be mislabeled as drug allergies. *Drug allergies* are reactions that have an immunologic basis. Of the 4 types of immune mechanisms associated with drug allergies, immunoglobulin (IgE)-mediated reactions are of the greatest concern because they can result in anaphylaxis. *Adverse reactions,* such as vomiting, can be idiosyncratic or nonimmune mediated. A *side effect* is an expected but undeniable consequence of taking a medication. Families often attribute any symptoms a patient experienced while taking a medication to a drug allergy. It is, therefore, important to know which side effects are associated with a medication to determine whether an allergy is present. Any medication that has been associated with an allergic reaction (eg, skin eruptions, swelling, urticaria, respiratory difficulty) should not be used without consulting a specialist.

Also important is to consider what other medications the patient is taking. This may influence the drug of choice. Metabolism of 1

drug may influence the metabolism of another. Drug metabolism is divided into 2 types. Phase 1 reactions include oxidation, reduction, and hydrolysis. Phase 2 reactions involve adding subgroups to a drug.

Other drugs can affect reactions during either phase. For example, the enzyme activity of the cytochrome P 450 system involved in oxidation can be induced or inhibited depending on other medications being taken, resulting in an altered rate of metabolism. A common drug used in pediatrics that inhibits the cytochrome P 450 system is erythromycin, while phenobarbital and phenytoin induce the system. Drug interactions are not a contraindication to the use of a therapeutic, but it may be necessary to closely monitor the dose or serum level.

Disease Epidemiology

Etiologies for many common diseases may differ depending on the patient's age group. Some drugs to which the patient's condition may be susceptible are contraindicated in certain patient populations. Treatment duration may also vary depending on the patient's age group (eg, an adult with an uncomplicated urinary tract infection may receive only a 1- to 3-day course of treatment, while a child may receive 7–10 days of treatment because of the high recurrence of infection that has been observed in children given a shorter treatment duration).

Safety Profile

Medications have benefits and risks; these constitute a safety profile. When choosing a medication, the *safety profile* (ie, risks vs benefits) must be evaluated. Some risks may be caused by the duration of treatment, dose, or interactions with other medications. Therapeutic index, which is 1 means of quantifying the risk associated with a specific dose, may be a consideration in medication choice. The *therapeutic index* is the difference between the dose that provides a desired effect and the dose that provides an undesired effect. For example, a medication with a wide therapeutic index is one in which a desired effect is achieved with a dose much lower than that required to produce a toxic effect. In general, a medication with a wide therapeutic index, such as ibuprofen, is considered safer than a medication with a narrow therapeutic index. The higher the morbidity and mortality associated with a condition, the narrower the accepted therapeutic index can be. Food-drug interactions and drug-drug interactions are other risks that can be anticipated. There are also risks that are independent of the dose of the therapeutic, which are called *idiosyncratic effects.* These are unexpected and usually unavoidable risks associated with the medication.

In the United States, a *black box warning,* also known as a *black label warning*, is a type of warning that appears on prescription drugs that may cause serious side effects. A black box warning is the strictest warning that can be put on a label. The name came about from the black border that usually surrounds the text of the warning. Black box warnings mean that medical studies indicate that a drug carries a significant risk of serious or even life-threatening adverse effects. An example of a medication used in pediatrics that has black box warnings is antidepressants. This warning does not prevent the use of the medication but requires the physician and family to evaluate the risks and benefits of its use.

Patient Compliance

Medications and therapeutics are only useful if patients take them as prescribed. Factors that contribute to patient adherence include, but are not limited to, administration convenience and ease of taking the medication, the patient's and family's understanding of the benefits and risks of the medication, and adverse effect profile.

Because children are dependent on their caregivers to administer medications properly, the caregiver must understand why the drug was prescribed, how it should be dispensed, and why it must be taken for a specific length of time. For a medication to achieve its maximal therapeutic usefulness, accurate dosing is important. A staff member should demonstrate how to measure and dispense the medication. The caregiver should then be asked to demonstrate the process. This will make an important difference in adherence to the medication regimen. Having a standardized drug dispensing tool, such as a syringe or marked dosing cup, will potentially improve the ability to give the appropriate medication dose successfully.

In pediatrics, palatability is a major factor in patient adherence. If children do not like the taste or texture of a medication, they will refuse to take it. Physicians who prescribe medications for children should be familiar with the taste and texture and be prepared to find alternatives. Prednisone is a common example of this; it is available as a pill and a suspension. The suspension may taste differently depending on the preparation prescribed. Children often vomit the less-palatable version. Knowing in advance what children will take may prevent future problems associated with noncompliance.

Cost-effectiveness

Cost-effectiveness is defined as outcome per unit cost. *Outcome* is the treatment of the condition or alleviation of the symptoms for which the medication was prescribed. *Cost* includes the price of the medication or treatment as well as the physician's and family's time. Therefore, if a patient is prescribed a medication that is less effective for the child's condition because of cost, it many end up costing more because of the need for additional doctor visits and more medications. In many practice settings, the pharmacy has a set formulary of medication limiting the selection of medications for specific conditions. From the patient side, many families have limited or no health insurance and may have to pay the full cost of a medication. The cost of treating a common condition such as otitis media can differ as much as 10-fold depending on the medication prescribed. Thus, an appropriate drug of choice is influenced by the out-of-pocket cost to the family. The perceived cost-effectiveness of a therapeutic is different for each situation and depends on external factors affecting the physician and family.

Drug Dosing

Compared with the adult population, in which drug doses are based on a standard dose for an individual regardless of age, size, or weight, pediatric medications are usually dosed based on weight or body

surface area. For medication dosing determined by weight, when a child reaches 40 to 50 kg, the dosing is often changed to a standard adult dose. With the increasing prevalence of childhood obesity, many school-age children weigh more than 50 kg, thereby making it important to know the maximum daily dose because calculating milligrams per kilogram can easily exceed this amount. For drugs with narrow therapeutic indexes, such as chemotherapy or immunosuppressive medications, body surface area is used to determine appropriate dosing. Once a therapeutic agent is chosen, an appropriate dosing schedule must be determined. Dosing guidelines can be presented as total dose per 24 hours or an amount per dose. An example for dosing acetaminophen for a 1-year-old is given in Box 13.2.

Medication Errors and Adverse Drug Events

Pediatric patients are at greatest risk for medication errors because of the need to calculate dose based on weight. Between 5% and 27% of all pediatric medication orders result in medical error. Pediatric inpatients incur 3 times more medication errors than adult inpatients. The incidence of adverse drug events in pediatrics is about 2.3%. The most vulnerable populations are patients younger than 2 years; those in intensive care units; those in the ED, especially if they are seriously ill; or those receiving chemotherapy. More than half of these errors occur during the prescribing phase when the medication dose is calculated. Dosing error checking is complicated by the fact that children's weights vary from as little as 500 g to much more than 100 kg. Therefore, a dose range for a medication may be very large. The second most common causes of error in pediatric prescriptions is missing information and illegibility. In 2001, the Institute for Safe Medication Practices published guidelines to decrease pediatric medication errors. Their recommendations included computerized physician order entry, bar coding technology, unit dose dispensing systems, and educational programs for all health care professionals. There is no literature to support these recommendations. There have been multiple studies trying to identify definitive interventions, but, to date, no studies have been able to elucidate effective solutions.

The American Recovery and Reinvestment Act of 2009 provided much-needed momentum toward widespread electronic health records, which include e-prescribing. Systems that have computerized physician order entry or e-prescribing can reduce medication errors by having alerts for inappropriate dosing, improved legibility, warnings for drug interactions, and just-in-time information on the most appropriate drug choice. Not all errors will be rectified by e-prescribing; examples of errors that elude decision-support programs include inappropriate selection of medication for the condition being treated and failure to recognize a change in patient status.

Box 13.2. Dosing Example: Acetaminophen

A 1-year-old has a fever, and the family wants to know how much acetaminophen to give her. She weighs 11.2 kg (24.7 lb). The recommended dose of acetaminophen is 10 to 15 mg/kg every 4 to 6 hours. Acetaminophen is sold as a suspension with the concentration of 160 mg/5 mL.

1. Determine the amount of medication needed by multiplying the weight of the child by the recommended dose.

$$11.2\ \text{kg} \times 10\ \text{mg/kg} = 112\ \text{mg acetaminophen}$$

2. Determine the volume of medication based on the concentration of acetaminophen to be used.

Dosing volume = (amount of medication) ÷ (concentration of medication)

Suspension

$$\text{Dosing volume} = 112\ \text{mg} \div 160\ \text{mg/5 mL}$$
$$= (112 \times 5)/160$$
$$= 3.5\ \text{mL}$$

This family can be instructed to give the 1-year-old 3.5 mL of the suspension of acetaminophen orally every 4 to 6 hours as needed for fever.

CASE RESOLUTION

After obtaining the history and performing a physical examination, the pediatrician determines that the patient has acute otitis media. Depending on the age of the child and the severity of symptoms, American Academy of Pediatrics clinical practice guidelines suggest a stratified approach to therapeutics. For infants and children between 6 and 24 months of age, pediatricians can treat with antibiotics if the diagnosis is certain or observe the patient without antibiotics if the patient is otherwise healthy. In this case, the pediatrician discusses the options with the family and, because of the severity of pain and previous ear infections, chooses to treat the infection. The antibiotic of choice for treatment of otitis media is amoxicillin at a dose of 80 to 90 mg/kg/day. The mother states that her daughter had hives with amoxicillin, a type 1 hypersensitivity. Other antibiotic choices would include cefdinir 14 mg/kg/day in 1 to 2 doses per day. Treatment of pain is essential with otitis media. The patient can take oral acetaminophen or ibuprofen.

The mother raises a concern about her daughter's cough and runny nose and would like to use an OTC cough medication. The US FDA does not recommend use of cough preparations in this age group. Educating the mother about conservative therapies, including nasal suctioning, humidification, and nasal saline, to treat her daughter's respiratory symptoms is more appropriate.

If the patient were not allergic to amoxicillin, it would have been the drug of choice. It is inexpensive, has a narrow microbiological spectrum, and is palatable. Amoxicillin does require refrigeration, which would be of concern if the family were traveling. While this case illustrates several obvious constraints, it is important to emphasize that choosing the appropriate medication is dependent on the intrinsic needs of the patient and extrinsic factors that can affect adherence and, ultimately, the effectiveness of treatment.

CHAPTER 14

Pediatric Pain and Symptom Management

Kevin Madden, MD, and Richard Goldstein, MD, FAAP

CASE STUDY

You are caring for a Kayla, a 10-year-old girl with stage 4 neuroblastoma who is at home receiving palliative care. Her tumor is refractory. She receives oral chemotherapy and transfusions as an outpatient to offset the bone marrow depletion caused by her tumor. Pain from her metastases is becoming increasingly problematic, especially in her chest wall and right femur. Her spine is also involved, but she does not experience weakness. Although fatigued, she derives great pleasure from attending school and being surrounded by friends and family members, playing as she is able. She hates the hospital and her parents have chosen to avoid it, intending to keep her comfortable at home until she dies. You have remained closely involved throughout her illness and would like to help with the management of her symptoms.

Questions

1. What is the approach to pain management in children?
2. How does the physician assess the level of pain in children?
3. What is meant by adjuvant therapy?
4. What are nonpain symptoms that can cause distress?
5. What is the management of nonpain symptoms?

Ill or injured children experience distressing physical symptoms, particularly in the case of illness or injury that is chronic or life-limiting. The appropriate management of such symptoms is fundamental to minimizing discomfort and optimizing quality of life. Pain can not only diminish a child's physical well-being but also can affect psychological, social, and spiritual health. Children experiencing poorly controlled pain will withdraw interpersonally and be unable to engage in the activities that make their life, however limited, meaningful. Similarly, a child troubled by nausea will experience distress from the symptom while also losing the simple pleasure of eating and its accompanying comforts. Symptom management improves the lives of children who are medically fragile.

Parents or caregivers of children who are seriously ill worry most about their child's symptoms not being satisfactorily controlled. Studies of dying children have noted that distressing symptoms often go untreated. Research investigating the symptoms and experience of children dying from cancer found that most of the children experienced fatigue, pain, dyspnea, anorexia, nausea and vomiting, and constipation in the last month of their lives (Figure 14.1). Similar findings have since been noted in other populations. Children with neurologic impairment are particularly at risk because of their limited verbal abilities and atypical responses to pain. Symptom management of seriously ill children has been improved significantly since early studies. As more children with chronic and serious illnesses are cared for and sometimes die at home, the management of their illnesses will increasingly involve their primary care pediatrician.

This chapter reviews the basic medical approaches to pain and symptom management in children, particularly those with serious illnesses. In addition to pain, approaches to nausea, anorexia, fatigue, secretions, and delirium are presented. The focus is on the medical management issues a primary care pediatrician may attempt to manage in the community setting. When the primary care pediatrician is insufficiently familiar with such treatment, consultation with pain or palliative care specialists is appropriate.

Pain

Pain is an integrated biophysical and "existential" construct. It involves complex mechanisms of nociception modulated by biochemical factors, neuroplasticity, genetic and familial factors, and an individual's past experience with painful events. Each child experiences pain in a unique way and quickly develops learned behaviors related to it. As such, no simple correlation exists between the objective degree of injury and the experience of pain. More accurately, physical, psychological, interpersonal, and existential factors all contribute in important ways to the experience of pain. A comprehensive approach to pain addresses all these elements.

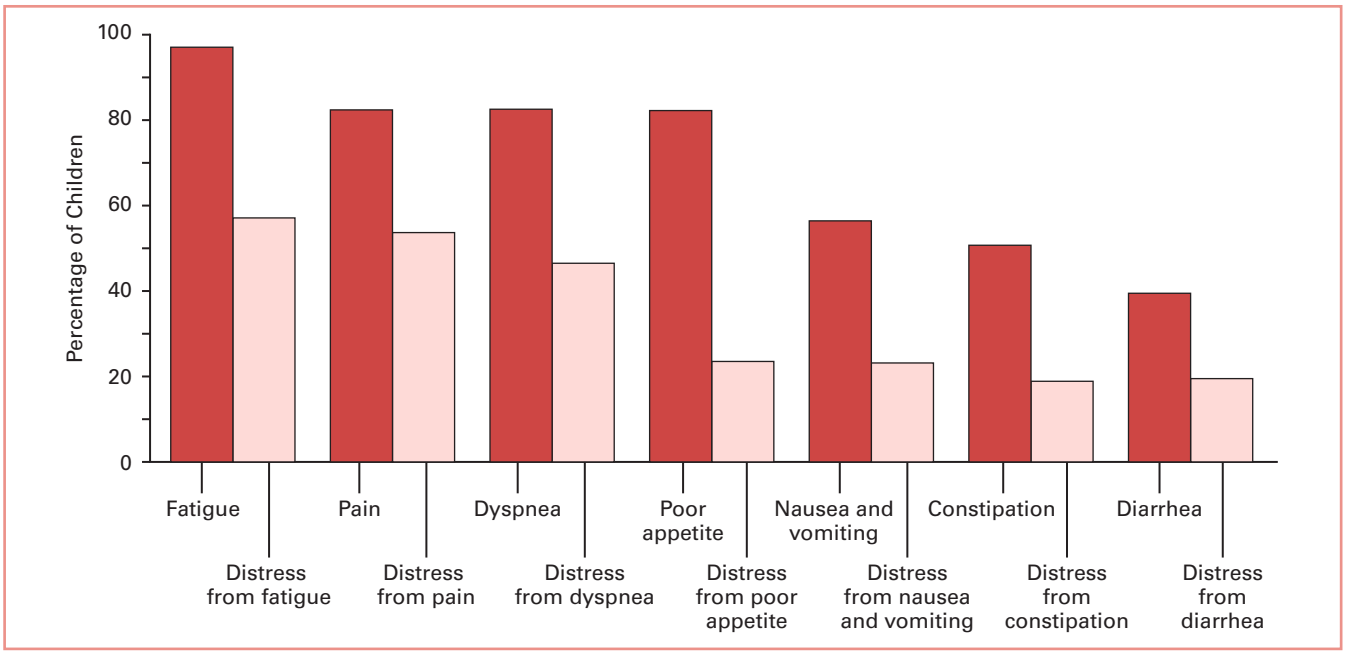

Figure 14.1. The presence and degree of distress from specific symptoms in the last month of life.

Assessment

The 2 basic types of pain are nociceptive and neuropathic. An understanding of the presentation of each type can help differentiate the source of pain in children. *Nociceptive pain* is the activation of peripheral nerve receptors when noxious stimuli cause tissue damage, and its intensity is related in part to the location and the amount of damage. *Somatic pain* refers to nociceptive pain from musculoskeletal, bony, or superficial sources (eg, skin, mucosa). Deep somatic pain tends to be localized and concentrated and is described as stabbing, aching, or throbbing (eg, bone pain is deep and aching). Superficial somatic pain is sharper and can be burning or pricking. The source of nociceptive pain can also be visceral. *Visceral pain* is usually poorly localized; can be described as cramping, gnawing, or pressure; and may follow daily patterns of varying intensity.

Neuropathic pain is caused by injury or dysfunction of the central nervous system (CNS) or peripheral nerves. It can be described as burning, tingling, shooting, or scalding. Its presence points to neuropathies, CNS insult, or evolving damage to the nervous system. Understanding whether the source of pain is somatic, visceral, or neuropathic helps guide treatment decisions.

Pain should be a part of the medical evaluation of every child. Pain is phenomenological and thus, although its existence is "real" and "objective," it can be experienced and described only by the affected person. Fundamentally, the patient's report of the presence or severity of pain is the key to the assessment. In children, especially children with developmental issues, objective assessment tools may be useful to identify the presence of pain and quantify its severity. In most patients these scales are also helpful in understanding the symptom of pain over time.

Standardized pain scales are used to assess the intensity of pain. Analog pain scales, which generally score intensity on a scale of 1 to 10, have some reliability when used in the same patient over time (Figure 14.2). Younger children may have difficulty with the concept of quantity or the meaning of greater intensity. An important modification of the analog scale for children with impaired communication skills or cognition is the *Individualized Numeric Rating Scale*, on which parental or caregiver observations of their child's facial expression, body movements, activity and interaction, crying, and ability to be consoled as they experience worsening pain are used to label the points of the scale.

For children older than 3 years, the *Wong-Baker FACES Pain Rating Scale* (Figure 14.3) is often used. After showing children the faces, they are instructed that each face is for a person who has no pain (no hurt), some pain, or a lot of pain. The child is then asked to choose the face that best describes how the child is feeling. More comprehensive pain assessment tools are available that also assess function and mood, but they are less widely used. The perspective of parents or caregivers and others familiar with the child is crucial to any assessment of a child's pain.

The child in pain must be relieved of it; however, it is advantageous to make a strong effort to understand the source of the pain and manage conditions amenable to nonpain medication. For example, chest pain may be caused by candidal esophagitis or abdominal pain resulting from constipation. Thinking clearly about the etiology of pain rather than simply providing analgesic agents in a reflexive manner has the benefits of preserving alertness, sparing side effects, and sustaining the least impaired quality of life. Pain can be eliminated by eliminating the underlying condition responsible for it. The optimal management of pain also includes addressing psychosocial and spiritual distress and making efforts to enhance a child's function as part of an integrated approach to pain-related distress.

Medical Management

Opioids are the pharmacologic mainstay of pain management. Familiarity with the basic principles of treatment with these agents is fundamental to care for the child with serious acute and life-limiting illness. In cases of complex pain or those involving daunting polypharmacy, it may be best to seek guidance from pain or palliative care specialists. Additionally, certain medications (ie, methadone, selective norepinephrine reuptake inhibitors) or invasive approaches (ie, intrathecal pumps, regional blocks, surgical or radiotherapeutic approaches to pain control), or the management of chronic pain, particularly in adolescents, should involve consultation with or referral to pain and palliative care specialists.

The use of opioids in children since approximately 1990 roughly parallels wider trends observed in their use in adults. The 1990s and early 2000s saw a dramatic increase in the number of opioid prescriptions in the United States, motivated by the assessment that pain in seriously ill children was being undertreated. Changing prescribing practices also heralded a new public health crisis, the opioid-overdose epidemic. Currently, opioid overdoses are the leading cause of death of Americans younger than 50 years. The philosophical pendulum is now swinging back towards a more scrutinized prescribing environment. Some commercial pharmacies limit new prescriptions of opioids for noncancer pain to a 7- to 10-day supply, and many state medical boards now require physicians to review prescription drug monitoring program databases on a routine basis. Parents have responded to this widely publicized phenomenon with renewed caution about opioids, while seeking the benefits of appropriate use. Proposing an opioid for a child now demands considerable investment by the physician to provide a comprehensive pain plan that highlights consistent reassessment of the need for an opioid, directly addresses the specter of dependency before initiation of an opioid, and reassurance that the child's best interest will always be the focus of treatment.

Pain must be understood as a multidimensional symptom with a meaning for the individual that influences the experience of it, worthy of its own attention. In the context of "total pain," other etiologies of pain should be considered, assessed, and managed, especially when a child's or parent's/caregiver's report of pain intensity seems incongruous with the amount of opioid provided. *Total pain* conceives of pain as having 4 interrelated domains: physical, psychological, social, and spiritual. The use of opioids may unintentionally alleviate psychological, social, and spiritual pain as the limbic system also possesses mu receptors, but it cannot substitute for attention to all the elements of pain. Activation of these specific mu receptors upregulate mood, which can easily become intertwined and confused with relief of physical pain.

Dose escalation should proceed until the pain is controlled, provided that side effects are tolerable. Opioids have no maximum or "ceiling" dose. The child on long-term opioid treatment often receives surprisingly high doses yet, provided the treatment is successful in controlling pain, is comfortable and functional. Generally, infants younger than 6 months should be started at one-third the general pediatric dose. Anticipated side effects of opioids include constipation, pruritus, and nausea and vomiting. The pruritus and nausea and vomiting are usually short-lived, disappearing in a week, but constipation persists. All patients on scheduled opioids should also receive scheduled doses of stool softeners and stimulant laxatives.

Parents or caregivers and some physicians may overestimate the benefit of distraction in pain management. Distraction is best thought of as an assessment tool and may be an adjunct to but not a treatment for pain. If a child can be substantially distracted from the pain for a significant period, the pain need not be managed with medication. If the child's distress is apparent despite the distraction, however, pharmacologic intervention for the pain is necessary. What must be avoided is a distressed child engaging in the distraction to please adults while the pain goes unabated. Similarly, the use of placebos has no place in the treatment of pain.

The World Health Organization 2-step approach to pharmacologic management of pain is the most important guide to pain management in children. It presents a stepwise and additive approach to "capture" a child's pain as well as to augment the pharmacologic treatment of pain. The model is premised on using a 2-step strategy, dosing at regular intervals, using the appropriate route of administration, and individualizing treatment to the particular child.

The child with mild pain who has not received any analgesic medication is managed with oral analgesics, such as acetaminophen and ibuprofen (step 1). In certain cases, intravenous acetaminophen or ketorolac tromethamine may be used. Adjuvants may be added if appropriate. Acetaminophen can be given orally or rectally. Compounded ibuprofen can be given rectally. The topical application of these agents in ketoprofen cream or aspirin cream may also

be of benefit. Rarely, a role may exist for a cyclooxygenase-2 inhibitor. All nonsteroidal anti-inflammatory drugs have ceiling doses and gastrointestinal toxicities. With the exception of acetaminophen and celecoxib, all affect platelet function and hemostasis.

Adjuvants are non-analgesic drugs that are helpful in the management of a child's pain. For example, anxiety experienced by a child who is medically fragile may potentiate the child's pain and distress, even at step 1. A benzodiazepine may be helpful in such cases, but it should be prescribed with an awareness of other medications. An alternative to benzodiazepines for anxiety is the antipsychotic agent haloperidol. At very low doses it provides an anxiolytic effect without sedation or the synergism with opioids that can result in respiratory depression. A lidocaine patch can help with some somatic pain. Certain forms of mild to moderate pain (ie, neuropathic pain) may be adequately managed with gabapentin or pregabalin, minimizing the use of opioids.

Step 2 addresses children with moderate to severe pain and involves the addition of opioids to the treatment plan (Table 14.1). "Weak opioids" (eg, codeine, tramadol hydrochloride) are no longer recommended. Research has shown that codeine may be a weaker analgesic than a standard dose of many nonsteroidal anti-inflammatory drugs, and it has a ceiling effect. The oral bioavailability of codeine is widely unpredictable, at 15% to 80%. Most importantly, codeine is a prodrug that must be metabolized by the liver into morphine. This is problematic because it is estimated that 35% of children do not metabolize codeine in the anticipated manner, resulting in great uncertainties in a calculated effect. The use of tramadol hydrochloride is only weakly recommended because of concerns

Table 14.1. Essential Pharmacopeia for Symptom Management in Pain and Palliative Care

Symptom	*Agent*	*Initial Oral Dosing*	*Initial IV Dosing*	*Available Formulations*
Pain	Hydromorphone	0.04–0.06 mg/kg every 3–4 hours (max, 2 mg/dose)	0.015 mg/kg every 2–3 hours (max, 0.6 mg/dose)	Immediate release: tablet, liquid Extended release: tablet IV
	Morphine	0.2–0.3 mg/kg every 3–4 hours (max, 15 mg/dose)	0.05–0.1 mg/kg every 2–3 hours (max, 5 mg/dose)	Immediate release: tablet, liquid Extended release: capsule, tablet IV
	Oxycodone	0.1–0.2 mg/kg every 3–4 hours (max, 10 mg/dose)	N/A	Immediate release: tablet, liquid
Anorexia	Cyproheptadine hydrochloride	0.25 mg/kg/day in 2–3 divided doses (max, 12 mg/day)	N/A	Tablet
	Megestrol acetate	10 mg/kg/day in 1–4 divided doses[a]	N/A	Tablet, liquid
Delirium	Haloperidol	0.01–0.02 mg/kg every 4–6 hours (max, 0.5–1 mg/dose)	0.01–0.02 mg/kg every 4–6 hours (max, 0.5–1 mg/dose)	Tablet, liquid, IV
	Olanzapine	1.25–5 mg every 4–6 hours	N/A	Tablet, oral disintegrating tablet
	Quetiapine fumarate	12.5–50 mg every 6–8 hours	N/A	Tablet
Dyspnea	Any opioid	33%–50% of opioid dose for pain	33%–50% of opioid dose for pain	Any formulation
Dystonia	Baclofen	2.5–5 mg every 8 hours	N/A	Tablet, liquid
	Diazepam	0.5 mg/kg/dose every 6 hours as needed	0.5 mg/kg/dose every 6 hours as needed	Tablet, IV, rectal gel[b]
Fatigue	Methylphenidate hydrochloride	2.5–5 mg daily or twice a day	N/A	Tablet, transdermal patch[c]
Nausea	Ondansetron hydrochloride	0.15 mg/kg/dose every 8 hours (max, 8 mg/dose)	0.15 mg/kg/dose every 8 hours (max, 8 mg/dose)	Tablet, oral disintegrating tablet, liquid, IV
	Metoclopramide hydrochloride	0.1–0.2 mg/kg every 6 hours (max, 5 mg/dose)	0.1–0.2 mg/kg every 6 hours (max, 5 mg/dose)	Tablet, liquid, IV
Respiratory secretions	Atropine 1% ophthalmic drops	1 drop every 2 hours as needed	N/A	Liquid
	Glycopyrrolate	0.04–0.05 mg/kg every 4 hours	0.004–0.005 mg/kg every 4 hours	Tablet, liquid, IV

Abbreviations: IV, intravenous; max, maximum; N/A, not applicable.

[c] Dose equivalent to oral dose.

about risks for seizures and hyperserotonergic symptoms with its use.

When pain persists or worsens, morphine, hydromorphone, and oxycodone are recommended initial choices. Doses are escalated until pain is controlled, using the least invasive form of administration necessary. This step may involve the addition of controlled-release preparations of opioid or methadone, while using shorter-acting agents for breakthrough pain. To calculate the as-needed dose for breakthrough pain, a general rule is that the as-needed dose is 10% to 15% of the 24-hour total opioid dose or its equivalent, given orally every 3 to 4 hours.

An in-depth discussion of methadone and fentanyl citrate exceeds the scope of this chapter, but it is worth making several points about them. Neither has active metabolites, making them important options for patients with renal failure in whom accumulated metabolites from other opioid agents can cause myoclonus, confusion, or hyperalgesia. Fentanyl citrate, a potent analgesic, is available in a transdermal patch, which is an important nonintravenous, non-oral option for children having difficulty swallowing. The child must have adequate body fat, because the drug is deposited across the rate-limiting membrane into fat reservoirs and is absorbed from that reservoir into the child's bloodstream. Methadone has some distinct analgesic advantages. It is inexpensive, its half-life allows for more convenient twice-a-day or 3-times-a-day dosing, and it is especially helpful in managing neuropathic pain. It is complicated to dose, however, and its long and variable half-life make it a more complicated choice for those not familiar with its use.

The management of moderate and severe pain over time can result in the development of difficult unintended effects, including sedation, nausea and vomiting, pruritus, and urinary retention. At high doses or when metabolites accumulate, patients may develop delirium, myoclonus, or hyperesthesia. Opioid rotation can be quite helpful in these situations. This method involves converting 1 form of opioid to an equivalently analgesic dose of another.

Rotation of the opioid agent (ie, using a different opioid) holds the promise of maintaining analgesia with lesser amounts of the newly introduced drug and eliminating side effects. *Tolerance* is the term used to describe the need over time for increased amounts of a specific opioid to achieve the desired analgesic effect. Although opioids lack a ceiling dose, higher doses may have an accompanying increase in adverse effects (ie, the emergence of the intolerable side effects noted previously, the accumulation of toxic metabolites, or high cost resulting from the required amounts of the drug). Because of multiple mu opioid peptide receptors as well as different selectivity of opioids for specific mu opioid peptides, the cross-tolerance from 1 opioid to another is not complete. An equianalgesic dose of another opioid will require less of the medication and achieve a more favorable balance between analgesia and side effects. See Box 14.1 for an example of opioid conversion.

Physicians lacking experience in pain management may be concerned about the difficulty of addressing uncontrolled pain. Because expert and effective management is a critical skill in the care of seriously ill children, especially those facing the end of life, the primary care physician may choose to consult with palliative care or pain treatment specialists to ensure that the child's needs are adequately addressed. Alternatively, hospice medical directors can provide palliative care consultations if hospital-based teams are not available.

The optimum of opioids is impacted by factors related to both patients and physicians. Foremost is the concern about respiratory depression. The risk of respiratory depression while using an accepted escalation rationale is quite small, however. Patients may fall asleep when their pain is "captured," but this generally is the result of exhaustion related to the previously unrelieved pain. Even in mild to moderate pain, patients do not notice a change in dose increase when they are less than 25% above baseline. In cases of moderate to severe pain, a dose escalation of 50% to 100% is appropriate. For acute pain crises, protocols exist that allow physicians to safely mitigate pain, but consultation with pediatric palliative care or pediatric pain specialists may help the less comfortable physician act more decisively. It is nonetheless important to recognize that the

Box 14.1. Opioid Conversion Example

Kayla is receiving 30 mg of long-acting oxycodone every 8 hours and 15 mg of immediate release oral morphine every 4 hours as needed for breakthrough pain. She receives approximately 4 doses of as-needed morphine per day. She can no longer walk and finds it progressively more difficult to swallow pills. The decision is made to rotate (ie, change) her opioid to intravenous (IV) hydromorphone.

Steps in opioid conversion

1. Calculate the total 24-hour dose of each opioid
   a. 30 mg oxycodone × 3 = 90 mg oxycodone
   b. 15 mg morphine × 4 = 60 mg morphine
2. Convert 24-hour total of each opioid to the morphine equivalent daily dose (MEDD), always expressed as oral mg of morphine
   a. 90 mg oxycodone = 135 mg oral morphine (oxycodone is ≈1.5 times more potent than oral morphine)
   b. 60 mg oral morphine = 60 mg oral morphine
   c. MEDD = 135 + 60 = 195 mg oral morphine
3. Convert MEDD to new opioid (use opioid equivalency table [Table 14.2])
   a. 195 mg / 20 (IV hydromorphone is ≈20 times as potent as oral morphine) = 9.75 mg IV hydromorphone/day
4. Dose reduce the MEDD by 33%-50% to account for incomplete cross-tolerance
   a. 9.75 mg × 0.66 = 6.5 mg/day
      i. 6.5 mg / 24 hours = 0.27 mg/hour
5. Determine an as-needed dose, that is, 10%-20% of the 24-hour opioid dose
   a. 6.5 × 0.1 = 0.65 mg IV every 2 hours as needed for breakthrough pain ***OR***
   b. 6.5 × 0.2 = 1.3 mg IV every 2 hours as needed for breakthrough pain

For Kayla

IV hydromorphone infusion of 0.27 mg/hour with IV hydromorphone 0.65-1.3 mg IV every 2 hours as needed for breakthrough pain

Table 14.2. Opioid Equivalency

Drug	*Oral Route*	*Parenteral Route*	*Conversion Ratio to Oral Morphine*	*Equianalgesic Dose of Oral Morphine*
Morphine sulfate	30 mg	10 mg of parenteral morphine	Parenteral morphine is 3 times as potent as oral morphine.	30 mg
Oxycodone	20 mg	N/A	Oral oxycodone is approximately 1.5 times more potent than oral morphine.	30 mg
Hydrocodone	20 mg	N/A	Oral hydrocodone is approximately 1.5 times more potent than oral morphine.	30 mg
Hydromorphone	7 mg	1.5 mg of parenteral hydromorphone	Oral hydromorphone is approximately 4–7 times as potent as oral morphine. Parenteral hydromorphone is 20 times as potent as oral morphine.	30 mg
Fentanyl citrate	N/A	15 mcg/hour	Transdermal fentanyl citrate is approximately 80 times as potent as morphine.[a]	30 mg

Abbreviation: N/A, not applicable.

[a] This is based on studies converting from morphine to fentanyl citrate. Currently, there are no empirical studies converting fentanyl citrate to morphine.

Adapted with permission from Periyakoil VJ. Opioid conversion equivalency table. Palliative.stanford.edu website. https://palliative.stanford.edu/opioid-conversion/equivalency-table/. Accessed July 3, 2019.

co-administration of an opioid and benzodiazepine increases the risk for apnea and respiratory insufficiency. When alveolar pCO_2 (partial pressure of carbon dioxide) reaches 60 mm Hg, normal alveolar minute ventilation increases almost 10-fold from baseline, yet the compensatory increase in alveolar minute ventilation is largely absent when an opioid (eg, fentanyl citrate) is co-administered with a benzodiazepine (eg, lorazepam). In the rare situation in which naloxone hydrochloride is required to reverse a worrisome respiratory effect, the experienced physician can slowly titrate it to reverse respiratory insufficiency and preserve the analgesic effect of the opioid rather than administer the entire dose at once. Physicians may also be unfamiliar with appropriate dosing, may not view pain control as a priority of care, or may be worried about difficulties ensuring follow-up and ongoing assessment. Families, for their part, may believe that pain is an inevitable part of the child's disease, may worry about the "symbolism" of starting a morphine drip as a hastening of death, or may worry about addiction or the stigma of having their child on such medications. Cultural and religious factors may also elicit reluctance. Such concerns should be addressed directly. The greatest concern should be to minimize any distress caused by inadequately managed pain.

The management of neuropathic pain presents a considerable challenge. The source of neuropathic pain is the insult or dysfunction of the CNS, peripheral nervous system, or autonomic nervous system. Pediatric patients may experience this pain as the result of degenerative CNS processes or injury as well as the result of treatment-related injuries to the nervous system from drug toxicities, radiation therapy, surgery, or physical compression of a nerve by a tumor. Infection may also cause neuralgia. Children describe neuropathic pain as jolts of burning, stabbing, or shooting; the pain seems to worsen at night and, compared with nociceptive pain, usually has an abrupt, unpredictable onset and a shorter duration, sometimes lasting only minutes and thereby making it difficult to manage exacerbations of pain. It also causes allodynia, dysesthesia, and hyperalgesia. The results of various approaches to the management of neuropathic pain are mixed, and a multimodal approach, including an emphasis on physical therapy and more than 1 therapeutic agent, is recommended. Adjuvant medications are offered as first-line therapy in children, with gabapentin beginning at 10 mg/kg/day divided 3 times a day and titrating upward to doses as high as 60 mg/kg/day. Emerging evidence in adults indicates that the serotonin–norepinephrine reuptake inhibitor duloxetine hydrochloride may provide better neuropathic pain control than gabapentin, with fewer side effects (eg, fatigue, excessive somnolence). Strong opioids, including methadone hydrochloride, may be included in an appropriate regimen. Tricyclic antidepressants tend to be used less for children in the management of neuropathic pain because of concerns of arrhythmia risk.

Dystonia and neuroirritability, although not properly neuropathic pain, present similar challenges in children with neurodegenerative conditions. Generalized dystonia is a condition in which sustained, erratic, painful muscle contractions occur, causing twisting and repetitive movements or abnormal postures. *Neuroirritability* is a term used to describe the difficulty in settling and persistent crying seen in some children who are cognitively impaired with metabolic and neurodegenerative conditions. These symptoms are distressing and often occur in children whose impairments make assessment of their experience difficult. Benzodiazepines, typically diazepam, are the first-line therapy for dystonia (see Table 14.1). Trihexyphenidyl hydrochloride is also commonly considered, as are valproate sodium, baclofen, carbamazepine, and tetrabenazine. In severe, intractable cases the implantation of deep brain stimulators is increasingly considered, although the empiric basis for that decision remains under study. Anticonvulsant agents are the mainstay in the management

of neuroirritability. Phenobarbital is often the first medication tried. The management of these conditions is generally determined in consultation with a child neurologist.

Management of Nonpain Symptoms

Agents used in the management of nonpain symptoms are listed in Table 14.1.

Dyspnea

Many similarities exist between the management of severe dyspnea and severe pain. Dyspnea is caused by increased work of breathing, hypoxia, and hypercapnia and the driving desire of the brain to relieve these conditions. Experientially, it may cause a feeling similar to that of being underwater too long and needing to surface. Like pain, dyspnea has a physical basis; however, the distress is potentiated by psychological, interpersonal, and existential aspects. After oxygen, opioids are the treatment of choice, and they are dosed at one-third the dose for pain management. The inexperienced physician may be concerned about exacerbating the patient's dyspnea by causing respiratory depression, but strong evidence exists for the effectiveness and safety of low-dose opioids: At appropriate doses, opioids reduce breathlessness and provide benefit to patients with limited risk of respiratory depression. Because of the anxious state dyspnea often causes and because anxiety worsens dyspnea, an appropriate dose of a benzodiazepine may also be helpful, although never as the principal medication. Environmental measures, such as the breeze from an electric fan on the patient's face or decluttering the room, also can bring relief. It is important to recognize that dyspnea is a subjective sensation and that although the patient may report improved dyspnea, tachypnea, increased work of breathing, and retractions may persist. The goal of managing dyspnea is making the patient feel better, not necessarily look better.

Nausea and Vomiting

Nausea and vomiting are common symptoms in children with complex illnesses and those facing the end of life and are significant sources of distress and discomfort. These conditions can have different etiologies, principally gastrointestinal, CNS, or treatment related. The child with neurologic impairment can experience retching, and many of the medications used in the management of the impairment have nausea among their side effects. Children are especially vulnerable to *anticipatory nausea*, a conditioned behavioral response in anticipation of a medication or procedure that has caused nausea and vomiting in the past. Anorexia can be a symptom of low-grade nausea. An approach to nausea and vomiting based on an understanding of the cause of the symptom exacerbation and of the symptom mechanism can prove valuable. A careful history and physical examination, with special attention to medications and procedures, is crucial.

Although a patient's presentation may be complex, determination of appropriate management may be simplified by understanding the 4 pathways to nausea and vomiting. The vomiting center, which lies in the brain stem, receives input from the chemoreceptor trigger zone (CTZ), the cerebral cortex, peripheral pathways in the gastrointestinal tract, and the vestibular system. The CTZ responds to toxins and medications in blood and spinal fluid; the cerebral cortex responds to sensory input, anxiety, meningeal irritation, and elevated intracranial pressure; peripheral pathways are stimulated by mechanical stretch in intestinal obstruction and by mucosal injury; and the vestibular system is affected by motion and labyrinth disorders. Each pathway involves different neuroreceptors for targeting in mechanism-based therapy.

The CTZ can be suppressed by the blockage of dopamine D_2 receptors with haloperidol, olanzapine, prochlorperazine, chlorpromazine, or metoclopramide hydrochloride. Peripheral pathways can be addressed by identifying the underlying cause and with the blockage of 5-hydroxytryptamine, serotonin 3 receptors by ondansetron hydrochloride. The cortex can be addressed with anxiolytics, attention to sensory stimuli (eg, smells, tastes), and, in cases of elevated intracranial pressure, high-dose steroids. Dronabinol may also be helpful. The vestibular system is managed by blocking muscarinic acetylcholine and histamine receptors with scopolamine, hyoscyamine, and diphenhydramine. Although promethazine hydrochloride is useful in adults, it should be avoided in children because of its implication in sudden death in some individuals in that population.

The symptoms of nausea and vomiting often involve multiple pathways. For instance, opioid-induced nausea and vomiting may be the result of constipation or gastroparesis, stimulation of the CTZ, or sensitization of the labyrinth. Choices must be made about how to approach the possible causes in a stepwise manner. The literature suggests that mechanism-based therapy is more effective, uses a systematic approach that identifies all possible contributors, and encourages the management of underlying causes. It uses medication in a targeted manner, thereby reducing the risk of untoward effects and oversedation. Finally, the risk of extrapyramidal side effects is greater in children than adults, and when using high doses of metoclopramide hydrochloride or the phenothiazines, premedication with diphenhydramine is recommended.

Anorexia

Anorexia is an anticipated symptom at the end of life. Some parents and caregivers have great difficulty with this symptom and can feel overwhelmed by the loss of a concrete expression of their nurturing. They want their child to eat to be better able to fight the illness. Food preparation and feeding the child is something concrete a parent or caregiver can do for their child. Children who are dying want to please their parents or caregivers as much as healthy children if not more so. It is important to acknowledge the feelings behind the desire of parents and caregivers for their child to eat. Small portions of the child's favorite foods or new favorites the child requests may be comforting to all.

Times exist earlier in an illness when it may be appropriate to improve appetite. Cyproheptadine hydrochloride has a long history of safe use in children and has been shown to be helpful in some cases. Megestrol acetate has been shown to be effective in increasing weight but not muscle mass and may be considered in children over the age of 10 years, although use in children has not received US Food

and Drug Administration approval. Although cannabinoids stimulate appetite, they have not been demonstrated to increase weight. The use of steroids, which are likely to improve appetite, often comes at an unacceptable cost of irritability and immunosuppression.

One other consideration related to feeding is whether children are "starving" when they no longer have the desire to eat, a commonly expressed concern of parents and caregivers. Research comparing the anorexia-cachexia syndrome with starvation shows 2 quite different metabolic states. Differences in energy expenditure, protein synthesis and proteolysis, glucose metabolism, and hormonal levels reinforce the belief that anorexia-cachexia is a hypermetabolic state, whereas starvation in the healthy individual is an effort by the body to conserve itself. An understanding of this difference enables the physician to explain to parents or caregivers how the disease is robbing the child's energy and that it is not the fault of their efforts or the lack of food. In fact, research on adults dying of advanced cancer found that even the patients who ate the most lost weight.

Respiratory Secretions

Respiratory secretions are a common symptom in children who are seriously ill. Children with neuromuscular diseases and neurologic impairment can have difficulty managing secretions. The presence of a tracheostomy can further complicate matters. The use of suction- and cough-assist machines is important, particularly in the setting of acute respiratory illnesses that cause increased secretions. In children at this stage of illness, drying agents (eg, glycopyrrolate, atropine, scopolamine, hyoscyamine) are sometimes helpful, but they may increase the risk of acute obstruction by thickening secretions and causing mucus plugging.

Terminal secretions (the "death rattle") are understandably quite distressing to parents and caregivers, although the child is not typically bothered by them. These secretions are not relieved by suctioning, and they often worsen because the stimulus of the suction catheter can reflexively increase saliva and mucosal secretions; however, the obstruction and noise of secretions often respond to repositioning of the head and neck. Drying agents are usually prescribed in this setting. Switching between agents lacks much advantage if the effect is not substantial, although more than 1 agent should be tried. Glycopyrrolate is the only such agent that does not cross the blood-brain barrier and thus, it is the least likely to cause CNS effects such as confusion, agitation, and delirium.

Fatigue

Fatigue is a highly prevalent symptom at the end of life. In a study of children with terminal cancer, 96% were found to have experienced fatigue in their last month. This symptom is especially disheartening, because fatigued children may have the desire to do things that provide a quality of life but not feel up to the task. Fatigue may be caused by illness, treatments, stress, isolation, poor sleep hygiene and circadian disorientation, mood, or the lack of pleasure or activity. The sedative effects of some medications certainly contribute. Sleep, exercise, nutrition, anemia treatment, increased interactions, and activity all have been shown to have a beneficial effect in decreasing fatigue. Medical therapy with methylphenidate hydrochloride or modafinil may be helpful, dosed at lower amounts than typically prescribed for attention-deficit/hyperactivity disorder.

Delirium

Delirium is most simply conceived as organic brain dysfunction and is common at the end of life. The diagnosis of delirium can be challenging, especially in children, because of the vast developmental range. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, diagnostic criteria are a disturbance in attention, a change in cognition, and whose onset is acute and whose intensity fluctuates during the day. Delirium can manifest as hyperactivity (ie, agitated, combative), hypoactivity (ie, withdrawn, appear to be sleeping), and mixed (ie, hyperactive and hypoactive). Given these challenges, use of a validated, behavioral-observational tool is encouraged, such as the *Cornell Assessment of Pediatric Delirium*. It is important to counsel families that delirium can cause disinhibited behavior, commonly seen as increased pain expression. Delirium must be aggressively managed with haloperidol, olanzapine, or quetiapine fumarate to also achieve good pain control.

CASE RESOLUTION

Kayla lived for 4 more months, was never again admitted to the hospital, and until her last days, remained engaged and as playful as her fatigue allowed. Her primary care pediatrician teamed with the pediatric palliative care team at the closest children's hospital and was assisted with many of the decisions about symptom management. In her last days, the patient was on methadone, morphine boluses, lorazepam, citalopram hydrobromide, gabapentin, ondansetron hydrochloride, polyethylene glycol 3350, senna, and as-needed methylphenidate hydrochloride. Her pediatrician made home visits and remained available for evolving symptoms. The pediatrician was in the child's home when the child died.

CHAPTER 15

Complementary and Integrative Medicine in Pediatric Primary Care

Miriam T. Stewart, MD, FAAP, and Erica M.S. Sibinga, MD, MHS, FAAP

CASE STUDY

A 14-year-old girl is brought to your office for follow-up on her migraine headaches. She has no other significant medical history but has experienced intermittent migraine headaches over the past few years. The headaches occur approximately weekly in the evenings, do not wake her from sleep, and improve with ibuprofen (400 mg), which was previously prescribed at your office. At this visit, the girl states that she wishes she did not have to take medication for her headaches. Her mother reports that a family friend has suggested acupuncture or herbs for the headaches and asks whether there are other complementary and integrative medicine (CIM) approaches that they could try.

Questions

1. What are CIM therapies?
2. How does a provider explore if any CIM approaches are appropriate for the treatment of chronic or recurrent conditions, such as headaches, in a child or an adolescent?
3. What is the best way to determine whether a family is using CIM?
4. What is the best way to communicate with a family about CIM therapies?
5. What is the best way to monitor the safety of CIM approaches?

Complementary and Integrative Medicine

Complementary and integrative medicine (CIM) refers to a wide variety of therapies that are not typically part of "conventional" medical approaches. Conventional medicine (sometimes called *Western medicine*) is the general approach of medical doctors, doctors of osteopathy, and allied health professionals. The specific therapies thought of as CIM when compared with conventional medicine may change over time as research on CIM practices grows and those that are found to be of benefit are incorporated into evidence-based conventional medicine.

CIM therapies may be used in a number of different ways. When CIM therapies are used by patients in addition to the therapies recommended by conventional medical providers, they are termed *complementary;* this is by far the most common way CIM therapies are used. *Alternative medicine* refers to therapies used instead of conventional care. Increasingly, health professionals are incorporating both conventional approaches and evidence-based nonconventional approaches into their practice, a practice referred to as *integrative medicine.* Complementary and alternative medicine has been used as the umbrella term to describe CIM, but in view of the rare use of these modalities in place of conventional medicine and the increasing use of an integrative approach, *integrative medicine* is replacing *alternative medicine* in many settings, including the National Institutes of Health (NIH) National Center for Complementary and Integrative Health (NCCIH), formerly known as the National Center for Complementary and Alternative Medicine (NCCAM).

Pediatricians are learning about and using integrative therapies in a variety of ways. Many pediatric clinicians review evidence in the medical literature for specific therapies in certain clinical scenarios and integrate approaches into their clinical practice that show potential for benefit and safety. Interested clinicians may also attend continuing education courses and/or trainings in integrative approaches to gain knowledge and skills that can be incorporated into direct patient care. At many institutions, exposure to integrative medicine has expanded during residency training, including didactic and experiential instruction. In addition, a small but growing number of pediatric clinicians have received extensive training in integrative medicine at the fellowship level. Thus, a broad spectrum of approaches to pediatric integrative medicine currently exists.

Epidemiology

The use of CIM has risen steadily over the past several decades and now comprises a significant subset of health-related visits and expenditures. In 2012, 33.2% of American adults surveyed reported having used some form of CIM in the previous 12 months. Out-of-pocket expenditures for CIM totaled $30.2 billion in 2012, up from $27 billion in 1997. These statistics demonstrate the importance of physician awareness of CIM and support the routine inclusion of questions about CIM in the medical history.

A growing body of evidence reveals that the pediatric population is also using CIM. A large-scale survey of caregivers revealed that approximately 1 in 9 children uses CIM (11.6%). Higher prevalence, up to 60%, has been found among certain populations, such as children with cancer, epilepsy, sickle cell disease, or another chronic disease. The most commonly used CIM modalities are dietary supplements, chiropractic or osteopathic manipulation, yoga, and deep breathing exercises. A survey in 2017 revealed that use of yoga by children and use of meditation by children had increased over the previous 5 years from 3.1% to 8.4% and from 0.6% to 5.4%, respectively. Complementary and integrative medicine therapies are most likely to be used for back or neck pain, head or chest cold, anxiety or stress, and other musculoskeletal conditions. Adolescents are more likely to use CIM than younger children. Other factors associated with CIM use by children include parental education beyond high school; higher household income; coverage by private health insurance; use of prescription medications; and number of health conditions, doctor visits, or school days missed for illness in the past year. Non-Hispanic white patients are more likely to use CIM than Hispanic patients or black patients, although the strength of this association diminishes when data are adjusted for confounding factors. When worry about cost prevents the receipt of conventional medical care, children are more likely to use CIM. The strongest predictor of CIM use by children is CIM use by a parent; children whose parents use CIM are 5 times more likely to use CIM. When discussing CIM with families who are using it for their children, pediatricians need to be aware that parents may also be using CIM.

Motivations for Using CIM

Complementary and integrative medicine can be used for health maintenance; for symptomatic relief, as an adjunct to curative conventional medical care; for relief from adverse effects of conventional medical care; or in place of conventional medical care. Families choose to use CIM for many reasons. Word of mouth and belief in the efficacy of the treatment can be strong motivators. Some parents express a desire for more options and feel a sense of empowerment in their parental role as a result of CIM use. Complementary and integrative medicine may also be more congruous with a family's values, philosophies about health, and understanding of the basis of disease. Parents may fear the adverse effects of conventional medications or be dissatisfied with the care their child receives in conventional medical settings. Families may seek the additional personal attention afforded by CIM providers. For some families, CIM offers additional hope when conventional medical care fails. Underlying all these motivations is the desire for the child's health and well-being and the quest for safe and effective treatments of disease. Physicians and families can find common ground in this most basic of motivations, which can inform conversations about CIM and conventional medical care.

CIM Categories

Complementary and integrative medicine therapies can be thought of as falling into 5 categories: whole medical systems, mind-body therapies, biomechanical therapies, bioenergetic therapies, and biochemical therapies (Table 15.1). Besides whole medical systems, these categories are chosen to reflect purported similarities in the underlying mechanism of effect. A particular therapy may be used as part of a whole medical system approach or on its own. For example, acupuncture may be part of an individualized, comprehensive traditional Chinese medicine (TCM) treatment approach, also consisting of herbs and lifestyle recommendations, or a standardized acupuncture treatment may be used without evaluation and treatment by a TCM provider, in which case it can be thought of as a bioenergetic therapy. In addition, a particular therapy may belong to more than 1 category; for example, herbal preparations may have a biochemical and placebo (mind-body) effect.

Whole Medical Systems

Whole medical systems, including conventional medicine, are whole-system approaches to treatment, consisting of an underlying theory of healing, standardized training, and diagnostic and treatment approaches reflective of the underlying theory. For instance, TCM is based on the theory that illness and symptoms result from yin-yang energy imbalances. These energy imbalances are diagnosed through history and physical examination and treated by altering the energy balance using acupuncture (or other mechanical or thermal stimuli), herbs, and lifestyle changes (eg, diet, sleep, physical activity).

Mind-Body Therapies

Mind-body therapies are intended to enhance the mind's ability to benefit health. A number of mind-body therapies are integrated into conventional medical treatment, such as psychotherapy, group therapy, imagery, and biofeedback. Others are still considered CIM, such as meditation and hypnotherapy.

Biomechanical Therapies

Biomechanical therapies aim to improve health through physical manipulation of the body. This may involve working with muscles (as with massage) or spinal alignment (as with chiropractic and osteopathic approaches). Massage therapies range from relatively light muscle work to deep tissue massage and may be incorporated into physical therapy to work with muscles and joints. Spinal manipulation therapies are used commonly in the United States and are most often practiced by chiropractors or doctors of osteopathy.

Table 15.1. Selected Examples of Complementary and Integrative Medicine Therapies by Category			
	Modality	***Description: At a Glance***	***Licensure and Regulation***
Whole Medical Systems	Ayurveda	Originated in India several thousand years ago and is still used by 80% of the population exclusively or in combination with Western medicine. Health and disease are thought to relate to a person's constitution (prakriti), which is composed of a unique combination of the 3 life forces (doshas). Imbalances between the doshas can lead to disease. Treatments are tailored to the individual's unique constitution and are aimed at eliminating impurities, reducing symptoms, increasing resistance to disease, reducing worry, and increasing harmony in the patient's life. Treatments include herbs, vitamins and minerals, massage, yoga, enemas, and specialized diet and lifestyle recommendations.	Ayurvedic medicine is not accredited in the United States, although several states have accredited Ayurvedic schools. In India, Ayurvedic medicine can be studied at the bachelor and doctorate levels.
	Native American healing	Broad term that encompasses the healing traditions of hundreds of indigenous tribes. Has been practiced in North America for >40,000 years. Can combine religion, spirituality, herbal medicine, shamanic healers, purification activities, and symbolic rituals in the treatment of medical and emotional problems. Treatments may be individual or may involve the entire community. Treatment is often a slow process that is spread over days and weeks. There is a strong belief in the therapeutic value of the relationship with the healer.	There is no government oversight of education of or licensure for Native American healers.
	Naturopathy	Developed in Germany and the United States in the late 19th to early 20th centuries. Central belief is that nature has healing power; practitioners view their role as supporting the body's inherent ability to restore health. Naturopathic practitioners strive to use the most natural, least invasive approach to restore and maintain health. Treatment modalities used by naturopaths include nutrition, vitamins and minerals, herbal medications, homeopathy, therapeutic massage and joint manipulation, hydrotherapy, exercise, and lifestyle counseling.	Naturopathic physicians (ND or NMD degree) complete a 4-year graduate-level program at a naturopathic medical school accredited by the Council on Naturopathic Medical Education, which is recognized by the US Department of Education. States vary in their licensing of naturopathic physicians and the scope of naturopathic practice, including the ability to prescribe drugs, perform minor surgery, and assist in childbirth. The American Association of Naturopathic Physicians (www.naturopathic.org) is the national professional society of naturopathic physicians.
	TCM	Originated in China >5,000 years ago; rooted in the Taoist philosophy. TCM practitioners view the human body and mind as an integrated whole in which tissues, organs, and parts function interdependently. Yin-yang theory—the concept of 2 opposing but interdependent forces that shape the world—is a core principle. Health and disease relate to balance between yin and yang in the body. Treatments to restore balance include herbs, massage, acupuncture, diet, and exercises such as tai chi and qigong.	Most states license acupuncture but vary in their inclusion of other TCM treatments in licensure. Acupuncture and TCM schools are accredited by the federally recognized Accreditation Commission for Acupuncture and Oriental Medicine.

(*Continued*)

Table 15.1. Selected Examples of Complementary and Integrative Medicine Therapies by Category (*continued*)

	Modality	*Description: At a Glance*	*Licensure and Regulation*
Mind-Body Therapies	Biofeedback	Technique that trains people to improve their health by controlling certain bodily processes that typically happen involuntarily, including heart rate, blood pressure, muscle tension, and skin temperature. Biofeedback practice involves attaching the patient to electrodes (or other monitoring devices) that monitor the desired process (eg, muscle tension, skin temperature). The therapist leads the patient in exercises designed to assist in controlling the desired variable, while the electrodes provide real-time feedback on the patient's success. Biofeedback is used to treat a variety of conditions, including high blood pressure, headaches, chronic pain, and urinary incontinence.	The Biofeedback Certification International Alliance certifies individuals who have met their educational and training standards, which include didactic training, supervision hours, patient sessions, and case manifestations. Treatment of pelvic floor muscle dysfunction is a subspecialty within biofeedback that requires specialized training. Only licensed health care professionals may apply for certification in this specialty.
	Hypnotherapy	Hypnotherapists use exercises that bring about deep relaxation and an altered state of consciousness, also known as a trance. Through hypnosis, people learn how to master their own states of awareness. By doing so, they can affect their own bodily functions and psychological responses. Hypnotherapy has been studied in treatment of a number of conditions, including state anxiety (eg, before medical procedures or surgeries), headaches, smoking cessation, pain control, hot flashes in breast cancer survivors, and irritable bowel syndrome. It is also used in managing pain during childbirth.	Most hypnotherapists are licensed MDs, registered nurses, social workers, or family counselors who have received additional training in hypnotherapy. Several national bodies provide training certificates. The American Society of Clinical Hypnosis (www.asch.net) is the largest organization of health care professionals using clinical hypnosis and provides hypnotherapy training.
	Meditation and mindfulness	There are many types of meditation, most of which originated from ancient religious and spiritual traditions. Some of these include mindfulness meditation, transcendental meditation, and Zen Buddhist meditation. Through meditation, a person learns to focus attention. Some forms of meditation instruct the practitioner to become mindful of thoughts, feelings, and sensations and to observe them in a nonjudgmental way. Meditation is believed to result in a state of greater calmness, physical relaxation, and psychological balance and can change how a person relates to the flow of emotions and thoughts. Meditation has been studied in a variety of populations and is used for general wellness and various health problems, including anxiety, pain, depression, stress, insomnia, and physical or emotional symptoms that may be associated with chronic illnesses such as AIDS and cancer.	There is a broad diversity of meditation practices, each of which may have its own training programs and certification policies. There is no national or state-based accreditation for meditation practitioner education or licensing. However, meditation programs may be eligible for continuing education credits toward licensing for health care professionals. The University of Massachusetts Medical School Center for Mindfulness in Medicine, Health Care, and Society (www.umassmed.edu/cfm) is a long-standing mindfulness program associated with an academic institution and is a source of training and research on mindfulness and mind-body medicine.
	Yoga	Yoga practice was developed in ancient India, with fully developed practice appearing around 500 BCE. There are numerous branches or paths of yoga. Derived from the Sanskrit word meaning "union," yoga strives to connect the body, breath, and mind with the goal of energizing and balancing the whole person. Yoga practice can be individual or class based and consists of physical postures (asanas), breathing exercises, and meditation. Yoga is used for maintaining health and has also been studied in treatment of a wide variety of conditions, including anxiety, arthritis, asthma, cancer, back pain, diabetes, heart disease, pregnancy (when modified for pregnancy), and chronic headaches.	There is no government oversight of yoga training or practice. Numerous organizations and training programs in the United States and worldwide offer training. The Yoga Alliance (www.yogaalliance.org) is the most widely recognized educational and professional organization for people who teach yoga in the United States. It accredits yoga training programs using a minimum training standard. Teachers who complete Yoga Alliance–accredited training are eligible to become Registered Yoga Teachers.

Table 15.1. Selected Examples of Complementary and Integrative Medicine Therapies by Category (*continued*)			
	Modality	***Description: At a Glance***	***Licensure and Regulation***
Biomechanical Therapies	Alexander technique	Educational method that emphasizes changing faulty postural habits to improve mobility and performance. Treatment has 2 components: table work (hands-on manipulation) and guided activity, in which the practitioner observes the person in action and gives verbal, visual, and physical cues to help the person perform the activity with greater ease. People use the Alexander technique to improve performance in performing arts and sports as well as in treatment of musculoskeletal problems, repetitive stress injuries, and chronic pain.	To be certified by the American Society for the Alexander Technique (www.amsatonline.org), practitioners must complete 1,600 hours of training over 3 years. There is no government oversight of training or licensure.
	Chiropractic care	Developed in the United States at the end of the 19th century. Based on the notion that the relationship between the body's structure—most notably the alignment of the spine—and its coordination by the nervous system affects health. People most often seek chiropractic care for musculoskeletal concerns (back, neck, and shoulder pain), headaches, and extremity problems. Hands-on spinal adjustment and manipulation is a core treatment in chiropractic care, but treatment can also include heat and ice, electrical stimulation, exercise, and counseling about diet, exercise, and lifestyle.	Chiropractic practitioners must meet the licensing and continuing education requirements of the states where they practice. All states require chiropractors to complete a DC degree at an accredited college The American Chiropractic Association (www.acatoday.org) is the largest professional organization representing DCs.
	Feldenkrais Method	A method of somatic education that uses gentle movement and directed attention toward movement patterns to expand movement options and improve functioning. Treatment can be carried out via verbal guidance in a class setting or with hands-on gentle manipulation. People use the Feldenkrais Method to maintain well-being and enhance performance in performing arts and athletics, as well as in the treatment of a variety of conditions, including multiple sclerosis, stroke, cerebral palsy, and repetitive stress injuries.	Feldenkrais Method practitioners must complete 700–800 hours of training over 3–4 years to apply for certification. Certification and training is governed by the Feldenkrais Guild of North America (www.feldenkrais.com). There is no government oversight of training or licensure.
	Massage therapy	Massage therapy has been in use for thousands of years in diverse cultures, including those of China, Japan, India, Egypt, and Europe. The term *massage therapy* encompasses >100 distinct techniques, but the core practice is manipulation of the muscles and soft tissues of the body using the hands and fingers. People use massage for general wellness, as well as to treat a wide range of conditions, including sports injuries, stress, pain, musculoskeletal concerns, anxiety, and depression.	Most states have laws regulating massage therapy and typically require a minimum number of training hours and passage of a national examination. Massage training can be accredited by state boards or an independent agency. The National Certification Board for Therapeutic Massage and Bodywork (www.ncbtmb.org) certifies massage practitioners who pass a national examination. The American Massage Therapy Association (www.amtamassage.org) is the nation's largest professional organization for massage practitioners.
	Osteopathy	Developed in the United States at the end of the 19th century. Core principle is that disease and illness begin with structural problems in the spine and result in abnormalities in the function of the nervous system. DOs not only receive conventional medical training but are also trained in osteopathic manipulation techniques and craniosacral therapy, both of which involve hands-on manipulation of bones and tissues. People seek care from DOs in conventional medicine and specifically for musculoskeletal conditions.	DOs complete a 4-year training program in conventional medicine and osteopathy and also complete medical residencies in their specialty of choice. DOs are recognized for full practice rights in all 50 states once they are licensed. The American Osteopathic Association (http://osteopathic.org) is the primary professional organization and accreditation agency for DOs in the United States.

(*Continued*)

Table 15.1. Selected Examples of Complementary and Integrative Medicine Therapies by Category (*continued*)

	Modality	*Description: At a Glance*	*Licensure and Regulation*
Bioenergetic Therapies	Acupuncture	Acupuncture is a modality of TCM. The earliest recorded use of acupuncture dates from 200 BCE. The core principle of acupuncture is the belief that a particular type of life force or energy (chi) circulates through the energy pathways (meridians) in the body. Chi maintains the dynamic balance of yin and yang. An imbalance of chi can cause symptoms and disease. Acupuncture treatment involves stimulation of specific points along the meridians using pressure (acupressure), thermal energy (moxibustion), or very fine acupuncture needles. Acupuncture has been studied in treatment of a variety of conditions, including chronic pain, postsurgical recovery, chemotherapy-related nausea, musculoskeletal problems, headaches, substance use, asthma, and menstrual problems.	Most states require a license to practice acupuncture, although licensing and education standards vary from state to state. Licensure confers the degree of LAc. In 1997, the NIH recognized acupuncture as a mainstream medicine healing option with a statement documenting the procedure's safety and efficacy for treating a range of health conditions. The American Academy of Medical Acupuncture (www.medicalacupuncture.org) maintains a database of licensed physicians who are also trained to perform acupuncture.
	Homeopathic remedies	Developed by a German physician at the end of the 18th century. Based on 2 core principles: the principle of "similars" ("like cures like") states that a disease can be cured by a substance that produces similar symptoms in a healthy person, and the principle of dilutions ("law of minimum dose") states that the lower the dose of the medication, the greater its effectiveness. Homeopathic remedies are so dilute that few or no molecules of the healing substance remain in the diluent. It is believed that the substance has left its imprint, which stimulates the body to heal itself. Homeopathic remedies are derived from natural substances that come from plants, minerals, or animals.	Homeopathic remedies are prepared according to the guidelines of the *Homoeopathic Pharmacopoeia of the United States,* which was written into federal law in 1938. The US FDA requires that homeopathic remedies meet legal standards for strength, purity, and packaging, but because they contain little or no active ingredients, they are not subject to the same safety and efficacy testing as other over-the-counter medications. If a homeopathic remedy is claimed to cure a serious disease such as cancer, it needs to be sold by prescription.
	Reiki	Developed in Japan in the early 20th century. Based on the idea that a universal energy supports the body's innate healing abilities. Practitioners seek to access this energy, allowing it to flow to the body and facilitate healing. During treatment, the practitioner's hands are placed lightly onto or just above the client's body, palms down, using a series of 12–15 hand positions to promote the flow of energy. Each position is held for 2–5 minutes. People use Reiki for relaxation, stress reduction, symptom relief, and general well-being. It can also be used to help promote peace at the end of life.	No licensing or government accreditation exists for the training or practice of Reiki. Multiple organizations offer training programs and certifications.
	Tai chi	Originated in ancient China as a component of TCM. Rooted in the principles of yin-yang balance and the balanced flow of a vital life force or energy (chi). There are many different styles, but all involve slow, deliberate movements that flow into each other. Meditation, deep breathing, and maintenance of good posture during continuous movement are foci of the practice. People use tai chi to improve overall fitness, balance, coordination, and agility. It is also used to treat chronic pain, gout, heart disease, high blood pressure, arthritis, osteoporosis, diabetes, headaches, and sleep disorders.	No licensing or government accreditation exists for the training or practice of tai chi. A variety of organizations offer training programs and certification in tai chi.

Table 15.1. Selected Examples of Complementary and Integrative Medicine Therapies by Category (*continued*)			
	Modality	***Description: At a Glance***	***Licensure and Regulation***
	Therapeutic touch	Developed in the 1970s in the United States. Based on the belief that problems in the patient's energy field that cause illness and pain can be identified and rebalanced by a healer. The technique consists of using the hands to release harmful energy and direct healthy energy for healing purposes. During a session, the hands are held 5–15 cm (2–6 in) away from the body and there is no direct physical contact between practitioner and patient.	No licensing or government accreditation exists for the training or practice of therapeutic touch. Multiple organizations offer training programs, including some hospitals. Many therapeutic touch practitioners are nurses or other licensed health care professionals.
Biochemical Therapies	Nutritional approaches	Nutritional approaches are an integral part of many whole medical systems, including Ayurveda, TCM, and naturopathy (see the Whole Medical Systems section in this table). Numerous specialized diets have been promoted as offering benefits of health maintenance, weight loss, or treatment of disease. Examples of diets that have demonstrated evidence of benefit in adult randomized controlled trials include the DASH (Dietary Approaches to Stop Hypertension) diet, low carbohydrate diets (such as the Atkins diet), the Mediterranean diet, and a plant-based diet. Few specialized diets have been studied in treatment of the pediatric population.	Certification of registered dieticians is controlled by the Academy of Nutrition and Dietetics (www.eatright.org). Forty-seven states currently regulate licensure and certification of dieticians. Dieticians in Integrative and Functional Medicine is a specialty practice group within the Academy of Nutrition and Dietetics composed of practitioners who self-identify as using an integrative approach to nutrition (https://integrativerd.org).
	Dietary supplements	Dietary supplements contain ≥1 dietary ingredient, including vitamins, minerals, herbs, or amino acids, or their constituents. Herbal medications are considered a subset of dietary supplements in the United States. Some dietary supplements have been proven to prevent or treat disease (eg, folic acid in the prevention of neural tube defects, calcium and vitamin D in the prevention of osteoporosis), while other claims about dietary supplements are unproven. The most commonly used dietary supplements are fish oil, *Echinacea,* flaxseed, ginseng, multivitamins, vitamins E and C, calcium, and vitamin B complex.	In the United States, dietary supplements can be sold without being tested to prove they are safe and effective. They must be made according to good manufacturing practices. In the United States, no organization regulates the manufacture or certifies the labeling of dietary supplements.
	Herbal medicine	Herbal medicine refers to using a plant's seeds, berries, roots, leaves, bark, or flowers for medicinal purposes. Plants have been used for medicinal purposes since long before recorded history in a wide range of human cultures. According to the World Health Organization, 80% of the world's population relies on herbal medications for some part of their primary care. Nearly one-third of Americans use herbs. The most commonly used herbal supplements in the United States include *Echinacea,* St. John's wort (known botanically as *Hypericum perforatum)*, gingko, garlic, saw palmetto, ginseng, goldenseal, chamomile, feverfew, ginger, valerian, evening primrose, and milk thistle. Herbal remedies are used in conventional medicine as well as a variety of CIM practices, including naturopathy, TCM, Ayurveda, and Native American healing. Many people also use herbal remedies on their own, without the advice of a health care professional.	In the United States, herbal supplements are classified as dietary supplements and can thus be sold without being tested to prove they are safe and effective. They must be made according to good manufacturing practices. In the United States, no organization regulates the manufacture or certifies the labeling of herbal preparations.

Abbreviations: BCE, before the Common Era; CIM, complementary and integrative medicine; DC, doctor of chiropractic; DO, doctor of osteopathy; FDA, Food and Drug Administration; LAc, licensed acupuncturist; MD, medical doctor; NCCIH, National Center for Complementary and Integrative Health; ND, naturopathy doctor; NIH, National Institutes of Health; NMD, naturopathy medical doctor; TCM, traditional Chinese medicine.

Information in this table is adapted from the health topics pages at the NCCIH website (https://nccih.nih.gov) and the American Cancer Society "Complementary and Alternative Medicine" page (www.cancer.org/Treatment/TreatmentsandSideEffects/ComplementaryandAlternativeMedicine/index).

Bioenergetic Therapies

Bioenergetic therapies are directed at improving health through altering the body's energy as it runs through, on, or around the body. Because conventional training does not include the concept of energy in this way, bioenergetic therapies tend to draw skepticism from conventional medical providers. With increasing scientific evidence of its beneficial effects, acupuncture is purported to affect the body's vital energy (chi) as it courses through energy channels called *meridians.* In 1997, an NIH consensus panel declared the evidence sufficient for integration of acupuncture into a number of conventional treatments, including treatment of chemotherapy-associated nausea and emesis, anesthesia-associated nausea and emesis, and pain syndromes. Homeopathic remedies are theoretically bioenergetic therapies, as the "ingredients" are successively diluted beyond the point of significant molecular presence; therefore, it is the resulting change in the energy of the diluents (sometimes called the "memory of the molecule") that is responsible for the therapeutic effect. In addition, a number of therapies aim to affect energy at or near the surface of the body, including therapeutic touch and Reiki, both of which involve a trained practitioner identifying the energy imbalance and directing the patient's own energy to improve the patient's energy balance and promote healing.

Biochemical Therapies

Biochemical therapies are intended to improve health through their biochemical effects and include nutritional approaches, herbal remedies, and dietary supplements. Nutrition is an important part of many CIM approaches, such as Ayurveda, TCM, and naturopathy, and is also an accepted part of the conventional medicine approach to disease prevention and treatment. As the body of research on integrative nutritional approaches has grown, some interventions that originated as integrative approaches, such as the Mediterranean diet, have become part of evidence-based conventional medicine. Herbal remedies and dietary supplements are conceptually related to the biochemical mechanism of effect of conventional medications but have a few important differences. First, herbal remedies are by nature complex mixtures of chemicals, so their effects are likely caused by multiple biochemical reactions. Second, there is currently no federal regulation or oversight of the production of herbs or supplements in the United States, as there is with pharmaceuticals, so quality control is extremely variable. Third, safety concerns are addressed not before they are available commercially to consumers, as with pharmaceuticals, but only after products are on the market and adverse events are reported to the US Food and Drug Administration. Because of the lack of oversight of production and premarket safety, it is important for practitioners to research not only the evidence of an herb's effect and potential adverse effects but also the particular formulation's production and quality control.

Approaching CIM Use From a Conventional Medicine Perspective

As with any treatment option, the safety (risks) and efficacy (benefits) of a CIM modality must form the basis for therapeutic decision-making about its use. Table 15.2 can be a helpful guide in directing physician responses to a particular CIM therapy.

Table 15.2. Guide to Complementary and Integrative Medicine Treatment Recommendations

		Is the Therapy Effective?	
		Yes	**No**
Is the Therapy Safe?	**Yes**	Recommend	Tolerate
	No	Monitor closely or discourage	Discourage

If there is insufficient evidence to assess safety or efficacy

- Establish a plan with the family for monitoring response to treatment.
- Discourage if adverse reactions develop.
- Tolerate if no adverse reactions develop.

Assessing Efficacy

Data on the efficacy of CIM treatments are increasingly available as CIM becomes a greater focus of research effort and funding in the United States and worldwide. When searching the medical literature for CIM evidence, international and foreign-language articles can be useful, as certain CIM modalities may have been studied in greater depth or over a longer period in other countries. As with any research data, it is important to consider study design, outcome measures, sources of bias, methods of data analysis, and applicability of results for a given indication, patient, or patient population. With herbal remedies and supplements, it is also important to acknowledge that formulations differ, so efficacy as reported in a clinical trial may be altered if a different formulation is used.

Assessing Safety

The huge diversity of CIM makes it difficult to discuss safety in general terms. Each CIM modality has its own unique risk profile. However, awareness of broad categories of risk can help physicians prevent bad outcomes.

- *Delay of conventional care:* In studies of CIM risks for the pediatric population, the risk associated with the highest morbidity and mortality rates is delay of conventional care. This delay can come about for a number of reasons, including a family's perception that care from a CIM provider obviates the need for conventional care, a family's inability to afford conventional care, or a family's belief that conventional care will be harmful. It may be helpful to contract with families that they will seek conventional care before or in conjunction with CIM care for a new symptom or acute illness to rule out disease processes that require conventional treatment.
- *Drug-drug interactions:* Certain supplements and herbal remedies may interfere with or alter the effects of conventional medications. Particular attention has been given to substances that are inhibitors or inducers of hepatic drug metabolism by the cytochrome P-450 enzymes, with St. John's wort (used for depression; known botanically as *Hypericum perforatum*) and grapefruit juice being the most well-known examples. See the Resources for Physicians section for online

resources for checking drug-drug interactions with herbal remedies and supplements.
- *Adverse reactions:* Allergic reactions, adverse effects, and idiosyncratic reactions are possible with CIM therapies as well as conventional therapies. Close follow-up is helpful in monitoring response to therapy.

Regulation and Licensure

Licensure and accreditation for CIM providers varies from state to state. Chiropractic care, massage therapy, acupuncture, naturopathy, and homeopathy have licensing bodies in some states. In states where licensing exists for a CIM modality, it is incumbent on the physician to ensure that any referrals are made to licensed practitioners. None of these licenses authorizes the practitioner to practice medicine. Other CIM modalities may have a national organization that supervises training and certifies practitioners. Although these are not subject to government oversight, there still may be value in preferentially seeking out providers who are approved by their national organization, as these providers have had to meet a standard established by their colleagues.

Regulation of herbal remedies and supplements is the subject of ongoing scrutiny and debate. Currently, the US Food and Drug Administration does not regulate production or marketing of these products, so it is often difficult to verify their composition, safety, or efficacy unless they have been independently studied. The burden of researching products and manufacturers falls to the consumer.

Communication About CIM Use

Most caregivers of children who use CIM do not disclose this use to their pediatrician despite that most report a desire to discuss it. The high rate of nondisclosure is alarming, as it places patients at risk for drug-drug interactions with conventional medications, robs physicians of the opportunity to monitor for adverse reactions, and interferes with the development of trust in the patient-physician relationship. Reasons cited by patients and caregivers for nondisclosure include
- Negative experiences with past disclosures to physicians.
- Fear of disapproval or judgment on the part of physicians.
- Belief that physicians do not need to know.
- Lack of time with physicians.
- Physicians do not ask.

Many of these barriers can be addressed by the physician.

Physicians may be reticent to discuss CIM, as evidenced by the fact that CIM discussions are patient initiated in most cases. Physicians may worry about legal liability if there is a bad outcome. They may fear conflict with families over use of CIM. They may be afraid to reveal their lack of knowledge about CIM and may worry that this lack of knowledge will threaten a family's trust in their abilities. They may feel pressured by time constraints and overwhelmed by the need to acquire new knowledge. There is often a disconnect between the meaning that patients and families attribute to CIM use (more options and a greater sense of empowerment) and the meaning that physicians may attribute to it (irrationality given lack of evidence and the threat of interference with conventional medical care). This disconnect can influence patients and physicians to avoid the subject of CIM.

Communication Tips

Effective communication about CIM use is a wonderful opportunity to improve rapport and better understand a patient and family (Box 15.1). Communication can be a powerful tool for ensuring safety and reducing harm, as well as for broadening physician knowledge and building trust with families. Even if they do not initiate or recommend a CIM treatment, pediatricians can play an important role by monitoring a child's response to the treatment over time and engaging the family in a discussion about risks and benefits if adverse reactions arise. Discussion about CIM may also bring about a greater understanding of families' explanatory models of illness as well as their expectations of health care professionals and their beliefs about conventional medications. Deeper insight into a family's health beliefs and values can facilitate a more successful patient-physician partnership and better patient care.

Box 15.1. Complementary and Integrative Medicine Communication Tips

- Make questions about complementary and integrative medicine (CIM) use a routine part of the medical encounter.
- Pose questions about CIM use in an open and nonjudgmental way. For example, "For me to take the best possible care of your child, it is helpful to know about all the ways your family manages health and illness. Are there any treatments, medications, herbs, or supplements that your child uses but we have not talked about yet? Does your child see any other providers for health-related care or treatments?"
- Explore details of CIM use. Ask families not only what CIM modalities they are using but also why they chose each treatment, how it works, whether they have noticed a difference, and if there have been any downsides to the treatment.
- Validate the family's desire for health and well-being for their child.
- Do not be afraid to acknowledge the limits of your knowledge. If asked to provide a recommendation about an unfamiliar CIM modality, offer to do further research, and revisit the question at a follow-up visit.
- Seek out information about CIM, including literature on safety or efficacy.
- Involve families in the thinking process of comparing risks with benefits of a CIM intervention or modality. Provide evidence-based advice when possible. If there is little or no evidence to support or discourage use of a CIM modality, share this information with families.
- Make a plan with families to monitor their child's response to treatment, including measurable outcomes (eg, symptom relief, increased quality of life) and any adverse effects.
- Encourage families to share information about CIM use continually, even if they choose to continue a treatment about which you have raised concerns.
- Document CIM-related discussions in the medical record.

CASE RESOLUTION

Explaining that CIM is not your area of expertise, you ask the family to return in 1 week to discuss this further. After consulting the NCCIH website and conducting a brief review of the medical literature, you find that there are data on efficacy and safety of CIM therapies for migraine headache prevention, including acupuncture and self-hypnosis. At the follow-up visit, you discuss these options with the family. The girl is interested in both modalities but decides to try acupuncture first. You offer her support for this choice and ask that she keep close track of her headaches and return in 1 month to let you know how she is doing with the acupuncture treatments and her headaches.

Resources for Physicians

CAM on PubMed
https://nccih.nih.gov/research/camonpubmed
The NCCIH provides a link to a PubMed search box that is limited to the CIM subset of PubMed.

Cochrane Complementary Medicine
https://cam.cochrane.org/evidence
Link to more than 700 Cochrane reviews on CIM interventions. The Cochrane Collaboration is an independent, international network of leaders in the health care field who are committed to helping health care professionals make evidence-based decisions. Subgroups devoted to specific topic areas produce systematic reviews of available evidence of health-related interventions. The CIM-related subgroup is coordinated through the University of Maryland School of Medicine Center for Integrative Medicine.

ConsumerLab.com
www.consumerlab.com
This for-profit organization carries out independent testing of dietary supplements and herbal remedies by request of manufacturers and for the benefit of the public. In either case, samples for testing are obtained not directly from the manufacturer but from the consumer marketplace. The ConsumerLab.com seal that appears on vitamin bottles can be purchased by manufacturers once their product has been tested by ConsumerLab.com.

Medscape Drug Interaction Checker
https://reference.medscape.com/drug-interactionchecker
Free website that offers users the opportunity to look up drug-drug interactions and includes herbal supplements as well as conventional prescription and over-the-counter medications.

National Center for Complementary and Integrative Health at the National Institutes of Health
https://nccih.nih.gov
The NCCIH is the federal government's lead agency for scientific research on CIM. The website provides information about CIM modalities for providers and patients, results of clinical trials supported by NCCIH, lists of ongoing trials, and information about training and funding opportunities in the field of CIM.

Natural Medicines (Product Information)
https://naturalmedicines.therapeuticresearch.com
Subscription-based site that includes evidence-based information on CIM modalities as well as online tools to check for drug-drug interactions.

NSF International
www.nsf.org/services/by-industry/nutritional-products
An independent organization that tests and certifies a wide range of products and systems, including dietary supplements. Before certifying a product, NSF International performs toxicology tests to ensure that the contents match what is on the label and that the product does not contain unhealthy levels of contaminants such as heavy metals, pesticides, or herbicides.

USP
www.usp.org/dietary-supplements-herbal-medicines
A nonprofit organization that develops and publishes standards for strength, quality, and purity of drugs, dietary supplements, and food ingredients. Dietary supplements must meet these standards to display a USP Verified Mark on their labels.

CHAPTER 16

Principles of Pediatric Surgery

Roxanne L. Massoumi, MD, and Steven L. Lee, MD, MBA, FACS, FAAP

CASE STUDY

A 4-month-old boy is evaluated by his pediatrician for swelling in the groin and is diagnosed with a right inguinal hernia. His parents are told that their child will be referred to a pediatric surgeon. The parents are concerned about surgery in such a young infant and ask their pediatrician multiple questions. Is he big enough to have surgery? Will he be able to eat before the surgery? Will he be in pain? Will he need to have blood drawn? Will he need to be hospitalized? Will he be put to sleep for the procedure?

Questions

1. What are the typical questions parents ask if their child is undergoing surgery?
2. What is the role of the primary care physician in advising patients and parents about surgical procedures?
3. What is the role of the surgeon in advising patients and parents about the surgery?
4. What are general guidelines for feeding infants and children prior to surgery?
5. What are the risks of general anesthesia in infants and children?
6. How long is the hospitalization after surgery?
7. How do physicians prepare children who are about to undergo surgery?
8. What laboratory studies are needed prior to surgery?

No matter the age of the patient, the prospect of surgery is generally anxiety-provoking for the patient and the patient's parents. As with any stressful patient encounter, communication is the key to educating, calming, and reassuring patients and their parents. This is particularly true in case in which patients are being referred, even initially, for surgical consultation. Pediatricians can provide significant support by giving the parents basic information about surgical care. It is also important for primary care physicians and surgeons to communicate with each other to provide the highest level of care.

Preoperative Care

Initial Consultation

When a surgical problem is suspected, the first task of the primary care physician is to initiate a referral to a pediatric or general surgeon. The purpose of the initial surgical visit is to confirm the diagnosis and discuss surgical and, if applicable, nonsurgical, treatment options. Surgical procedures are rarely performed during this consultation, and this fact should be stressed by the primary care physician prior to the surgical consult. Many children and parents mistakenly think that surgery will occur at the time of the first encounter and are therefore unduly anxious. Some parents even schedule time off from work unnecessarily with the expectation of having to provide postoperative care for their child, and they become disappointed and even angry when the surgery is not performed. Sometimes the diagnosis of the primary care pediatrician is incorrect, in which case the surgeon can reassure parents about the correct diagnosis and advise them that surgery is not necessary.

The parents and children are given a significant amount of information during the surgical consultation. A referring diagnosis is either confirmed or not, and a decision is made about whether the patient requires an operation. If surgery is indicated, it is described in detail to the parents and, if age-appropriate, to the patient as well. A thorough review of the risks and benefits of as well as any alternatives to the procedure is undertaken. An estimate of how long the procedure will take is given. A general discussion on the expected recovery is conducted, such as whether the procedure will be performed as outpatient or inpatient, where hospitalization occurs, how long the child will miss school, and whether any activity restrictions exist.

Parents and patients should be encouraged to compile a list of questions before their first clinic visit to make sure that questions are not left unanswered. Parents and patients should also write down the answers to refer to them at a later time. Typical questions include the length of time of the procedure itself, the use of anesthesia, and the length of recovery time. If parents agree to proceed with surgery, the surgeon starts the process and paperwork. Often, this is the only visit required before the date of the operation. However, some hospitals require patients to be seen by the surgeon within 30 days of the procedure; thus, a return visit may be required if the date of surgery is beyond that time frame. Additionally, some hospitals and surgery centers require patients to undergo a preoperative evaluation by the anesthesia team prior to surgery.

Preparation of Anesthesia for Infants and Children

Anesthesia is extremely safe in infants and children, and the risk of a poor outcome from general anesthesia is less than 1% at most institutions. Specialized pediatric anesthesiologists provide anesthetic care for infants and young children. If a pediatric anesthesiologist is not available, anesthetic care for infants and children is often limited to a set of experienced general anesthesiologists. Parents and patients often experience anxiety about undergoing anesthesia. Videos have been created and are available at many institutions to help explain the anesthesia process. These videos have been shown to increase medical knowledge and decrease anxiety about undergoing anesthesia.

Many types of anesthesia exist, including moderate sedation (ie, conscious sedation), regional anesthesia, and general anesthesia. Typically, the type of anesthesia is determined by the surgeon and anesthesiologist; however, the anesthesiologist makes the final decision. Although the least amount of anesthesia is desired, all patients must be treated as though they may require general anesthesia in case moderate sedation or regional anesthesia is inadequate to provide the required anesthesia for the individual operation.

To minimize the risk of aspiration when undergoing general anesthesia, the stomach must be empty of food and liquids. Although each hospital has its own specific policies, Box 16.1 lists frequently recommended guidelines for the interval between meals and surgery. In general, most infants and children must miss 1 meal before surgery. Often, it is possible to replace this meal with clear liquids.

All medications should be continued unless otherwise directed by the surgeon or anesthesia staff, and they can be taken with a small sip of water on the morning of surgery. It is also recommended that the parents or guardians bring a list of the child's medications on the day of the operation so that the surgical staff can review the list preoperatively.

Box 16.1. Guidelines for the Interval Between Eating/Drinking and Surgery in Infants and Children

<6 Months of Age

- 4 hours for human milk/formula
- 2 hours for clear liquids[a]

6–36 Months of Age

- 8 hours for solids
- 6 hours for human milk/formula
- 2 hours for clear liquids[a]

>36 Months of Age

- 8 hours for solids/milk
- 2 hours for clear liquids[a]

[a] Formula, milk, orange juice, and colas are *NOT* considered clear liquids. Clear liquids include any liquid that can be seen through (eg, water, sugar water, apple juice, Jell-O, broth).

Laboratory Studies

Laboratory studies, such as complete blood cell count, electrolyte panel, and/or blood typing, should be performed if indicated by the patient's underlying comorbidities or current disease process. Blood products may be needed during or after surgery if there is blood loss. If blood loss is anticipated, parents or other family members will be given the option to directly donate blood prior to the procedure. Direct donation of blood can take days to weeks depending on the specific blood bank, however, and it may not be an option for urgent or emergent operations. Additionally, the cost of directly donating blood is often the responsibility of the patient. If primary care physicians need laboratory tests performed for other reasons, often the necessary blood work can be obtained while the patient is under anesthesia.

Imaging Studies

The parents or guardians should bring with them to the surgical consultation copies of any imaging studies obtained by the primary care physician. Hard copies or electronic files of the imaging itself as well as the final report by the radiologist are strongly recommended. If imaging studies are needed for further workup or preoperative planning, these studies can be ordered later by the surgeon. If studies are to be ordered preoperatively by the primary care physician, that physician should contact the surgeon to confirm which specific studies to order. This communication will avoid obtaining unnecessary studies or the need to repeat any studies that were not done appropriately.

Patients Requiring Urgent/Emergent Surgery

Patients with acute conditions often present first to their pediatrician or primary care physician. Common conditions include abdominal pain consistent with appendicitis, an abscess requiring drainage, an incarcerated hernia, or vomiting caused by pyloric stenosis. Such patients should be directed to the emergency department (ED) for further workup and management, and the pediatric surgeon should be notified. Any time a patient is sent to the ED for a possible surgical issue, it is essential to remind the parents to not give the patient anything to eat or drink (ie, nil per os [NPO]). If parents feed patients en route to the ED, treatment will be delayed because of anesthesia-related concerns. The NPO guidelines in Box 16.1 are enforced even in urgent conditions; only in life-threatening emergencies may the guidelines be disregarded. In most acute situations, patients are often dehydrated as a result of vomiting, poor oral intake, or third-spacing of fluid. Thus, it is essential that patients be adequately resuscitated preoperatively. A standard intravenous (IV) fluid resuscitation of 20 mL/kg of lactated Ringer injection or normal saline should be administered, followed by continuous administration of maintenance (or slightly higher rate of) fluids. Appropriate antibiotics also should be administered as indicated. Patients with acute appendicitis should be started on single-, double-, or triple-agent broad-spectrum antibiotics depending on their symptoms and the preferences of the surgical team. Patients with abscesses should be administered

antibiotics with excellent gram-positive coverage, with special attention to methicillin-resistant *Staphylococcus aureus*, given its high prevalence. Pain medication is given as needed. It is rare that a true surgical condition is masked by the appropriate dose of pain medication; thus, pain medication can be given even if the surgeon has not yet evaluated the patient. Finally, basic laboratory studies, such as a complete blood cell count and electrolyte panel, should be obtained.

Perioperative Care

The final operating room schedule for elective cases is often made the day before surgery. Thus, the specific time of an elective procedure is not known until 1 day prior to surgery. Often the surgeon can give parents an estimated start time. Families are contacted the day before surgery to confirm the time of the procedure as well as when and where to arrive. Patients are typically asked to arrive 1.5 to 2 hours before the scheduled start time to allow sufficient time to ensure patient safety by completing all necessary steps before the actual operation.

In general, patients are put under anesthesia when they arrive in the operating room. For infants and young children, an IV line is placed after the patient is asleep. To minimize anxiety, preanesthetic sedation is administered orally before proceeding to the operating room. Once in the operating room, patients are often administered an inhalational anesthetic, followed by placement of the IV line, then intubation. Some institutions allow parents to accompany their child to the operating room and see the child put to sleep with the inhalational anesthetic.

After the operation is complete, patients are brought to the recovery room. Parents typically are allowed in the recovery room until the time of discharge. Criteria for discharge from the recovery room are listed in Box 16.2. For children who have undergone outpatient surgery, careful written instructions are provided to parents along with dates and times of follow-up appointments as well as telephone numbers for use should problems arise. Children who have undergone inpatient procedures are discharged from the recovery room to the pediatric inpatient service, along with appropriate orders for nursing personnel. Child life specialists are available at many institutions to help acclimate patients to the hospital and perioperative setting. These specialists provide information, comfort, and reassurance, and they offer general positive reinforcement to patients.

Box 16.2. Criteria for Discharge After Outpatient Surgery

- Patient is stable and exhibits age-appropriate vital signs
- Age-appropriate ambulation
- Ability to tolerate oral fluids
- No bleeding
- No respiratory distress
- No pain that cannot be controlled by oral medication
- Age-appropriate alertness

Controversy persists about the postoperative management of former preterm infants after undergoing general anesthesia because they are at increased risk for postoperative apnea. Reasonable recommendations for typical outpatient operations include overnight admission with apnea monitoring for former preterm infants who were born at 52 weeks' postconception age or younger. However, each institution has its own specific policy, and the exact age for required admission varies. The decision for admission is also based on the patient's current health and comorbidities and should be made by the surgeon, anesthesia team, primary care physician, and the patient's parents. Table 16.1 lists the most common elective and urgent/emergent operations and anticipated postoperative hospitalization stays.

Table 16.1. Common Elective and Urgent/Emergency Operations and Anticipated Postoperative Hospitalization

Type of Procedure	*Procedure*	*Length of Hospitalization*
Elective	Inguinal hernia repair	None[a]
	Umbilical hernia repair	None[a]
	Cyst excision	None[a]
	Central venous catheter insertion/removal	None[a]
	Orchiopexy	None[a]
	Laparoscopic cholecystectomy	None[a]
	Lymph node biopsy	None[a]
	Ostomy takedown	3–4 days
	Lung resection	3–4 days
	Imperforate anus repair	3–4 days
	Pectus excavatum repair (ie, Nuss procedure)	4–5 days
Urgent/Emergency	Laparoscopic or open appendectomy for nonperforated appendicitis	1–2 days
	Laparoscopic or open appendectomy for perforated appendicitis	5–7 days
	Pyloromyotomy	1 day
	Intussusception reduction	1 day
	Bowel resection	5–7 days
	Bowel obstruction	5–7 days
	Tumor resection (ie, Wilms tumor or neuroblastoma)	7 days
	Choledochal cyst or portoenterostomy	5–7 days
	Pull-through for Hirschsprung disease	5–7 days

[a] Outpatient procedure.

Postoperative Care

Parents often call their child's primary care physician with questions postoperatively; thus, it is important that the physician be knowledgeable about routine postoperative care. Most children recover from anesthesia and surgery faster than adults. Unless otherwise specified, such as after an appendectomy for perforated appendicitis, a normal diet can be resumed as soon as the patient has an appetite. If patients cannot tolerate a normal diet, a bland diet and plenty of fluids are recommended. Furthermore, unless otherwise specified patients should resume taking all their preoperative medications the evening of or morning after surgery.

Almost all surgical wounds are closed with absorbable sutures and covered with thin adhesive strips. Additional dressings can be removed 1 to 2 days postoperatively or as needed. By 48 hours postoperatively, wounds do not need to be covered unless they are open or there is drainage. Unless otherwise specified, most wounds can be exposed to water (ie, shower, quick bath) 48 hours after surgery. With the exception of thin adhesive strips, dressings should be removed prior to bathing.

The surgeon provides parents and the child details about activity limitations and returning to school. Often, heavy physical activity, such as physical education in school or organized sports, should be avoided until the surgeon sees the patient after discharge. Although heavy physical activity is to be avoided after surgery, patients should be encouraged to walk as well as to cough and breathe deeply many times a day to avoid atelectasis. Patients can return to school when they feel ready and have only minimal pain.

The main reasons to contact the surgeon postoperatively are a temperature above 38.6°C (101.5°F), worsening or persistent pain, persistent emesis, and any wound drainage or redness. Additional instructions specific to the operation are also provided to the parents.

CASE RESOLUTION

In this case, the pediatrician reassured the parents that many patients have been referred to this surgeon. The parents were assisted by the pediatrician in crafting their questions for the surgeon. The surgeon subsequently confirmed the diagnosis of an inguinal hernia and recommended surgery. All details were provided, and the parents' questions were answered. The patient was scheduled for outpatient surgery, and everything went smoothly. Postoperatively, there were no concerns, and the patient saw the surgeon and pediatrician in the course of standard follow-up care.

CHAPTER 17

Image Gently Approach to Pediatric Imaging

Jane S. Kim, MD; Lindsay S. Baron, MD; and Benjamin H. Taragin, MD

CASE STUDY 1

A 15-year-old boy comes to your office reporting back pain after exertion for the past week. He reports no significant recent trauma. He plays varsity basketball but has not had any falls during recent games. He is otherwise healthy, with no significant medical history.

The pain does not prevent him from playing sports or attending school. He has no history of prior episodes of back pain. He reports that the pain is relieved by nonsteroidal anti-inflammatory drugs. On physical examination, he has left-sided paraspinal focal tenderness in the L3-L4 region. He has limited range of motion twisting to that side.

CASE STUDY 2

A 10-year-old girl is brought to your office with runny nose, congestion, cough, and headache. You saw this patient 6 weeks ago as well as 4 months ago, when she had similar symptoms. Her mother reports full compliance with the antibiotic regimen you prescribed but states that her daughter's symptoms have never fully resolved. On physical examination, the child is afebrile with purulent nasal discharge. Tenderness to palpation is elicited over the cheeks and forehead.

Questions

1. How does imaging contribute to the diagnosis of a patient's condition?
2. How does the physician determine which imaging studies are appropriate for an individual patient?
3. What is the ALARA principle?
4. What information is available for counseling patients about the risks of diagnostic radiation?
5. Where can appropriate imaging recommendations for pediatric patients be found?
6. Does patient history influence the choice of imaging studies?
   a. Would imaging be appropriate for the patient in Case Study 1 had he recently experienced significant trauma?
   b. Would imaging be appropriate for the patient in Case Study 2? What if her symptoms had been new and begun only the week before this latest office visit?

Overuse of medical imaging is a growing problem in the United States, with financial and medical repercussions. The primary care physician must often decide what, if any, imaging is appropriate for a particular patient. In many situations, clinical assessment and physical examination are adequate for diagnosis. In some instances, however, imaging provides vital information that cannot be adequately obtained from other sources. Patients and their families may also insist on diagnostic imaging based on the belief that the more technologically advanced the evaluation, the better the care.

Approximately 370 million studies using diagnostic radiation are performed annually in the United States (Figure 17.1). The most dramatic increase has been in the use of computed tomography (CT). In 1982, 1 million CT scans were performed in the United States. In 2006, 67 million CT scans were performed, with an estimated 4 to 7 million of these performed in children. In response, many concerned health professionals and radiologists gathered to create the national *Image Gently* Campaign, with a focus on minimizing the use of diagnostic radiation when possible and using appropriate pediatric imaging for children in the United States. Because of the widespread attention and highly concerted efforts of the organizations involved in this effort, several recent studies have observed a slight downward trend in CT use for pediatric patients in the United States. Because of the substantial variation among different imaging practices, however, the opportunity exists for continual improvement.

Basic Concepts

Diagnostic radiology examinations that use ionizing radiation include plain radiography, fluoroscopy, CT, and nuclear medicine. Ionizing radiation may cause damage to DNA molecules. Children are more radiosensitive than adults secondary to children's growth of rapidly proliferating cells and longer life span. Certain organs are more radiosensitive than others, and children in particular are at an increased risk for breast cancer, thyroid cancer, and leukemia.

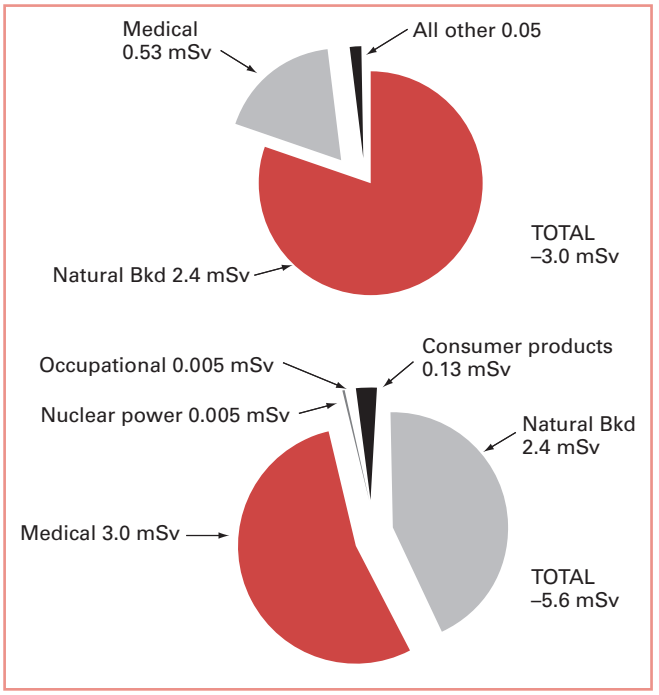

Figure 17.1. Charts showing the United States annual per capita effective radiation dose from various sources. Upper: Chart for 1980. Lower: Chart for 2006.

Abbreviation: Bkd, background.

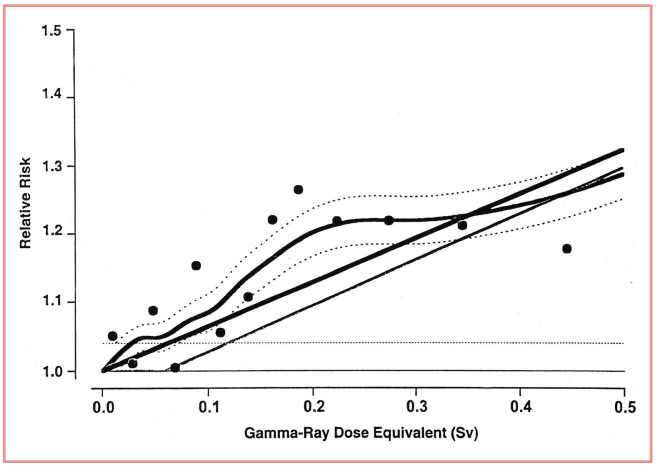

Figure 17.2. Graphic representation of the relative risk of contracting cancer in atomic bomb survivors. The dashed curves represent 61 standard error for the smoothed curve. The straight line is the linear risk estimate computed from the range 0–2 Sv. Because of an apparent distinction between distal and proximal zero-dose cancer rates, the unity baseline corresponds to zero-dose survivors within 3 km of the bombs. The horizontal dotted line represents the alternative baseline if the distal survivors were not omitted.

Reprinted with permission from Pierce DA, Preston DL. Radiation-related cancer risks at low doses among atomic bomb survivors. *Radiat Res.* 2000;154(2):178–186.

One of the most common ways to measure radiation dose is by the effective dose, measured in sieverts, which takes into account all the exposed tissues and the relative radiosensitivity of each organ. The effective dose also provides a way to compare radiation dose across different imaging modalities. For example, for children 1 CT scan of the chest imparts an effective dose equivalent to up to 150 chest x-rays (Table 17.1).

The ALARA Principle

In recent years, increasing attention has been paid to and research done on patient radiation exposure from diagnostic imaging. Much of this concern stems from data derived from survivors of the atomic bombs used in World War II. The radiation dose to each survivor was calculated based on each individual's distance from ground zero, and more than 50,000 of these patients were followed for more than 50 years. The data showed an increased cancer risk for many of the survivors. Based on this observation, a mathematical model was created which states that the risk of cancer proceeds in a linear fashion without threshold (Figure 17.2). According to this model, even a small amount of radiation increases the risk of cancer. Current estimates vary concerning diagnostic radiation and the risk of cancer. Based on research by multiple radiation biologists, the American College of Radiology (ACR) estimates that for adults, 1 fatal cancer is induced for every 1,000 CT scans performed. The risk is higher in children, with 1 fatal cancer occurring for every 500 to 1,000 CT scans performed. This figure is superimposed on the national cancer incidence of 42%.

This research spurred the founding of the *Image Gently* Campaign, which stresses a multifaceted approach that is intended to minimize radiation exposure to children. The campaign has brought together 60 medical and professional organizations representing more than 700,000 imaging specialists from the fields of pediatrics, radiology, physics, and radiology

technology. The as low as is reasonably achievable principle (*ALARA principle*) is based on the notion that any amount of radiation exposure, no matter how small, can increase the chance of negative biologic effects. The aim of the ALARA principle is to balance the goals of minimizing the amount of radiation while obtaining sufficient imaging quality, resulting in accurate diagnostic information.

The Role of the Radiologist

The pediatrician can often determine whether any imaging study is needed based on the history and physical examination. In some conditions (eg, acute trauma), imaging is important to assess the nature and extent of the injury. In other conditions, such as infectious processes (eg, cough, symptoms of sinusitis), medical management is warranted initially before any imaging is performed.

Communication and coordination between medical specialists and radiologists is often helpful. When in doubt, a call to the local radiologist, regardless whether that person is a dedicated pediatric radiologist, can guide the specialist in determining which test is reasonable for a specific patient. Radiologists have many means by which to tailor examinations to minimize radiation. The first step often involves asking whether nonionizing diagnostic examinations, such as ultrasonography or magnetic resonance (MR) imaging, can be performed to answer the same diagnostic question. In particular, ultrasonography often can be used as a screening examination to evaluate conditions that can be clarified with other studies that involve radiation if needed. For certain indications, MR imaging is a great alternative to CT; however, in some cases, the need for sedation and other risks of MR imaging may outweigh the risks of CT. Radiologists are also required to monitor equipment and study protocols to ensure radiation dosage does not exceed the recommended range. All commercial CT scanners used in the United States include multiple methods to adjust the radiation dose. A low-dose technique should be used whenever appropriate. Newer-generation CT scanners use a significantly decreased dose while maintaining imaging quality. Breast and gonadal shielding can offer additional protection to children.

Resources for Physicians and Parents

The ACR has established appropriateness criteria for imaging of specific medical conditions and presentations; these criteria were coauthored by clinicians and radiologists. The criteria are available free online and can be downloaded and incorporated into computerized ordering and electronic health record systems (https://www.acr.org/Clinical-Resources/ACR-Appropriateness-Criteria).

The Image Gently website (www.imagegently.org) offers educational materials for parents to help them understand the risks and benefits of diagnostic imaging and the associated radiation. The website also has printable child imaging history cards for parental use to track all diagnostic radiation examinations performed on their child (Figure 17.3).

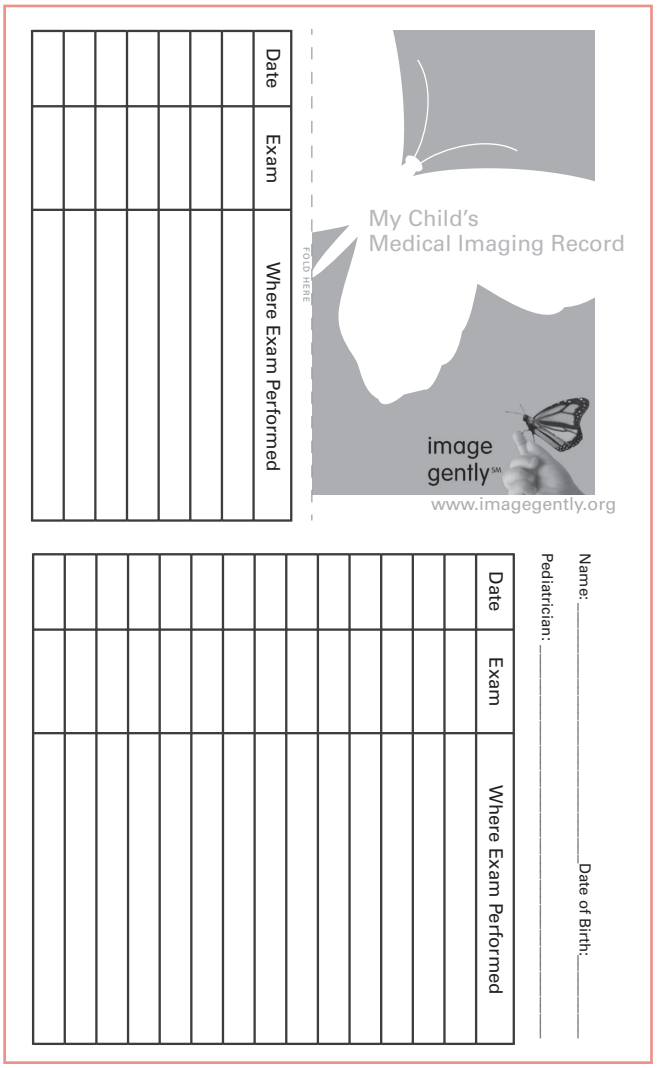

Figure 17.3. Child imaging history card on which parents can record their child's exposure to imaging studies.

CASE STUDY 1

Case Study 1: The Importance of the Patient History

Back pain is a common symptom in active adolescent patients. Many studies have evaluated the use of imaging in patients with atraumatic back pain. In the absence of significant trauma, most studies have found that there is little value in imaging otherwise healthy adolescents who present with musculoskeletal pain. If this patient had experienced significant trauma or demonstrated focal neurologic findings suspicious for significant injury to the spinal cord or a disk, MR imaging would be the most appropriate examination. Radiographs of the spine are not helpful in assessing disk disease or central nervous system injury. Radiographs are helpful in adult patients to evaluate the extent of multilevel disk disease. For this patient, the physician should obtain a comprehensive history and perform a complete physical examination to help define the differential diagnosis and assist in the determination of the appropriate imaging study. See Resources for Physicians at the end of the chapter for a link to the ACR Appropriateness Criteria for back pain in a child.

Case Resolution

The physician should recommend rest, nonsteroidal anti-inflammatory drugs, and stretching exercises for 4 to 6 weeks. If the pain persists after that time, magnetic resonance imaging of the lumbar spine without contrast would be a reasonable next step in the workup of this patient.

CASE STUDY 2

Case Study 2: Symptom Duration and Response to Treatment

Imaging should be obtained in cases of chronic sinusitis that do not respond to treatment and persist for months without resolution. Computed tomography of the sinuses is useful in the evaluation of the soft tissues, extent of disease, and any potential intracranial complications. Computed tomography also provides important anatomic detail should surgery be required. Radiographs have limited utility in evaluation of sinusitis because of the lack of soft tissue, anatomic detail, and low sensitivity. This is particularly true in very young children whose sinuses are not yet well aerated. Imaging is not appropriate in the setting of acute sinusitis in an otherwise well child. See Resources for Physicians at the end of the chapter for a link to the ACR Appropriateness Criteria for child sinusitis.

Case Resolution

The physician should order a computed tomography scan of the sinuses, because the patient has signs and symptoms of chronic sinusitis despite treatment. Had the patient been presenting for the first time with signs and symptoms of sinusitis, medical treatment would be indicated and imaging would be considered were the patient not to respond to that medical management.

CHAPTER 18

Simulation in Pediatric Health Care

Tom Kallay, MD

CASE STUDY

An 8-year-old boy presents to your office for a follow-up appointment after an asthma exacerbation. He reports feeling better while at home this morning, but on the car ride to your office his chest started "hurting," and he began to experience shortness of breath. During his intake he appears to be in a moderate amount of distress, with evidence of tachypnea and tachycardia. His pulse oximeter reports a value of 90%. Your staff administers nebulized bronchodilator therapy and oxygen, and a call is made for paramedic transport to the nearby hospital. Within the next few minutes the staff becomes concerned that he may need emergent airway support, but you are not sure if the equipment is functioning properly since the last time it was used. The paramedics arrive and safely transport the child to a facility that provides a higher level of care. Although emergency interventions were not required during this situation, you and your staff feel that you could have been better prepared. You decide to take measures to optimize the function of your staff and office environment for the rare emergency.

Questions

1. What is simulation?
2. How does simulation apply to health care?
3. What modalities of simulation are available for medical training?
4. How does one create and deliver simulation training?
5. Why should a primary care physician use simulation?

Simulation is a powerful tool for learning. In the most general sense, simulation is a learning technique in which people or technology are used to mimic real-life encounters. These encounters are practiced in simulated conditions, and typically the learner receives performance feedback as if the learner were in the real situation.

Simulation has a long legacy of use for education and evaluation in many high-risk industries. Examples include flight simulators for pilots and astronauts, war games for military personnel, and technical operations for nuclear power personnel. Simulation provides learners of all levels an opportunity to practice and develop knowledge and skills without the threat of causing harm to individuals. Currently, high-risk industries use robust simulation programs that are embedded into the culture of training and skill maintenance. Because health care is a high-risk industry, it seems intuitive that simulation would have a place in medical training, with the purpose of improving patient safety and outcomes.

Simulation in Medicine

History

Simulation in medicine began in 1960 with Resusci Anne, a mannequin designed for mouth-to-mouth resuscitation training. This was a new resuscitation technique conceived by Peter Safar, MD, and James Elam, MD, in 1957, which influenced Norwegian toymaker Asmund Laerdal to create the mannequin for practicing the principles of resuscitation. The airway could be obstructed, necessitating neck hyperextension followed by thrusting the chin forward to insufflate the lungs. An internal spring placed in the chest of the mannequin permitted the practice of cardiac compressions, and subsequently, cardiopulmonary resuscitation (CPR) training was born.

Computer-controlled mannequins were developed in 1967 at the University of Southern California. Medical educator Stephen Abrahamson, PhD, along with anesthesiologist J. Samuel Denson, MD, collaborated with a group of engineers from the Sierra Engineering and Aerojet General Corporation to create Sim One. This prototype device was a computerized, adult-size mannequin that featured breathing, heart sounds, functional pupils, and an anatomically correct airway. It was used for airway management training for anesthesia residents from the late 1960s through the 1970s, with a noted benefit of training without placing patients at risk. Ultimately, however, Sim One did not gain acceptance and the program was terminated. For the next 3 decades, simulation in medical education remained relatively dormant.

The Growth of Simulation in Medicine

...[N]o industry in which human lives depend on the skilled performance of responsible operators has waited for unequivocal proof of the benefits of simulation before embracing it.
—David M. Gaba, MD

The Institute of Medicine (IOM) report *To Err Is Human: Building a Safer Health System*, published in the year 2000, drew attention to the perils of the health care system, highlighting the human and financial costs of medical errors. The period following the IOM report witnessed a resurgence of simulation in medicine as a response to the reinvigorated emphasis on patient safety. Government and medical institutions began to embrace simulation as a means of improving health practitioner and team performance to improve outcomes. In 2001, the Agency for Healthcare Research and Quality (AHRQ) published an analysis of patient safety practices and dedicated a chapter to the potential benefits of simulation.

With the publication of increasing evidence that simulation could be applied to patient safety, it began to find its way into the language of accreditation and certification. The Accreditation Council for Graduate Medical Education has embraced simulation as an effective training method and now mandates that simulation resources be available for programs such as anesthesia and surgery, and more programs are following suit. In 2008, Accreditation Council for Graduate Medical Education program requirements mandated having available simulation resources for 3 out of 159 residency requirements; as of today, that number has grown 10-fold, to 30.

A body of pediatrics literature demonstrating the benefits of simulation has been published. This knowledge has been used to improve skills ranging from complex resuscitations to lumbar puncture (LP) and has demonstrated applicability to inpatient and outpatient settings.

For example, the literature on pediatric outpatient emergencies shows that offices are frequently ill-equipped to manage an emergency. In 2000, the American Academy of Pediatrics Committee on Pediatric Emergency Medicine published *Childhood Emergencies in the Office, Hospital, and Community: Organizing Systems of Care*. This resource highlights how preparation of the staff, office environment, and community are crucial for delivering high-quality emergency care and advises that simulated mock scenarios or codes are an essential part of an office emergency preparedness plan. Currently, many resources provide the necessary tools for providing simulation education in the field of pediatrics.

Simulation is increasingly used in the health care field. In 2004, the Society for Simulation in Healthcare was established by professionals who use simulation for education, testing, and research in health care. Members now include physicians, nurses, allied health and paramedical professionals, researchers, and educators from around the globe, and the society hosts an annual meeting. Since 2006, the AHRQ has been funding simulation research as part of its safety mission. This research has expanded our knowledge on how to effectively use simulation in a variety of clinical settings. Additionally, the AHRQ in collaboration with Society for Simulation in Healthcare created the *Healthcare Simulation Dictionary* to provide uniform terminology and definitions for users of health care simulation. In response to demand, the medical simulation equipment industry has blossomed, and currently products that can simulate virtually any situation encountered in medicine are available. With the development of not only the technology but the technique of simulation, it has become apparent that for health care, as in other high-stakes industries, simulation has found its place.

This chapter provides a broad overview of simulation in health care—the associated terminology, available resources for health care education, and techniques for providing this mode of training.

Terminology

The term *simulator* refers to the equipment, such as a simulated arm for venipuncture, a computerized mannequin that replicates human physiology, or a virtual reality computer with programming designed to practice laparoscopic surgery. *Simulation* is an educational technique described by the IOM in 2010:

> *The act of imitating a situation or a process through something analogous. Examples include using an actor to play a patient, a computerized mannequin to imitate the behavior of a patient, a computer program to imitate a case scenario, and an animation to mimic the spread of an infectious disease in a population.*

Simulation-based medical training is a systematically designed program that provides information, demonstration, and practice-based learning activities that are supported by the concept of deliberate practice.

A *simulation center* is an area designed to provide some or all of the aforementioned modes of simulation. It can range in size from a 60 m^2 room to a 3,000 m^2 building replicating a hospital with fully equipped patient rooms, clinics, and operating rooms. Such centers provide opportunities to practice all facets of medicine, depending on the learning goals. Spaces can be fashioned to appear like an emergency department or clinic office and may be wired with cameras and microphones so that learner actions and statements can be recorded and reviewed for evaluation and feedback. Some centers may use a control room adjacent to the simulation area, separated by 1-way mirrors, that allows the facilitator to observe and control the scenario without being in the room with the learner. If high-fidelity mannequins are used, they are controlled from this room via computer, and facilitators communicate with role players in the scenario by 2-way radio. There may be conference areas for viewing live simulations and debriefing, as well as storage areas for equipment. Multidisciplinary centers provide the best opportunity for cross-training among health professionals and building camaraderie.

In situ simulation comprises simulation activities embedded in an actual clinical environment. The advantage of in situ simulation is that medical scenarios can be practiced in the working environment, thereby providing the closest approximation of reality. Such simulation is excellent for team training, because all members of the medical staff can participate. Another advantage of in situ simulation is that it provides the ability to test the working environment for conditions that can predispose a person to make an error.

For example, a prospective randomized controlled trial was performed to evaluate the effect of a simulation-based intervention designed for emergencies in the pediatric office. Thirty-nine

practices were involved, with 20 in the intervention group and 19 serving as controls. The intervention involved 2 mock codes delivered by the investigators in the office (in situ), where staff responded using their own equipment and local emergency medical services. After the mock code, the investigators debriefed the staff, reviewed existing emergency equipment, and assisted with developing a resource manual designed for emergencies. A post-intervention survey was distributed 3 to 6 months later that included items on the following areas: purchase of new emergency equipment or medications; receipt or updating of basic life support, pediatric advanced life support, and advanced life support certification by staff members; and development of written protocols for emergencies. The control group received no intervention and completed the same survey.

Intervention practices were more likely than control practices to develop written office protocols (60% vs 21%; $P = 0.02$), and staff in intervention practices were more likely to be current on life support certifications by the time of the post-intervention survey (118 vs 54; $P = 0.02$). No significant differences existed between the 2 groups in terms of the purchase of new equipment or medications. Satisfaction with the simulation exercise was evaluated as well. At the time of the post-intervention survey, 90% of staff felt the exercise was useful for their practice, and 95% felt that the program should be continued.

Although in situ simulation is an effective tool, it does have shortcomings. In a busy hospital or clinic environment, staff may feel overburdened by having to perform extra tasks during work hours that may be perceived as unnecessary. It is the responsibility of the person organizing a simulation practice session to ensure that patient care is not compromised during the activity; it is also important to build a culture of patient safety in which staff feel a responsibility to provide excellent individual and team function in a well-prepared environment.

Medical Simulation Resources

Resources available for simulation in health care can be categorized into 1 of 5 areas: mannequin based, screen based, virtual reality, task trainers, and standardized patients (SPs) (Box 18.1). How these tools are used depends on the educational needs.

Mannequins are lifelike representations of human beings and range in size from a preterm neonate to a full-size adult. The spectrum of functionality spans from a simple form, such as Resusci Anne, to a high-fidelity mannequin. A *high-fidelity mannequin* is computer driven and has features that represent human physiology, such as breathing, heart sounds, and blood pressure. These mannequins are technology dependent and often expensive and require expertise in maintenance and operation. Mannequins are typically used for mock codes, which can be applied to almost any health care setting, such as an office, inpatient ward, or operating room.

Box 18.1. Resources for Medical Simulation Training

- Mannequin: simple or computer driven
- Screen-based simulation programs
- Virtual reality programs
- Task trainers
- Standardized patients

Screen-based simulated programs are more affordable and logistically easier than a mock code. Unlike a mock code, which often requires the coordination of more than 1 person, screen-based simulated programs can be performed by an individual at any location with a computer. Software programs are available that contain libraries of clinical scenarios in which patient history, examination findings, image studies, and laboratory tests can be represented graphically. Users can select diagnostic and therapeutic options as they work through the case and generate a record of performance. Immediate feedback is provided by preprogrammed software or an instructor at a later time.

Task trainers are three-dimensional representations of body parts that allow the user to improve technique or develop psychomotor skill in many areas, such as intravenous line insertion, LP, or bag-valve mask. Task trainers exist for nearly every procedure and discipline, with options ranging from preterm neonates to adults. Some trainers provide visual, auditory, or printed feedback to the learner based on the quality of the performance. For example, when practicing bag-valve mask on a baby head, an airway connected to inflatable lungs allows learners to visualize the effectiveness of their technique. Task trainers are especially useful for practitioners to gain familiarity with the equipment being used, whether they are first learning to use the equipment or refreshing their skills after a period of nonuse.

Virtual reality and haptic systems use the most sophisticated computer programming for procedural practice. *Virtual reality* refers to the re-creation of environments or objects as a complex, computer-generated image. *Haptic systems* provide the capability of tactile learning, and these programs can provide detailed feedback on procedural skill based on the kinetic actions of the user. Typically, virtual reality and haptic systems are used with a task trainer; most of the products available are for vascular access, surgical procedures, bronchoscopy, or endoscopy. Evidence shows that virtual reality is superior to traditional training; it is likely that simulation-based medical education will further incorporate virtual reality in the future. Currently, virtual reality programs are relatively cost-prohibitive and limited in scope; however, this may change as programming and options continue to develop.

Standardized patients have been used in graduate medical education for years. An SP is an actor playing a role and provides trainees an opportunity to practice communication, physical examination skills, or history taking. Although SPs typically play the role of a patient, they can also play the role of a family member or a fellow health practitioner.

Hybrid simulation, which combines 2 modes of simulation for a more realistic experience, is an excellent opportunity to provide a multifaceted learning experience. For example, when creating a scenario for a child with diabetic ketoacidosis (DKA), a mannequin

and an SP can incorporate scripts written for DKA as well as for a mother who must be told that her child has a new diagnosis of diabetes mellitus. Learners have the opportunity to both apply their knowledge in assessing and treating DKA and use their skills in having difficult conversations. Afterward, feedback is provided to the learners about their medical knowledge, decision-making skills, and communication skills. The term *confederate* is sometimes applied to role players who work together with the instructor in scenarios.

Technique

The Culture of Simulation

This section describes the elements that are needed when designing and delivering education using simulation. But before these steps are illustrated, it is important to discuss the culture of simulation learning and how it fits with the current culture of medicine.

Traditional medical education emphasizes the importance of error-free practice, with intense pressure to achieve perfection during diagnosis and treatment. Furthermore, when mistakes are made, the psychological toll for the practitioner cannot be underestimated. It is often said that there are 2 victims in the case of a medical error: the patient and the health professional. Reports of provider depression, substance abuse, and suicide highlight the need for engendering a productive rather than destructive response to medical errors, which is 1 of the central aims of simulation. The technique of practicing technical skills or decision making skills in an environment absent of the "shame and blame" response can assist in developing healthy reactions to mistakes, in which the factors leading to the error are objectively reviewed and analyzed and improvements instituted. When a mistake is made, the goal is to change the thinking from what the repercussions will be to how health professionals can better themselves to improve care for their patients. As the practice of medicine is an art, so is the practice of becoming a better health professional.

The learning environment for simulation education activities must connote a safe learning environment in which mistakes can be made without reproach. In fact, simulation is an area in which it is desirable for health professionals to make mistakes so that the practice of improvement can occur. It is the responsibility of the facilitators to explicitly state this to help create an atmosphere conducive to constructive discussion.

Simulation activities also provide an opportunity for health professionals to train together and build effective communication skills and team camaraderie. The training of health professionals—nurses, physicians, medical or physician assistants—generally occurs in parallel, which can have the unintended consequence of poor communication between team members. This potentially can create an environment that may not always be conducive to fair and open discussion of mistakes, which is necessary if optimal learning and improvement are to occur. When delivered with creativity and enthusiasm in a nonthreatening environment, simulation can provide a venue for building effective relationships between practitioners while imparting educational benefits.

Steps for Delivering Simulation Learning

Developing simulation activities requires multiple steps and careful planning to achieve learning goals (Box 18.2). Health professionals are often busy and have little spare time, so in addition to making simulations accessible, the educational product must be sound and worth the time spent. Learning events that are not well planned or delivered can have an adverse effect on an individual's perception of simulation education, which can have a negative effect on that person's learning. The first step in delivering simulation learning is the creation of a mock code or scenario, followed by deliberate practice, a concept of instruction that is applicable to scenario or procedural training.

Mock Scenario Development

The first step in creating a scenario is to identify what needs to be improved; this may be related to medical knowledge, technical skill, communication, team function, or a combination of these. Adverse as well as routine events in the office or hospital setting often provide opportunities for learning and improvement and can set the educational framework.

The case study provided in the beginning of the chapter, for example, highlights a situation in which a mock code could be helpful in improving performance. Practicing a mock scenario of anaphylaxis can address multiple needs: teamwork, communication, locating and operating equipment, performing proper advanced life support techniques, and disposition. After a scenario is developed, it can be practiced by the office staff until performance standards are met.

When writing a mock code or scenario, the first task is to create succinct learning objectives. Writing clear objectives is an underappreciated skill and is a crucial part of any educational program. Good objectives are important because they focus teaching and enable the evaluation of the effectiveness of the activity. A helpful way to start thinking about objectives is to begin with the phrase, "By the end of this session, the learner will be able to..." followed by the

Box 18.2. Steps for Providing Simulation-based Medical Education

1. Determine learning needs.
2. Create learning objectives.
3. Create learning lesson.
   a. Script, if performing mock scenario.
   b. Simulated patient history and physical examination, laboratory data, images, and case progression.
   c. Consequences of anticipated interventions and disposition.
   d. Identification of required equipment and space.
   e. Identification of role-players.
4. Session delivery.
   a. Create a safe learning environment.
   b. Deliberate practice.
5. Feedback/debriefing.
   a. Advocacy inquiry.
   b. Plan for improvement.

learning objective. Objectives should be specific and measurable and use words that are open to few interpretations. For example, the objective, "By the end of the session, the learner will understand the complications of bag-mask ventilation.", is open to many interpretations, whereas the statement, "By the end of the session, the learner will be able to list the complications of bag-mask ventilation.", is open to fewer interpretations.

The learning objective in the first example is vague; it may be answered in multiple ways. Additionally, the instructor does not have a clear standard for how to measure what has been learned. The second objective not only focuses the teacher and learner but provides a concrete way to measure knowledge by requesting a finite list. Depending on educational needs, typically 2 to 4 objectives are sufficient for a session. The use of too many objectives can be overwhelming and can have a dilutional effect on the knowledge being imparted. Box 18.3 provides examples of words that are open to fewer or more interpretations.

After the learning objectives are established, a script is written that describes the flow of events and consequences of anticipated interventions. A list of required equipment or props, role-players needed with instructions on how to act, a history and physical examination of the simulated patient, and laboratory tests or images are also included. It is helpful to write the scenario such that an individual other than the writer can use it for future sessions. Eventually, if multiple scenarios are written, a catalog of cases with various clinical scenarios can be developed that can serve as a sustainable learning resource. Many templates are available that can be helpful in writing a scenario, with varying degrees of complexity. The important thing is for instructors to use the method that fits their time and needs.

After preparation is complete, the session can be delivered. How well the instructor introduces the simulation learning experience can set the tone for all that follows. Before any simulation begins, the facilitator helps participants clarify what is expected of them and helps them understand the benefits and limitations of the simulated clinical setting. Learners must understand whether and how the case, event, or procedure will later be debriefed (ie, discussed and analyzed) and whether the simulation will be video recorded. The instructor must explicitly state that the focus is on learning, not on catching people in a mistake. This helps create an environment in which participants feel safe in sharing thoughts and feelings about the upcoming simulation and debriefing without fear of being shamed or humiliated.

Participants often worry that simulations are designed to expose their weaknesses or humiliate them. To counter these thoughts, facilitators should convey the understanding that learners have good intentions and are trying to do their best but will likely make mistakes. Learners should be reassured that mistakes are desirable in the simulation environment because they provide focus on areas in need of improvement, which in turn can result in improved patient care.

After the scenario is complete, the next step is to debrief the case. This is the time to review the stated objectives; however, the overall goal of debriefing is to allow trainees to explain, analyze, and synthesize information and emotional states to improve performance in similar situations in the future. This can be challenging, because voicing critical thoughts can result in hurt feelings or defensiveness on the part of the learner. It is the responsibility of the instructor to lead a discussion that encourages objective reflection of practice without being confrontational.

One general framework of inquiry commonly used is: "What went well? What did not go well? What could we do to improve next time?" This gives participants the opportunity to voice their opinions and concerns. The techniques helpful for good debriefings are designed to increase the chances that the learner will process what the instructor is saying rather than become defensive. Advocacy-inquiry is 1 technique that can be used to help guide debriefing sessions.

Advocacy-inquiry is founded in the theory of reflective practice, which is a means of analyzing one's own work practices and examining the foundation of their existence. When incorrect actions are performed, the goal of debriefing is to elicit the framework of the participants' thought processes, which have been formed by their knowledge and experience. There may have been a previous situation in which an instructor provided incorrect information or in which miscommunication occurred that may have had a significant formative effect on the learner's understanding and subsequent behavior.

An advocacy is an observation, whereas an inquiry is a question. When the 2 are paired together, instructors state in the advocacy their hypothesis and test the hypothesis with an inquiry in a nonthreatening manner. For example, during a mock code drill for a patient with asystole, the instructor notices that cardiac compressions were not started immediately. During the debriefing, the instructor might say to the learner, "So, I noticed that you were working on providing oxygen to the patient after you noticed the lack of a heart rate" (ie, advocacy). "I was thinking there was possibly an additional maneuver to be done. I'm curious—how were you seeing the situation at that time?" (ie, inquiry). Rather than making

Box 18.3. Words or Phrases Open to More or Fewer Interpretations

Open to More Interpretation

- Know
- Understand
- Be able
- Know how
- Appreciate
- Grasp the significance of
- Learn

Open to Fewer Interpretations

- List

- Demonstrate
- Perform
- Rank (ie, rank as important)
- Describe

a judgmental comment, such as, "Do you realize that it took you 2 minutes before you started chest compressions?", the instructor is using advocacy-inquiry to elicit the learner's framework of thinking that guided the learner's actions. The participant might state, "I was once admonished during my training for not doing things in the right sequence." Having elicited this description of a prior training experience, the instructor has an opportunity to refine the thought process of the learner.

Just as the delivery of simulated scenarios requires practice, so does the facilitation of a productive debriefing process. In 2007, Rudolph et al published a good article on learning the technique of debriefing.

Although simulated clinical scenarios and mock codes are complex processes, the task of teaching procedures is generally more straightforward. An excellent framework for teaching procedures in a simulated environment involves using the concept of deliberate practice.

Deliberate Practice

Education research has demonstrated that acquisition of expertise in medicine or other fields (eg, professional sports, musical performance, chess) is based on a set of principles governed by the concept of deliberate practice, which is among the cornerstones of simulation-based medical education. To summarize, *deliberate practice* dictates that the learner will engage in repetitive performance of cognitive or psychomotor skills with direct assessment, which provides the learner with feedback tailored to improve performance. The elements of deliberate practice are listed in Box 18.4.

Coupled with simulation, deliberate practice has been shown to improve performance in many medical and surgical specialties. Studies ranging from general pediatrics to vascular surgery have demonstrated improvements in skills, knowledge, and team function when simulation with deliberate practice is used.

A randomized, controlled trial evaluated the effectiveness of deliberate practice simulation-based training compared with audiovisual training only for improving infant LP skills among pediatric residents. After a baseline assessment of LP skill and knowledge, all participants viewed an educational audiovisual presentation. The intervention group went on to participate in a simulation-based deliberate practice session on an infant LP simulator. The primary outcome was self-reported clinical success on the first infant LP after training. Fifty-one residents reported on 32 LP encounters; 94% of the intervention group reported success, compared with 47% in the control group, a marked difference. When the residents were evaluated on an observed clinical examination at 6 months, however, no difference was found between the groups. These findings suggest that although simulation training with deliberate practice is effective, skills decline over time and continual practice and retraining are necessary.

In adult medicine, a randomized trial with wait-list controls evaluated the acquisition of advanced cardiovascular life support skills among internal medicine residents using a mannequin simulator. Residents who received the simulation-based medical education with deliberate practice scored 38% higher on a reliable skills evaluation than residents in the wait-list control group. After crossover and a deliberate practice session with the control group, the scores surpassed the performance outcomes of the first intervention group. The authors concluded that deliberate practice, in addition to time and experience, is helpful in achieving competence.

The concept of close observation by experts with provision of constant real-time feedback can be applied to almost any procedure. However, deliberate practice is only 1 tool in achieving procedural excellence; continual practice is a key component to maintaining a high level of performance.

Box 18.4. Features of Deliberate Practice

1. Highly motivated learners with good concentration
2. Engagement with a well-defined learning objective or task
3. Appropriate level of difficulty
4. Focused, repetitive practice
5. Rigorous, precise measurements
6. Informative feedback from educational sources (eg, simulators, instructors)
7. Monitoring, correction of errors, and more deliberate practice
8. Evaluation to reach a mastery standard
9. Advancement to another task or unit

Benefits of Simulation

Despite all the points demonstrating that simulation is a valid teaching tool for medical training, concerns exist about its role. The time taken away from real patient experience, significant effort and time required to create and deliver simulation training, cost of equipment, and potential for humiliation are all points that cause trepidation. Furthermore, the question remains whether it is effective.

Simulation is an evolving science, and a growing body of evidence indicates that it can be effective in improving medical knowledge and skills, team function and communication, and patient safety and outcomes and that its use can result in hospital cost savings in terms of return on investment. Health care payers and liability insurers have noticed simulation as the potential effects on patient safety are now being realized. For the development of the health professional, simulation does not and should not replace the benefits of real patient experience; however, it can serve as an important component in the professional's education. After an individual grasps the technique, simulation education can be provided without the use of elaborate and expensive simulators but instead (with some creativity) with the use of lower-cost materials. The future of simulation in medicine depends on the dedication and ingenuity of the health care simulation community to see that improved patient safety and educational outcomes can be realized using this method. Potential benefits and applications of simulation are outlined in Box 18.5.

Box 18.5. Benefits and Applications of Simulation

- Avoidance of risks to patients and learners
- Tailoring of procedural training or scenarios to educational need and attributes of the learner
- Practicing of skills and scenarios as many times as necessary
- Enhancing transfer of skills from the classroom to the clinical arena
- Determination of educational needs
- Training for optimal team or organizational function
- Practicing communication skills
- Providing opportunity to practice rare critical events
- Assisting in the testing of new equipment or facilities
- Refresher training for staff at all levels
- Serving as formative or summative assessment tool at all levels

Conclusion

Health care simulation is a technique to augment real experiences with guided, interactive encounters that approximate reality. The past 25 years have witnessed tremendous growth in the health care training industry, with applications in medical education and patient safety practices. Simulation provides a training method that does not place patients at risk and that can be tailored to meet the needs of learners at any level. When delivering simulation education, it is important to highlight to participants the goal of improvement and acceptance of errors to connote a safe learning environment. Additional work is required to continue to advance this technique to assist in improving the health care system for patients.

CASE RESOLUTION

You and your staff review what occurred in the case of the child who experienced a severe asthma exacerbation and identify the educational and environmental needs of your practice. You determine that your educational objectives are related to accessing the emergency equipment, having well-defined staff roles when advanced life support measures are required, and providing effective bag-valve mask ventilation. You obtain an inexpensive mannequin to serve as a model for the child and write the script of the case. You discuss with your office staff what your plans are and that the goal is to improve office function in emergent situations. You schedule an appropriate time and deliver the mock scenario with the entire office staff. It is discovered that some of the equipment is not operational, and some staff members voice a lack of confidence in their bag-valve mask skills, which they have not had to use for some time. A practice session is held in which staff members can practice the skill of bag-valve mask ventilation on the mannequin and receive constructive feedback on technique. Afterward, you lead a discussion with the group, review the points that require improvement, and develop a plan to rectify the equipment issues, knowledge gaps, and skills gaps. The mock code intervention was universally well received by the staff, and confidence in the ability to manage emergent situations in the office setting was improved.

CHAPTER 19

Pediatric Hospital Medicine

Melanie Rudnick, MD, FAAP, and Grant P. Christman, MD, FAAP

CASE STUDY

A 15-month-old girl presents to a community hospital emergency department with fever, cough, and rhinorrhea. On initial evaluation, she is found to be in moderate respiratory distress, with decreased air movement and scattered bilateral wheezes and crackles on lung examination. Her oxygen saturation is 87% on room air and rises to 96% with the application of 1 L/min of supplemental oxygen via nasal cannula. The physician diagnoses the patient with bronchiolitis and treats with nebulized albuterol and an oral dose of prednisone. The hospital has no inpatient pediatric service, so the emergency physician calls the local children's hospital to arrange a transfer. The emergency physician signs the patient out to a hospitalist, who accepts her onto the inpatient pediatric service and arranges for ground basic life support transport.

Questions

1. What is the role of hospitalists in inpatient pediatric care?
2. How can hospitalists implement principles of family-centered care and evidence-based medicine into the clinical care of hospitalized children?
3. How can hospitalists promote quality improvement and patient safety in the hospital setting?
4. What communication strategies can hospitalists use to ensure safe transitions of care within the hospital and back to the outpatient medical home after discharge?

Introduction

Every primary care physician (PCP) must periodically make the decision to hospitalize a patient who can no longer be cared for effectively in the outpatient setting. In 2015, 2.1% of all children and teenagers younger than 18 years, or more than 1.5 million patients, required hospitalization.

Common reasons for hospitalization include need for close monitoring due to existing or expected clinical compromise, initiation of an intensive diagnostic workup, expected need for surgical procedures, and administration of treatments that are complex and technology intensive or have a high adverse effect profile.

In the traditional model of providing hospital care, the PCP admits the patient to the hospital and continues to personally direct the patient's care, examining the patient while on rounds in the hospital daily; writing all orders for diagnostic studies, medications, and other care; and consulting directly with subspecialists as needed. Due to economic and structural pressures from a changing health care system, a second model has emerged in which, once the PCP admits the patient to the hospital, further care is coordinated by a pediatrician specializing in inpatient medicine: a hospitalist.

The term *hospitalist* was first coined by Wachter and Goldman in 1996. Although hospitalists existed prior to that time, the prevalence of hospitalists has increased significantly in the decades since. The Society of Hospital Medicine defines the scope of the hospitalist's work to include the clinical care of acutely ill, hospitalized patients; education, research, and leadership in the field of hospital medicine; and working to enhance the performance of hospitals and health care systems.

While hospitalists are unable to provide the uninterrupted continuity of care that PCPs provide in the traditional model, hospitalist systems offer a different advantage: the extended physical presence of a physician in the hospital who is responsible for the patient's care—as much as 24 hours a day, 7 days a week in some systems—which is impossible to sustain for a PCP with a busy outpatient practice.

Inpatient Pediatric Care

Every patient presenting for admission to the hospital requires a thorough initial evaluation (history and physical examination) following a direct verbal handoff from the health professional requesting the patient be admitted. If admission is requested by someone other than the PCP (eg, emergency physician, surgeon following a surgical procedure), the hospitalist should consider contacting the PCP to establish a relationship, gather more information about the presenting symptom, and learn more about the patient's established medical problems and routine care. Primary care physicians may not always be available, and, as such, it is helpful if patients have been thoroughly educated on their medical conditions and carry a list of their medications and allergies with them.

Inpatient pediatric care should be *patient and family centered,* which has been defined by the American Academy of Pediatrics as "health care that is grounded in a mutually beneficial partnership among patients, families, and providers that recognizes the importance of the family in the patient's life." In the hospital setting, this may take the form of *multidisciplinary family-centered*

rounds, a system in which doctors, nurses, and other allied health professionals make rounds together on hospitalized patients with their families at the bedside. During rounds, health professionals educate patients and families, hear their preferences, and include them in the medical decision making process. Some families may prefer not to participate in rounds, and this preference should be respected as well. If there is a language barrier, in-person, video, or telephonic interpreters should be used to facilitate making rounds, in accordance with the principle of equitability of care. A *child life specialist* may be consulted to help the patient cope with the hospitalization, including daily rounds and anxiety-provoking or painful procedures, by clarifying what is discussed in terms the child can understand and helping the child process or be distracted from these events through various types of creative play.

Patient- and family-centered care is complemented by the application of *evidence-based medicine* principles to medical decision-making. Questions of diagnosis, prognosis, treatment, or avoidance of harm should be clearly defined to facilitate an effective review of the medical literature. One way of developing a focused clinical question is through the PICO process, wherein the physician identifies the applicable *p*atient population, the *i*ntervention (ie, treatment, diagnostic test, or prognostic factor), the *c*omparison (ie, control or placebo group), and the *o*utcome (ie, diagnosis, prognosis, or harm to the patient). For example, in formulating a diagnostic workup for a 5-year-old patient presenting with an asthma exacerbation, the physician might ask whether school-age children with asthma (P) who undergo chest radiography (I) have a shorter length of hospital stay (O) than children who undergo no imaging (C).

Advances in technology have made it possible to consult medical evidence at the point of care—even in the patient's room during bedside rounds—with the use of laptops, tablets, and in-room computers. When searching through primary research studies, such as randomized controlled trials, to answer a clinical question, the physician must determine whether the results are valid and generalizable to the patient under consideration. It may be more efficient and just as legitimate to use a summary of the evidence, such as a systematic review, which may be available through an established medical journal or a web-based service. Having the PCP as an ally during the hospital stay may give the hospitalist more insight into how applicable a certain study is to the patient for whom the hospitalist is caring.

Hospitalists should also make use of clinical practice guidelines as a way of providing standardized and evidence-based care. The Health and Medicine Division of the National Academies (formerly known as the Institute of Medicine) defines *clinical practice guidelines* as "statements that include recommendations intended to optimize patient care that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options." In applying clinical practice guidelines, hospitalists should consider factors specific to the individual patient, such as comorbid conditions, limited availability of services in specific hospital settings, and patient values and preferences, that may warrant deviating from aspects of care recommended by the guidelines. Many of the guidelines used by hospitalists include discharge criteria, which are often dependent on availability of outpatient follow-up. This is yet another example of importance of communication with PCPs throughout patient hospitalization.

In addition to providing routine inpatient care, some hospitalists also provide specialized care, such as procedural sedation, palliative care consultations, and surgical or medical comanagement. Hospitalists often play a role in accepting patients for admission to the inpatient service, facilitating hospital-to-hospital transfers, and providing physician-assisted transport. They may also be tasked with determining the appropriate mode and level of transport.

Due to medical and technological advances leading to improved survival rates, hospitalists are increasingly caring for the growing population of children with complex medical needs. Providing quality care to these children is challenging due to their dependence on medical technologies and multiple medications, the paucity of applicable clinical evidence to support management strategies, and the need for time-intensive and complex care coordination. Depending on the resources available to the family and the PCP's familiarity with the patient (which may be limited if the patient has had frequent or prolonged hospital stays), transitioning the patient to the outpatient medical home may be particularly challenging. Specific efforts should be made to ensure a quality handoff so that there are no lapses in care and the PCP fully understands any adjustments made to the care plan during hospitalization.

Patient Safety and Quality Improvement

While it is important for individual physicians to engage in clinical practice that is family centered and evidence based, the next step is to ensure that quality care is being systematically delivered at the hospital level, and where it is not, that quality improvement (QI) programs are initiated. In its 2001 report, *Crossing the Quality Chasm,* the Institute of Medicine defined quality health care as having 6 characteristics: safe, effective, efficient, patient centered, timely, and equitable. Opportunities to improve the quality of care delivered by the hospital may be suggested by issues faced in individual patient encounters, quality metrics tracked by hospital administration (eg, length of stay, readmissions), or feedback from patients, their families, and their PCPs.

One model for the creation of QI projects is the *Plan-Do-Study-Act* cycle. In the Plan phase, the hospitalist identifies a problem or aim, defines a change that could be made to address the problem, and determines how the effectiveness of the change will be measured. It is usually necessary to form a team of like-minded physicians, administrators, nurses, and other allied health professionals early in the planning process. In the Do phase, the change is implemented, and data are collected about its effectiveness. These data may include *process measures* (ie, how

consistently the change is implemented) and *outcome measures* (ie, the effect of the change on the patient population, hospital system, costs). In the Study phase, data are analyzed, and successes and failures of the program are identified. Finally, in the Act phase, the team determines whether the change should be continued and adopted more widely in the hospital, modified in some way, or discarded altogether. Depending on the project, additional Plan-Do-Study-Act cycles may be needed to maximize the breadth and depth of the effect. Successes should be shared publicly with the hospital community to promote support for further QI efforts.

Physicians should also promote a *culture of safety* in the hospital, meaning that the hospital's processes and workforce are dedicated to the promotion of patient safety. *Adverse events,* a term encompassing all injuries caused by medical management, are common and are often caused by preventable medical errors, especially medication errors (eg, incorrect dosing, administering medications to the wrong patient). Common initiatives to improve patient safety include use of electronic health records and computerized order entry, review of orders by multiple health professionals, promotion of sterile technique and handwashing, work-hour limitations to prevent fatigue, and having time-outs before procedures to verify the patient's identity and the site of the procedure. Hospitals should hold regular morbidity and mortality conferences to review cases in which adverse events occur. These conferences should be confidential and focus not on blaming individual health professionals but on identifying systemic failures that may be corrected to prevent future adverse events. When adverse events occur, patients and their families should be informed in a timely fashion, according to procedures established by the hospital.

Transitions of Care

Inpatient systems in which hospitalists work in shifts typically have physician-to-physician handoffs of patient care responsibility at least once every 24 hours. Resident work hours in teaching hospitals have been limited to promote patient safety, but this also results in more frequent patient handoffs. If there is inadequate communication, handoffs may increase risk for medical errors and adverse events. Safe handoffs may be promoted by written handoff notes and strategies for effective verbal handoffs. One such strategy uses the I-PASS mnemonic, with the letters standing for a 5-step process in verbal handoffs (Box 19.1).

The discharge process should begin as soon as the patient is hospitalized. Goals of the hospitalization, discharge criteria, potential barriers to discharge, and an anticipated date of discharge should be identified in concert with the patient and family and reviewed during daily rounds. The hospitalist should formulate the discharge plan together with the other health care and allied health professionals involved in the care of the patient, including subspecialists, nurses, social workers, and discharge planners. For patients with complex needs, issues to address may include procurement of durable medical equipment, insurance coverage for medications, scheduling of follow-up appointments, and provision of other services, such as in-home nursing. The use of written or computerized discharge checklists may help ensure that no element is delayed long enough to prolong the hospital stay or forgotten altogether.

Box 19.1. I-PASS Mnemonic for Verbal Handoffs

- Illness severity (ie, stable or unstable)
- Patient summary (ie, summary statement, events leading up to admission, hospital course, ongoing assessment, plan)
- Action list (ie, to-do list, timeline, ownership)
- Situation awareness and contingency planning (ie, know what's going on and plan for what might happen)
- Synthesis by receiver (ie, receiver summarizes what was heard, asks questions, and restates key action items)

The final result of the discharge process is the transition of care from the hospitalist back to the PCP and medical home. If communication is poor, this transition carries with it the potential for significant information loss (eg, the hospital course, new diagnoses, future outpatient care needs such as subspecialty referrals and laboratory testing) and resulting adverse events for the patient. Ideally, the hospitalist should strive to communicate periodically with the PCP throughout the hospitalization, especially at the time of any important events. Most essential is communication at the time of discharge, which may take the form of verbal updates by telephone, emailed updates, and faxing or emailing of discharge summaries.

Education

A large portion of pediatric residency training occurs on inpatient units, and hospitalists are at the front line of pediatric resident education. When leading traditional resident-covered inpatient teams, hospitalists may contribute added educational value through direct observation of trainee history taking and physical examination skills, providing frequent and effective feedback, and promoting trainee autonomy on family-centered rounds. Due to resident duty hour restrictions, hospitalists are increasingly providing direct patient care on services without residents or other trainees, and many hospitalists practice in community hospitals without training programs. In these cases, there may be opportunities to educate non-pediatrician physicians (eg, surgeons, emergency physicians), nurse practitioners, and physician assistants in topics related to pediatric care.

Conclusion

The use of hospitalists to provide inpatient pediatric care has been on the rise over the past 2 decades since the term was first introduced. Studies of hospitalist systems suggest that the quality of care provided by hospitalists is equivalent to, and in some ways may improve on, care delivered via the traditional model. When attention is paid to maintaining communication, hospitalists have the potential to be partners in care with PCPs and the outpatient medical home.

CASE RESOLUTION

The patient is admitted to a monitored bed, and, after the initial assessment, the hospitalist concurs with the diagnosis of bronchiolitis. Based on current clinical practice guidelines, the hospitalist discontinues the use of systemic steroids and bronchodilators. The hospitalist obtains the number of the PCP from the family and places a call on the day of admission; during the call, the hospitalist learns that the patient has a penicillin allergy that was not reported by the parents during the history and physical examination. The hospitalist also begins to explore the possibility of initiating a quality improvement project in the management of bronchiolitis, which would use the clinical practice guidelines to create a set protocol for admissions with an order template in the electronic health record. The patient improves over the subsequent 3 days and is transitioned off oxygen. The hospitalist, together with a discharge planner, reconnects with the PCP, faxes a discharge summary, and arranges a follow-up appointment 3 days after discharge at a time when the parents are available. The patient is seen by the PCP at the scheduled appointment time. The parents tell the PCP they were told to monitor her respiratory effort, oral fluid intake, and urine output, all of which have been normal. While the parents have noticed that she still has a runny nose and cough, these symptoms have improved since discharge from the hospital.

CHAPTER 20

Pediatric Genomic Medicine

Moin Vera, MD, PhD, and Henry J. Lin, MD

CASE STUDY

A 4-year-old boy with moderate global developmental delay is brought to his pediatrician's office for evaluation. The patient has an unremarkable family history and normal physical examination findings. Previous evaluation included normal karyotype and fragile X syndrome DNA test results. The patient's parents would like to know whether there is anything else that can be done to determine the etiology of the delay. In addition, his mother has recently read about companies that offer multiple genetic tests to consumers and wonders whether these tests will be useful as well.

Questions

1. What is microarray technology, and how is it useful in pediatric practice?
2. How is next-generation sequencing technology affecting current practice?
3. What are the limitations of these new technologies?
4. What is direct-to-consumer genetic testing?

The National Human Genome Research Institute at the National Institutes of Health describes genomic medicine as the incorporation of an individual's genomic information into clinical care. In this way, care involves diagnosis, therapeutic decision-making, health outcomes, and policy implications. The Human Genome Project (HGP) was an extensive, broad-based, and multidisciplinary research effort to develop knowledge of biology and disease—leading to the potential for so-called precision medicine, based on genome sequence information. The first essentially complete human sequence was published in 2003. The cost of sequencing a human genome has decreased from approximately $100 million in 2003 to about $1,000 in 2018, according to National Human Genome Research Institute data.

Whole exome sequencing (WES) uses next-generation sequencing to focus on exons, the regions of the genome that contain the actual DNA code for making proteins. Overall, the exons amount to about 1.5% of the human genome. Whole exome sequencing costs less than whole genome sequencing, and the functional significance of variants within exons is easier to interpret. Whole exome sequencing or whole genome sequencing is an appropriate study when a single-gene (or mendelian) disorder is suspected.

Chromosomal microarray analysis—compared with standard chromosome analysis—dramatically increased diagnostic yields for patients with intellectual disability, autism spectrum disorder (ASD), and multiple congenital anomalies. Genetic testing via gene sequencing panels (eg, 20–1,000 genes) and WES have driven diagnostic yields still further. Direct-to-consumer genetic testing is also available, designed to provide information without physician input. Pharmacogenomics, which promises individualized drug therapy based on genomic data, is moving toward applications to common diseases.

Epidemiology: Human Genome Anatomy

Human cells have 2 haploid genomes (ie, 23 pairs of chromosomes, 1 pair of most genes), each containing 3 billion base pairs with an estimated 20,000 to 25,000 protein-encoding genes, plus a variable number of copies of the mitochondrial genome. On average, 2 humans share 99.9% of their DNA. There are at least 10 million single nucleotide polymorphisms (SNPs), which are single base changes that are present in a substantial percentage of the population (>1%). A small percentage of SNPs fall within known coding or regulatory regions of genes and directly influence gene function. The remaining SNPs may have unclear effects on gene function, but they may be inherited in recognizable patterns (haplotypes) with other SNPs.

Recently, it has become evident that most human DNA variation is not represented by SNPs. Instead, copy number variants, in which DNA segments containing up to several million base pairs are duplicated or deleted, account for a substantial portion of variation among individuals. Approximately 12% of the genome can exhibit copy number variation, but the effect of such variation on individual phenotypes is unknown.

Autosomal recessive disorders are caused by pathogenic variants in each of the 2 copies of a disease-associated gene. Carriers of such disorders, with only 1 variant or disease allele, are typically asymptomatic. Although most autosomal recessive disorders are rare, most humans are carriers of several different recessive disease alleles. In a 2011 study, an average of 2.8 recessive variants was observed per person, among 448 genes involved in severe autosomal recessive disorders.

Pathophysiology: Genotype and Phenotype Correlations and Environment

Genomic data provide information about the genes on which pathogenic mutations are found. But many diseases are caused by a combination of genetic susceptibility and environmental factors. The first examples of such interactions were monogenic conditions, such as complement deficiency (which predisposes patients to bacterial meningitis) or mendelian cancer syndromes (which cause extreme radiation sensitivity). However, the gene-environment connection is now recognized to be more complex. For example, certain environmental conditions have been found to cause DNA methylation, a mechanism for gene silencing without changing the DNA sequence. These so-called epigenetic changes may persist across generations. As an example, mothers exposed to wartime famine may birth children who are predisposed to conservation of energy. When these children are fed a typical American diet, they are prone to development of obesity and diabetes. Also, fetal cells that persist in maternal circulation (fetal microchimerism) may play a role in tumor prevention and susceptibility to autoimmune disease. Finally, our bodies contain more bacteria than human cells, and the interaction of the bacterial and human genomes is thought to play an important role in the development of some diseases.

Clinical Presentation, History, and Physical Examination

A thorough history and physical examination will continue to be critical components of patient assessment in the genomic age of medicine. Large databases will be needed to correlate human genotypes with corresponding phenotypes defined by the patient's clinical presentation. Even when genetic and epigenetic sequencing is commonplace, the only way to measure the effect of the disease on the individual is by clinical assessment.

Laboratory Tests

Microarray testing, which includes a wide range of different technologies, has had a dramatic effect on the evaluation of common pediatric conditions, such as intellectual disability and ASD. Comparative genomic hybridization (CGH) microarray testing uses closely spaced DNA probes to detect chromosomal deletions or duplications at 100 to 10,000 times the resolution of standard karyotyping. The diagnostic yields for patients with intellectual disability and multiple congenital anomalies has increased from 3% to 4% to 15% to 20%, using this technology. For example, patients with ASD with normal karyotypes may have microdeletions or microduplications of 16p11.2. Several relatively common genetic conditions, such as 1p36 deletion syndrome, a form of severe intellectual disability that affects 1 in every 5,000 to 10,000 newborns, have been delineated through the use of microarray testing.

Single nucleotide polymorphism microarray testing has largely replaced CGH. It detects the same chromosomal imbalances as CGH, but SNP microarray testing can pinpoint regions of homozygosity, which represent identical sequences on both copies of a chromosome. The information may be useful to consanguineous couples, because it suggests areas where abnormal autosomal recessive disorder genes may be found. In addition, SNP microarray testing can detect some cases of uniparental isodisomy (inheritance of 2 identical copies of a chromosome from 1 parent) and may suggest the presence of an imprinting disorder, such as Prader-Willi syndrome.

Although microarray testing has largely replaced standard karyotyping, microarray testing cannot detect carriers of balanced translocation or patients with mosaicism (when the proportion of abnormal cells is <25%–30%). Some deletions or duplications detected by microarray testing are benign variants. Therefore, lack of availability of parental samples may hinder interpretation of an abnormal finding in a child.

Next-generation sequencing is a term used to describe methods for parallel sequencing of billions of base pairs at relatively low costs. Whole exome sequencing focuses on the 1% of the genome that encodes proteins and has been used for clinical testing in the past several years. A 2013 report shows a diagnostic yield of 25% for this technology in 250 samples studied. Whole genome sequencing has also become clinically available, although perhaps large-scale discovery of variation in regulatory elements located outside the coding regions has yet to be fully realized. These technologies have created a major paradigm shift, by decreasing the time to diagnosis and averting many costly and invasive procedures, such as muscle biopsy. Improvements in the technology and the bioinformatics used to interpret results are expected to increase the use of these tools.

Next-generation sequencing methods have certain limitations that should be addressed as technology progresses. Some genes, particularly those with high guanine-cytosine content, are not well captured or sequenced with current high-volume technologies. Exome sequencing cannot capture triplet repeat conditions, such as fragile X syndrome. Microduplications and microdeletions (of exons) are not normally detected with current technologies and must be assessed separately, using a microarray.

A patient's next-generation sequencing results will have thousands of differences from reference sequences. Bioinformatic algorithms must be used to sift through the data and determine the changes that are potentially relevant to the patient's condition. Parental testing often provides an essential reference but may not always be available. The testing laboratory classifies variants found into 5 categories: pathogenic, likely pathogenic, variants of unknown significance, likely benign, and benign. Family counseling may be limited for variants of unknown significance. Technology will drive down the price of sequencing over time, but the cost of bioinformatics will dominate the price of these new technologies as the amount of data increases.

Direct-to-Consumer Genetic Testing

Several commercial testing companies now market genetic tests directly to consumers. These tests purport to provide disease risk information by analyzing multiple SNPs along with common disease mutations. However, the tests may lack sensitivity and specificity, because analyses are based on limited genetic markers without

family history or phenotype information. Many consumers (and their physicians) are ill-equipped to understand the results, and patients of color may have indeterminate results. These companies argue that consumers have the right to know their genetic information, and some offer genetic counseling services. In 2010, the US Food and Drug Administration decided to develop regulations for the sale of direct-to-consumer genetic tests.

Management: Pharmacogenomics

Individualized pharmacological treatment has always been 1 of the goals of the HGP. Although pharmacogenomics is a fairly young field, several tests are available that can reduce the risk of an adverse drug reaction. Patients with variant thiopurine methyltransferase alleles may experience severe toxicity to azathioprine and 6-mercaptopurine. Children with a 1555A>G mutation in the mitochondrial genome are susceptible to aminoglycoside-induced hearing loss, even after a single dose of an aminoglycoside antibiotic. Pharmacogenomic treatment of common diseases (eg, asthma) is an active area of investigation and may allow for a more rational choice of drug regimens.

Future Developments

The huge potential of the HGP now influences several areas of medicine, including pediatrics. During the next decade, genomics will likely continue to revolutionize the diagnosis of rare or previously uncharacterized mendelian disorders. The impact of genes on common diseases, such as atherosclerosis, is being investigated through ever larger genome-wide association studies and polygenic risk scores. Although molecular diagnoses of previously unidentified diseases have increased over the past several years, our understanding of disease pathogenesis and treatment has not kept pace with the explosion in information. It is unclear how individuals will use genomic information to improve health—whether by altering lifestyles or by use of precision drugs, or both.

In addition, whole exome and whole genome sequencing create various ethical issues. If a patient presents with heart disease and testing shows an increased risk for Alzheimer disease, should this information be returned to the patient? It is certain that pediatricians will need to familiarize themselves with genomic medicine, because the number of tests—and patients seeking testing—will exceed the availability of medical genetics specialists.

Glossary	
Autism spectrum disorder	A medical condition resulting in deficits in social communication and social interaction and characterized by restricted, repeated interests and behaviors starting in early childhood. Other formal criteria are also used to establish a diagnosis.
Comparative genomic hybridization	A chromosomal microarray method in which tens of thousands of DNA probes for regions along the genome can be used to detect chromosome deletions or duplications at 100 to 10,000 times the resolution of standard karyotyping. Comparative genomic hybridization has largely been replaced by single nucleotide polymorphism microarray methods. The DNA probes (for binding to patient DNA) are immobilized on glass slides—called *microarrays*.
Copy number variant	Variants in the structure of the genome having different numbers of copies of DNA segments (usually between 1 kilobase and 5 megabases long). Copy number variants form a large part of human DNA diversity, including causes of some genetic conditions.
Human Genome Project	The worldwide effort to determine the DNA sequence of the *Homo sapiens* genome (3 billion bases). The project was launched in the United States by the US Department of Energy and the National Institutes of Health. Efforts were also started in France, the United Kingdom, and Japan. Other countries joined later (eg, Germany, China). The project ran from approximately 1988 to 2003. A review of the effort stated: "For everyone, this achievement represents a major turning point in our quest to learn how all the components of the human genome interact and contribute to biological processes and physiological complexity."
National Human Genome Research Institute	One of the 27 institutes and centers of the National Institutes of Health. It was established in 1989 and is "devoted to advancing health through genome research."
Single nucleotide polymorphism	The most common and simplest type of DNA polymorphism, in which 1 base is changed to another. These polymorphisms occur roughly every 1,000 base pairs in the genome. Those that occur in or around genes may change the amino acid sequence of the encoded protein, may produce or remove a stop codon, may impair the usual processing (splicing) of the messenger RNA, may change how the gene is controlled, or may have no effect at all.
Single nucleotide polymorphism (SNP) microarray testing	A chromosomal microarray method that has largely replaced comparative genomic hybridization. It may contain a few million oligonucleotide probes (approximately 25 nucleotides long) for regions along the genome. In addition to detecting chromosome deletions and duplications, SNP microarray testing can also detect long regions of homozygosity, indicating uniparental disomy or consanguinity. The diagnostic utility of chromosomal microarray testing among children with intellectual disability, autism spectrum disorder, and congenital anomalies has been estimated to be 10% to 20%.
Whole exome sequencing (WES)	Sequencing all the known coding regions in the genome. The diagnostic utility of WES among children with intellectual disability, autism spectrum disorder, and congenital anomalies has been estimated to be at least 30% to 40%.

CASE RESOLUTION

The patient's microarray testing results show a small microdeletion in chromosome 6. Parental testing indicates that the microdeletion is present in the patient's father, who has had normal development. Further testing includes WES, which shows a potential missense mutation in *CASK*, a gene on the X chromosome that may cause developmental delay. This alteration is not found in the patient's mother, implying that it is most likely deleterious. The parents receive genetic counseling about future pregnancies.

CHAPTER 21

Principles of Quality Improvement: Improving Health Care for Pediatric Patients

Bonnie R. Rachman, MD

CASE STUDY

During a routine staff meeting at your group pediatric practice, it was noted that many of the patients cared for by your practice are behind in their immunizations. The reasons for this are unclear, because you and your colleagues are strong proponents of the timely administration of preventive immunizations. You want to develop a mechanism to determine what factors are resulting in delayed vaccine administration.

Questions

1. What is quality improvement?
2. How does assessing the delivery of recommended health maintenance relate to quality?
3. How is the prevention of medical errors related to quality improvement?
4. What is the difference between harm and error?
5. What factors are associated with medical errors?
6. What is meant by organizational culture?

History

The origin of medical quality improvement (QI) lies not in medicine but in industry and dates to the 1920s. Walter A. Shewhart, PhD, was an American physicist, engineer, and statistician. In 1924, Shewhart presented a memo in which he showed a schematic control chart. The diagram and text set forth all the essential principles and considerations involved in quality control. Shewhart pointed out the importance of reducing variation in a manufacturing process and noted that continual process adjustment in reaction to nonconformance actually increased variation and degraded quality. He went on to develop *data presentation rules* that remain important today: Data have no meaning apart from their context, and data contain signal and noise. To be able to extract information, it is imperative to separate the signal from the noise within the data.

In the 1950s, Shewhart's colleague, W. Edwards Deming, PhD, while working in Japan, taught top management how to improve design and, subsequently, service, product quality, testing, and sales. Deming, applying Shewhart's concepts, described the Plan-Do-Study-Act (PDSA) method as an approach to QI. He opined, "The key is to practice continual improvement and think of manufacturing as a system, not as bits and pieces."

In the 1970s, physician Avedis Donabedian, MD, MPH, proposed a model for assessing health care quality by describing 7 pillars of quality (Box 21.1). He posited that structure is the environment in which health care is provided, process is the method by which health care is provided, and outcome is the result of the care provided. He emphasized the importance of measurement and evaluation of health care quality, ensuring completeness and accuracy of medical records, observer bias, patient satisfaction, and cultural preferences for health care.

In 1991, Paul B. Batalden, MD, and Donald M. Berwick, MD, MPP, FRCP, helped found the Institute for Healthcare Improvement (IHI), which has resulted in the application of QI science to health care both in the United States and internationally. The IHI promotes the adoption of measurement and feedback to improve the quality of health care. The IHI is an easily accessible resource for education and information related to QI in health care.

Historically, QI efforts were focused on "quality assurance." The goal was to minimize "defects" as measured by audits. Currently,

Box 21.1. The Seven Pillars of Quality

- Efficacy
- Efficiency
- Optimality
- Acceptability
- Legitimacy
- Equity
- Cost

the emphasis is on QI, which focuses on moving the entire performance curve toward a higher level of performance by identifying and adopting best practices rather than simply focusing on low performers. Ongoing measurement is vital to sustaining any improvement. The process of QI requires careful planning, thorough documentation, consistent analysis, and open-mindedness to results. In health care, QI consists of systematic and continuous actions that result in a measurable improvement in health care services and the health status of the targeted patient group.

Quality Improvement in Pediatrics

Quality improvement works to strengthen systems and processes and, in medicine, focuses on patients and the use of data to drive improvement in patient safety and health care. To achieve a different level of performance and improve quality, an organization must be willing to change.

The specialty of pediatrics emphasizes health maintenance and disease prevention. Studies have shown that recommended targets are not being consistently realized, however. Mangione-Smith et al reported that children received only 46.5% of recommended care for preventive services, acute illness management, and ongoing care of chronic conditions. In 2017, as reported by the Centers for Disease Control and Prevention, this number had not changed. Shaughnessy and Nickel reported that 21% of outpatient prescriptions in a family medicine practice contained at least 1 error. Other investigators found that medication samples were dispensed with inadequate documentation. In a pediatric emergency department in Canada, 100 prescribing errors and 39 medication administration errors occurred per 1,000 patients. In a sample of new prescriptions for 22 common medications in outpatient pediatric clinics, approximately 15% were dispensed with potential dosing errors. Even with the use of electronic medical records and e-prescribing technology, prescribing errors continue to occur as the result of auto-populate errors and/or choosing the wrong medications and/or wrong formulations from the drop-down menus. Multiple medication alerts during the prescribing task distract the clinician, resulting in errors. In addition, these frequent and often irrelevant alerts may cause "alert fatigue." Outdated or incorrect information, such as weight entered as pounds rather than kilograms into the electronic medical records also may result in dosing errors.

The Learning from Errors in Ambulatory Pediatrics study aimed to learn the scope of, range of, potential causes of, and possible solutions to medical errors in pediatric ambulatory care. The study found that among 14 pediatric practice sites, 147 medical errors were reported during the 4-month study period. The largest group of errors was related to medical treatment (37%). Of the medical treatment errors, 85% were medication errors. Errors also were associated with patient identification (22%); preventive care, including immunizations (15%); diagnostic testing (13%); and patient communication (8%). According to the Medical Professional Liability Association (formerly the Physician Insurers Association of America), from 2003 through 2012 diagnostic errors accounted for 828 closed pediatric cases, with an average indemnity of $414,455, and medication errors accounted for 113 closed cases, with an average indemnity of $207,916. According to a systematic review, as many as 10% of all pediatric medication orders result in a medication error.

Many examples exist of errors in inpatient care as well. A study of inpatient medication errors found that among 1,000 children in 12 independent children's hospitals, 1 in 15 children was exposed to wrong medications, side effects, or drug interactions. Takata and Currier reported a rate of 11.1 adverse events per 100 pediatric inpatients; 22% of these errors were deemed preventable. In a 2014 report from The Joint Commission, the root causes of more than 80% of almost 2,400 sentinel events were human factors (eg, staff supervision issues), leadership (eg, organizational planning), communication (eg, with patients or administrators) and assessment, including timing and/or scope.

Kurtin and Stucky describe 5 barriers or challenges to high-quality care in the pediatric and adult health arenas, the first of which is widespread unnecessary variation in care (Table 21.1). To prevent medical error, it is necessary to understand how, when, and where it occurs; evaluate the system that allowed the error to happen; and keep the system open and blame-free (Box 21.2).

Factors associated with risk of error are not the individuals who work in the system but rather the system in which the individuals work. To reduce the risk of error, the language of patient safety must be understood by all health professionals, and a deeper understanding of the principles of systems analysis work models and other solutions must be developed.

Definitions

Understanding QI and improving patient safety requires familiarity with the terminology. The National Patient Safety Foundation defines *patient safety* as the avoidance, prevention, and amelioration of adverse outcomes or injuries stemming from the processes of health care. The Health and Medicine Division of the National Academies (formerly the Institute of Medicine [IOM]) defines *patient safety* as freedom from accidental injury.

An *adverse event* is injury caused by medical management rather than by an underlying condition. Some adverse events are not preventable. One example of a non-preventable adverse event is the patient who receives the appropriate antibiotic at the appropriate

Table 21.1. Barriers to High-quality Health Care

Barrier	*Explanation*
Unnecessary variation in care	Diagnostic or therapeutic interventions performed at the discretion of the ordering physician and not required by the patient's condition
Gap between knowledge and practice	The time—perhaps many years—from publication of a proven new practice in the medical literature to its use in routine clinical care
Failure of physicians to understand and work in the hospital's complex systems of care	Challenges to accessing information, data, personnel, and/or materials to facilitate patient care
Need to improve patient safety	No consistent mechanism in place
Slow adoption and routine use of practices that can improve clinical outcomes and patient safety	May be mitigated by the use of clinical pathways

Box 21.2. Factors Associated With Errors in Health Care

- Communication failure
- Frequent distractions and interruptions
- Inadequate supervision
- Medication issues
- Limited access to patient information
- Noisy work environment
- Lack of 24-hour pediatric pharmacy
- Emergency situations

time in an appropriate dose and who has an allergic reaction to the medication because of the existence of an allergy that was unknown to both the patient and the staff. This differs from *medical error*, which is the failure of a planned action to be completed as intended (ie, error in execution) or the use of a wrong plan to achieve an aim (ie, error of planning). *Outcomes* summarize the effectiveness of care, including adverse events.

James Reason, who did extensive work on organization models of accidents, further delineates the terminology. A *slip* is an error in execution, that is, the observable action deviates from what was planned. A *lapse* is an error in execution resulting from a memory failure. A *mistake* is a knowledge-based failure, that is, the plan was performed correctly, but the planned action was wrong for the situation. An *active error* (ie, sharp-end error) typically occurs in a patient care area by a frontline practitioner; the effects may be felt immediately. A *latent error* (ie, blunt error) is the result of a systems-based problem and may relate to poor design, incorrect installation, look-alike packaging, soundalike names, faulty maintenance, or bad management decisions. Latent errors are more difficult to identify and hard to recognize. Health care workers frequently develop work-arounds to bypass the problem, which often leads to the belief that the work-around is normal.

A *system* is a set of interdependent human and nonhuman elements that interact to achieve a common aim. In a hospital, a system may be a unit or a department. *Processes* are the means by which care is delivered. Questions related to process include the following: Are policies routinely followed? Are evidence-based medicine guidelines implemented? Does the transfer of patients occur in an organized manner? *Work models* provide a conceptual framework for investigating events and processes to ensure the evaluation of all contributing factors. The PDSA method is an example of a conceptual framework. The premise of all work models is that an organized, systematic approach to event investigation results in reliable data that may be used to develop a new system.

Continuous QI (CQI) is the continued process of reviewing and improving processes and procedures associated with providing goods or services. A CQI approach may involve evaluating structure, process, or outcome either individually or—because of the considerable overlap that exists between the components and quality of care—as a whole.

When evaluating the quality of health by comparing outcomes, it is important to understand the concept of *risk adjustment*, which allows statistical adjustment of patient differences (eg, severity of illness) to make comparisons of outcomes clinically meaningful. Use of risk adjustment enables the translation of statistically significant tests into clinically meaningful results.

Errors and How They Occur

The pervasiveness of the medical error problem is enormous. In 1999, the IOM published *To Err Is Human: Building a Safer Health System*, in which it was reported that medical error accounted for approximately 44,000 to 98,000 deaths annually in US hospitals. This is more deaths than from AIDS, motor vehicle crashes, or breast cancer. The types of errors included adverse drug events, improper transfusions, surgical injuries, wrong-site surgeries, mistaken patient identity, and failure to prevent patient suicides. Most errors occurred in intensive care units, operating rooms, and emergency departments. The annual total cost of these errors was estimated to be between $17 billion and $29 billion. The cost of additional care was $8 billion. This figure does not account for lost income and productivity. A 2004 report of inpatient deaths estimated that 575,000 deaths were caused by medical error between 2000 and 2002, approximately 195,000 deaths per year. In 2008, the US Department of Health and Human Services Office of Inspector General reported 180,000 deaths per year resulting from medical error among Medicare beneficiaries alone.

The IOM made many recommendations in their report, including a balanced approach between regulatory and market-based initiatives as well as the establishment of a national focus to create

leadership, research, tools, and protocols to enhance the knowledge base about safety. It recommended raising performance standards and expectations for improvements in safety through the actions of oversight organizations, professional groups, and group purchasers of health care. An additional recommendation was to implement safety systems in health care organizations to ensure safe practices at the delivery level.

In 2001, the IOM published a follow-up report, *Crossing the Quality Chasm: A New Health System for the 21st Century.* Safety was deemed the key dimension of quality. The report also indicated that only a systems approach would work to improve quality in health care; trying harder is an inadequate approach. Per the report, a stepwise correction of problems in the system is the key to success. Additionally, it indicated a need to overcome the culture of blame, because human error is to be expected. Table 21.2 defines types of errors in health care.

Typically, medical errors are neither isolated events, nor are they made by a single person. Normally, numerous safe points and double checks are built into the process; however, each layer of safety has gaps or holes. When these gaps align, the error reaches the patient. Standardized approaches can reduce variability and improve system efficiency. The goal is to make the gaps as small as possible or even eradicate them. Many factors are associated with medical error, including human factors triggered by interruptions, fatigue, time pressures, anger, anxiety, fear, and boredom. Mistakes can result from a wrong plan of action. Mistakes may involve misinterpretation of a problem, lack of knowledge, and habitual patterns of thought. A *violation* is a purposeful rule violation, whether reasoned or reckless. The factors associated with risk are not the individuals who work in the system but rather the system in which the individuals work.

Harm Versus Error

The ultimate goal of QI is to reduce patient harm. Early QI efforts targeted the elimination of error in the belief that reducing error would decrease harm. This is not true, however; most medical errors never harm patients and may be clinically insignificant (eg, 1-hour delay in administration of acetaminophen). So why does one differentiate? Focusing on harm puts the microscope on the system, not the individual.

Table 21.2. Types of Errors in Health Care

Error	*Definition*
Diagnosis	Delayed diagnosis: failure to use indicated tests, use of outmoded tests or therapy, or failure to act on results of monitoring or tests
Treatment	Error in the performance of an operation, procedure, or test; an avoidable delay in treatment or failing to respond to an abnormal test; inappropriate/not indicated care
Medication	The most frequent type of error, which includes error in the dose; method of using a drug
Prevention	Failure to provide prophylactic treatment, or inadequate patient monitoring or treatment follow-up

Quality Improvement and Organizational Culture

"This is the way we do things around here."

Patients expect to receive quality health care without experiencing preventable harm. The IOM defined *quality* in health care as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." One factor that influences quality in health care is organizational culture.

Many pediatricians are never taught about organizational culture. It is the invisible, powerful dictator of how things are done in an organization. Organizational culture is a latent and often unconscious set of forces that determines individual and collective behavior, ways of perceiving, thought patterns, and values. Hospitals have their own cultures. Subcultures exist among physicians and nurses as well as within departments (eg, critical care). It may be challenging to understand all the different subcultures within a hospital.

Activities or processes within a health care organization contain 2 major components: what is done (ie, what care is provided) and how it is done (ie, when, where, and by whom). Quality improvement can be achieved by addressing either component, but addressing both simultaneously has the greatest effect on QI. The goal of QI is to enable an organization to achieve the ideal critical pathway, which is one that allows proactive and efficient interaction between the care team and patient to achieve optimal health outcomes.

Promoting change is rarely easy. Some people may adapt and change appropriately, while others resist and become dysfunctional. Making changes requires an environment in which teamwork can grow. Groupthink must be avoided. The term *groupthink* was coined by Yale psychologist Irving Janis, PhD; it is "a way of thinking that people may adopt when they are members of a cohesive or homogeneous group; in particular, a group whose members seek unanimity of thought to the point that they cannot consider alternative ideas." It can prevent critical thinking and debate. Without disagreement, creativity can be lost. Negative effects of groupthink include an illusion of invulnerability, insulated leaders who may be protected from contradictory evidence, and members who accept confirming data and reject data that fail to fit their views. Alternatives are not considered, and individuals with conflicting views are discounted or demonized. Talented leaders welcome diversity of thought and ideas. Leaders must empower team members to have open discussions and offer ideas.

Communication is a key component of organizational culture. *Communication* involves 2 parts: message and meaning. The message is stated; meaning is interpreted and may be interpreted differently by different people. Strategies to improve communication are legion, including methods for remaining calm in high-workload, high-stress situations. Other strategies include increased verbalization, verbalizations that relate to problem-solving, speaking in the first-person plural, readback, and coordinating tasks to the

right person's experience level. Good communication encourages input from team members. Offering positive feedback builds confidence, reduces stress, and clarifies ambiguities. Team evaluations provide input on how well team members are communicating with each other and the progression toward achieving team goals. Benchmarking against a similar team may provide valuable information. An outside consultant may be hired to observe the team and provide feedback. Internally, the use of informal, regular meetings to discuss the team's progress and provide debriefing sessions to discuss the team process may be constructive in moving the team toward its goals and ensuring effective communication. All teams experience team conflict at some point. Conflict occurs when people come together to resolve a problem, dialogue about care improvement, or discuss changing processes to improve care. Team conflict must be managed effectively so that issues can be resolved while still providing the highest-quality patient care.

Teamwork has been defined by numerous organizations. In 2003, the IOM defined *teamwork* by stating, "All health professionals should be educated to deliver patient-centered care as members of an interdisciplinary team, emphasizing evidence-based practice, QI approaches, and informatics." The IOM defined a *multidisciplinary team* as one in which members cooperate, communicate, and integrate care to ensure that patient care is continuous and reliable.

Measuring Quality

Data are the cornerstone of QI. Ideally, measurements should evolve from the Health and Medicine Division of the National Academies quality aims (Box 21.3). Improvement measures may not be sufficiently valid and reliable for public dissemination yet may still be useful for benchmarking, for identifying best practices, or as part of QI initiatives.

Adult measures may not be appropriate for pediatrics. Pediatrics is unique because of the heterogeneity of patients, including age, size, diagnoses, and treatment modalities, including medication dosing.

Measures must be reliable. *Reliability* is the capacity of the measure to perform similarly under stated conditions over time. In health care, reliability and precision are often used interchangeably. *Precision* is the capacity of a measurement process to reproduce its own outcome. To achieve precision, a reliable system requires clear and concise definitions of the data fields to be collected. An effective approach is to train data collectors. A robust method for data coding and entry is also required. Reliability must be intermittently assessed within and between observers over time to ensure consistency.

Box 21.3. National Academy of Medicine Quality Aims

- Safe
- Effective
- Patient-centered
- Timely
- Efficient
- Equitable

Measures must also be valid. A measure is *valid* if it adequately represents the attribute of interest. *Internal validity* is the soundness of the developed indicator. *External validity* is the capacity for application of the indicator to a broader population.

Measures must be feasible and usable. *Feasibility* is the capacity to gather measures. For a measure to be usable, the intended audience must be able to understand the findings and use them in an appropriate fashion. A measure is *usable* if it enables the uncovering of meaningful differences between groups.

Three types of measure are essential to QI: outcomes measures, process measures, and balancing measures.

1. Outcomes measures: Address how the health care services provided to patients affect their health, functional status, and satisfaction (eg, the percentage of patients who died as a result of surgery).
2. Process measures: Address the health care services provided to patients (eg, the percentage of patients whose hemoglobin A_{1C} level was measured in the past year).
3. Balancing measures: Evaluate unintended consequences or the stability of the system being changed in the project (eg, ensuring that readmission rates are not increasing as a result of reducing length of hospital stay).

A balanced set of measures for a QI effort should include at least 1 outcome, 1 process, and 1 balancing measure. After measures are identified, an organization determines its data collection frequency and sampling. More frequent data collection allows an organization to focus its QI efforts more aggressively.

Quality Improvement Models

After opportunities for performance improvement have been identified, changes can be made to the underlying system targeted for improvement. The use of QI models alone or in combination is an effective approach for categorizing potential changes in the organization's system and identifying changes that have worked in similar settings.

Multiple QI models exist. Both the Care Model and Lean methodology provide frameworks for improving patient care, whereas the Model for Improvement, the FADE (focus, analyze, develop, execute and evaluate) model, and Six Sigma focus on processes. There are 6 fundamental aspects of care identified in the *Care Model*, which creates a system that promotes high-quality disease and prevention management. It does this by supporting productive interactions between patients, who take an active part in their care, and health professionals, who have the necessary resources and expertise.

Lean defines value based on what the patient wants. It maps how the value flows to the patient and ensures the competency of the process by making it cost effective and time efficient.

The *Model for Improvement* focuses on questions to set the aim or organizational goal, establish measures, and select changes. It incorporates PDSA cycles to test changes on a small scale.

The *FADE model* is separated into 4 broad steps: (1) focus: define the process to be improved; (2) analyze: collect and analyze data; (3) develop: develop action plans for improvement; (4) execute: implement the action plans, and evaluate (ie, measure and monitor the system to ensure success).

Six Sigma is a measurement-based strategy for process improvement and problem reduction. It is completed through the application of the QI project and accomplished with the use of 2 Six Sigma models: DMAIC (define, measure, analyze, improve, control), which is designed for use in examining existing processes, and DMADV (define, measure, analyze, design, verify), which is used to develop new processes.

Error Metrics

Measuring harm is often done using occurrence reports, which identify 2% to 8% of all adverse events in an inpatient setting. These reports may be done with retrospective, concurrent, or trigger-based chart review. No standardized methods exist for reporting, investigating, or disseminating information related to preventable adverse events. Historically, the qualitative concept of patient safety has been translated into quantitative metrics. Three frameworks that have been used include measuring error, measuring patient injuries, and measuring risk.

Error-based patient safety metrics are premised on the idea that the goal of medicine is to successfully implement the correct plan of care. It is an attractive measure of assessing safety because many errors occur and are somewhat easy to find. Many problems exist with error metrics, however, because few measures of error represent the true rate.

Error rate = (identified errors)/(potential opportunities for that error to occur)

The numerator (identified errors) may be hard to obtain because with reported events, only the errors reported are known, rather than the actual number of occurrences. Thus, the error rate is nothing more than a rate of reporting.

Another modality that has been proposed to obtain the true numerator is chart review. The difficulty with chart review lies in the number of steps in the process—error occurs, each error is recognized by a health professional, the error is documented by a health professional, the chart is reviewed, the reviewer recognizes the event during the chart review, and the error is attributed correctly. Ethnographic study (ie, the direct observation of people) is subject to the same pitfalls.

Other confounders include hindsight bias. To effectively rectify problems, the correct understanding and attribution of events that created the error must occur. The retrospective analysis of error creates the potential for incorrect or simplistic identification of causes of events. Subsystem failures are difficult to identify as a contributing cause of an adverse event. The incorrect or inadequate attribution of causality creates the potential for misguided actions to "solve" the wrong problem.

Focusing solely on active errors leaves latent failures unrecognized and unaddressed, thus increasing the vulnerability of the entire system to adverse events. Identifying errors is important, but focusing solely on errors may lead to "the blame game." Trends may be a barometer for organizational culture as it relates to patient safety. Identified errors provide learning opportunities, thereby preventing harm to other patients.

Injury-based patient safety metrics focus on unintended outcomes, such as catheter-related bloodstream infection, ventilator-associated pneumonia, in-hospital cardiac arrest, and death. Improvement efforts are more likely to focus on system vulnerabilities with a high potential for adverse events.

Risk-based patient safety metrics are a means of measuring hazards or risks. From a systems-based view, errors and injuries are the result of hazards or risks within the system of care. The focus is on hazardous conditions that increase the likelihood of downstream errors. Efforts are centered on 3 core areas: systematic risk identification, risk assessment, and risk reduction and/or elimination. This approach is proactive and saves counting errors and injuries. The elimination of risk includes the substitution of less risky alternatives, the development of administrative controls, and individual protection. It incorporates information gathered from the front-line bedside practitioner. The focus on risk reduction may decrease the need to quantify error rates or injury prevalence. This requires a shift in thinking from counting errors and injuries to proactively identifying risk. The goal is to identify systems-level problems that may be amenable to QI efforts.

Patient Safety and Error Prevention

The Institute for Safe Medication Practices developed a rank order of error-reduction strategies ranging from most effective (ie, forcing functions and constraints) to least effective (ie, education and/or information). In between are strategies (from most to least effective), such as automation and computerization, standardization and protocols, checklists and double-check systems, and rules and policies.

Education and information dissemination are important and helpful in that they increase awareness. Lectures are quickly forgotten, however, and signs are often ignored. Education and information dissemination is the least effective means to prevent the occurrence of error. Rules and policies are required by several agencies. Although rules and policies are a good resource, they are not an effective means of preventing a specific event.

Checklists, double-check systems, and bundles are very effective when they are a routine part of practice, but they are not foolproof. The best example of a double-check system is the surgical sponge and instrument counts done at the end of a surgical case. Checklists and bundles are also being used for other procedures, such as central line placement. Standardization minimizes the risk of error, and protocols bring a standard approach to a clinical issue. Checklists, bundles, and standardization are designed to eliminate variation from practitioner to practitioner and patient to patient. Any remaining weak points are prone to the occurrence of error. Automation and computerization are 2 of the best means of preventing medical error; however, there is still a risk of data entry error. Forcing functions and

constraints is the best way to prevent error through the use of safeguards. In this manner, systems and products are engineered to be safer from the ground up.

Plan-Do-Study-Act cycles are 1 method of developing and implementing change that results in improved patient safety and quality of care. Plan-Do-Study-Act cycles force small-scale, stepwise thinking; enable the making of predictions; force thoughtful deliberation on the increased knowledge; and subsequently facilitate change. The use of small-scale change can result in rapid adaptation and implementation of change in various health care settings.

Conclusions

The key elements to changing a system are the will to do whatever it takes to make the change, the ideas on which to base the design of the new system, and the execution of the changes to the system. Change is difficult, but sustaining change is even more complex. Hardwired sustainability in a new system is imperative. The old way must be more difficult or inconvenient to perform than the new way. In health care, spreading improvements depends on key individuals, and the role of leadership is a factor that is critical to success. Leaders must inspire and communicate a shared vision; model the way; challenge the current process; stop accepting the status quo; and enable others by ensuring access to resources, training, and time. Successes must be celebrated.

CASE RESOLUTION

During your staff meeting, you decide to use a PDSA cycle to examine the organization's vaccine administration practice, identify barriers to timely vaccine administration, and develop a plan to ensure that vaccines are administered in a timely fashion.

Plan: The charts of all patients seen for routine care in the past 3 months are pulled. The charts are audited using a premade checklist to identify vaccines given, vaccines missed, and barriers to administration. After analyzing the data, it becomes clear that many opportunities for immunization were missed because of inability to get parental consent. This seemed to coincide with a television program that discussed increasing rates of autism spectrum disorder associated with vaccination.

Do: At your next routine staff meeting, you present the data to your colleagues. You recommend rebutting the television show with a fact sheet and a discussion between the physician and parents. Your colleagues agree to implement this change, because it is low cost and easy to put into practice.

Study: Three months after implementation, you collect data and discover fewer missed opportunities for immunization and that your program has had some success. Some parents are still resistant to immunizing their children for fear of autism spectrum disorder.

Act: You present the follow-up data to your colleagues, and they agree to continue to implement the current strategy. The decision is made to reexamine the data again in 3 months to determine whether the program continues to be effective.

CHAPTER 22

Pediatric Palliative Care: Principles and Practice

Jori Bogetz, MD, FAAP, and Richard Goldstein, MD, FAAP

CASE STUDY

Jason is a 17-year-old boy with spastic quadriplegia, severe global developmental delay, seizures, dystonia, and cortical blindness who is supported by a tracheostomy but is not ventilator dependent. He was born at 24 weeks' gestation and had a turbulent neonatal course. Since leaving the intensive care unit at 6 months of age, he has lived at home, cared for by his family, a loyal home nursing team, and his primary care pediatrician. Medically he has been fairly stable, with only episodic respiratory infections and numerous orthopedic procedures. Over the past 2 years, however, he has spent substantially more time in the intensive care unit because of increasing respiratory fragility. With so many hospitalizations and so little time feeling well at home, his parents have begun questioning whether the intensive medical care Jason receives translates into quality of life for him and his family.

Questions

1. What is pediatric palliative care, and how is it practiced?
2. What children receive palliative care, and what are the benefits and barriers to these services?
3. What are some of the essential considerations when communicating with families of seriously ill children?
4. How do children of different ages understand serious illness, death, and dying?
5. What role do primary care pediatricians have in the palliative care of their patients?

The Scope and Practice of Pediatric Palliative Care

Pediatricians develop deep, meaningful relationships with patients and their families. Mostly, patient care involves the typical ups and downs of childhood with acute pediatric illnesses. But some patients are challenged by a degree of illness that requires high levels of continuous medical management, care coordination, and advocacy. These children and their families live with significant uncertainty about the future and a "roller coaster" of health experiences that may even involve the child's death. Along with these difficulties, many pediatricians describe caring for children and families with serious illness as among the most rewarding aspects of their careers.

Palliative care is a framework that prioritizes the well-being of patients and families experiencing serious illness. This is accomplished through careful symptom management; attention to the medical, psychosocial, and spiritual needs of patients through multidisciplinary care; and establishing goals of care based on family-centered priorities. The American Academy of Pediatrics states that pediatric palliative care should be integrated starting at diagnosis and extending into hospice care and bereavement for any child with a serious illness. This care should be provided along with that provided by primary care pediatricians and in conjunction with community-based teams. These standards are illustrated in the *concurrent model* of palliative care, which is care that incorporates palliative care with disease-directed treatment throughout a child's illness and extends into bereavement (Figure 22.1). Despite its growing acceptance, palliative care is often incorrectly equated with end-of-life and hospice care. *Hospice* is a program of coordinated services offering comfort-centered care at the end of life in the home or community setting. Although hospice and palliative care have a shared philosophy and an overlap of many of the priorities of care, palliative care should not be considered only at the end of life, nor is it exclusive of curative or disease-directed care.

Palliative care is often thought of as a specialized area of practice. Subspecialty palliative care (ie, *secondary palliative care*) is practiced by health professionals with additional training who often provide education and advocacy in the field of palliative medicine and provide direct patient care in quite complex clinical situations. Important elements of palliative care can be practiced by other health professionals with trusted longitudinal relationships and tremendous insights into family dynamics and priorities, however. *Primary palliative care* is the term used to describe the palliative care provided by nonsubspecialty health professionals. It is the most fundamental form of palliative care that patients and their families receive. The skills of primary palliative care include the abilities to hold basic discussions about prognosis and goals of care, manage basic pain and symptoms, and address family and sibling issues

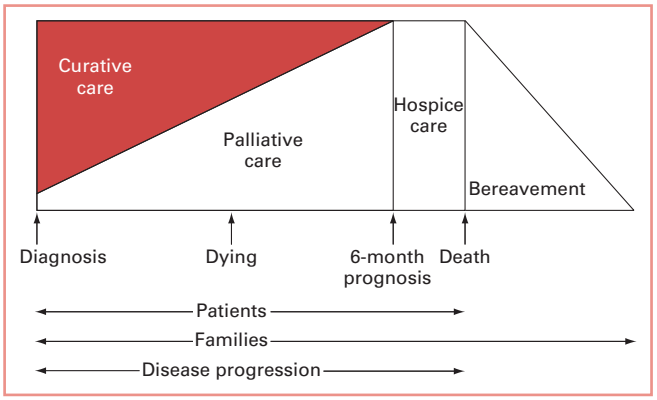

Figure 22.1. Integration of palliative care along with disease-directed treatments and continuing into bereavement.
Adapted with permission from Ferris FD, Balfour HM, Bowen K, et al. A model to guide patient and family care: based on nationally accepted principles and norms of practice. *J Pain Symptom Manage*. 2002 Aug;24(2):106-23.

that arise related to the illness course. Another important part of primary palliative care is the relationship that remains between the clinician and family after a child dies. Both primary and secondary palliative care are necessary in helping children and their families live as well as possible with serious illness.

Palliative care for children may be considered in the context of 4 major categories of serious illness: conditions for which curative treatment is possible but may fail (eg, cancer with a poor prognosis, complex congenital heart disease); conditions requiring intensive long-term treatment aimed at maintaining quality of life (eg, cystic fibrosis, muscular dystrophy); progressive conditions in which treatment is exclusively palliative after diagnosis (eg, Tay-Sachs disease, leukodystrophy); and conditions involving severe, nonprogressive disability, causing extreme vulnerability to health complications (eg, holoprosencephaly, extreme preterm birth with severe comorbidities). Many of these conditions are affected by medical advances and evolving clinical practices. The use of bone marrow transplant, gene therapy, and immunotherapy, as well as the increasing application of known therapies such as noninvasive ventilation, have important implications when counseling patients and families. These evolving norms provide opportunities for health professionals to consider categories of illness while simultaneously embracing uncertainty about outcomes for their patients in using a palliative care framework.

To implement appropriate palliative care, families often need an array of different providers, including doctors, nurses, social workers, psychosocial health professionals, developmental specialists, and spiritual supports. They often rely on a hospice or community-based palliative care program, a home nursing agency, or their primary care physician to help coordinate care. The care of children with serious illness may additionally involve representatives from school, camp, child life services, massage, hippotherapy, developmental therapists (eg, art, occupational, speech, physical), and others. Strong communication and reliable continuity within the team are essential. Ultimately, the goal of primary and secondary palliative care, as well as hospice care, is to promote the sense that a child's life was lived with identity and value, in contrast to a life determined by the course of illness alone.

Communicating Prognosis, Disclosure, and Decision Making

The care of children with serious illness can be marked by periods of intense uncertainty and fearful realities. Helping families determine the goals of care, appropriate treatment choices, and all aspects of planning for the child's life is facilitated by thoughtful communication. Research has found, however, that many parents feel they receive confusing, inadequate, or uncaring communication related to prognosis and treatment. They report often feeling left to reach decisions with an understanding of medical details that is different from that of their child's health professionals. Such decisions are especially difficult in a setting of misunderstanding, disagreement, or, worse, lack of trust. When feeling misunderstood or judged, parents may feel conflicted about stating their true perspective.

To this end, parents benefit from honest, clear communication about their child's illness. This is a difficult task, not only because imparting bad news is an uncomfortable and complex task but also because providing an exact prognosis is fraught with challenges. The most recent systematic reviews on prognosis prediction have found that physicians are accurate only approximately 25% of the time and tend to be overly optimistic. Although more experienced health professionals tend to err less, the longer the length of a relationship with a patient, the greater the likelihood that the prognosis they share will be incorrect. Parents nonetheless seek a clear disclosure that allows them to have a sense of the future. They interpret hidden or minimal information as evidence that the health professional is withholding frightening information. In fact, parents who receive more elements of prognostic disclosure are more likely to report communication-related hope, even when the likelihood of cure for their child is low. Often the specific details about prognosis are not necessary and instead, generalities about the expected timeline (eg, hours to days, days to weeks, weeks to months, months to years) provide sufficient information for the family's planning, coordination, and memory making. Research has also shown that earlier recognition of a poor prognosis predicts an earlier do-not-resuscitate order, decreased use of disease-directed therapies in the last months of life, and an increased likelihood of incorporating the child's comfort as a goal. It allows for some sense of control and expression of values in overwhelming circumstances.

These difficult conversations can be facilitated through a shared understanding about how a child's health and function have changed over time. When given time to reflect, families can often recognize these changes. Providing anticipatory care about feeding, breathing, or mobility changes related to the progression of illness can provide a more concrete, tangible basis for action in families related to their child's increased fragility. Uncomfortable as it is, anticipating death and addressing it clearly and frankly allows some children and families to make choices about how to spend the time remaining.

Recent research shows that health professionals can help parents feel like "good parents" to their seriously ill children by letting families know that all that can be done for their child is being done and not giving families the sense that health professionals are "quitting"; respecting parental decisions; providing comfort to the child and family; demonstrating knowledge of the particular needs of the individual child/family and that the child is uniquely special; coordinating care and providing honest, factual information; inquiring about spiritual needs; and telling parents that they are seen as acting as good parents to their child. Table 22.1 outlines a stepwise approach to communicating with children and families after prognostic information has been shared to introduce palliative concepts and better understand how to support an individual child and family in these difficult circumstances. Health professionals who support families in these ways have profound effects on meaning making and bereavement after a child's death. Even when health professionals are unsure what to say, acknowledging parents as "good parents" can show humility, build trusting relationships, and provide meaning during an incredibly difficult time.

Suffering and the Power of Hope

Initially, the topics of suffering and hope can seem to be untechnical and unprofessional to the practice of medicine. However, it is hard to imagine concepts more central to the art of healing and medicine's true purpose. Serious illness and its treatment can cause physical distress, and research has shown that dying children have many physical symptoms, such as pain, fatigue, and dyspnea (see Chapter 14). The effects of a serious illness are much larger and more complex than a physical sensation, however. Suffering was best described by Eric J. Cassel, MD, as "the state of severe distress associated with events that threaten the intactness of a person." This distress comes from a threat to any of the multiple aspects of personhood—"the lived past, the family's lived past, culture and society, roles, the instrumental dimension, associations and relationships, the body, the unconscious mind, the political being, the secret life, the perceived future, and the transcendent dimension." Some authorities recommend using terms other than "suffering" to avoid describing persons as victims or with other emotional terms that are suggestive of helplessness. Figure 22.2 shows a sample of the myriad concerning symptoms that can be interrelated for a child with serious illness, all of which must be considered when thinking about distress in seriously ill children. In caring for patients with serious illness, understanding all aspects of suffering is critical to effective care, and listening and reflection are prerequisites to the necessary healing presence required to care for dying children and their families. Pain and symptom management are foundational, but the relief of suffering requires helping a child and family struggle with issues of meaning and transcendence.

Hope evolves from expectations for or belief in a worthy future. It carries a sense of trust and resilience. Serious illness can make it difficult to know what to hope for, trust in, or rely on. Research increasingly shows, however, that aspects of hope and resiliency are sustained throughout the disappointments and upheaval associated with serious illness and even death. This process of evolving goals

Table 22.1. Communicating With Children and Families About Palliative Care

Steps and Goals	*Sample Statements*
Step 1: *Open* **Goal:** Setting a respectful tone of shared decision-making and asking permission	I would like to talk about what is ahead with your child's health and do some thinking and planning in advance. Talking about it now allows us to think things through without the pressures that come when your child is acutely ill and immediate decisions are needed. Would that be alright with you?
Step 2: *Assess* **Goal:** Understanding the family's prognostic awareness, hopes, fears, and worries	What is your understanding of where your child is now with this illness? If your child's health situation worsens, what are your most important goals for your child and your family? What are your biggest fears and worries about the future with this illness?
Step 3: *Align* **Goal:** Sharing emotional understanding of worries and wishes with the family	I see these same issues, and I am also worried that your child's health is getting worse. I wish that things were different.
Step 4: *Disclose* **Goal:** Understanding how information is shared within and with the family	How much have you and your child talked about, that is, how aware is your child of, these issues? How much information do you want, and how much information can your child handle about what is likely ahead with this illness?
Step 5: *Explore* **Goal:** Getting to a shared understanding of trade-offs and limits of interventions as perceived by the family	If your child becomes sicker, how much do you think it makes sense to have the child undergo different treatments for the possibility of gaining more time? Are there specific conditions or states that you would not find acceptable for your child to be in?
Step 6: *Close in alliance* **Goal:** Providing a summary, sharing recommendations for next steps, and expressing non-abandonment	It sounds like _____is very important to you. Given what is important to you and what we know about your child's illness at this stage, I recommend _____. Let's meet again tomorrow to talk some more. I want to make sure I am answering all your questions as best as I can.

Adapted from Goldstein RD. *Eliciting and communicating goals of care for seriously ill patients.* EQIPP Course under development, American Academy of Pediatrics, 2018.

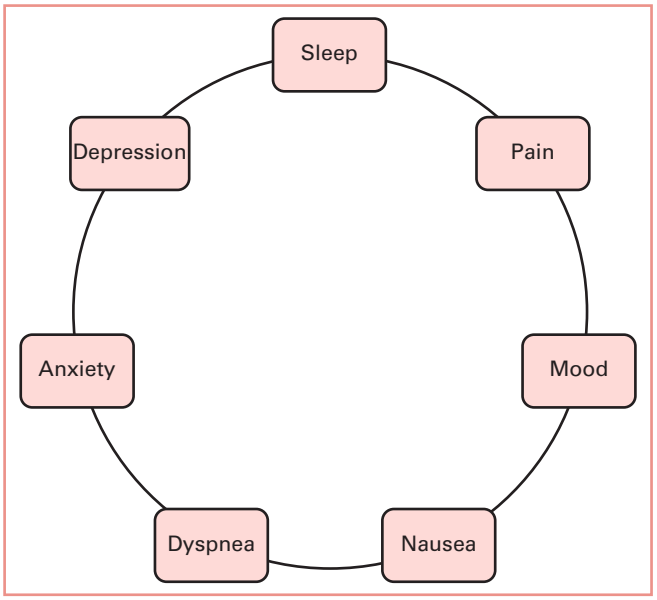

Figure 22.2. Interrelated symptoms of distress in children with serious illness.

of care or changing hopes (eg, from hope for cure to hope for time with family or a trip to the beach) occurs naturally, and families often need clear communication about what to expect to engage in this process of "regoaling." In this way, hope can be sustained when a meaningful way forward is elucidated even in the face of a dismal diagnosis or the loss of a child.

Barriers to Palliative Care

Parenting a child with serious illness can be frightening, confusing, frustrating, and exhausting. A decision to involve palliative care professionals is in no sense a decision by parents or other health professionals to stop working tirelessly for the child. It is crucial to introduce palliative care with sensitivity and thoughtfulness. Often palliative care is inaccurately viewed as an act of abandonment or "giving up." Research shows that often health professionals are reluctant to engage palliative supports for families because of perceptions of the family "not being ready" to acknowledge or accept a child's poor prognosis. This is counter to the growing body of research demonstrating that parents generally accept palliative care and believe that it is offered late. This delayed involvement of palliative care specialists results in not only worse symptom management and quality of life for ill patients, but may also result in shorter survival. Additionally, children who receive palliative care supports take fewer medications, undergo fewer invasive interventions, and are less likely to die in an intensive care unit compared with those who do not receive such care.

One of the greatest obstacles to palliative care and hospice for children has historically been lack of trained specialists. This is becoming less of a barrier as more hospitals and communities have access to pediatric palliative care specialists and with broader education, advocacy, and knowledge about the field. Workforce shortages are also eased by training in primary palliative care skills for primary care pediatricians. Despite concerns about the time needed to address a family's palliative care concerns, these practices can help pediatricians feel more useful and create deeply meaningful experiences with their seriously ill patients and families.

Another barrier has resulted from the payment model for pediatric palliative care, which historically has been based on Medicare hospice benefits that require patients to have a prognosis of 6 months or less and to forego curative care. Understandably, parents find it quite hard to give up curative efforts for their children. Although some states offer palliative care programs to remedy this, the Patient Protection and Affordable Care Act of 2010 removed the prohibition against curative treatment as a hospice benefit by or on behalf of a Medicaid or Children's Health Insurance Program eligible child. Despite these changes, eligibility still requires a physician to certify the child as likely to die in the next 6 months. It is not uncommon for children to live beyond their expected prognosis, and in these instances children can be re-enrolled to continue receiving hospice benefits. States are still not required to provide pediatric specific hospice services, however, although doing so is increasingly the norm. Advocacy for increased access to palliative and hospice services for all children with serious illness is crucial to expanding expert palliative supports for these children and their families.

A Child's Understanding of Death

Although death itself is an unknown experience, parents want to know what their children can understand during the dying process. Caregivers, too, wonder what a child knows as they try to anticipate needs or reckon with enigmatic statements from them. Most would agree that a child's distress resulting from avoidance of discussions of their fears about their condition and death is especially tragic and counterproductive.

Health professionals should, when possible, communicate with children about what is happening to their bodies, while respecting the cultural and personal preferences of each family. A developmental understanding of children's concepts of illness and death can help frame these discussions and serve to advise parents in their own conversations with their children. The understanding of a child's concept of death can be extrapolated from Piaget's work in cognitive development and is based on 4 stages: sensorimotor, preoperational, concrete operations, and formal operations. These developmental stages of understanding of death along with their typical chronologic ages, along with sample language to use when talking to children about illness and death, are shown in Table 22.2. Having limited cognitive abilities will affect a child's understanding of these issues. In contrast, illness profoundly changes development, and it is not uncommon for seriously ill children to possess a precocious and advanced understanding of certain things, such as the details of their illness or the way to address their symptoms, while simultaneously being less mature in other developmental areas.

Parents can struggle with whether they should talk with their child about the child's imminent death. Although research supports a bias toward speaking frankly to dying children, each individual situation should be considered unique and based on the child's age, cognitive development, disease, timeline of disease, parental psychological

Table 22.2. Ages and Developmental Understanding of Death

Age Group	*Conceptualization*	*Interventions*	*Example of Age-Appropriate Language*
0–2 years	No cognitive understanding of death Concern for experience of death as abandonment and/or separation Understand events in terms of direct experience Identify when adults are in distress	Maintain routines Avoid separation from significant others Presence is more important than words	"Mommy did not want to leave"
2–6 years	Believe death is temporary and reversible Often blame themselves for the death Magical thinking	Use concrete, clear, and simple language Avoid euphemisms; use "death," "dying," and "died" when possible Clarify question the child is asking Use repetition and consistent language Reflect on past experiences with the death and dying process; pet, grandparent, others Play-based activities to assist in expressing feelings	"Bobby is dead; that means he won't ever live with us again, but we will always remember him."
6–8 years	Death is final and irreversible Fear death Concerned for others' safety Believe death is not universal	Clear, realistic information Ongoing discussions about death Discuss physical details of death Establish safe space at school where the child can seek guidance when necessary	"When someone dies, that means their body is no longer working. Their heart stops beating, they no longer need to eat or sleep, their brain stops thinking, and they no longer feel any pain. They don't need their body any longer. That means we will never see them again as we could before."
8–12 years	Understand death is final, irreversible, and universal Comprehend biological aspects of death Curiosity about death and dying Intellectualize death	Open and honest discussion about one's own emotions Assure children that they will be informed about major events of concern Allow children the choice to participate in activities surrounding the death, including funeral services and hospital visits	"I, too, am very sad that Katie is sick. Grandma is going to come take care of you while I go to the hospital with Katie, but we will have Grandma bring you to the hospital if something happens."
12–18 years	Adult understanding that death is inevitable Ability to think abstractly and philosophically Curiosity surrounding existential implications of death	Support independence and access to peers Monitor social media Maintain familiar routines	"If you want to talk, I am here to listen. If you do not want to, then I am here if or when you do. I can't imagine what you are feeling right now, and I want you know I am here to support you."

Adapted with permission from Himelstein BP, Hilden JM, Boldt AM, Weissman D. Pediatric palliative care. *N Engl J Med.* 2004;350(17):1752–1762.

state, and family culture. In studies of parental disclosure to children with impending cancer death, parents who talked with their child about their death had no regrets, but among those who did not speak frankly about imminent death, more than 25% regretted not having done so. During these difficult times, primary care pediatricians can provide essential contributions to the care of seriously ill children and their families by serving as a resource for these conversations and providing guidance to families. Collaboration with pediatric palliative care specialists can support pediatricians' involvement through education and an added layer of support.

Pediatric Primary Care at the End of Life: Normal and Extraordinary

Primary care pediatricians can play an important role in the care of children with serious illness. The presence of a constant, continuous physician who understands the child, siblings, and family holistically in the community can contribute profoundly to care as part of the medical home. Because caring for these children is a rare experience in general practice, the complexities of care can be daunting. Primary care pediatricians can benefit from creating a network with others

involved in the care of the child (eg, home nurses, social workers, teachers, pediatric subspecialists, hospice) to support their direct care of seriously ill children and families throughout illness and end of life.

For seriously ill children and their families, general pediatric care from their primary care pediatrician also can be an important affirmation of the normal and can contribute to quality of life. For the child, routine health care visits, vaccinations, and developmental assessments are important, because the rationale for this care is not their disease but the positive and ordinary characteristics of childhood. The focus on development, education and learning, social engagement, play, and involvement with family and community affirms the whole child and the importance of the child's life. The primary care pediatrician is often seen as a trusted advisor who understands the family and child in this normal context and thus "knows" them best. The pediatrician is the child's doctor without qualification.

A trusted primary care pediatrician also has a role in complex disease management. The primary care pediatrician is in the best position to assess the family's level of understanding and address any gaps in that understanding. Importantly, the pediatrician can help families understand complex medical information, terminology (ie, medical jargon), and other specific medical details. They can also help the medical team better understand the patient and family perspective. The primary care pediatrician can ease the adjustment between home and hospital and help ensure more seamless transitions in either direction. Relevant involvement of the pediatrician in crucial developments requires timely sharing of information among all members of the team, the generalist, and the specialist. Ideally, the primary care pediatrician should participate in hospital-based family and provider team meetings. This is especially important during meetings in which goals of care and medical decision making are the focus. Fostering collaboration between the primary care pediatrician and the palliative care specialist is essential. Currently, this can more readily be accomplished through advances in technology, such as telehealth and videoconferencing.

When a child is facing the end of life at home, the primary care pediatrician has additional responsibilities to facilitate care for the child, siblings, and family. The primary care pediatrician can work with the hospice team to continuously fine-tune approaches to pain and symptoms. Primary care pediatricians can also play a central role in delineating resuscitation orders. Research indicates that parents consider end-of-life decisions to be the most difficult treatment decisions they face. Thoughtful conversations with a trusted primary care pediatrician who has a broad perspective on the medical details as well as the family identity and priorities is invaluable. A powerful resource to guide these discussions is the document *My Wishes*, which offers open-ended prompts with spaces to draw pictures for young school-age children to better understand their worries and hopes. *Voicing My Choices* is another excellent resource for adolescents and young adults; this resource captures not only who the patient is as a person but also the patient's end-of-life wishes. *Five Wishes* can be used when working with adults and is a legally recognized advance care planning tool when completed correctly. Another important form to consider completing with families is the Physician Orders for Life-Sustaining Treatment (POLST) form. The POLST form differs slightly by US state and serves as a home-based do-not-resuscitate order. For instance, emergency medical technicians in the field must resuscitate a child found in cardiac or respiratory failure unless orders exist to refrain. After a family has come to the difficult decision to limit interventions, it is important to advocate for these wishes in all settings and to complete documents to communicate these decisions. Asking parents to sign these forms can be heartbreaking, but framing their completion as a part of documenting a conversation can be helpful. Reaching out to local palliative care specialists to talk through the documents and communication strategies beforehand is equally beneficial.

Loss and After

The loss of a child or sibling changes life forever. It begins a process of *bereavement*, the psychological and spiritual accommodation to death on the part of the child's family, and *grief*, the emotional response caused by the loss. Grief can cause distress and physical and emotional pain, but, except in cases of prolongation, it is a normal adaptive human response, not a disease. *Anticipatory grief* begins with the awareness of impending loss or death in parents and children with sufficient awareness and cognitive development. Palliative care attends to the grief reaction before and after death. Assessing the coping resources and vulnerabilities of the affected family system before death occurs is central to the palliative care approach.

Generally, parental grief is more intense and sustained than other types of grief. Parents may never completely accept the loss of their child. Research suggests that parents who share their problems with others during their child's illness, who have had access to psychological support during the last month of their child's life, and who have had closure sessions with the attending staff are more likely to resolve their grief. Surviving siblings also grieve. The American Academy of Pediatrics recommends that primary care pediatricians reach out to children and families at the time of loss to evaluate their bereavement and to understand the personal meaning of their loss and their process of mourning. Those involved in the care of children and families appreciate how meaningful simple things, such as condolence letters and attendance at funerals or memorial services, are to families. Notes remembering the anniversary of the deceased child's birthday or helping the family think about developing the child's legacy or a remembrance also contribute to improved bereavement and meaning making after a child's death. Helping bereaved children safely remember their deceased siblings and appreciating their successes as they integrate the loss can be a powerful part of a health care visit and the long-standing caring relationship between primary care pediatricians and families. Often primary care pediatricians can be in contact with the school and other community organizations that can support bereaved siblings. When necessary, referrals to skilled mental health professionals should be offered, including referrals to bereavement specialists.

Many resources are available to support primary care pediatricians caring for seriously ill children and their families. Helpful resources include the Palliative Care: Conversations Matter campaign

(www.ninr.nih.gov/newsandinformation/conversationsmatter/about-conversations-matter) and Together for Short Lives (www.together-forshortlives.org.uk/about-us/). For families, the Courageous Parents Network (https://courageousparentsnetwork.org/) is an excellent resource that describes many aspects of caring for a seriously ill child. Most importantly, pediatric palliative care specialists locally and nationally are available to support the essential work of primary care pediatricians in their care of seriously ill patients and families. Working together, the pediatrician and palliative care specialists can address the needs of these children and their families.

CASE RESOLUTION

The hospital-based palliative care team arranged to meet with Jason's parents. During their conversation, they helped the parents articulate what gave Jason's life meaning, what happiness was for him, and what their hopes were. Jason's parents decided they would still opt for ventilatory assistance should he become compromised by an acute, likely reversible illness but could not imagine cardiac resuscitation being consistent with their goals. Therefore, a limitation was placed on cardiac resuscitation, and a POLST form was completed. With the parents' permission, the palliative care team spoke with Jason's primary care pediatrician and home nursing team.

The palliative care team continues to meet with Jason and his family for each hospital admission and connects regularly with Jason's primary care pediatrician for ongoing care transitions and health care needs.

PART 3

Health Maintenance and Anticipatory Guidance

(*continued*)

CHAPTER 23

Neonatal Examination and Nursery Visit

Niloufar Tehrani, MD

CASE STUDY

You are performing an examination on a 16-hour-old newborn who was born at 39 weeks' gestation to a 28-year-old, healthy, primigravida via normal spontaneous vaginal delivery. No complications occurred at delivery, and the Apgar score was 8 at 1 minute and 9 at 5 minutes. The newborn weighed 3,200 g (7 lb 1 oz) and was 50 cm (19.7 in) long at birth, with a head circumference of 34 cm (13.4 in). The mother received prenatal care beginning at 10 weeks of gestation; had no prenatal problems, including infections; and used no drugs, alcohol, or tobacco during the pregnancy. Her blood type is O Rh-positive. She is negative for hepatitis B surface antigen and group B streptococcus, and she is nonreactive for HIV, syphilis, chlamydia, and gonorrhea. The father is also healthy.

On physical examination, the newborn is appropriate size for gestational age, with length and head circumference in the 50th percentile. Aside from small bilateral subconjunctival hemorrhages, the rest of the physical examination is entirely normal.

Questions

1. What aspects of the maternal and birth history are important to review before performing the neonatal physical examination?
2. What other history is important for a complete newborn assessment?
3. What aspects of the physical examination of newborns are essential to explain to parents?
4. What physical findings mandate a more extensive workup prior to discharge?
5. What is the routine hospital course for a normal newborn?
6. What are important points to cover with parents at the time of discharge for a healthy, full term newborn?
7. What laboratory studies, if any, should be performed prior to discharge?

The initial newborn physical examination is an important first encounter with the pediatrician, the newborn, and the newborn's parents all establishing relationships with each other. The key purpose of this examination is to assess the status of the newborn and detect any underlying medical problems. Relaying this information to the parent or parents is essential and answers the question foremost in a parent's mind: "Is my baby 'normal'?" By performing a physical examination in the parent's or parents' presence during the first 24 hours after the newborn's birth, pediatricians can play a major role in allaying parental anxiety. The pediatrician's role includes identifying medical problems or high-risk conditions in the prenatal screening (including ultrasonography), neonatal examination, and history. Evaluation and treatment, if necessary, can be initiated before discharge from the nursery.

Pediatric Prenatal Visit

The prenatal visit during the third trimester is recommended for all expectant families. This is the ideal time to establish the medical home and provides the pediatrician with the opportunity to speak with the parent or parents at a prenatal visit before meeting them in the hospital. The prenatal meeting provides a chance for parents to interview the physician, as well as the rest of the office staff, about general policies and procedures for well-child appointments, sick visits, and contacting the physician after hours. It also is a time to discuss what will take place at the hospital and explain the role of allied health professionals (eg, lactation specialists) in the overall care of the mother and newborn. For pediatricians and other health professionals, the prenatal visit is a time to gather vital medical information about the current pregnancy, identifying any high-risk conditions, and to inquire about any problems with previous deliveries. The pediatrician should also review any pertinent family history. In addition, the pediatrician needs to note specific needs of the parent or parents, which may include alternative medicines, cultural rituals, or ceremonies surrounding the birth of a newborn, such as circumcision. Whether the newborn will be born at home, in a birthing center, or in a typcial hospital setting, arrangements should be made to accommodate the wishes of the family.

The prenatal visit also allows physicians to assess any psychosocial issues that may negatively influence initial mother-newborn bonding, such as maternal drug use, no partner involvement, absence of a supportive social network, or lack of housing. Any of these issues may necessitate intervention by social services. The social environment that will surround the newborn at home will have a great effect on the child's future. In addition, this visit provides an opportunity to emphasize the importance of breastfeeding and educate parents on its many benefits. Anticipatory guidance issues also can be discussed, including positioning the newborn on the back to sleep, safe bedding, and child passenger safety.

Neonatal Nursery Visit

At birth, the newborn undergoes a screening examination and risk assessment by the nursery personnel when the newborn is stable after any needed resuscitation. In the absence of abnormalities, the pediatrician is notified of the birth. The American Academy of Pediatrics (AAP) and the American College of Obstetricians and Gynecologists recommend that the pediatrician should evaluate the newborn within 24 hours after birth to identify medical conditions that need to be addressed and determine the course of newborn care. In the delivery room, the newborn is dried, Apgar scores are assigned, and the newborn is placed skin to skin on the mother's chest, with a blanket placed over the mother and newborn, to facilitate bonding and early breastfeeding.

If perinatal or delivery complications occur, such as maternal fever, maternal medication during labor and delivery, meconium aspiration, asphyxia, preterm birth, obvious newborn malformations, or distress, the newborn should be supported as necessary and kept on a radiant warmer for further assessment. The physician should be promptly notified to perform the neonatal physical examination, evaluating any problem and initiating treatment.

Evaluation

Perinatal History

The perinatal history is the beginning of the newborn's medical history and is significant in the newborn evaluation. To obtain all the pertinent history, it may be necessary to review the maternal medical record. Results of maternal laboratory tests, such as blood type; rapid plasma reagin status; purified protein derivative; HIV and hepatitis B status; chlamydial, gonococcal, and group B streptococcus cultures; and toxicology screen results should be noted (Box 23.1). The pediatrician also should obtain triple screen, prenatal ultrasonography, and amniocentesis results, if available. Maternal history, including medical conditions and medications used during pregnancy or delivery, prior deliveries, type of delivery, delivery room events, and Apgar scores should be reviewed before performing the neonatal physical examination. Given the Zika virus outbreak in the Americas in 2015 to 2016, it may be necessary to elicit travel history and perform appropriate screening in the mother and possibly the newborn. Obtaining this information helps focus the examination on findings suggested by previous medical history. Additionally, the occurrence of any unusual circumstances surrounding the delivery should be explained to the parent or parents at the time of the examination. For example, the need for a vacuum-assisted or emergent cesarean section may not have been understood. It is important to be prepared to discuss the medical implications of such events. Unexpected events related to the delivery, such as an emergency cesarean section, may be viewed as traumatic by the mother and predispose her to perinatal mood and anxiety disorders.

Box 23.1. What to Ask

Neonatal Examination

- Did the mother receive prenatal care? If so, since what month of gestation?
- Were all prenatal studies normal?
- Does either parent have a history of sexually transmitted infections, such as syphilis, gonorrhea, or herpes?
- Does either parent have a history of alcohol, tobacco, or illicit drug use?
- Did the mother take any prescribed or over-the-counter medications routinely during pregnancy?
- Did the mother have any complications, such as bleeding or decreased fetal movement, during pregnancy?
- Were there any indications of a complicated delivery, including administration of maternal medications?
- Is there a family history of congenital anomalies or diseases?
- Is the mother planning to breastfeed?
- Does the neonate have any siblings? If so, what are their ages?
- Is anyone available to help with the new baby or siblings?

Physical Examination

Every attempt should be made to perform the neonatal physical examination at the mother's bedside. This gives the physician the opportunity to meet with the parent or parents and answer all their initial questions immediately. In certain circumstances, such as preterm birth or in cases in which the mother is being treated for a medical complication, it may be impossible to perform an initial bedside examination. Regardless of the timing of the examination, the physician or other health professional should discuss the results with the parent or parents after the examination has been completed.

The neonatal examination is performed with the newborn completely unclothed and the newborn's body temperature maintained. The newborn is assessed for evidence of birth trauma and congenital malformations, and organ systems are assessed for normal physiology. The newborn's birth weight, length, and head circumference are plotted. The physician should bear in mind that these measurements are often made in the delivery room and may be subject to error. The diagnosis of small for gestational age (SGA; weight <10th percentile) or large for gestational age (LGA; weight >90th percentile) can predispose a newborn to several medical problems. Temperature, respiratory rate, and heart rate are reviewed via the nursery record. In a newborn with suspected cardiac or renal anomalies, blood pressure is also measured. Feeding, voiding, and stooling patterns are also available in the nursery record and should be reviewed.

The newborn evaluation includes an expanded Ballard score, which includes parameters for neuromuscular and physical maturity

to accurately estimate gestational age. A late preterm or near-term newborn (ie, 35–37 weeks of gestation) frequently does not have the physiologic maturity to feed vigorously and maintain body weight, glucose, or body temperature. These newborns are at high risk for readmission for treatment of jaundice, dehydration, and hypoglycemia. They should be closely followed.

The newborn's overall appearance is noted, particularly for the presence of any dysmorphic features. The physician should determine whether the newborn looks normal or has any abnormal facial features, such as low-set ears and widely spaced eyes (see Chapter 84).

Skin

In the newborn, a thick layer of white vernix caseosa composed of sebaceous secretions and epidermal cells is frequently seen. The presence and location of any rashes or birthmarks should be carefully described and pointed out to the parent or parents. The particular location of the lesion as well as the pathology of the epidermal lesion may aid in specific diagnosis of it. Skin lesions resulting from birth trauma are documented and managed as necessary. Bruising should be differentiated from the benign dermal melanocytosis that often occurs in the sacral area. Skin color is noted. Cyanosis may be indicative of congenital heart disease, the presence of jaundice is suggestive of hyperbilirubinemia, and plethora may be a sign of polycythemia.

Head

Head size and shape are evaluated, including the size of the fontanels and position of the sutures. The head may be significantly molded into a cone deformity secondary to pelvic pressure at the time of delivery. This deformity resolves within days after birth, which may result in a significant change in the head circumference. A *cephalohematoma*, which is a subperiosteal bleed that does not cross the suture line, appears as a unilateral or bilateral discrete lump on the side of the head. This finding may predispose the newborn to hyperbilirubinemia, and it may take up to 2 months for the condition to resolve. A cephalohematoma should be differentiated from a *caput succedaneum*, which is scalp edema that crosses the midline and may be ballotable. Edema usually resolves rapidly. Skull fractures may occur with birth trauma and may present as a step-off or crepitus on palpation of the skull. Such fractures are associated with cephalohematoma, but treatment is rarely required. Any unusual findings about the head may be a source of parental concern.

Eyes

The eyes are evaluated for subconjunctival hemorrhages, colobomas, pupillary reaction, extraocular movements, and presence of red reflexes. If it is not possible to elicit a red reflex, an ophthalmologic evaluation is essential. Absence of this reflex is suggestive of conditions such as congenital cataracts or retinoblastomas. The color of the sclera and the spacing and symmetry of the eyes are also evaluated, because abnormalities may be suggestive of an underlying syndrome. For example, upslanting palpebral fissures can be seen in the setting of trisomy 21, and blue sclerae may be indicative of osteogenesis imperfecta.

Ears

The placement, size, and shape of the ear pinnae are noted as well, along with any preauricular or postauricular pits or appendages. The presence of a significant auricular abnormality may correlate with hearing loss or be suggestive of a genetic syndrome and necessitates further evaluation.

Nose

The nose is checked carefully for patency of the nares. This is easily accomplished by occluding airflow from 1 nostril and observing airflow from the other. Choanal atresia is an important condition to rule out, because newborns are obligate nose breathers until 3 months of age, and choanal atresia may result in respiratory distress. A nasal fracture also can occur during the delivery process. Such fracture presents as an asymmetric nose. If the physician presses on the nasal tip and the nares are symmetric, the diagnosis is a deformity that will resolve. If the nose falls to 1 side, however, the presence of a nasal septum fracture is probable, and prompt evaluation by an otolaryngologist is warranted.

Mouth

The oropharynx is examined closely for any defects in the hard or soft palate. A bifid uvula may be indicative of a submucosal defect of the soft palate that may be difficult to appreciate without palpation (see Chapter 85). Common normal findings in the oropharynx, including Epstein pearls located at the midline on the hard palate and epithelial cysts along the gum line (ie, Bohn nodules), are also noted. Loose natal teeth should be removed to prevent the possibility of aspiration (see Chapter 31). The tongue is evaluated for macroglossia or a tight lingual frenulum (ie, ankyloglossia), which may interfere with effective breastfeeding.

Neck

The neck is palpated for sternocleidomastoid hematomas, masses, torticollis, and skin redundancy. The clavicles are evaluated for fractures, which are more common in newborns who are LGA or in the setting of a delivery complicated by shoulder dystocia.

Chest

The chest is inspected for respiratory effort and the lungs auscultated to ensure normal breath sounds throughout. The quality of the newborn's cry is assessed as well. Laryngeal webs or a paralyzed vocal cord may present in the newborn. Chest wall deformities, such as pectus excavatum, are noted. If an absent rib is suspected, a chest radiograph should be obtained. The presence of breast buds is normal; however, supernumerary nipples are minor malformations, although no treatment is indicated. Widely spaced nipples are a common minor malformation in patients with Turner syndrome.

Heart

The heart is auscultated to ensure that it is in the proper position on the left side of the chest. Femoral and brachial pulses are palpated. The physician should listen for and document the presence of cardiac murmur. The presence of a murmur does not always

indicate complex congenital heart disease. In the first 24 hours, a murmur may be a closing ductus; additionally, newborns can have functional murmurs. *Peripheral pulmonic stenosis* is a common benign heart murmur in the newborn that is characterized by transmission to the right side and back. The AAP, American Heart Association, and American College of Cardiology recommend universal screening for critical congenital heart disease by pulse oximetry reading for which the AAP algorithm is most commonly used (Figure 23.1). However, every murmur should be evaluated on an individual basis. If further assessment is indicated, 4 extremity blood pressures, an electrocardiogram, and a chest radiograph should be obtained. The presence of abnormal findings or a murmur associated with cyanosis, tachypnea, poor feeding, or congenital anomalies is highly suspicious for a pathologic cause. A consultation with specialists in pediatric cardiology should be sought and an echocardiogram obtained.

Abdomen

It is easiest to palpate the abdomen before feeds. The abdomen is assessed for any masses or organomegaly (eg, polycystic kidneys, hepatosplenomegaly, adrenal hemorrhage) that warrant further investigation. Bimanual palpation may be helpful to identify masses. The umbilicus is examined to identify 3 vessels as well as the quality of the cord. A small, atretic cord can be the cause of low weight in the newborn. Erythema and swelling of the skin around the cord may be indicative of omphalitis, which is a serious infection.

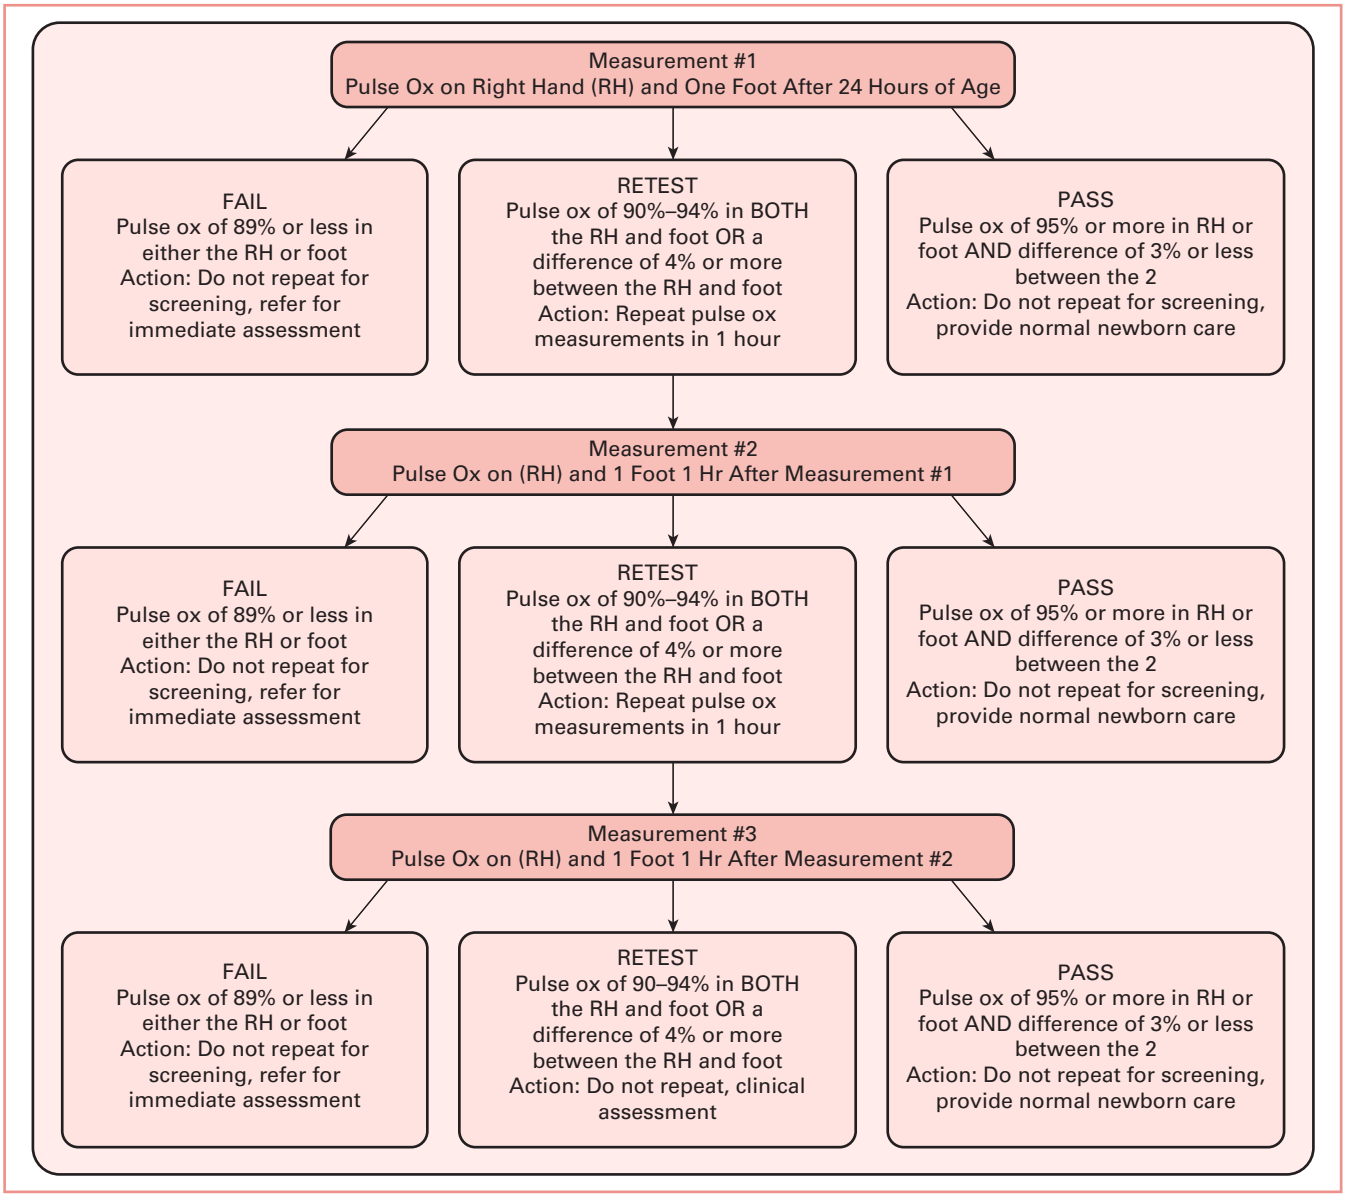

Figure 23.1. Critical congenital health disease screening protocol.

Genitalia

In female neonates, the labia majora may be swollen, but the urethra and vaginal opening should be visualized to ensure patency. Hymenal tags are a common finding. Clitoral size is noted. Parents should be told that a physiologic vaginal discharge and the presence later of a pink or blood-tinged discharge are a normal neonatal response to maternal estrogen withdrawal. In male newborns, the penis is examined for size and length. The foreskin should be retracted sufficiently to reveal the location of the urethral meatus to assess for hypospadias. A testicular examination can rule out hydroceles, inguinal hernias, and cryptorchidism. Atypical genitalia may be indicative of an underlying disorder, such as congenital adrenal hyperplasia or disorders of sexual differentiation, and necessitates further evaluation (see Chapter 107).

Anus

The patency and location of the anus are assessed. Patency is confirmed after the newborn passes meconium, typically by 48 hours of age. An imperforate anus may be an isolated finding, or it may be indicative of a syndrome, such as vertebral, anal, cardiac, tracheal, esophageal, renal, and limb syndrome.

Skeleton

The newborn skeleton is assessed for evidence of skeletal dysplasia. All long bones are examined for a potential fracture secondary to birth trauma. The neonatal hip examination is important to detect developmental dysplasia of the hip, which is most likely to occur in cases of a breech position in utero. The Ortolani maneuver is performed to detect a dislocated hip. The "clunk" felt when performing the examination is the relocation of the femoral head of the affected hip in the joint capsule. In contrast, a "click" may be indicative of normal perinatal ligament laxity. The Barlow maneuver detects an unstable hip that may be at risk for dislocation. A positive result on either test is indicative of a hip that is or could be dislocated and warrants an orthopedic consultation. Treatment with a Pavlik harness is initiated until confirmatory testing on ultrasonography is reliable at 6 weeks of age (see Chapter 113). The spine is palpated completely to the sacrum. Sacral defects, deep sacral pits, or sacral tufts of hair warrant an investigation for conditions such as spina bifida occulta. The fingers and toes are counted and assessed for syndactyly or other abnormalities. The feet may be turned inward, outward, or up and are gently moved to a normal position to ensure flexibility. Deformities secondary to intrauterine pressure are common. Clubfoot or equinovarus deformations warrant evaluation by an orthopedic surgeon.

Neurologic Examination

A newborn's resting position is assessed to evaluate tone. All extremities should be flexed. The newborn then can be held prone for further evaluation of tone. Newborns are observed for motor activity, that is, moving arms and legs symmetrically. Response to sensory stimulation and deep tendon reflexes should be elicited. Facial movements are closely observed for symmetry. Primitive reflexes, such as suck, rooting, grasp, stepping, and especially Moro, are an important part of the newborn neurologic examination. The behavior of the newborn also can yield information about an intact neurologic system. The newborn should respond to sound, fixate on a face, and be capable of attempts at self-consolation.

Normal findings of the nursery physical examination are summarized in Box 23.2. Significant findings should be addressed

Box 23.2. Common Benign Physical Findings in Newborns

Skin
- Milia
- Erythema toxicum
- Salmon patch
- Nevus flammeus
- Hemangiomas
- Dermal melanosis
- Lanugo (ie, body hair)
- Vernix

Head
- Cephalohematoma
- Caput succedaneum
- Molding

Face
- Swollen overall appearance
- Minor malformations

Eyes
- Swollen eyelids
- Subconjunctival hemorrhages

Ears
- Preauricular appendages/pits
- Folded pinnae

Nose
- Flattened nose
- Milia over bridge

Mouth and Throat
- Epstein pearls
- Epithelial pearls
- Natal teeth
- Shortened frenulum

Chest
- Supernumerary nipples
- Breast buds
- Galactorrhea
- Pectus excavatum or carinatum

Genitalia
- Females: swollen labia, hymenal tags, vaginal discharge
- Males: hydrocele, undescended testicle (palpated in inguinal canal)

Hips
- Click or clunk sound

Extremities
- Feet turned up, in, or out, but malleable

Neurologic Examination
- Primitive reflexes: Moro, grasp, rooting, stepping

immediately when noted at the initial nursery examination, including evidence of hydrocephalus, a ductal-dependent cardiac lesion, cyanotic congenital heart disease, a diaphragmatic hernia, an abdominal mass, or a possible chromosomal abnormality (eg, trisomy 13 or trisomy 18), all of which can be life-threatening. The physical conditions associated with trisomy 21 are rarely life-threatening, although suspicion of the diagnosis warrants consultation with a geneticist as well as evaluation for cardiac, abdominal, and other anomalies (see Chapter 42).

Laboratory Tests

Few laboratory tests are necessary for the healthy newborn. The only test that all newborns in the United States receive is the state-mandated newborn screening test prior to discharge from the nursery (see Chapter 25). Heel-stick blood usually is evaluated for inherited conditions, such as phenylketonuria, galactosemia, hypothyroidism, hemoglobinopathies, cystic fibrosis, congenital adrenal hyperplasia, and inborn errors of metabolism. The newborn screen varies by state and depends on the prevalence of a particular disease in a given region (see Chapter 25). In all states, hearing screening is also part of the mandated newborn screening. Screening methods may be by automated auditory brainstem response, otoacoustic emission testing, or conventional auditory brainstem response. The newest screening test is the addition of pulse oximetry at 24 hours of age to rule out transposition of the great vessels, tetralogy of Fallot, hypoplasia of the left heart, and other critical congenital heart disease.

Serum glucose testing may be performed for newborns at high risk for hypoglycemia, such as newborns who are SGA or LGA, newborns of diabetic mothers, and symptomatic newborns. Evaluation of hematocrit level is necessary in jaundiced, pale, or ruddy-appearing newborns; SGA and LGA newborns; and twins and multiples. In cases of ABO or Rh incompatibility, it is important to perform serum bilirubin and antiglobulin (ie, Coombs) tests. Screening for hyperbilirubinemia to prevent kernicterus is recommended for all newborns. Bilirubin screening is easily done by a transcutaneous reading; if the transcutaneous reading is elevated, the serum level is evaluated as well (see Chapter 126).

Imaging Studies

Routine radiographs are not indicated in neonates whose examination is normal and should be ordered only if indicated by the examination. Some minor malformations, such as pectus excavatum, do not require radiographic evaluation. Vertebral radiography, ultrasonography of the lumbosacral spine, or magnetic resonance imaging are appropriate in the neonate with a deep sacral pit or sacral tuft of hair in patients in whom spina bifida occulta is suspected. Clavicular radiographs are indicated in the patient with swelling or pain located in the clavicular area or in whom an asymmetric Moro reflex is elicited. A chest radiograph, electrocardiogram, and echocardiogram are warranted for a significant murmur. If hydronephrosis was detected on prenatal ultrasonography, follow-up renal ultrasonography should be performed in the neonatal period. If multiple anomalies are found, renal ultrasonography should be performed to evaluate for malformations of the kidneys; a skeletal survey may be helpful as well. More extensive studies are indicated in cases in which an emergent physical finding is discovered.

Management

After stabilization in the delivery room, the newborn is thoroughly dried and given to the mother for breastfeeding and bonding. If mother and baby are healthy, the newborn should stay with the mother. Every hospital should encourage rooming-in of the newborn with the mother. The newborn should feed in the delivery room if breastfeeding or within 2 hours of birth if formula feeding and continue to feed every 2 to 3 hours to prevent hypoglycemia. The preferred feeding method is breastfeeding, and the mother should receive sufficient postpartum support to ensure success (see Chapter 29). An initial bath is only necessary to remove blood or meconium after the newborn's temperature is stable. The administration of intramuscular vitamin K to prevent hemorrhagic disease of the newborn and the application of ophthalmic antibiotic ointment or silver nitrate in the newborn's eyes to prevent gonorrheal infection is universal. Hepatitis B vaccine is recommended for all newborns at birth regardless of mother's serology; based on maternal risk factors (eg, history of maternal IV drug use), hepatitis B immune globulin should also be considered.

Vital signs are monitored every 30 minutes until stable during the transition to extrauterine life (which can last 4–8 hours), then every 4 hours. Daily weights as well as strict documentation of voiding and stooling patterns are necessary to monitor the newborn for adequacy of intake and signs of potential dehydration. Weight loss is expected, but loss of more than 7% of birth weight requires physician assessment. Umbilical cord care remains controversial, but in developed countries, leaving the cord to dry is sufficient treatment.

If desired, circumcision is usually performed on the day of discharge (see Chapter 27). The newest guidelines from the AAP note that the benefits of circumcision outweigh the risks. Local anesthesia is universally recommended for the procedure. After the procedure, parents are instructed to leave the gauze or Plastibell device in place. It will fall off spontaneously. Petroleum ointment may be placed on the corona of the penis to prevent it from sticking to the diaper. The physician should be notified if excessive bleeding or oozing occurs (eg, soaking of the diaper with blood) after discharge from the nursery.

Discharge Planning and Counseling

In most cases, mother and newborn should be discharged home together. The recommended hospital stay is 48 hours for a vaginal delivery and 96 hours for a cesarean section. The physician should reexamine the newborn on the day of discharge to identify problems that may have developed and counsel the parent or parents. A bilirubin assessment is required. This examination is best performed at bedside. The newborn's physical findings and hospital course should be reviewed with the parent or parents. If studies other than routine neonatal screening were performed, the physician should also share those results.

Discharge is the best time to review anticipatory guidance issues. Topics that should be covered at the bedside include feeding patterns and what to expect, sleeping and elimination patterns in the newborn, umbilical cord care, bathing the newborn, and safety issues (eg, car safety seats, sleeping position, safe sleep environments). Guidelines on symptoms of illness and when to call the office or emergency department also should be addressed. These include a rectal temperature of 38.0°C or above (≥100.4°F), respiratory distress, irritability, lethargy, decreased feeding, and evidence of dehydration. If parents have any concerns about their newborn, they should be encouraged to call the physician's office. A follow-up visit should be arranged at 3 to 5 days of age for any newborn being breastfed to give breastfeeding support and to assess the newborn for evidence of jaundice or dehydration. An early follow-up appointment may also be indicated in a newborn with social risk factors and near-term newborns who are at increased risk for complications. If the newborn is born via cesarean section or is formula feeding, a follow-up visit at 1 week after discharge may be appropriate.

Early newborn discharge is an option if desired by the mother. The AAP has published guidance recommendations on discharge of the newborn younger than 48 hours. Generally, the history, including social risk factors, physical examination, and hospital course, all should be low risk and the newborn should have been observed for at least 12 hours. If the newborn is stable and is sent home at less than 48 hours of age, a mandatory follow-up appointment should be scheduled within 2 days of discharge. The newborn born at home should undergo medical evaluation within 24 hours of birth and again 48 hours after the first evaluation. Hospitalists have been assuming more of the hospital care for newborns in many communities. The complete hospital record and results of screening tests must accompany the newborn to the medical home. This coordination of transfer of care can be challenging, but it is essential for optimal care.

CASE RESOLUTION

The parents should be advised that the newborn's weight, length, and head circumference are all normal. The examination is reviewed at bedside, and the subconjunctival hemorrhages should be shown to the parents and their benign, self-limited nature explained. Parents should be reassured about all other normal aspects of the physical examination. The newborn's blood type from cord blood should be obtained, because the mother has blood type O Rh-positive. Routine neonatal screening, feeding, sleeping, elimination, bathing, and safety should be reviewed. Before discharge, the newborn should receive the hepatitis B vaccine and should undergo newborn screening tests and bilirubin assessment. A follow-up appointment should be made for 48 hours after discharge to follow breastfeeding progress. Results of all newborn screening tests should be reviewed when available.

CHAPTER 24

Maternal Perinatal Mood and Anxiety Disorders: The Role of the Pediatrician

Carol D. Berkowitz, MD, FAAP

CASE STUDY

You are evaluating a 3-week-old boy who is the product of a 39-week gestation pregnancy to a 30-year-old gravida 1, para 1 mother who has been breastfeeding the newborn. The newborn's birth weight was 3,650 g (8.0 lb), and the newborn now weighs 3,380 g (7.5 lb). The mother expresses concern about her ability to breastfeed. She also admits to being exhausted and feeling detached from the baby. She is overwhelmed by being a mom, something she had looked forward to since she was a little girl. She has difficulty concentrating and has no appetite. She asks you if it is normal to feel this way.

Questions

1. What is the spectrum of perinatal mood and anxiety disorders?
2. What are the signs and symptoms of perinatal mood and anxiety disorders?
3. What are the risks to newborns of mothers who experience perinatal mood and anxiety disorders? To older children?
4. What is the role of the pediatrician in assessing mothers for perinatal mood and anxiety disorders?
5. What screening instruments are available to assist in assessing mothers for perinatal mood and anxiety disorders?
6. What are the risks and benefits of the use of psychopharmacology during pregnancy and postpartum if breastfeeding?
7. What resources are available to offer to mothers who may be experiencing perinatal mood and anxiety disorders?

The term *perinatal mood and anxiety disorders* (PMADs) is the preferred nomenclature to denote the spectrum of mental health issues facing mothers (and fathers) related to the pregnancy and birth of a neonate. Peripartum depression had been used to encompass a cadre of mental health problems that new mothers may experience, but now there is recognition that mental health issues can be present preconception, through pregnancy, and into the infant's first postnatal year. These issues include not only depression but other mental health disorders. Despite public disclosures and open discussions by celebrities such as Brooke Shields and Gwyneth Paltrow, these conditions are under-recognized, and as a result, many mothers go undiagnosed and untreated. The stigma related to mental health is a barrier to maternal disclosure and seeking help. Too often, maternal symptoms are dismissed as fatigue related. The pediatrician is in an ideal position to assess a mother for these symptoms following the birth of a baby because the pediatrician usually sees the mother-baby dyad prior to the obstetric postpartum visit at 6 weeks following the baby's birth. The recommended time points for screening for PMADs coincide with health supervision visits: 2 weeks, 2 months, and 6 months. In addition, women are likely to follow up with their baby's pediatric appointments more than their own. While fatigue is a common report of new mothers as well as new fathers, other symptoms, particularly those of impaired functioning and diminished ability to care for the baby, may suggest a more significant disturbance.

Epidemiology

Maternal depression is the number 1 complication of pregnancy, exceeding diabetes and hypertension. The incidence of perinatal depression varies with the population studied, with the estimated range being from 5% to 25%. Between 15% and 25% of pregnant women experience depressive symptoms while pregnant, and approximately 13% of women take an antidepressant at some time during their pregnancy. Women who experience depressive symptoms during pregnancy are twice as likely to be depressed postpartum as those with no depressive symptoms while pregnant. The prevalence of PMADs is much higher at 40% to 60% in certain

groups, including women in low-income households, certain ethnic minorities (including Hispanic, black, and Native American), pregnant and parenting teenagers, mothers of multiple births, women who served in the military, and members of the lesbian, gay, bisexual, transgender, questioning/queer, intersex (LGBTQI) community. The World Health Organization notes that depression is the fourth leading cause of disease burden in the world. In spite of the high prevalence across all groups, fewer than 50% of cases of PMADs are identified.

Often, there is reluctance on the part of obstetricians or psychiatrists to treat pregnant women with antidepressants because of concerns about the potential adverse effects of the medications on the developing fetus. These potential effects include fetal malformations, cardiac defects, pulmonary hypertension, and reduced birth weight. However, untreated PMADs in pregnancy increase the risk of preterm delivery, low birth weight, and a newborn's own ability to regulate emotions and stress. The American College of Obstetricians and Gynecologists and the American Psychiatric Association have issued joint guidelines on the management of pregnant women with depression, which include indications for psychotherapy as well as psychopharmacology in the pregnant woman. Pediatricians are usually not involved in this part of the decision-making process but should be knowledgeable about the possible complications that the newborn may experience following birth from exposure to antidepressants or untreated maternal mental illness. The issue of psychotherapeutics in breastfeeding mothers is also relevant to the pediatrician. Approximately 6% to 10% of fathers experience peripartum depression, with the highest rates seen between 3 and 6 months following the birth of the baby. Paternal rates of depression are higher when there is maternal depression, and the effect on the infant is greater than if the father is not affected. Depressed fathers have an increased rate of substance use.

There is a wide range of symptomatology that can be categorized as PMADS (Box 24.1). *Baby blues* or *maternity blues* are used to describe the very common experience of new mothers, said to affect 50% to 80% of postpartum women in the first few days after delivery. There is no *Diagnostic and Statistical Manual of Mental Disorders,* 5th Edition (*DSM-5)* categorization of baby blues. Generally, symptoms improve over 1 to 2 weeks and functioning is not impaired, although baby blues may herald later depression. Mothers experience sadness, crying, mood swings, anxiety, and worrying.

A diagnosis of *peripartum depression* meets the criteria of depression according to *DSM-5,* which include a depressed mood, diminished pleasure (anhedonia), changes in appetite and sleep, psychomotor agitation or retardation, fatigue, feelings of worthlessness or inappropriate guilt, decreased ability to concentrate, and recurrent thoughts of death or suicide. Suicide is the leading cause of death in mothers during the first year postpartum. Technically, symptoms of depression must begin within 4 weeks of delivery and may persist for 1 year, although the onset is often insidious and does not come to medical attention until later than 1 month postpartum.

Postpartum psychosis is less frequent, occurring in 1 to 3 per 1,000 deliveries within the first 4 weeks after delivery. There is severe impairment, with paranoia, mood shifts, hallucinations, delusions, and suicidal and homicidal ideation. Sometimes there is a history of a preexisting bipolar disorder. Affected mothers require hospitalization, in part because the infanticide rate is 4% to 5%.

Box 24.1. Perinatal Mood and Anxiety Disorders Symptomatology

Baby Blues
- Sadness
- Crying
- Mood swings
- Anxiety
- Worrying
- First few days after delivery
- Resolves in 1–2 weeks

Peripartum Depression
- Meets *Diagnostic and Statistical Manual of Mental Disorders,* 5th Edition, criteria for depression
- Depressed mood
- Diminished pleasure
- Change in appetite
- Change in sleep
- Fatigue
- Feelings of worthlessness or guilt
- Inability to concentrate
- Recurrent thoughts of death or suicide

Postpartum Psychosis
- Severe impairment
- Paranoia
- Mood shifts
- Hallucinations
- Delusions
- Suicidal/homicidal ideation
- Usually requires hospitalization

Other disorders that have been recognized as being pregnancy and birth related or exacerbated include anxiety disorders, panic disorder, postpartum posttraumatic stress disorder, postpartum bipolar disorder, and postpartum obsessive-compulsive disorder; 5% of mothers report intrusive thoughts of harming their baby.

It is estimated that 400,000 neonates are born to mothers who are depressed. These neonates are at risk for a host of adverse physical and developmental consequences.

Pathophysiology

The precise pathophysiology of PMADs has yet to be elucidated, but sleep deprivation related to the demands of caring for a newborn, genetic factors, other biological or inflammatory processes (cytokines), and hormonal changes are felt to be contributing factors. While there are rapid decreases in the levels of estrogen, progesterone, and cortisol, the hormonal levels noted in mothers

who experience peripartum depression do not differ from women who do not experience peripartum depression. Perhaps more significantly, there are a number of risk factors that have been associated with its development, including prior history of depression in general but especially during a previous pregnancy; mood disorders, including premenstrual dysphoric disorder; substance use; alcohol dependence; low socioeconomic status; a history of infertility; prior perinatal loss (eg, miscarriage, sudden unexpected infant death, bed-sharing death); lack of social support or community network; unintended or unwanted pregnancy; or a family history of depression. Other social or familial factors include marital discord, divorce, and intimate partner violence. Homicide is the leading cause of death among pregnant women. It is important to recognize that depression can affect adoptive mothers, who experience stress and anxiety during the adoptive process, remain concerned that the birth mother may reclaim her baby, have issues related to prior infertility, and tend to have less familial support.

Peripartum depression is less easy to recognize in fathers. Paternal depression is often covert or masked. Fathers are less likely to seek help or have ongoing access to health professionals. They may feel excluded from the mother-baby relationship. Often, they become workaholics as a means of coping with depression.

Evaluation

Mother

Screening for PMADs is within the scope of the pediatric practice. Studies have shown that mothers are comfortable being queried by pediatricians about how they are doing. Some pediatricians express concern about the appropriate strategies for screening and what to do if they determine that a mother has symptoms of depression.

It is important to couch any depression screening in language that makes a new mother feel comfortable and not judged in any way. Postpartum Support International promotes the "universal message" to share with depressed new mothers: You are not crazy; you are not alone; and with the right help, you will get better.

There are several instruments used to screen for PMADs. A simple tool, called the Patient Health Questionnaire-2 (PHQ-2), begins with a background statement related to depression as a common and treatable condition that often goes unrecognized. There follows justification citing the recommendation of the US Preventive Services Task Force that all adults be checked for depression. The question, "Over the past 2 weeks, how often have you been bothered by any of the following problems?" is asked, with the following 2 categories: "Little interest or pleasure in doing things," and "Feeling down, depressed, or hopeless." For both categories, the following responses are possible: 0, not at all; 1, several days; 2, more than half the days; 3, nearly every day. A score of 3 or more has a sensitivity of 83% and a specificity of 92% for major depressive episode and indicates the need for a more extensive assessment to make the diagnosis of depression.

A second instrument is the *Edinburgh Postnatal Depression Scale* (*EPDS*), which is available on the internet at no cost. A sample question from the scale is given in Box 24.2. The scale was developed in 1987 and consists of 10 questions completed by the mother. The mother is asked to check the response that comes the closest to how she has been feeling in the previous 7 days, with there being 4 choices ranging from "often" to "never." All items must be completed, and the mother must respond by herself unless she has limited English skills and the questionnaire has not been provided in the mother's native language. The maximum score is 30. A score greater than 10 indicates risk for depression. A positive response to question 10, which asks about suicidality by itself, is considered a positive screening result. The instrument is available in more than 40 languages.

Box 24.2. Sample Question From *Edinburgh Postnatal Depression Scale*

As you are pregnant or have recently had a baby, we would like to know how you are feeling. Please check the answer that comes closest to how you have felt IN THE PAST 7 DAYS, not just how you feel today.

Here is an example, already completed.

I Have Felt Happy:

☐ Yes, all of the time.
☒ **Yes, most of the time.**
☐ No, not very often.
☐ No, not at all.

This would mean: "I have felt happy most of the time" during the past week. Please complete the other questions in the same way.

Adapted with permission from Cox JL, Holden JM, Sagovsky R. Detection of postnatal depression. Development of the 10-item Edinburgh Postnatal Depression Scale. *Br J Psychiatry.* 1987;150:782–786.

A third instrument is the Patient Health Questionnaire-9 (PHQ-9). Like the *EPDS*, the PHQ-9 includes 10 questions (9 questions and a follow-up question if any of the first 9 indicated any problems) related to the signs and symptoms of depression. The respondent notes whether the symptoms are present "not at all," "several days," "more than half the days," or "nearly every day." A score is then generated based on the mother's answers to assess her degree of depression. Mothers may be asked to complete these questions while in the waiting area. The PHQ-9 is not limited to postpartum mothers but can be used for all patients older than 18 years. Some electronic health records require the PHQ-9 as part of routine annual health screening.

Infants and Children

Infants and children may experience a number of problems as a consequence of maternal depression. Exposed children may develop disorders of attachment, particularly insecure attachment, and are at risk for the subsequent development of conduct or other behavior disorders. Language development may be adversely affected because depressed mothers speak fewer words and have fewer social interactions with their children. Maternal depression has also been associated with the decision not to breastfeed or the early cessation of breastfeeding. Classic environmental failure to thrive can be related to maternal depression and reduced mother-baby interactions. The effects of maternal depression can be detected in 2-month-olds who

regard mothers who have depression less frequently, have poorer state regulation, interact with objects less frequently, and have lower levels of overall activity than infants of mothers who do not have depression. These symptoms are attributed to the notions of the need for reciprocity between the mother and infant: mirror neurons, skill beget skill, and serve and return. The persistent absence of responsive care disrupts brain development. Long-term effects of maternal depression on child development have been demonstrated in magnetic resonance imaging of the brains of such children and increased cortisol levels at the time of school entry. Children are characterized as anxious, wary, and withdrawn. Social skills are noted to be poor. Early diagnosis and intervention may prevent the development of these problems.

Management

The major role of the pediatrician is to assist in the early identification of mothers who are experiencing PMADs and to make the appropriate referral for more definitive management. Support for this recommendation comes from a number of sources, including the 1999 and 2001 reports of the US Surgeon General; *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents;* the American Academy of Pediatrics (AAP) National Resource Center for Patient/Family-Centered Medical Home; and AAP policies on family-centered care. Practices that include the presence of social workers or mental health specialists can avail themselves of these individuals to assess, counsel, and refer mothers as appropriate. The mother may be referred back to her obstetrician for a visit prior to the 6-week checkup. Alternatively, mothers may be referred to local mental health specialists when such resources are known and available.

The pediatrician should also be familiar with the possible adverse effects of psychotropic medications on the fetus and newborn and recommendations about these medications in relation to breastfeeding. The decision to initiate psychotropic medication ingestion during pregnancy is made by the obstetrician or psychiatrist caring for the mother. There is no antidepressant specifically approved by the US Food and Drug Administration for use during pregnancy. All antidepressants cross the placenta and are never category A (no risk). Animal studies reveal no teratogenic effects of these medications, and the treating physician has to balance the risks of untreated depression versus the use of selected serotonin reuptake inhibitors (SSRIs). Paroxetine (eg, Paxil) has been associated with abnormalities of the right ventricular outflow tract. There is an increased risk of a septal defect with the use of any SSRI. It is noted that the risk of preterm labor increases from 6% to 22% when SSRIs are used, but the risk of preterm labor with untreated maternal depression is 20%. Newborns who have been exposed to SSRIs may exhibit poor neonatal adaption or neonatal abstinence syndrome. Symptoms include respiratory distress, irritability, jitteriness, hypotonicity, poor latching and feeding, and, rarely, seizures. The prevalence of persistent pulmonary hypertension increases from 1 to 6 in 1,000. Even if the mother is on an SSRI, she should be encouraged to breastfeed. As it relates to the use of SSRI and breastfeeding, we have the most experience with sertraline (eg, Zoloft) and paroxetine. Low levels of drug are detected in human milk but are not detected in the newborn's blood. If the mother is on a different medication, checking the medication website may provide additional information. Of note, there is a newly licensed medication, brexanolone, which appears to be effective for severe postpartum depression. To date there is no information related to breastfeeding and the use of brexanolone, but treated mothers have all been hospitalized because of the severity of their depression.

There are a number of internet sites that are very helpful in providing information about community resources. Postpartum Support International (www.postpartum.net; 800/944-4PPD [4773]) provides geographically specific information. The website can be accessed even while the mother is in the pediatrician's office. It is also important to have an emergency protocol in place, such as calling 911 or a psychiatric emergency team, should a woman endorse suicidality while in the pediatrician's office. Having such resources and protocols in place can go a long way toward reducing pediatricians' anxiety about screening for depression and suicidality.

Some perinatal programs offer home visitation or the use of doulas (ie, women who support other women through labor and delivery and after the birth of a baby in a nonmedical capacity), which assist mothers-to-be as well as recent mothers with the demands of birth and parenting. Such programs may offer a preventive and early intervention approach to peripartum depression by offering help and emotional support to new mothers as well as by screening for PMADs on a routine basis.

Older children who have been affected by maternal depression may be treated with other modalities that focus on mother and child to help address attachment disorders. Research on these dyadic interventions has demonstrated they are associated with decreased psychiatric symptoms and significant improvement in functioning of the mother and child. Internalizing and externalizing child behaviors are reduced when maternal depression, anxiety, or other conditions are addressed. Some programs include parent-child interactive therapy and parent-child psychotherapy. The program Circle of Security International involves video-based intervention that focuses on strengthening care giving.

Prognosis

The prognosis for PMADs and their effects on newborns, infants, and children are contingent on early recognition and appropriate intervention. Promoting screening is critical to ensuring a positive outcome. Pediatricians still face barriers, however, including the need to screen for a number of other conditions (eg, parental smoking, interpersonal violence), insufficient time, inadequate training, lack of appropriate resources, and lack of payment for services. A number of models have demonstrated that screening for PMADs can be successfully undertaken in a pediatric practice. The Assuring Better Child Health & Development project has been implemented in 28 states and involves the AAP chapters in those states. Pediatricians in Illinois, for example, can be paid through Medicaid if they administer the *EPDS*. *Bright Futures,* the health supervision guidelines developed by the AAP, endorses assessing parental social and emotional

well-being. Incorporating questioning into the health supervision visits at 1, 2, 4, and 6 months is recommended. Additional information about individual state initiatives can be found at the National Academy for State Health Policy ABCD Resource Center website (www.nashp.org/abcd-resources).

CASE RESOLUTION

While many of this mother's symptoms are common, her self-assessment that she is unable to function suggests that she is experiencing peripartum depression rather than baby blues. You ask her if it is all right to contact her obstetrician to see if she could be seen sooner. She agrees. When you reach her obstetrician, she schedules the mom to come in the following morning. The obstetrician tells you she has a therapist in her office who will be able to meet with the mother at that time.

CHAPTER 25

Newborn Screening

Henry J. Lin, MD, and Moin Vera, MD, PhD

CASE STUDY

A 1-week-old boy is brought to the pediatrician's office for a positive newborn screening test result for congenital adrenal hyperplasia. The baby was a product of a 38-week gestation and was born by normal spontaneous vaginal delivery to a 30-year-old gravida 2, para 2 woman with an unremarkable pregnancy. Birth weight was 3,300 g (116.4 oz), and the baby is feeding and acting appropriately. Family history is unremarkable, and the physical examination is normal.

Questions

1. What are the proposed benefits of newborn screening?
2. Which newborn screening tests are most commonly performed?
3. How are the results of newborn screening tests reported to physicians?
4. How should a patient with an abnormal newborn screening result be managed?
5. What are the most common causes of false-positive and false-negative results?
6. What are the ethical issues and future challenges surrounding newborn screening?

Newborn screening programs are designed to identify neonates at risk for catastrophic outcomes from treatable illnesses. Technologic advances in the past 50 to 60 years, such as tandem mass spectrometry, have made it possible to test for more than 50 metabolic disorders from a single blood spot. New techniques in molecular biology, including high-throughput DNA sequencing, allow for rapid diagnostic testing of conditions such as cystic fibrosis.

From the inception of newborn screening in the 1960s until 2005, each state in the United States chose a different set of conditions for its newborn screening program, based on disease prevalence, cost, availability of treatment, and false-positive rates. In 2005, an expert panel from the American College of Medical Genetics and Genomics recommended 29 core disorders for which newborn screening was most effective, as well as 25 secondary disorders that are in the differential diagnosis of a core disorder. In 2010, severe combined immunodeficiency (SCID) was added to the core list. Screening for critical congenital heart disease (by pulse oximetry) was endorsed by the American Academy of Pediatrics in 2011. By the end of 2013, all states offered testing for the 29 original core disorders, although screening for secondary disorders and SCID was variable.

Since 2015, development of federal recommendations for newborn screening has been the responsibility of the Advisory Committee on Heritable Disorders in Newborns and Children (under the US Department of Health and Human Services). The conditions on the Recommended Uniform Screening Panel include metabolic disorders, hemoglobinopathies and thalassemias, congenital hypothyroidism, SCID, hearing screening (see Chapter 88), and critical congenital heart disease. Advances in treatment (eg, enzyme replacement therapy) have resulted in recent expansion of the panel. As of July 2018, the latest additions to the Core Conditions list were disease type II (ie, Pompe disease), mucopolysaccharidosis type I (ie, Hurler syndrome), X-linked adrenoleukodystrophy, and spinal muscular atrophy (caused by homozygous deletion of exon 7 in *SMN1*; Table 25.1). The Recommended Uniform Screening Panel also has a list of Secondary Conditions, based on the earlier recommendations (Box 25.1).

Primary care physicians have 3 crucial roles in newborn screening. First, they provide education to parents about the newborn screening process. Second, they ensure that specimens are drawn under proper circumstances and that the results are promptly followed up. Finally, they provide medical follow-up and referral in cases of positive test results. All physicians must have contact information for state newborn screening programs and local pediatric subspecialists. Contact information for these groups is listed in Table 25.2.

Epidemiology

More than 4 million newborns are screened each year in the United States. The National Newborn Screening 2006 Incidence Report shows that newborn screening identifies 1 in 3,200 newborns with a metabolic disorder, 1 in 2,200 with congenital hypothyroidism, 1 in 2,200 with sickle cell disease or a related hemoglobinopathy, and 1 in 29,000 with congenital adrenal hyperplasia. Several disorders are more common in particular ethnic groups. For example, cystic fibrosis has an incidence of 1 in 2,500 in whites, and sickle cell disease has an incidence of 1 in 400 in blacks.

Clinical Presentation

Most neonates with disorders detected on newborn screening are clinically asymptomatic in the first 2 weeks after birth, but others may have significant signs and symptoms (see Table 25.1). The

Table 25.1. Recommended Uniform Screening Panel Core Conditions[a]

Type of Disorder	*Core Condition*	*Possible Signs and Symptoms in Neonates*
Metabolic: Organic acid	Propionic acidemia	Lethargy, vomiting, hypoglycemia, ketoacidosis, hyperammonemia, neutropenia, thrombocytopenia
	Methylmalonic acidemia (ie, methylmalonyl-CoA mutase) Methylmalonic acidemias (ie, cobalamin disorders)	Same as above
	Isovaleric acidemia	Lethargy, vomiting, odor of sweaty feet, hyperammonemia
	3-Methylcrotonyl-CoA carboxylase deficiency	Lethargy, vomiting; may be asymptomatic[b]
	3-Hydroxy-3-methylglutaricaciduria	Lethargy, vomiting, hypoglycemia, hyperammonemia, elevated transaminases
	Holocarboxylase synthetase deficiency	Lethargy, vomiting, hypoglycemia, ketoacidosis, hyperammonemia
	β-Ketothiolase deficiency	Lethargy, vomiting; may be asymptomatic[b]
	Glutaric acidemia type 1	Macrocephaly possible; otherwise asymptomatic[b]
Metabolic: Fatty acid oxidation	Carnitine uptake defect/carnitine transport defect	Lethargy, cardiac decompensation, hypotonia, hypoglycemia, liver dysfunction; may be asymptomatic[b]
	Medium-chain acyl-CoA dehydrogenase deficiency	Lethargy, coma, sudden death, hypoglycemia, liver dysfunction, arrhythmias, symptoms similar to those of Reye syndrome; may be asymptomatic[b]
	Very-long-chain acyl-CoA dehydrogenase deficiency	Lethargy, cardiac decompensation, coma, sudden death, hypoglycemia; may be asymptomatic[b]
	Long-chain L-3-hydroxyacyl-CoA dehydrogenase deficiency	Lethargy, cardiac decompensation, hypoglycemia, liver dysfunction; may be asymptomatic[b]
	Trifunctional protein deficiency	Same as above
Metabolic: Amino acid	Argininosuccinicaciduria	Lethargy, vomiting, seizures, coma, hyperammonemia
	Citrullinemia type I	Lethargy, vomiting, seizures, coma, hyperammonemia
	Maple syrup urine disease	Lethargy, vomiting, seizures, coma, maple syrup odor
	Homocystinuria	Asymptomatic[b]
	Classic phenylketonuria	Asymptomatic[b]
	Tyrosinemia type I	Vomiting, diarrhea, liver dysfunction (jaundice, bleeding, hypoglycemia), boiled cabbage odor; may be asymptomatic[b]
Endocrine	Primary congenital hypothyroidism	May be asymptomatic[b]; umbilical hernia, enlarged fontanelle, macroglossia, jaundice
	Congenital adrenal hyperplasia	Virilization in females, salt-wasting crisis
Hemoglobin	SS disease (ie, sickle cell anemia)	Asymptomatic[b], dactylitis
	S β-thalassemia (ie, sickle β-thalassemia)	Asymptomatic[b]
	SC disease (ie, hemoglobin C sickle cell disease)	Asymptomatic[b]
Other	Biotinidase deficiency	Lethargy, hypotonia, seizures; may be asymptomatic[b]
	Critical congenital heart disease	Hypoxemia
	Cystic fibrosis	Meconium ileus, intestinal obstruction
	Classic galactosemia	Lethargy, vomiting, diarrhea, jaundice, hepatomegaly, cataracts, sepsis (*Escherichia coli*)
	Glycogen storage disease type II (ie, Pompe disease)	Hypotonia, hypertrophic cardiomyopathy; may be asymptomatic[b]
	Hearing loss	Deafness, speech delay

(continued)

Table 25.1. Recommended Uniform Screening Panel Core Conditions[a] (*continued*)

Type of Disorder	*Core Condition*	*Possible Signs and Symptoms in Neonates*
Other (*continued*)	Severe combined immunodeficiencies	Recurrent infections
	Mucopolysaccharidoses type I	Inguinal hernia, upper respiratory tract infection; may be asymptomatic[b]
	X-linked adrenoleukodystrophy	Asymptomatic[b]
	Spinal muscular atrophy caused by homozygous deletion of exon 7 in *SMN1*	Impaired motor function

Abbreviations: CoA, coenzyme A; *SMN1*, survival of motor neuron 1.

[a] As of July 2018.

[b] Asymptomatic covers the first month after birth and does not exclude very rare case reports of neonatal presentations.

Adapted from Advisory Committee on Heritable Disorders in Newborns and Children. Recommended Uniform Newborn Screening Panel Core Conditions (as of July 2018). Washington, DC: U.S. Department of Health & Human Services; 2018 www.hrsa.gov/sites/default/files/hrsa/advisory-committees/heritable-disorders/rusp/rusp-uniform-screening-panel.pdf.

Box 25.1. Recommended Uniform Screening Panel Secondary Conditions[a]

Organic Acid Disorders
- Methylmalonic acidemia with homocystinuria
- Malonic acidemia
- Isobutyrylglycinuria
- 2-Methylbutyrylglycinuria
- 3-Methylglutaconicaciduria
- 2-Methyl-3-hydroxybutyricaciduria

Fatty Acid Oxidation Disorders
- Short-chain acyl-CoA dehydrogenase deficiency
- Medium/short-chain L-3-hydroxyacyl-CoA dehydrogenase deficiency
- 2,4-Dienoyl-CoA reductase deficiency
- Carnitine palmitoyltransferase type I deficiency
- Carnitine palmitoyltransferase type II deficiency
- Carnitine acylcarnitine translocase deficiency

Amino Acid Disorders
- Argininemia
- Citrullinemia type II
- Hypermethioninemia
- Benign hyperphenylalaninemia
- Biopterin defect in cofactor biosynthesis
- Biopterin defect in cofactor regeneration
- Tyrosinemia type II
- Tyrosinemia type III

Hemoglobin Disorders
- Various other hemoglobinopathies

Other Disorders
- Galactoepimerase deficiency
- Galactokinase deficiency
- T-cell related lymphocyte deficiencies

Abbreviation: CoA, coenzyme A.

[a] As of July 2018.

Adapted from Advisory Committee on Heritable Disorders in Newborns and Children. Recommended Uniform Newborn Screening Panel Secondary Conditions (as of July 2018). Washington, DC: U.S. Department of Health & Human Services; 2018 www.hrsa.gov/sites/default/files/hrsa/advisory-committees/heritable-disorders/rusp/rusp-uniform-screening-panel.pdf.

presence of such features may require a more urgent work-up or even hospitalization. Unfortunately, severe forms of some metabolic disorders may cause coma and encephalopathy by 48 hours of age. In these cases, newborn screening results are critical, because they will suggest a probable diagnosis and allow early optimization of therapy.

Differential Diagnosis

Although newborn screening techniques are continually improved, false-positive and false-negative results may occur. Mislabeled specimens, technical errors, and reporting errors can occur in any laboratory. Any specimen collected before 12 hours of age is at risk for a false-negative metabolic result or a false-positive hypothyroidism result. Preterm newborns have a reduced metabolic capacity and therefore may exhibit higher metabolite levels compared with levels in full-term infants, which can produce false-positive results. Anemia or polycythemia can affect the amount of plasma per blood spot, which may lead to false-negative results. Transfusion may alter galactosemia and hemoglobinopathy testing. Neonates receiving hyperalimentation may have increased amino acid and lipid levels, especially if the newborn screen is drawn from a central line (rather than a heel stick). To ensure accurate and uniform testing and interpretation, it is imperative that relevant clinical information be included when the newborn specimen is submitted.

Newborn Screening Practices

Parental Education and Consent

All parents should be informed of the state screening program at the prenatal visit or during the initial newborn examination. Written materials that explain the screening program are available from state screening offices. Health professionals are responsible for educating parents on the method for obtaining the blood specimen, the risks and benefits of screening tests, conditions on the screening panel, and the implications of positive results.

It is important to tell the parent or parents that a positive result does not necessarily mean that the newborn has a particular

disorder. Results must be confirmed by more specific tests. In addition, the parent or parents should be advised that in some children disorders are missed because of sampling errors, faulty testing, or inadequate accumulation of the abnormal metabolite at the time of testing.

Newborn screening is mandatory in all states, although many states allow exemptions for religious beliefs or other reasons. In most states, parents have given verbal informed consent when practitioners have discussed the state-mandated program with them and the parents have agreed to participate. A few states require signed consent to opt into the newborn screening program, and several more require consent to disclose identifiable information. Physicians should document parental refusal regardless of state laws.

Specimen Collection and Handling

Proper specimen collection and handling are essential components of a successful screening program. All newborns should be screened before discharge from the hospital, ideally between 24 and 48 hours of age. Screening too early increases the chance of a false-negative metabolic result or a false-positive hypothyroidism result. For this reason, some states have a mandatory second screen between 1 and 6 weeks of age, whereas others require a second screen only if the first screen is obtained before a specified time (eg, 12 hours, depending on the state). Late screening increases the sensitivity of metabolic testing but also increases the risk for delayed diagnosis of a life-threatening condition, such as galactosemia. If possible, blood samples should be obtained prior to any transfusions or dialysis. If not possible, screening should still be performed as outlined previously, and arrangements should be made to repeat the screen at an appropriate time.

Several drops of blood are needed to fill each circle on the newborn screening filter paper, and the sample must saturate the paper evenly. The use of needles and glass capillary tubes for blood collection is discouraged, because they may cause hemolysis or microtears in the filter paper. Specimens must be individually air-dried in a horizontal position to avoid contamination and excessive exposure to heat. They should be mailed or preferably, sent by courier, to the laboratory within 24 hours of collection. Inadequate specimen collection and handling can result in test inaccuracies, delays in reporting results to physicians, and unnecessary repetition of screening tests. Therefore, all individuals who are involved in the newborn screening process should strictly adhere to the procedures set forth by their state program.

Reporting of Results

In most states, all results of neonatal screening tests, whether normal or abnormal, are reported to the physician of record. Normal results are mailed to the physician for placement in the patient's medical record. Abnormal results are usually reported by telephone or letter, depending on the severity of the potential condition. Results are also sent to the hospital in which the neonate was born for inclusion in the medical record. The physician of record is responsible for contacting the parent or parents about the need for confirmatory testing and, if necessary, referral to an appropriate subspecialist. If a newborn is no longer under the care of this physician or if the family cannot be located, state and local public health departments can assist in the search for the newborn and family.

Diagnostic and Therapeutic Considerations

A health care team consisting of a primary care physician and staff, state newborn screening office personnel, state newborn screening laboratory, local laboratories, and a subspecialty physician is responsible for care and follow-up of patients with positive newborn screening results. All newborns with abnormal results, whether borderline or clearly significant, should be evaluated by their primary care physician. A complete patient history and physical examination as well as a family history should be obtained. Positive results for newborn screening tests often normalize on follow-up testing or on a second screen. Therefore, most follow-up evaluations focus on targeted diagnostic tests. Depending on the nature of the suspected disorder, initiation of treatment before confirmatory laboratory results are known may be appropriate. For example, prophylactic antibiotics should be administered if sickle cell anemia is suspected. After confirmatory results have been received, the treatment can be modified or halted.

Potentially life-threatening conditions in the newborn period, such as galactosemia, maple syrup urine disease, and congenital adrenal hyperplasia, are particularly important to evaluate and treat emergently. Depending on the clinical picture, suspected disorder, and experience of the physician, telephone consultation with a specialist or immediate referral to a regional medical center may be necessary.

Almost all of the diseases in the current newborn screening panel are inherited in an autosomal recessive manner. Families of affected newborns should be offered genetic counseling for future pregnancies, in addition to written information about the newly diagnosed condition. Depending on the condition, it may be necessary to evaluate older siblings. For some conditions, such as 3-methylcrotonyl coenzyme A carboxylase deficiency, a positive newborn screen may be indicative of an affected asymptomatic mother, whose circulating metabolites are also present in the blood of her newborn.

Current Issues and Future Challenges

Protecting patient privacy is of utmost importance, and most programs have laws to protect a patient's personal information, blood spots, and genetic information. Great concern exists among parents and physicians that insurance companies will use newborn screening information to discriminate against children and their families.

It is indisputable that newborn screening saves lives. Additionally, from a purely economic standpoint the cost of newborn screening programs is outweighed by the resulting reduction in morbidity and mortality. However, some diseases that are now on the Recommended Uniform Screening Panel, such as lysosomal storage disorders, have extremely costly treatments that may total millions of dollars over the lifetime of the patient and produce significant morbidity. Cost-benefit analyses will be crucial to shaping future newborn screening panels. Pediatricians and other health professionals must advocate for insurance coverage for newborn screening panels, especially as hospital charges for newborn testing increase.

Several newborn screening tests may detect asymptomatic carrier status in newborns. Although knowledge of a patient's carrier status may be of some use for childbearing decisions, it has no immediate benefit for the newborn and may inadvertently result in discrimination and stigmatization. The parents of affected newborns, who usually are asymptomatic carriers, are presented with the same dilemma and may wish to forego additional testing concerning their own carrier status.

New challenges will emerge as genetic technology advances toward the idea of using genomic sequencing as the standard test for newborn screening. The thought that genomic sequencing could someday be applied to all newborns seems less remote today than it did a few years ago, judging by statements in published reviews. The technical feasibility, ethics, legal questions, and medical outcomes of genomic testing remain topics for dialogue and research. Health professionals may refer to current medical literature to stay abreast of this interesting and developing area.

CASE RESOLUTION

The patient should undergo a full evaluation, including an electrolyte panel, because of the possibility of salt-wasting congenital adrenal hyperplasia. Confirmatory testing, including measurement of precursor hormones such as 17α-hydroxyprogesterone and subsequent molecular testing, as well as glucocorticoid therapy should be considered in consultation with a pediatric endocrinologist.

CHAPTER 26

Caring for Twins and Higher-Order Multiples

Soina Kaur Dargan, MD, FAAP, and Lynne M. Smith, MD, FAAP

CASE STUDY

An expectant mother visits you. She has been advised by her obstetrician that a sonogram shows she is pregnant with twins. She asks about care of twins and what special considerations she should keep in mind as she looks forward to the delivery. In particular, she is concerned about the feeding schedule and whether she will be able to breastfeed.

Questions

1. What is the incidence of twin births?
2. What is the difference between fraternal and identical twins?
3. What major medical problems may affect twins and higher-order multiples?
4. What developmental and behavioral problems are associated with raising twins?

With the advent of artificial reproductive therapy 40 years ago, the incidence of twins and higher-order multiples has increased. Counseling the parents of multiples provides a unique opportunity for pediatricians. Much of what is known about caring for multiples comes from work with twins.

Parents of multiples often have many questions about the care of their children, but they rarely pose them to health care professionals. In a study in which 18 out of 29 mothers breastfed their twins, only 3 received information about breastfeeding from their physicians. One mother had been told by her obstetrician that she could not breastfeed her twins. Physicians should become knowledgeable about caring for multiples and the unique challenges they present to parents related to feeding, sleeping, and behavior.

Epidemiology

On July 25, 1978, Louise Brown was the first baby born as a result of in vitro fertilization (IVF). Since then, improved prenatal care and IVF methods have contributed to the increase in multiple births. According to the American Society for Reproductive Medicine, the rate of twins has increased more than 75% over the last 40 years in the United States. Twin rates have also increased in Finland, Norway, Austria, Sweden, Australia, Hong Kong, Japan, Canada, Singapore, and Israel, with the highest rate increase in Nigeria. A major contributor to the increase in multiple births is that women are starting their families later than in previous generations. The Centers for Disease Control and Prevention reports that from 1980 to 2009, twin birth rates increased 76% for women aged 30 to 34 years, nearly 100% for women aged 35 to 39 years, and more than 200% for women aged 40 years and older.

Because of the increased risk of infertility with advanced maternal age, more couples are choosing to conceive with assisted reproductive technologies, including ovulation-stimulating drugs, IVF, and intracytoplasmic sperm injection. More than one-third of twins and more than three-quarters of triplets and higher-order multiples in the United States resulted from conception assisted by fertility treatments.

The overall natural prevalence of twin births is about 33 in 1,000. Twins account for just slightly more than 1% of all births, and 20% of neonates born at fewer than 30 weeks' gestation are twins. The average prevalence of monozygotic or identical twins, which is the same for all women regardless of race and age, is about 1 in 300 births. The incidence of dizygotic or fraternal twins varies among different groups and by method of conception. In the United States, blacks and whites have comparable incidences of live-born twin deliveries, and both have significantly higher rates than Hispanic women. A maternal family history of dizygotic twins correlates most strongly with an increased incidence of twins. A family history of monozygotic twins or a paternal family history of dizygotic twins does not increase the likelihood of twins.

Pathophysiology

Higher-order multiples, conceived naturally or via artificial reproductive technology, may be fraternal or a combination of monozygotic twins and fraternal siblings. Monozygotic twins result from the splitting of a single egg. They may share a placenta (monochorionic) (Figure 26.1A and 26.1B) and, in rare cases, may also share an amniotic sac (monoamnionic). When splitting occurs early (after several cell divisions of the zygote), each fetus develops its own

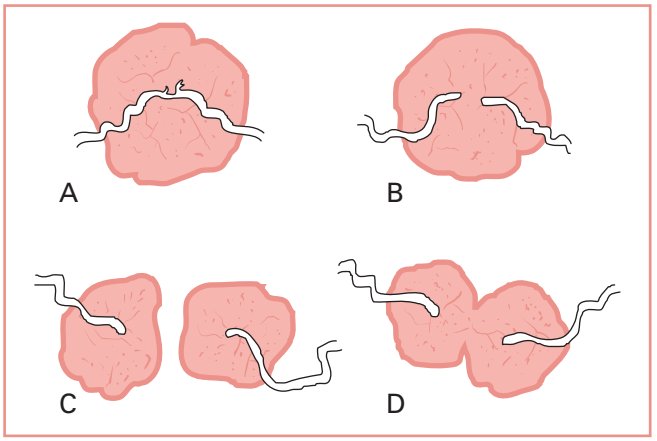

Figure 26.1. Variations in placentas in twin births. A, Monochorionic placenta, cords close together. B, Monochorionic placenta, cords farther apart. C, Dichorionic placentas, separate. D, Dichorionic placentas, fused.

chorion and amnion, leading to dichorionic and diamnionic placentas. Dizygotic twins result from 2 eggs, with each egg fertilized by a different sperm. Dizygotic twins have 2 placentas (Figure 26.1C). Although these placentas may fuse together like 2 pancakes, they are almost always dichorionic and diamnionic (Figure 26.1D). Ultrasonography at 14 weeks or sooner has been found to be 96% predictive of monochorionic twins and can also predict monoamnionic twins, anomalies, and syndromes.

Following birth, many parents want to determine whether twins are monozygotic or dizygotic. Different-sex twins are almost always dizygotic, although monozygotic twins of different sexes have been reported in the literature. This occurs when 1 twin loses a Y chromosome and becomes a phenotypic female with Turner syndrome (XO). Occasionally, the male twin may have an XXY chromosome complement and have Klinefelter syndrome.

To determine whether twins are monozygotic or dizygotic after birth, a number of procedures can be undertaken. Visual or pathological examination of the placenta is helpful. About two-thirds of monozygotic twins have a common chorion and share 1 placenta. Finding a single chorion usually means the twins are monozygotic, unless the placentas of dizygotic twins have fused together. DNA testing is the preferred method for determining zygosity. Most commercially available testing, often referred to as zygosity testing, involves examining DNA obtained from buccal swabs from each child. Identification of short tandem repeats via polymerase chain reaction is typically accurate 99% of the time and is similar to techniques used in forensic medicine. Commercial laboratory charges range from $100 to $200, although prices vary significantly depending on the company and whether zygosity is being tested for twins or higher-order multiples.

Recent research on monozygotic twins has also focused on the effect of epigenetics, or how the environment affects genetics. By analyzing the DNA of monozygotic twins, researchers are hoping to identify epigenetic tags that mark a change in gene expression. Although DNA cannot be altered, DNA methylation, which affects the strength of gene expression, may be a process that, in the future, can be manipulated to reverse some complex disorders, such as autism spectrum disorder.

Differential Diagnosis

Diagnosing multiples is not difficult, but physicians should be aware of the problems these newborns may experience.

Perinatal Complications

Multiple births are associated with a significantly higher risk of perinatal complications relative to singleton births. The maternal complication most commonly reported with multiples is pregnancy-induced hypertension. Maternal preeclampsia rates are higher in twins and increase nearly 5-fold with triplets. In addition, mothers of twins who conceived via IVF have a higher rate of preeclampsia than mothers of twins who conceived naturally. Other maternal complications include placenta previa, antepartum hemorrhage, gestational diabetes mellitus, anemia, uterine atony, and maternal death.

Monozygotic twins are at increased risk for death and cerebral palsy because of complications such as severe birth weight discordance and twin transfusion syndrome (TTS). Twin transfusion syndrome is seen in 10% to 15% of monochorionic pregnancies and results from unbalanced blood flow due to vascular anastomoses within the shared placenta. The diagnosis is suspected by ultrasound when 1 fetus is growth restricted with oligohydramnios and the other fetus has evidence of volume overload with polyhydramnios. Both twins are ultimately at risk for fetal hydrops or death. Without treatment, TTS-induced death of at least 1 twin is as high as 80% to 100%. Of additional concern, the death of 1 twin is associated with neurologic damage or subsequent death of the surviving twin, with 1 in 10 surviving twins developing cerebral palsy.

Until recently, treatment was drainage of amniotic fluid in the twin with polyhydramnios to reduce the risk of preterm delivery. Endoscopic laser ablation of placental anastomoses has emerged as the treatment of choice for severe TTS pregnancies diagnosed and treated prior to 26 weeks' gestation. Laser ablation addresses the primary pathology and results in an average gestation at delivery of 33 weeks, which is a significant improvement from the average 29 weeks with serial amniotic fluid reductions. Laser ablation is not without risks, however; reported complications include premature rupture of membranes, amniotic fluid leakage into the maternal peritoneal cavity, vaginal bleeding, and chorioamnionitis.

One percent of monozygotic twins are monochorionic–monoamnionic. Although monoamnionic twins have a lower risk of TTS, they are at very high risk for cord accidents. Monoamnionic pregnancies are monitored closely, and once the fetuses reach viability, emergent delivery is indicated if fetal distress is noted to avoid fetal death. Because fetal death significantly increases the risk of cerebral palsy and other neurologic disorders in the surviving twin, it is no longer recommended to allow fetal death in 1 monoamnionic twin to lengthen the gestation of the non-distressed twin.

Congenital Malformations

Twins and higher-order multiples have an increased risk of anomalies. Monochorionic twins have a higher risk of cardiac anomalies than dichorionic twins, increasing their need for fetal echocardiograms. Multiples conceived via IVF or intracytoplasmic sperm

injection have increased risk for anomalies and aneuploidy. Disorders of genetic imprinting (eg, Beckwith-Wiedemann syndrome, Angelman syndrome) are also increased with intracytoplasmic sperm injection. These genetic complications are thought to be secondary to the underlying cause of infertility instead of artificial reproductive technologies. Because the costs associated with infertility treatments are substantial, many couples choose not to obtain a comprehensive chromosomal analysis looking for deletions or translocations on themselves prior to using reproductive technologies. Nuchal translucency and chorionic villus sampling can be used to detect and confirm suspected aneuploidy as early as the first trimester.

In addition to increased risks of malformations, multiples are at risk for deformations secondary to crowding, including torticollis, hip dislocation, plagiocephaly, and foot deformities. Monochorionic twins are also at risk for becoming conjoined twins, estimated to occur in 1 in 50,000 to 200,000 gestations, with more than 50% dying in utero or being stillborn and 35% dying within the first 24 hours after birth. Although monochorionic twins are more commonly males, conjoined twins are often female. Conjoining occurs because of incomplete splitting of the embryo or after a secondary fusion between 2 previously separate embryos. Prenatal ultrasonography is commonly used to diagnose this condition; more recently, prenatal magnetic resonance imaging has been used to evaluate specific anomalies. Due to surgical advances, some parents continue the pregnancy with hopes the live-born neonates can be separated.

Postnatal Complications

Approximately 60% of twins and 90% of triplets are born preterm, increasing the risk of morbidity and mortality. On average, most single pregnancies last 39 weeks, twin pregnancies 36 weeks, triplets 32 weeks, quadruplets 30 weeks, and quintuplets 29 weeks. The most common cause of preterm delivery in these neonates is premature rupture of membranes.

Although growth in twins tends to be normal until 30 to 34 weeks' gestation, growth restriction is commonly associated with multiple births. Twins conceived by IVF are more likely to be born at a low birth weight than spontaneously conceived twins. Smaller twins have an increased incidence of hypoglycemia in the newborn period and have higher rates of targeted learning deficits and school failures during childhood. In addition, children born with growth restrictions have an increased risk for obesity and diabetes in later life. Selective intrauterine growth restriction (IUGR), when only 1 twin is affected by IUGR, occurs in 10% of monochorionic twins. This occurs when the twin with IUGR has reversed flow or persistent absent flow in the umbilical artery.

Neonatal mortality is 4-fold higher in twins and 15-fold higher in higher-order multiples. Neonatal morbidity is much higher in multiple births because of the increased incidence of preterm birth and growth restriction. The risk of these complications increases with the number of fetuses. The perinatal mortality of monozygotic twins is 8 times that of singletons and 4 times that of dizygotic twins. Twins and higher-order multiples are also at increased risk for cerebral palsy.

Evaluation

History

A general medical history should be obtained, including a history of the pregnancy. Any specific medical concerns should also be addressed (Box 26.1).

Physical Examination

The initial evaluation of newly born twins involves assessment of gestational age and determination of the presence of any medical problems or anomalies (see Chapter 23). Older twins may undergo health supervision visits at which routine as well as specific concerns are addressed.

Laboratory Tests

Newborns should be assessed for the presence of anemia or polycythemia with a hemoglobin level determination. Hypoglycemia may occur in the newborn period and should be assessed frequently until glucose levels are stable. If the twins are preterm, they may have many of the problems seen in singleton preterm newborns, such as neonatal respiratory distress syndrome and necrotizing enterocolitis.

Older children should receive an appropriate evaluation for age, with a specific focus on any behavioral concerns.

Management

The focus of the management of multiples involves counseling parents about issues related to routine care and anticipated stress of caring for more than 1 newborn simultaneously. Parents often care for 2 or more children at the same time, but multiples present unique issues related to multiple children who are developmentally and chronologically at the same point. Many parents experience anxiety about the upcoming challenges they will face. Baby care books that specifically discuss birthing and raising multiples are available. Support groups and websites also provide information for families of multiples.

Feeding multiple newborns is often an exhausting challenge for parents, and consultation with a lactation expert is recommended. The physical demands of feeding multiple newborns are often compounded by women recovering from prenatal complications such as preeclampsia. Because preterm birth is common, newborns may have an immature suck reflex, making feeding more challenging. Few multiples are still exclusively breastfed by 4 months of age, and common reasons cited for unsuccessful breastfeeding of multiples

Box 26.1. What to Ask

Caring for Twins

- Did the mother have any problems during the pregnancy?
- How long did the pregnancy last?
- Did the mother take any medications, including fertility drugs?
- Did the children have any problems after the delivery or in the newborn nursery?

include maternal stress, depression, fatigue, perceiving they were producing insufficient milk, and time burden. Despite these obstacles, parents should know that breastfeeding is possible even for triplets and understand the benefits of breastfeeding to the newborns' health. It is recommended that mothers begin breastfeeding as soon as possible to establish their milk supply. An electric pump is a useful adjunct to help establish and continue breastfeeding. If supplemental nutrition is needed, utilizing a medicine dropper, syringe, spoon, cup, or finger feeding instead of a bottle will reduce the risk of newborns developing a preference for an artificial nipple.

Some options for breastfeeding are outlined in Box 26.2.

Sleeping in the same crib is no longer recommended because of concerns about co-sleeping. Approximately 3,500 babies die from sleep-related deaths per year. Although co-sleeping is not recommended, room sharing, in which infants sleep in the same room as parents, is recommended for infants 6 to 12 months of age.

Travel can be challenging with twins and higher-order multiples. Planning ahead is the key to making this a positive and constructive experience. Having a separate diaper bag in each car and additional car seat adapters may make travel easier, but safety should never be compromised. It is important to counsel parents about car safety seats. Parents who cannot afford the cost of multiple car safety seats may resort to placing 1 baby in the car safety seat and the others on the seat of the car, a dangerous practice that is illegal throughout the United States. Parents should be advised of the need for car safety seats for all babies.

In the interest of safety, bathing should be done separately until babies can sit up.

Box 26.2. Breastfeeding Twins and Higher-Order Multiples

1. Position

a. Babies may be put in a number of positions. Regardless of position, it is important to make sure that the baby's head and neck are supported just enough so the baby can adjust its head to breathe during breastfeeding. The mother can be sitting and cradling (across the chest) 1 baby while holding the other like a football. Alternatively, the mother may cradle both babies so that they are cross-positioned over one another with their legs make an X across the mother's lap, or she may have both under her arms in a football position. Breastfeeding pillows designed for feeding multiples are helpful, but several firm pillows are also sufficient.

b. Maternal positions can be sitting up with pillow back support, reclining, or lying down. To help prevent maternal fatigue, reclining and lying down are preferred.

2. Timing of Feeds

a. Feed both babies at the same time, with 1 on each breast. This method is recommended only after adequate breastfeeding has been established in each twin, typically not until after 1 week after birth. It is advised that the baby having fewer problems latching be placed on the breast first so that the milk ejection reflex is already established for the poorer-feeding baby. Because the babies may not drink the same amount, it is important that they feed on the opposite breast for the next feeding to maximize milk production.

b. Feed the babies at different times. The mother breastfeeds 1 and then the other, starting with the more vigorous feeder. This approach may pose a problem; both babies may be hungry at the same time, and maternal fatigue may inhibit success because the chance for sleep is diminished with this method. Some mothers prefer this method because it provides individualized attention and opportunities for attachment with each baby.

c. Breastfeed 1 baby and bottle-feed the other, which gives the mother a free hand. Most parents use a combination of breastfeeding and bottle-feeding. A mother can let the first baby feed on demand but awaken the second when the first is done. Eighty percent of parents of twins acknowledge that they prop the bottle instead of holding it, and they should be counseled against this. There are several effective feeding positions that do not require bottle propping, and parents should be encouraged to adopt 1 of these positions.

3. Higher-order Multiples

Breastfeeding triplets and higher-order multiples is even more challenging than breastfeeding twins. Mothers of triplets exclusively breastfeeding report they feed 2 babies, 1 on each breast, and the third follows on both breasts. Because the hind milk has higher fat content, it is important to rotate the feeding order of the babies. Another popular option is to breastfeed 2 and have the third bottle-feed simultaneously.

4. Maternal Considerations

a. Feeding twins or higher-order multiples may decrease the amount of sleep a mother gets. Because sleep deprivation is associated with maternal depression and exclusively breastfeeding mothers of multiples report more sleep problems compared with mothers who do not breastfeed or who formula-feed and breastfeed, these factors should be discussed when offering feeding options to parents. Encouraging paternal involvement with feeding may alleviate some maternal stress and sleep deprivation.

b. Maternal nutrition plays a key role in quality and quantity of milk produced. Research shows that the higher the nutrition value of the mother's diet, the higher the nutrition quality of her milk. According to the Centers for Disease Control and Prevention, the mother should increase her calorie intake by 450 to 500 kcal per baby per day. In addition, a multivitamin may be recommended.

Toilet training is reportedly easier with some twins because 1 twin learns from the other via modeling or peer pressure.

Maintenance of individuality for multiples may be challenging. Researchers suggest that mothers can bond to only 1 newborn at a time, a concept called *monotropy.* In addition, mothers bond more strongly with the twin who leaves the hospital first. Twins are often dressed alike and given similar names because this may facilitate the bonding process. To help with individual development, physicians are encouraged to obtain history and examine each child individually. Physicians should attempt to distinguish the children from one another independent of parental reminders. Twins should not be referred to as "the twins" but by their respective names. As multiples get older, issues related to classrooms and birthday parties frequently arise, and they should be consulted about their preferences. Individual birthday parties and gifts should be considered, as some multiples comment on their disappointment at receiving the same present for birthdays and holidays. There is no surprise in opening gifts if the other twin opened a gift first.

Whether multiples should be placed in the same or different classrooms is unclear. Placement in different classrooms or schools is advocated to support each child's individual development. However, being in the same classroom ensures the same educational standard and may be more convenient for families. Research is variable on whether separate or same classrooms are better or even make a difference for twins with regard to emotional and academic outcomes. Some studies do suggest that boys do better emotionally when they are together versus separated. It is currently recommended that school districts have a flexible policy addressing school placement of twins. Online resources are available to assist families and schools in determining the best school placement for twins. Families with higher-order multiples are more likely to have children in separate schools because of the higher risk that some of the children will have developmental delays.

Sibling rivalry is common in all families but is different among co-multiples as well as other siblings within a family. Twins are often directly compared to one another, while older siblings may resent the attention paid to the new babies. Because twins often exclude siblings and peers socially, parents are encouraged to schedule times when 1 twin and sibling are with 1 parent and the other twin is alone with another family member. Isolating twins (or 2 triplets from a third) fosters more sibling interaction and less dependency between the twins. These separations are encouraged to begin early in development because the later in development twins are separated, the less agreeable twins are to being apart.

Developmental differences among multiples may also contribute to sibling rivalry. The child who is smaller or more delayed may become jealous of the co-multiple. Conversely, typically developing children may become frustrated when the sibling with special needs receives more attention than they receive. Parents and family should be encouraged to acknowledge and praise individual characteristics of each twin.

Until age 3 years, language and speech development is delayed in twins relative to singletons. A contributing factor to language delay is less time for individual facilitated play, which is helpful for language development. If twins communicate with a private language, they have an increased risk of language and cognitive delays. Language delays usually become much less pronounced by mid-childhood. Attention-deficit/hyperactivity disorder is more common in twins but not as common as language delay. The smaller twin has a higher rate of specific learning deficits and school difficulties. The temper tantrums multiples display can be severe and are understandable given the heightened need to gain parental attention from their sibling. Having twins in the home is a risk factor for child abuse, either to a twin or to their siblings.

The risk of cerebral palsy is increased with higher multiples because of the increased rates of preterm birth and IUGR. Fetal death of a co-multiple and monochorionic placentas are the biggest risk factors for developing cerebral palsy.

The effect on families of twins and higher-older multiples starts prior to delivery and includes higher risk to maternal health as well as anticipatory anxiety. Prior to delivery, parents should be made aware that maternal depression is frequently reported after the birth of multiples. The physical stress of caring for multiple newborns can be overwhelming, and parents often feel isolated at home. The incidence of depression is higher in mothers of twins than of singletons, with sleep deprivation cited as a contributing factor. It is important to suggest that parents of multiples obtain outside aid to decrease fatigue and increase their ability to experience respite even for short periods.

In addition to exhaustion and isolation, the increased financial demands that accompany multiple newborns can strain the parents' relationship. Mothers often have to leave work earlier in the pregnancy than women with singleton pregnancies, adding financial burden, especially if they are single or have other children. The medical costs associated with preterm birth can be substantial. To cover for the loss of income at a time of increasing family expenses, the father is often required to work more hours. This increased occupational stress comes at a time when child care demands at home have increased significantly. Financial burdens are especially difficult with multiples conceived artificially because of the cost associated prior to birth. This may be a contributing factor to why parents of twins conceived artificially have reported less satisfaction than parents of twins conceived naturally.

Grief is another significant contributor to parental depression. Approximately 15% of children from multiple births grow up as a singleton survivor. Birthday celebrations serve as reminders to the parents of the death of the other child. Parents grieving the loss of 1 of their twins have comparable grief to those grieving the loss of a singleton pregnancy. It is imperative that physicians caring for the family acknowledge the parents' grief because family and friends often do not acknowledge the parents' pain if there is a surviving newborn.

Surviving children born preterm or small for gestational age are at increased risk of developmental delays. The stress of raising a child with special needs is also a source of grief because parents mourn the loss of their dreams of having a "normal" child.

Prevention

Regardless if conceived naturally or via artificial reproductive technology, it is impossible to guarantee singletons or higher-order multiples. Nonetheless, a maternal family history of dizygotic births increases the likelihood of higher-order multiples. Artificial reproductive technology often results in higher-order multiples. However, the number of embryos implanted via artificial reproductive technology has decreased following high-profile births of grand multiples that highlighted the financial difficulties placed on families, as well as the increased risk of developmental delays in the children.

Prognosis

Although multiples have a higher prevalence of perinatal and postnatal problems, appropriate anticipatory guidance, routine health maintenance, and treating each child as an individual can help families optimize their children's outcome.

CASE RESOLUTION

The mother is advised that breastfeeding is not only possible but recommended. She is told about the options for timing and positioning of the newborns. The issues of family history and child passenger safety are also discussed, and anticipatory guidance on the potential stress of raising multiples is given.

CHAPTER 27

Male Circumcision

Jung Sook (Stella) Hwang, DO, FAAP, and Lynne M. Smith, MD, FAAP

CASE STUDY

An expectant mother learns that the sex of her fetus is male. She visits you prenatally. She talks about circumcision in addition to issues related to breastfeeding and car passenger safety. Her husband is circumcised. She is unclear about the medical indications for circumcision and asks your opinion about circumcision in the newborn period.

Questions

1. What are the benefits of male circumcision?
2. What are the indications for circumcision in older children?
3. What are the techniques used to perform circumcision?
4. What are the complications of circumcision?
5. What is the current status of insurance coverage of circumcision?

Male circumcision, a procedure in which the foreskin of the penis is removed, has been performed for more than 6,000 years. It is routinely performed in certain groups, most notably among Jewish and Muslim people. In some other cultures (eg, Australian [Aborigine], Polynesian), circumcision is presumably performed to facilitate intercourse. Circumcision can be viewed as a ritual procedure, but its role as a medical procedure has long been controversial.

The benefits of male circumcision have been debated for years. In the past 20 years, even the American Academy of Pediatrics (AAP) has changed its official position on the medical indications for circumcision. The AAP stated in 1999 and reaffirmed in 2005 that circumcision carried potential benefits, although the procedure was not medically indicated. However, in 2012 the AAP released an updated policy stating that the health benefits of circumcision outweigh the risks of the procedure. This statement was based on a systematic evaluation of peer-reviewed literature that demonstrated preventive health benefits of elective male circumcision, including reductions in the risk of urinary tract infections (UTIs) in the first year after birth, decreased risks of heterosexual acquisition of HIV and other sexually transmitted infections, and a decreased incidence of penile cancer. Additionally, the statement noted that male circumcision does not adversely affect penile sexual function/sensitivity or sexual satisfaction and that complications related to circumcision are infrequent and rarely severe.

Disadvantages of routine circumcision in newborns include expenses associated with the procedure and the risk of complications; however, some analyses have demonstrated that neonatal male circumcision is cost-effective in that it reduces the risk for future disease. The procedure is sometimes criticized as an archaic and maiming ritual. Female circumcision, which may involve clitoridectomy or resection and closure of the labia minora or majora, is infrequently practiced in Western culture and is not discussed in this chapter other than to emphasize that female circumcision has no medical benefit.

Circumcision in newborns has been performed in a routine and preventive manner, much the same way immunizations are administered. Primary care physicians should be aware of the risks and benefits of the procedure to enable them to counsel parents and make referrals to consultants should certain medical conditions arise.

Epidemiology

The prevalence of neonatal circumcision, a procedure that became increasingly popular in the United States in the 1950s and 1960s, once ranged from 69% to 97% depending on cultural mores. In the United States, the procedure is commonly performed during the newborn period, and it is the most common surgical procedure performed in the country. During the past decade, the circumcision prevalence in males aged 14 to 59 years increased from 79% to 81%; specifically, 91% in white males, 76% in black males, and 44% in Hispanic males. The estimated prevalence of circumcision for Australian-born men is 59% (newborn rate estimated 10%–20%); in Canada, 32% of men; and in the United Kingdom, 15% of men. A reported 10% of uncircumcised newborn males ultimately require circumcision as adults because of complications of phimosis and balanitis. Uncircumcised males with diabetes are particularly prone to these complications.

Clinical Presentation

Most often, parents will query their child's pediatrician about the advisability of circumcision, and the newborn will not have any clinical symptoms suggestive of a need for the procedure. Older infants and children in need of circumcision may present with symptoms of phimosis, in which the foreskin balloons out on urination; *paraphimosis*, in which a retracted foreskin cannot be returned to its normal position; or recurrent problems of infection or inflammation of the foreskin (*posthitis*), glans (*balanitis*), or both (*balanoposthitis*).

Pathophysiology

In uncircumcised males, the foreskin adheres to the glans until approximately age 6 years, after which a gradual, normal lysing of the adhesive bands connecting the foreskin to the underportion of the glans occurs. Nonphysiologic phimosis occurs as a result of scarring of the preputial wing. Lysing of adhesions in an attempt to treat the phimosis usually results in additional adhesions. If the foreskin is retracted and remains in that position, paraphimosis occurs.

Differential Diagnosis

The differential diagnosis relates to conditions that may be managed with circumcision, including phimosis, paraphimosis, and infection and inflammation of the penis. Conditions such as hypospadias may be mistaken for a partially circumcised penis, because the condition is associated with absence of the ventral foreskin. A careful patient history will differentiate hypospadias from a circumcision.

Evaluation

History

In cases involving newborns, the history should include the presence of any coagulopathies among family members, which would preclude the performance of circumcision. In older infants and children, the history should include problems related to voiding, such as ballooning of the foreskin or difficulty initiating the urinary stream.

Physical Examination

The physical examination should assess the genitalia, with particular emphasis on determining whether evidence exists of *hypospadias*, in which the urethral orifice is not located at the tip of the glans. In such a situation, circumcision should be delayed because the foreskin is used to reconstruct the urethra. In the patient with phimosis, the degree of phimosis also should be assessed.

Laboratory Tests

Routine laboratory tests are not indicated, although a urinalysis may be obtained in children with a history of a prior UTI. Coagulation studies are appropriate in the case of a family history of a bleeding disorder.

Imaging Studies

Imaging studies are not indicated in most children undergoing circumcision. Such studies are relevant, however, should concern exist that the urogenital anatomy might be abnormal.

Benefits

It has been stated that circumcision facilitates penile hygiene by removing the foreskin, which may serve as a repository for bacteria, smegma, and dirt. Ability to retract the foreskin increases with age (Table 27.1); thus, penile hygiene is easier to achieve in older children. The term *phimosis* refers to inability to retract the foreskin. In male infants beyond the newborn period, phimosis is the major indication for circumcision. Phimosis is normal in children up to approximately 6 years of age but is nonphysiologic if urination results in ballooning of the foreskin, regardless of age. When the retracted foreskin acts as a tourniquet in the mid-shaft of the penis, paraphimosis occurs, preventing the return of lymphatic flow. Paraphimosis is commonly related to traumatic retraction of the foreskin, typically during cleaning or by medical personnel during bladder catheterization. Because of this, parents are no longer advised to retract the foreskin in an effort to lyse adhesions. The incidence of paraphimosis is increasing in adults secondary to body piercing. Newly placed penile rings can cause pain sufficient to prevent foreskin retraction.

Table 27.1. Ability to Retract the Foreskin in Boys, by Age

Age	*Percentage With Retractable Foreskin*
Birth	4
6 months	15
1 year	50
3 years	80
6 years	90

Balanitis, or inflammation of the glans, is not uncommon in infants. It is frequently associated with *Candida* infection, and the glans is swollen and erythematous. Posthitis, or inflammation of the foreskin, is also often secondary to *Candida* infection. Other organisms, including gram-negative microbes, may be associated with balanitis. The presence of recurrent balanitis is an indication for circumcision. In older males, indications for circumcision include phimosis, paraphimosis, balanitis, posthitis, and balanoposthitis.

Urinary tract infections reportedly occur 10 times more often in uncircumcised infants than circumcised infants (1 in 100 and 1 in 1,000, respectively). In young uncircumcised boys, UTIs are directly related to colonization of the foreskin with urotoxic organisms. Pyelonephritogenic, fimbriated *Escherichia coli* bind to the inner lining of the foreskin within the first few days after birth. Other bacteria preferentially bind to this mucosal surface, including fimbriated strains of *Proteus mirabilis* and nonfimbriated *Pseudomonas, Klebsiella,* and *Serratia* species. According to several studies, the rate of UTIs has increased as the rate of circumcision has. A 2012 meta-analysis of 22 studies examining the incidence of UTIs in males found a 23% lifetime risk of UTI in uncircumcised males compared with 8.8% in circumcised males. Thus, the lifetime risk of UTI markedly exceeded the 1.5% circumcision complication rate; most of these complications were minor. Complications associated with UTIs have been reported, in particular, bacteremia, meningitis, and death.

The annual incidence rate of penile cancer is 0.58 per 100,000 men in the United States but is 2.9 to 6.8 per 100,000 men in Brazil. These regional differences are thought to be related to lack

of circumcision of the penis. Only a few isolated cases of cancer of the penis occur in circumcised men. Phimosis is strongly associated with invasive penile cancer, with other cofactors such as human papillomavirus (HPV) infection and poor hygiene possibly contributing. Smoking is consistently associated with penile cancer and is further reason to strongly advocate for smoking cessation programs.

Cervical carcinoma among the partners of uncircumcised men is increasingly being reported. In addition, current partners of circumcised men with a history of multiple sexual partners have a lower risk of cervical cancer than partners of uncircumcised men. Circumcision in adolescent boys and men in Uganda was associated with a marked decreased incidence of HPV and human herpesvirus 2 infection. Circumcision has also been associated with a reduced risk for HIV infections. Three randomized, controlled trials conducted in South Africa, Kenya, and Uganda confirmed the findings of observational studies that circumcision is protective against HIV infection. In addition, circumcision was not associated with increased HIV risk behavior. Based on these findings, in 2007 the World Health Organization stated that male circumcision should be part of a comprehensive strategy for HIV prevention. Since the World Health Organization made this recommendation, nearly 15 million voluntary male circumcision have been performed for HIV prevention in 14 countries of eastern and southern Africa, which is estimated to help prevent more than 500,000 new HIV infections through 2030. It remains critical, however, to promote the practice of safe sex, because circumcision confers only partial protection against HPV, human herpesvirus 2, and HIV.

Risks

Risks related to circumcision are related to complications of the procedure (Box 27.1) and are discussed in the Management section of this chapter. Elective circumcision should be performed only if the newborn is stable and healthy.

Parental Counseling

Parents of Newborns

In the newborn period, proper counseling of parents is important, including a discussion of the risks and benefits of circumcision. Opponents to neonatal circumcision cite psychological trauma to neonates from such a painful procedure. Local anesthesia minimizes this effect. Parents should be informed about the benefits of circumcision, including a reduction in the occurrence of UTIs, sexually transmitted infections, and cancer of the penis and cervix. Problems related to the foreskin itself, such as phimosis, paraphimosis, posthitis, and balanitis, also should be discussed.

It is appropriate to tell parents that boys who are not circumcised in the neonatal period may need to be circumcised later in life. Parents should be informed about the risks associated with circumcision in newborns, which are discussed later in the chapter. In older individuals, risks of circumcision include hemorrhage, infection, and injuries to the penis and urethra. In addition, parents should be informed that approximately 2% of circumcised neonates require a second circumcision because of inadequate foreskin removal during the first procedure.

Research has shown that parents are more influenced by the circumcision status of the father, religion, and ethnicity than by physician attitude concerning their ultimate decision about circumcision. The 2012 AAP policy statement emphasizes that parents should consider health benefits and risks in conjunction with their own religious, cultural, and personal preferences, because the medical benefits alone may not outweigh these other considerations for individual families. Counseling during the second trimester of pregnancy results in no change in parents' decision about circumcision. Parents of newborn boys should be instructed in the care of the penis at the time of discharge from the newborn hospital stay, regardless whether the newborn is circumcised.

Parents of Infants and Older Children

The need for circumcision in male infants who present with UTIs is problematic. Patient evaluation involves an attempt to determine the existence of other conditions that may predispose the patient to a UTI. Investigators disagree on the need for circumcision after an initial UTI in uncircumcised boys. No evidence definitively indicates that circumcision at this time decreases the incidence of future UTIs; thus, the decision whether to circumcise is based on parental preference rather than medical evidence. In children who present with significant phimosis or paraphimosis, circumcision is usually recommended to prevent recurrence of these problems. Medical management, including the use of topical steroids for phimosis, may obviate the need for surgery in some children. Such treatment involves the daily external application of betamethasone cream from the foreskin tip to the corona glandis for 4 to 6 weeks. If the frenulum is tight and tearing, local anesthetic can be applied and the frenulum can be transected. Patient history, including the duration of symptoms and whether the child has had similar episodes in the past, helps in formulating appropriate management.

Management

The medical attitude toward circumcision has changed in the past 40 years, with an initial inclination toward circumcision, followed by a move away from circumcision. The present position on circumcision as described by the AAP Task Force on Circumcision suggests that

Box 27.1. Complications Associated With Circumcision

- Bleeding
- Inclusion cysts
- Infection
- Meatal stenosis
- Meatitis
- Penile cyanosis
- Penile lymphedema
- Penile necrosis
- Phimosis
- Repeat circumcision
- Skin bridges
- Urethrocutaneous fistulae
- Urinary retention
- Wound dehiscence

newborn circumcision has potential medical benefits and advantages as well as disadvantages and risks. When circumcision is considered, benefits and risks should be explained to parents, and informed consent should be obtained. Parents should be advised that third-party payers may deny payment for circumcisions, particularly for routine circumcisions in the newborn period.

Contraindications

Circumcisions should be performed only in completely healthy neonates. Contraindications to circumcision are well defined. Any abnormalities of the penis, such as hypospadias, absence of any portion of the foreskin, or chordee, preclude circumcision. Atypical genitalia and preterm birth are contraindications as well. Circumcision should be delayed in preterm and ill term newborns until they are ready for discharge from the hospital. Patients with a personal or family history of bleeding diathesis should not be circumcised. Newborns from such families should be assessed for evidence of coagulation problems and, if present, circumcision should not be performed.

Circumcision Procedure

Numerous techniques are used to perform circumcisions. These procedures may involve clamp techniques with the Gomco clamp, Mogen clamp, or Plastibell device. Any of these techniques is believed to give comparable results when performed by trained, experienced operators. Formal surgical excision also may be performed, usually in older children and adults. Three guidelines should be followed to reduce the incidence of complications: marking of the coronal sulcus in ink, dilation of the preputial wing, and retraction of the foreskin so that the urethral meatus is visualized to prevent cutting the meatus. Electrocautery should never be used in conjunction with metal clamps because of the danger of extensive injury.

Appropriate anesthesia in newborns undergoing circumcision is the standard of care. The pain and stress of circumcision is evidenced by changes in neonate state and behavior. Non-pharmacologic techniques, such as positioning and sucrose pacifiers, are insufficient to prevent procedural pain but may be used in conjunction with other forms of analgesia. Local anesthesia is the preferred method of pain management. *Dorsal penile nerve block*, which involves the subcutaneous injection of a local anesthetic agent at the base of the penis, is effective in reducing pain responses during circumcision. *Ring block*, which involves subcutaneous circumferential injections of a local anesthetic agent around the mid-shaft of the penis, has also been shown to be effective and avoids the potential complication of injecting local anesthesia toward the dorsal vessels. Topical application of lidocaine and prilocaine cream (eg, EMLA, Lidopril) or oral sucrose solution on a pacifier also reduces pain and associated stress but to a lesser extent than local anesthesia. Studies have shown that blocks seem to be more effective than topical cream or oral sucrose, and the ring block is better than the dorsal penile nerve block. Infants who receive block anesthesia cry less and have less tachycardia and irritability in addition to fewer behavior changes during the 24 hours after the procedure. For older, prepubertal children who require formal surgical excision, sutureless circumcision using tissue glues has been associated with reduced surgical time and improved cosmetic outcome.

Post-Procedure Care

Oral acetaminophen can be administered for apparent pain or irritability. Analgesia is rarely needed after 24 hours. The parent or caregiver should be advised to watch for and report any bleeding or signs of infection. Mild redness and a yellowish crust may persist for 1 week. To keep the glans from sticking to the diaper, the parent or caregiver should apply a smear of petrolatum to the front of the diaper for 1 week.

Complications

Several complications are associated with circumcision in newborns (Box 27.1). The most common complication is bleeding, which may occur in 0.2% to 8% of patients. Typically, bleeding can be controlled using local pressure. More significant bleeding may require local pressure with 1:1,000 adrenaline-soaked gauze or with the use of other topical agents (eg, Surgicel, QuikClot). The second most common complication is infection, which is reported in up to 8% of circumcised newborns. The Plastibell device is associated with a higher incidence of infection than the Gomco clamp. Local treatment is sufficient to manage most infections, although intravenous antibiotics should be considered because neonatal sepsis and necrotizing fasciitis may occur secondary to infection following circumcision.

Poor cosmetic outcome is another complication of circumcision. Phimosis may occur if removal of the foreskin is insufficient. Inadequate freeing of the foreskin from the inner preputial epithelium may result in a concealed penis, with the shaft retracted backward into the abdominal wall. Skin bridges may form between the glans and shaft, resulting in the accumulation of smegma or tethering of the erect penis. Most post-circumcision adhesions are reported to resolve at the time of puberty with the onset of masturbation or sexual activity.

In the immediate postoperative period, urinary retention may occur secondary to tight surgical bandages. This complication can be prevented by applying local pressure rather than tight bandages to obtain hemostasis. Meatitis and meatal ulcers, which may be the result of irritation from ammonia or damage to the frenulum artery at the time of circumcision, have been reported in circumcised males. Inclusion cysts that represent implantation of smegma also have been reported. Additional injuries following circumcision may include penile lymphedema, urethrocutaneous fistulae secondary to misplaced sutures, penile cyanosis, and necrosis secondary to a tight Plastibell device. Wound dehiscence, which involves separation of the penile skin from the mucous membrane and denudation of the penile shaft, may occur more frequently with the Gomco clamp than the Plastibell device.

Meatal stenosis appears as a pinhole urethra with an angulated or narrow urinary stream and may be associated with enuresis or incontinence. Meatal stenosis is very rare in uncircumcised males; it is not clear whether circumcision is the direct cause of this rare, possibly late complication. A chronic inflammatory process resulting from inadequate post-procedure care, the use of superabsorbent

disposable diapers, urinary ammonia, or diaper dermatitis may contribute to the development of meatal stenosis.

Prognosis

The prognosis after circumcision is excellent, and complications are exceedingly rare.

CASE RESOLUTION

The risks and benefits of circumcision should be discussed with the mother. The father should be encouraged to participate in the decision making process. If the parents elect to forgo circumcision for their son, they should be instructed on the appropriate care of the uncircumcised penis, which involves gentle external washing without retraction of the foreskin.

CHAPTER 28

Nutritional Needs

Sara T. Stewart, MD, MPH, FAAP

CASE STUDY

At a routine health maintenance visit, a mother asks if she may begin giving her 4-month-old daughter solid foods. The infant is taking about 4 to 5 oz of formula every 3 to 4 hours during the day (about 32 oz per day) and sleeps from midnight to 5:00 am without awaking for a feeding. Her birth weight was 3.2 kg (7 lb), and her present weight and length (5.9 kg [13 lb] and 63.5 cm [25 in], respectively) are at the 50th percentile for age. The physical examination, including developmental assessment, is within reference limits.

Questions

1. What are some of the parameters that may be used to decide when infants are ready to begin taking solid foods?
2. Up to what age is human milk or infant formula alone considered adequate intake for infants?
3. At what age do infants double their birth weight? At what age do they triple their birth weight?
4. What allergy risks are associated with the early introduction of solid foods?

Good nutrition is essential for typical growth and development. The physician plays an important role not only in assessing the growth of children but also in counseling parents about the nutritional needs of maturing children. The primary care physician should be knowledgeable about key nutritional concepts for children, including typical growth patterns and assessment of the child's nutritional status, changing nutritional requirements and feeding patterns from infancy through adolescence, and common feeding and nutritional disorders.

Growth Patterns and Nutritional Requirements of Typical Children

Monitoring the growth and nutritional status of infants and children is an integral component of well-child care. The average expected increases in weight, height, and head circumference for the first several years after birth are listed in Table 28.1.

The energy and nutritional requirements of children vary with age. Postnatal growth is most rapid during the first 6 to 12 months after birth; hence, caloric and protein needs are very high at this time. The average daily energy and protein needs of children from birth to 18 years of age are presented in Table 28.2.

On average, newborns weigh 3.5 kg (7.7 lb), are about 50 cm (20 in) long, and have a head circumference of 35 cm (14 in). They lose about 5% to 10% of their birth weight during the first several postnatal days and usually regain this weight by the age of 10 to 14 days. During the first several months after birth, weight gain serves as an important indicator of infants' general well-being. Failure to gain weight during this time may be a clue to a wide variety of problems, ranging from underfeeding to malabsorption. Newborns and infants gain about 30 g/day (1.1 oz/day; roughly 1% of their birth weight per day) for the first 3 postnatal months and about 10 to 20 g/day (0.4–0.7 oz/day) for the rest of the first year. Infants double their birth weight by 6 months of age and triple their birth weight by 12 months of age. Children aged 2 years to puberty gain approximately 5 to 10 g/day (0.2–0.4 oz/day). On average, children weigh about 10 kg (22 lb) at 1 year of age, 20 kg (44 lb) at 5 years of age, and 30 kg (66 lb) at 10 years of age. A rough rule that can be used to estimate the expected weight of a child based on age is 2 × age (years) + 10 = weight (kg). A prepubertal child who does not gain at least 1 kg/year should be monitored for nutritional deficits.

Infants and young children grow about 25 cm (9.8 in) during the first postnatal year, 12.5 cm (4.9 in) during the second year, and 6.25 cm (2.5 in) per year after that until puberty. This is followed by the prepubertal-pubertal growth spurt. Girls grow 3 to 4 cm (1.2–1.6 in) every 6 months and boys grow 5 to 6 cm (2.0–2.4 in) every 6 months during this period.

Feeding Patterns of Infants and Children

Liquid Foods

Human milk is generally recommended as the exclusive nutrient for newborns and infants during the first 6 months after birth and then could be continued along with complementary foods through 12 months of age. However, there are situations in which breastfeeding is not possible for the mother or is contraindicated because of a disease or medication. Therefore, although breastfeeding is the most advantageous for mother and baby and should be encouraged, mothers should never be made to feel inadequate or guilty if they are unable to breastfeed. Human milk or an iron-fortified infant formula provides complete nutrition for infants during the first 4 to 6 months after birth. During the first postnatal month or 2, newborns and infants take about 2 to 3 oz of formula (approximately 10 minutes on each breast) every 2 to 3 hours.

Table 28.1. Expected Increase in Weight, Height, and Head Circumference of Newborns, Infants, and Children

Typical Weight Gain	
Age	*Expected Weight Increase*
0–3 months	25–35 g/day (0.9–1.2 oz/day)
3–6 months	12–21 g/day (0.4–0.7 oz/day)
6–12 months	10–13 g/day (0.4–0.5 oz/day)
1–6 years	5–8 g/day (0.2–0.3 oz/day)
7–10 years	5–11 g/day (0.2–0.4 oz/day)
Typical Height Increase	
Age	*Expected Height Increase*
0–12 months	25 cm/year (9.8 in/year)
13–24 months	12.5 cm/year (4.9 in/year)
2 years–puberty	6.25 cm/year (2.5 in/year)
Typical Increase in Head Circumference	
Age	*Expected Increase in Head Circumference*
0–3 months	2 cm/month (0.8 in/month)
4–6 months	1 cm/month (0.4 in/month)
7–12 months	0.5 cm/month (0.2 in/month)
Total increase	12 cm year (4.7 in) in first year

Table 28. 2. Energy and Protein Needs of Children

Age (years)	*Calories (kcal/kg/day)*	*Protein (g/kg/day)*
0–1	90–120	2.5–3.0
1–7	75–90	1.5–2.5
7–12	60–75	1.5–2.5
12–18	30–60	1.0–1.5

Because human milk is more easily digested than formula, it passes out of the stomach in 90 minutes; formula may take up to 4 hours. Therefore, during the first 4 to 6 postnatal weeks, breastfed newborns and infants want to feed more frequently (8–12 times in 24 hours) than formula-fed newborns and infants (6–8 times in 24 hours), with an increased number of nighttime feedings as well. By about 3 to 5 months of age, breastfed and bottle-fed infants do not differ in the number of nighttime feedings, although some breastfed infants continue to wake out of habit.

Most infants 6 months or younger consume about 4 to 5 oz per feeding every 4 to 5 hours. Under routine circumstances, human milk is preferred to infant formulas because it has emotional, nutritional, and immunologic advantages. Breastfeeding allows infants and mothers to develop a unique relationship that can be emotionally satisfying (see Chapter 29).

The composition of human milk varies over time. Colostrum, the first milk produced after delivery, is high in protein, immunoglobulin (Ig), and secretory IgA. Colostrum gradually changes to mature milk 7 to 10 days after delivery. The nutrient content of human milk of mothers who deliver preterm compared with those who deliver at term may vary considerably. Individual assessment may be necessary to determine the appropriateness of human milk for preterm newborns.

Nutritionally, human milk is uniquely tailored to meet the specific needs of babies. Human milk provides approximately 20 kcal/oz, the same as routine infant formulas. Table 28.3 compares the composition of human milk and several infant formulas. Human milk has relatively low amounts of protein compared with cow's milk (1% vs 3%), yet the levels are sufficient to provide for satisfactory growth of babies. Protein content is highest at birth at 2.3 g/dL, then declines over the first month to 1.8 g/dL, yet it ensures adequate protein status throughout the first postnatal year.

Qualitative differences also make human milk more desirable. Casein to whey ratio in human milk is about 30:70, making it easier to digest than most infant formulas, which tend to have higher casein to whey ratios at 82:18. Whey is more easily digested and associated with faster gastric emptying compared with casein. Newborns and infants who breastfeed tend to digest their milk more easily, have softer stools, and be less satiated overnight, requiring more feeds, than those fed formula. Other whey proteins, such as IgA, lysozyme, and lactoferrin, all contribute and help host defenses.

Lactose is the major carbohydrate of human and cow's milk, but it is present in higher concentrations in human milk. Lactose in human milk also contributes to softer stool consistency with nonpathological fecal flora and improved absorption of minerals. Oligosaccharides in human milk found in the carbohydrate polymers and glycoproteins have been structurally shown to mimic bacterial antigen receptors and may have a role in host defense. Fat is the primary source (50%) of calories in human milk. The fat in cow's milk, which contains primarily saturated fatty acids, is not as well digested by newborns and infants as human milk fat, which is predominantly composed of polyunsaturated fats. Within the last decade, the long-chain polyunsaturated fatty acids docosahexaenoic acid (DHA) and arachidonic acid (ARA) have been added to most infant formulas to simulate the higher levels found in human milk. Research continues to be inconclusive, however, as to whether DHA and ARA supplementation may enhance vision and improve growth and cognitive development in formula-fed infants.

Human milk from well-nourished women should provide adequate amounts of all vitamins and other micronutrients. However, vitamin K, vitamin D, iron, and fluoride are not present in sufficient quantities to satisfy all nutritional needs over a prolonged period, and supplementation should be considered. The American Academy of Pediatrics (AAP) recommends that all newborns receive a prophylactic dose of 0.5 to 1 mg of parenteral vitamin K in the immediate newborn period to help prevent bleeding disorders. Even though the vitamin D content of human milk is low compared with cow's milk, newborns and infants of healthy mothers have generally not been observed to develop rickets if

Table 28.3. Composition of Human Milk and Select Infant Formulas (Calories: 20 kcal/oz)

Formula	*Protein*	*Carbohydrate*	*Fat*
Human milk (mature)	40% casein and 60% whey	Lactose	Human milk fat
Cow's milk	80% casein and 20% whey	Lactose	Butterfat
Enfamil NeuroPro	Nonfat cow's milk and whey	Lactose	Palm olein, soy, coconut, and high-oleic sunflower oils; DHA, milk fat globule membrane
Similac Advance	Nonfat cow's milk and whey	Lactose	High-oleic safflower oil, coconut and soy oils, DHA
Enfamil ProSobee	Soy protein and methionine	Corn syrup solids	Palm olein, soy, coconut, and high-oleic sunflower oils
Similac Soy Isomil	Soy protein and methionine	Corn syrup solids and sucrose	High-oleic safflower oil, soy and coconut oils; DHA
Nutramigen with DHA & ARA	Casein hydrolysate, cystine, tyrosine, tryptophan	Corn syrup solids and cornstarch	Palm olein, soy, coconut, and high-oleic sunflower oils; DHA, ARA
Pregestimil with DHA & ARA	Casein hydrolysate, cystine, tyrosine, tryptophan	Corn syrup solids, modified cornstarch, and dextrose	MCT, high-oleic safflower, corn and high oleic vegetable oils, DHA, ARA
Similac Expert Care Alimentum	Casein hydrolysate, cystine, tyrosine, tryptophan	Sucrose modified tapioca starch	Safflower oil, MCT, soy oil, DHA, ARA

Abbreviations: ARA, arachidonic acid; DHA, docosahexaenoic acid; MCT, medium-chain triglycerides.

there is sufficient exposure to sunlight. Newborns require about 1 minute of exposure to sunlight on the face to produce enough vitamin D. However, adequate sun exposure is difficult to assess, and there are increasing concerns about the harmful effects of sunlight. Compared with the previous recommendation of an average intake of 200 IU of vitamin D per day, the 2010 Institute of Medicine, now known as the Health and Medicine Division of the National Academies, recommendation calls for an average intake of 400 IU of vitamin D per day to meet the needs of most infants younger than 12 months. Although human milk contains less iron than iron-fortified formulas (fortified to about 12 mg/L of iron), the bioavailability of the iron in human milk is greater. Breastfed infants do not need iron supplementation until 6 months of age. For children 6 months and older who live in communities with suboptimally fluoridated water, the AAP recommends systemic (dietary) supplementation. Such supplementation can be provided through the use of a fluoridated toothpaste twice a day (see Chapter 31).

Human milk has several immunologic advantages, which are allergy and infection protective, over standard cow's milk–based formulas. Its allergy-protective characteristics are attributed, in part, to the decreased intestinal permeability associated with human milk compared with standard formulas. The host defense factors present in human milk include Ig, complement, and cellular components (eg, macrophages, neutrophils, lymphocytes). Studies have shown that the incidences of viral and bacterial illnesses are lower in exclusively breastfed infants compared with their formula-fed peers.

The AAP recommends exclusive breastfeeding for about 6 months, followed by continued breastfeeding as complementary foods are introduced, with continuation of breastfeeding for 1 year or longer as mutually desired by mother and infant. Rarely, breastfeeding is contraindicated (see Chapter 29).

Solid Foods

Supplemental foods may be added to infants' diets between the ages of 4 and 6 months. Solid foods should be introduced as soon as infants require the additional calories and are developmentally mature (ie, infant can sit and support his or her head and has lost tongue thrust). Introduction of solid foods prior to 4 months of age can interfere with an infant's ability to take sufficient amounts of human milk or formula to meet nutritional needs. Waiting beyond 6 months of age to introduce solid foods may increase an infant's risk of having inadequate iron or zinc intake.

Infants should first be given cereal grains, fruits, and vegetables, although 2 to 3 days should separate the introduction of new foods. Once several of these foods have been tolerated, the early introduction of subsequent, more allergenic, foods, such as milk, eggs, soy, wheat, nuts, and seafood, between 4 and 6 months of age may decrease the risk of the infant developing food allergies. Factors that indicate infants may be ready for solid foods include current weight twice that of birth weight, or about 6 to 7 kg (13.2–15.4 lb); consumption of more than 32 oz of formula per day (if on a formula-only diet); frequent feeding (regularly more than 8–10 times per day or more often than every 3 hours); and perceived persistent hunger after nursing.

Iron-fortified infant cereal, most commonly rice cereal because it does not contain gluten, is usually the first solid food offered to infants. Other single-grain cereals, such as barley cereal or oatmeal, are also appropriate early supplemental foods. Precooked infant cereals can be mixed with a variety of liquids, including human milk, formula, water, or infant fruit juices. The vitamin C in juice increases the bioavailability of the iron in the cereal, hence the

recommendation to add it to dry cereal. Initially, the cereal should be mixed to a thinner consistency (eg, about 1 tablespoon of cereal to 2 oz of liquid). It is not unusual for infants to reject their first several spoonfuls of cereal because the tastes and textures are new. If they refuse the feeding, it should be stopped and reintroduction of the food delayed for 1 week. Once infants have accepted the new taste and texture, the mixture should gradually be worked to a thicker consistency. By about 7 to 8 months of age, infants should be taking 4 to 6 tablespoons of cereal mixed with enough liquid to give the mixture the consistency of mustard. Mixed cereal grains may be given to older infants.

Fruits and vegetables may be introduced within a few weeks of the introduction of cereal. The order is not as important as the need to add only 1 new food at a time and no more than 1 to 2 new foods per week. Meats may be introduced after 6 months of age.

A wide variety of commercially prepared baby foods designed to be developmentally appropriate and labeled by stage (ie, first, second, third) are available. The jars of different stages contain the amount of food that an infant at a given age should be able to eat at 1 sitting. This is not always the case, however, and opened jars of baby food may safely be stored in the refrigerator for 2 to 3 days. Infants should not be fed directly from the jar because saliva on the spoon mixes with the remaining food and digests it, causing it to liquefy. Vegetables and meats may be offered at room temperature but should be warmed slightly for greater palatability. Fruits and desserts may be at room or refrigerator temperature. Home-cooked fruits and vegetables should be thoroughly washed, pureed, and strained before giving to infants. Home-prepared foods tend to have a shorter shelf life than commercially bought baby foods because of lack of preservatives, but some may find that they are more palatable to the infant.

First-stage foods, for infants 4 to 6 months of age, include strained infant juices, single-grain cereals, and pureed strained fruits and vegetables such as bananas, carrots, and peas. These foods contain no egg, milk, wheat, or citrus, to which some infants may be sensitive. Second-stage foods, for infants about 6 to 9 months of age, are smooth, mixed-ingredient foods, such as mixed vegetables, or meat dinners, such as chicken noodle. Third-stage foods, or junior foods, are for infants about 9 to 10 months of age who can sit well without support, have some teeth, and have begun self-feeding. These more coarsely textured foods, such as vegetable and meat dinner combinations, contain a wider variety of nutrients. Finger foods, such as crackers, cheese wedges, or cookies, can also be introduced by 9 to 10 months of age, once infants have developed a pincer grasp. Most infants are eating the same meals as the rest of the family (table foods) by about 1 year of age. Foods that can easily be aspirated, such as raw carrots, nuts, and hard candies, should be avoided until children are older than 4 years.

Baby foods can be prepared at home as long as they are finely pureed or strained and contain enough liquid to make them easy for infants to swallow. One danger of preparing foods at home is that sugar, salt, or spices can be easily added to make foods palatable to adults. These ingredients are not necessary for infants. In addition, homegrown, home-prepared vegetables may be contaminated with high levels of nitrates (eg, because of contaminated well water) and nitrites (eg, in vegetables such as carrots, beets, and spinach). Nitrates and nitrites have been implicated in the development of methemoglobinemia, especially in infants younger than 6 months. Methemoglobinemia decreases the oxygen-carrying capacity of the blood, leading to anoxic injury and death. This is more of a concern in rural areas that primarily use well water.

Weaning from the breast or bottle to a cup usually occurs by 12 months of age but may be delayed up to 18 months of age in some children. Homogenized, vitamin D–fortified cow's milk may be given at 12 months of age. Fat-free (skim) and low-fat (1%) milk should not be given before 2 years of age.

Diet of Children and Adolescents

The caloric and protein needs of children decrease in the second year after birth, paralleling the decrease in growth rate during this time. Milk intake also decreases and may drop to 16 oz/day by 24 to 36 months of age. Except for increased caloric requirements, the diet of school-age children and adolescents should be similar to that of normal adults. Evidence that foods eaten during childhood may have long-lasting effects on adult health is increasing, and it is important that children develop healthy eating habits early in life. Atherosclerosis, osteoporosis, and obesity are some of the diseases that may have their beginnings during childhood.

The US departments of Agriculture (USDA) and Health and Human Services (HHS) have replaced the food pyramid with a new visual aid—a circular plate on a square mat. Half of the plate consists entirely of vegetables and fruits, whereas the other half of the plate is divided into one-quarter protein and one-quarter grains, with a small side of dairy. It's a much more visually descriptive tool that guides how to divide daily meals. The website www.choosemyplate.gov provides individual dietary guidance according to a child's age, sex, and activity level based on the USDA/HHS dietary guideline for Americans older than 2 years.

To promote lifelong heart healthy habits, the American Heart Association (AHA) released a statement of dietary recommendations for children and adolescents (Box 28.1). It recognizes that children are often offered nutrient-poor foods that are high in fat and sugar and overly processed. The AHA recommendations support USDA

Box 28.1. AHA Dietary Recommendations for Children and Adolescents

- Limit total fats to less than 25% to 35% of total daily calories.
- Limit saturated fat to less than 7% of total daily calories.
- Limit trans fat to less than 1% of daily calories.
- Remaining fat should come from natural sources of monounsaturated and polyunsaturated fats, such as unsalted nuts and seeds, fish (especially oily fish, such as salmon, trout, and herring, at least 2 times a week), and vegetable oils, such as canola oil.
- Limit cholesterol intake to less than 300 mg a day or, if you have coronary artery disease, less than 200 mg a day.

guidelines and include eating fruits and vegetables daily while limiting fruit juice intake, using vegetable oils, using butter instead of soft margarines, eating whole grain rather than refined grain breads and cereals, using nonfat or low-fat milk and dairy products, eating more fish, and reducing salt intake.

The AHA also encourages behaviors for parents and caregivers that promote healthy habits for the whole family. These recommendations ask parents and caregivers to choose mealtimes, provide a social context for eating by having regular family meals, lead by example in their own eating habits, and allow children to self-regulate food intake and not to force them to finish meals if they are not hungry.

Children who consume a varied diet do not need routine vitamin supplementation. However, children and teenagers who are considered picky eaters, as well as children at nutritional risk, may benefit from supplementation. This includes children and teenagers who are anorexic or those who follow fad diets, those with chronic diseases, those who consume a vegetarian diet, and those with failure to thrive (FTT). A standard pediatric vitamin-mineral supplement should contain no more than the dietary reference intakes of its components. Parents should be counseled to teach their children that supplements are not candy and to keep them out of reach. Serious overdoses can occur, especially with iron-containing formulations.

Bone health is determined by calcium and vitamin D intake as well as weight-bearing physical activity. Recent data suggest the possibility of other important health benefits throughout life of these key nutrients and behavior, in addition to bone growth and development. The 2010 Institute of Medicine guidelines call for a recommended daily allowance of 600 IU per day of vitamin D for children older than 1 year and 1,300 mg of calcium per day for children and adolescents 9 to 18 years of age. Unfortunately, calcium intake for most US children, particularly adolescents, is generally below the recommended levels. Barriers to adequate calcium intake may be due to the preference of sweetened juice and soft drinks over milk as well as lactose intolerance in certain populations. Nondairy calcium sources include salmon, white beans, broccoli, and calcium-fortified foods, such as orange juice, breakfast cereals, and soy milk. Adequate calcium intake can be achieved by eating 3 (or 4 for adolescents) age-appropriate servings of dairy products or other calcium-rich food per day. In children and adolescents who do not consume adequate amounts of calcium from dietary sources, a calcium supplement is recommended. This can be in the form of a multivitamin in the younger child or calcium carbonate tablets with or without vitamin D for the adolescent.

Adolescence is a period of tremendous physical and emotional growth, both of which greatly affect nutritional needs and habits. Although their rapid physical growth requires increased energy and nutrients, the common eating habits of teenagers do not always support their needs. Teenagers tend to skip meals, eat outside the home, consume fast food and snacks, and experiment with different restrictive fad diets or various forms of vegetarianism.

Teenage athletes also have their own unique nutritional concerns. They want to maximize performance while maintaining the desired physique for their particular sport or weight class. While there are many nutritional supplements, such as creatinine, carnitine, various amino acids, and dehydroepiandrosterone, that claim to enhance athletic performance, none has thus far been fully evaluated scientifically. Instead, teenage athletes should be counseled on the importance of a basic nutrient: water. Proper hydration does enhance performance and prevents heat injury. Approximately 4 to 8 oz of fluid for every 15 minutes of exercise is recommended regardless of actual thirst. Carbohydrate loading before competition is believed to enhance performance; however, this practice has no effects on non-endurance events and may confer only a modest effect for endurance events by prolonging time to exhaustion. In counseling a teenage athlete, specific questions should also be directed to elicit any unhealthy practices to maintain or lose weight.

Vegetarianism is gaining popularity among adolescents. Reasons for choosing vegetarianism are varied, including health benefits, means for weight loss, animal cruelty concerns, and religious beliefs. It is important to ask vegetarians about their specific restrictions, as these relate to their nutritional risks. Semi-vegetarians are those who avoid red meat but eat fish and chicken in moderation. Lacto-ovo vegetarians consume animal products, such as dairy and eggs, but avoid animal flesh. Vegans do not eat any animal products, such as dairy, eggs, honey, or gelatin. Those who follow a macrobiotic diet restrict not only animal products but also refined and processed foods, foods with preservatives, and foods that contain caffeine or other stimulants.

A well-planned vegetarian diet can provide all necessary nutrients; however, many teenagers experiment with vegetarianism in a non-vegetarian household and require guidance. The nutrients that may be deficient in a vegetarian diet are protein, calcium, vitamin D, vitamin B_{12}, iron, and zinc. Protein intake is usually not a concern for lacto-ovo vegetarians because eggs and dairy have high-quality proteins. Vegans and macrobiotic followers have a variety of plant-based protein sources from which to choose, such as legumes, cereals, nuts, seeds, and fruits. Because vitamin B_{12} is only found in animal-based foods, vegans and macrobiotic followers must ensure adequate intake via supplements or by consuming vitamin B_{12}-fortified foods, such as soy and nut beverages and cereals.

Lastly, familiarity with the latest fad diets is an asset for any primary care practitioner. These diets are usually restrictive in certain nutrients and recommend unusual dietary patterns that are inconsistent with current USDA guidelines. Although there are some suggestions that these diets work for some adults, there are almost no scientific data for children and adolescents. To keep abreast of the latest fads, refer to the Academy of Nutrition and Dietetics (www.eatright.org), which maintains an annual review of such popular fad diets.

Evaluation

History

Nutritional assessment begins with a complete dietary history. The dietary assessment should emphasize the quantity, quality, and variety of foods in the diet. Any special or restricted dietary habits

should be noted (eg, vegetarian diet, vegan diet, occasional vegetable juicing/fasting). A 3-day food record listing the types and quantities of food eaten throughout the day can be very helpful in evaluating dietary history.

In addition, the child's routine medical, family, and social history all may influence nutritional status. For example, the economic status of families may affect the variety and type of foods they may be able to purchase, and the level of education of parents influences their ability to understand the concepts of a healthy diet. Poverty and ignorance of nutritional needs are among the most common reasons for malnutrition in children. It is vital that the pediatrician stress to families the value of healthy food choices at each physical examination. Family access to food can be estimated by asking parents about how often the family skips meals during the average month. Such information assesses food insecurity within a household. Specific cultural food preferences and feeding practices should also be included in the history.

Physical Examination

Weight, length or height, head circumference, weight for length, and body mass index should be measured or calculated routinely and plotted on a longitudinal basis on appropriate growth curves. In addition to the charts provided by the Centers for Disease Control and Prevention and World Health Organization, additional charts are available for special populations for which growth is altered, such as infants and children with low birth weight and preterm birth, Down syndrome, Turner syndrome, Williams syndrome, and several other chromosomal and genetic disorders. Changes in the rate of growth over time are more useful than a single measurement in the assessment of nutritional problems. Calculation of the height age (age for which the child's height is at the 50th percentile), weight age (age for which the child's weight is at the 50th percentile), and ideal weight for actual height may be useful when deviations from reference are noted.

In addition to the overall impression of nutritional status, certain findings on physical examination may be characteristic of particular nutritional disorders. The evaluation of the hair, skin, eyes, lips and oral mucosa, dentition, and musculoskeletal system should be emphasized because the examination of these areas is most likely to show the effects of malnutrition. Muscle wasting; hepatosplenomegaly; skeletal deformities; decayed teeth; rough, dry skin; hair that is easily plucked; and irritability may all be signs of inadequate nutrition.

Laboratory Tests

Suspected malnutrition or nutrition-related disorders, based on history and physical examination, can be further investigated with laboratory studies. Tests that may be used in the evaluation of anemia, 1 of the most common nutrition-related disorders seen in children, include a complete blood cell count, reticulocyte count, serum iron, ferritin, and total iron-binding capacity. Investigation of suspected malnutrition begins with an assessment of protein status, with measures of indicators such as serum albumin, total protein, and transthyretin. Liver function tests and a lipid profile may also be useful in the evaluation of suspected malnutrition. Screening tests that may be used in the evaluation of FTT include thyroid function studies, urinalysis, and bone age (see Chapter 146). More specific tests, such as serum vitamin levels (eg, folate or vitamin B_{12} levels in suspected malabsorption) or hormone assays (eg, growth hormone levels in the evaluation of short stature), may be obtained in certain instances.

Common Feeding and Nutritional Problems of Childhood

Several gastrointestinal (GI) problems have been attributed to diet. A small amount of spitting up is seen in most children, especially during the first 6 months after birth. However, vomiting can be a sign of several disorders, ranging from viral GI tract infections to more severe illnesses, such as pyloric stenosis, urinary tract infection, GI obstruction, or inborn error of metabolism (see Chapter 120). Constipation, which is seen more commonly in formula-fed than breastfed infants, may be due to insufficient fluid intake (see Chapter 124). The simple addition of 2 to 4 oz of water to an infant's diet or temporary use of diluted apple or prune juice may solve the problem.

Chronic nonspecific diarrhea of childhood, or "toddler's diarrhea," may be seen in infants and children 6 months to 5 years of age with low dietary fat intake and excessive fruit juice consumption (see Chapter 123). Failure to absorb sugars, especially sorbitol and fructose, can lead to an osmotic diarrhea.

Underfeeding or a diet that is not nutritionally balanced may result in FTT (see Chapter 146). The opposite problem, obesity, is among the most common nutritional problems of children in the United States (see Chapter 155). The prevalence of this condition in children 6 to 11 years of age is estimated to be about 20% to 25%. Finally, the eating disorders anorexia nervosa and bulimia nervosa are estimated to affect about 1 in 100 adolescent females 16 to 18 years of age (see Chapter 64).

The picky eater is a common parental concern in the primary care setting. For practitioners who work with the Latinx population, the child who "no come nada," literally translated as the child who "does not eat anything," is a similar common parental concern. Parents can be reassured by their child's normal weight for height or body mass index and growth velocity. They should be counseled that it is normal for preschoolers to exert their individuality by limiting food preferences, the fact that it may take up to 10 exposures for a child to accept a new food, the difference between child and adult portion sizes, and the concept that children can self-regulate food intake to sustain normal growth and health.

Nutritional disorders include malnutrition and deficiencies of vitamins and minerals. Iron deficiency anemia is 1 of the most common nutrition-related problems seen in children and adolescents. Malnutrition is among the leading causes of childhood morbidity and mortality worldwide. Although primary protein-calorie malnutrition (PCM) is rare in most parts of the United States, surveys conducted on pediatric wards have demonstrated that about one-third of pediatric inpatients with chronic disease have evidence of

some degree of PCM. The most common deficits were weight for height below 90% of standard (ie, evidence of acute malnutrition) and height for age below 95% of standard (ie, evidence of chronic malnutrition). The 2 forms of PCM are marasmus (severe caloric depletion) and kwashiorkor (inadequate protein intake). Untreated PCM can result in impaired growth, poor intellectual development, and impaired immune functioning.

CASE RESOLUTION

The infant is ready to begin some solid foods because she is consuming 32 oz of formula per day and continues to be hungry. In addition, she has reached a weight of 5.9 kg (13 lb) and has almost doubled her birth weight. The mother is counseled to begin feeding her daughter a single-grain infant cereal mixed with formula. (The cereal should be fed by spoon, not given in a bottle.) Within a few weeks, once the infant is taking the cereal well, other first foods, such as fruits and vegetables, may be introduced. After she tolerates cereal and several fruits and vegetables, more allergenic foods, such as egg or diluted nut butters, should be introduced in small amounts to reduce the risk that she will develop a subsequent food allergy.

CHAPTER 29

Breastfeeding

Karen C. Bodnar, MD, IBCLC, FABM, FAAP

CASE STUDY

A 25-year-old pregnant woman comes to your office with her 18-month-old for a well visit. When asked, she reports that she had a difficult time breastfeeding her first child because of pain; however, she gave pumped milk for 4 months. She hopes to breastfeed directly for at least 6 months with this baby. She would like to know what advice you can give her. She expects a normal delivery, has had no breast surgery, and is not on any medications; however, she smokes cigarettes occasionally. She plans to return to work when the baby is 4 months old.

Questions

1. What is the normal physiology of lactation?
2. What are the benefits of breastfeeding?
3. What are the contraindications to breastfeeding?
4. What management maximizes a mother's success at breastfeeding?
5. How does the pediatrician manage some of the common problems that may arise during breastfeeding?

Human milk is the natural food source for human newborns and infants. It provides optimal nutrition and is an immunologically active compound that allows for early regulation of an infant's immune system and priming of the microbiome. All formulas are incomplete attempts at replication. Human milk is made of water, fat, lactose-containing carbohydrates, and protein, as well as vitamins, immunoglobulins, prebiotics, enzymes, hormones, and even phagocytes and lymphocytes. It is a dynamic fluid that changes in composition as newborns and infants grow. Early colostrum is high in lactose and protein, composed of casein and whey, and quite immunologically active. Through lactogenesis, it becomes mature milk with much greater quantity and higher fat content. It thus has a lower concentration of protein but continues to contain all the immunologically active components of colostrum.

Epidemiology

Historically, newborns and infants were totally dependent on breastfeeding by their mother or a wet nurse for their survival. When formula feeding was attempted in the 1800s, the mortality rate in exposed newborns and infants was as high as 85%. Thus, the advantages of breastfeeding were recognized and still promoted in the early 1900s. Following the advent of pasteurization, cow's milk formula became much safer than before pasteurization. Formula development allowed more mothers to enter the workforce, and breastfeeding rates declined over the course of the 20th century. Formula feeding became the norm as companies successfully marketed formulas. In 1972, at the nadir of breastfeeding, only 22% of babies were ever breastfed. However, current scientific understanding of the many benefits of breastfeeding for baby and mother has been the impetus to again promote breastfeeding as the preferred food source for newborns and infants.

In the United States today, following the Centers for Disease Control and Prevention Healthy People initiative, which included a national agenda calling for an increased rate of breastfeeding, 83.2% of mothers are initiating breastfeeding. The rate of mothers sustaining breastfeeding to 1 year of age is only 35.9%, however. Rates are lower in low socioeconomic groups and among women with lower levels of education. Ethnic disparities also exist, with the black population having the lowest rates of breastfeeding in the United States.

In 1991, the World Health Organization and the United Nations Children's Fund developed the Baby-Friendly Hospital Initiative, delineating 10 steps to undertake in the hospital to promote successful breastfeeding. This initiative is used worldwide to improve breastfeeding rates. The American Academy of Pediatrics published its policy statement, "Breastfeeding and the Use of Human Milk," in 2005 and a revised version in 2012. This policy endorses breastfeeding and delineates the physician responsibility to promote and support it. In 2011, the US Department of Health and Human Services issued *The Surgeon General's Call to Action to Support Breastfeeding.* A national imperative now exists to promote breastfeeding.

Anatomy and Physiology of Lactation

The breasts consist of lobules and alveoli where milk is produced, as well as the ductile system, leading to 9 to 15 milk duct openings in the nipple. During pregnancy, the breasts enlarge as lobules mature and differentiate in response to estrogen, placental lactogen, prolactin, and progesterone. The nipples darken, and the surrounding areolas enlarge. In the first 24 hours after delivery, only a small

volume of colostrum, approximately 40 to 50 mL total, is produced. By 3 to 4 days after delivery, however, increased milk production, termed *lactogenesis stage 2,* commences. This occurs as estrogen and progesterone levels drop and prolactin, from the anterior pituitary, is increased in response to nipple stimulation. Additionally, oxytocin is released from the posterior pituitary and causes contraction of myoepithelial cells, which squeeze milk from the alveoli. Although initial production of milk is not dependent on newborn suckling, the more the neonate feeds and the more often the breast is effectively emptied, the more milk is produced. If milk is not removed, an autocrine hormone in milk called feedback inhibitor of lactation acts locally within each breast to inhibit milk production. Early effective removal of colostrum, ideally starting within 1 hour of delivery, speeds the arrival of increased milk volume, and frequent milk removal increases supply in the weeks that follow.

Benefits of Breastfeeding

For the baby, the benefits of breastfeeding are myriad. Studies have demonstrated that breastfed infants have a decreased incidence and severity of infectious illnesses, including diarrhea, respiratory infections, otitis media, bacterial meningitis, and urinary tract infections. They have lower rates of hospitalization and mortality. The incidence of otitis media is 100% higher in formula-fed infants than exclusively breastfed infants. Studies have also demonstrated better performance on cognitive testing among children who were breastfed as infants. Among preterm infants fed human milk, the incidence of necrotizing enterocolitis is also significantly reduced. Breastfeeding in infancy also reduces the later incidence of atopy, allergies, asthma, childhood obesity, type 2 diabetes, and even childhood cancer. Decreased rates of sudden infant death syndrome (see Chapter 72) have also been documented. All these benefits are increased by increasing the length and exclusivity of breastfeeding.

For the mother, an immediate benefit to breastfeeding is oxytocin-induced decreased postpartum blood loss and enhanced mother-infant bonding. Lactation amenorrhea may serve subsequently as birth control. Breastfeeding has also been associated with quicker return to prepregnancy weight as well as decreased risk of breast cancer, ovarian cancer, diabetes, hypertension, heart disease, and osteoporosis. Some evidence suggests that breastfeeding decreases the risk of postpartum depression.

Societal benefits from breastfeeding include markedly decreased annual health care costs. An estimated savings of $10.5 billion annually could be generated if 80% of American families breastfed exclusively for the first 6 months after birth.

Barriers to Breastfeeding

Many studies have evaluated barriers to breastfeeding in the United States. Understanding these barriers is essential to improving breastfeeding rates. With effective physician, nursing, and peer support, most mothers should be able to breastfeed successfully. One of the most important barriers is the lack of knowledge of pregnant women about the benefits of feeding mother's milk. Education beginning at the first prenatal visit is vitally important.

Some mothers report feeling uncomfortable breastfeeding in public. Identifying this issue and helping these mothers feel more supported or find privacy when they need it can help them succeed with breastfeeding. Currently, laws exist in all 50 states and the District of Columbia that protect a mother's right to breastfeed in public.

Many new mothers have poor family support for breastfeeding, and it is necessary to include the entire family in breastfeeding counseling. The mother will not be successful if her family is encouraging her to use formula.

Some mothers find that their place of employment does not make accommodations for a breastfeeding mother. It may be that the workplace needs to be reminded of laws promoting breastfeeding in the workplace. The Patient Protection and Affordable Care Act includes a provision that the workplace must provide adequate break time and a private place for nursing mothers to pump for up to 1 year. Some states offer additional protections.

Hospitals may have practices or policies that interfere with successful breastfeeding, including high rates of cesarean section or no rooming-in policy. Physicians should work with their hospitals to minimize these potential barriers. Some medical professionals become barriers to exclusive breastfeeding because they lack the knowledge to properly manage problems as they arise.

Contraindications

Absolute contraindications to breastfeeding are few. The neonate with galactosemia type I as detected by newborn screening and who therefore is unable to metabolize lactose or galactose may not exclusively breastfeed. Newborns can also inherit defects in protein metabolism that may necessitate a special diet, precluding breastfeeding. In most states, newborn screening now includes testing for most of these metabolic disorders.

Maternal infections prohibiting breastfeeding include active, untreated tuberculosis and HIV. Additionally, if herpetic vesicles are present on the breast, the mother should not breastfeed from that breast.

Medications and Drugs of Abuse

Most medications are safe for a mother to use while breastfeeding, and the risk to the newborn or infant of not breastfeeding often outweighs the risk of exposure to subclinical doses of the medication in human milk. Each medicine should be reviewed for potential effects on the infant or possible negative effects on milk supply. The LactMed App is an excellent free resource (https://toxnet.nlm.nih.gov/help/newtoxnet/lactmedapp.htm). Chemotherapeutic agents, antimetabolites, radioactive isotopes, and drugs of abuse are all contraindicated for breastfeeding. However, a mother with a history of drug use may benefit from breastfeeding provided her toxicology results are closely monitored and are negative.

The 2018 American Academy of Pediatrics clinical report on marijuana use during pregnancy and breastfeeding states that because the potential risks of infant exposure to marijuana metabolites are unknown, women should be informed of the potential risk of exposure during lactation and encouraged to abstain from using any marijuana products while breastfeeding. Although marijuana is legal in

some US states, pregnant and breastfeeding women who use marijuana may be subject to child welfare investigations if they have a positive marijuana screening result.

Breastfeeding Management

The management of breastfeeding should begin in the prenatal period. The US Preventive Services Task Force endorses promotion and support for breastfeeding at all health care encounters. The pregnant woman should be educated by her pediatrician and obstetrician on the benefits of breastfeeding. Her history should be reviewed for potential contraindications. If none exist, she should be encouraged to breastfeed. If she commits to breastfeeding before the baby is born, she is more likely to be successful. Involving her partner in these discussions has also been shown to improve breastfeeding success rates.

At the time of delivery, if there are no complications, the neonate should be dried and placed skin to skin on the mother's abdomen or chest for warmth and contact. Initial Apgar scores can be assigned during this process. The newborn will find his or her way to the breast and latch on. This early breastfeeding experience greatly facilitates further breastfeeding. The neonate should not be separated from the mother except for medical reasons. If an infant or mother is not medically stable enough to breastfeed immediately after birth, hand expression should be initiated within 1 hour of delivery.

During the hospital stay, the newborn should breastfeed on demand on both breasts for as long as she or he wants. Hospital policies for rooming-in greatly facilitate breastfeeding. Generally, the neonate should nurse at least 8 times a day. A healthy full-term newborn has no medical need for formula supplements. Without pacifiers or supplemental feeds, the neonate will learn to breastfeed more quickly. The mother should be counseled on appropriate latch-on, positioning of the newborn, and manual expression of milk. Breastfeeding support should be available from all involved hospital staff, and a certified lactation consultant can be quite helpful. Early supplementation with expressed colostrum should be started for infants who are at high risk of breastfeeding problems, such as those who are preterm, multiples, weigh less than 2.7 kg (<6 lb), or feeding poorly for 12 hours, as well as for those whose mothers had cesarean section, prior breast surgery, or previous breastfeeding problems. Early supplementation with expressed colostrum can decrease excessive weight loss in the infant.

Urine and stool output can be a reliable indicator of the success of breastfeeding. A successful breastfeeding neonate should urinate 3 times a day and pass stool 3 to 4 times a day by 3 to 5 days of age. By day 5 to 7 of age, the neonate should urinate 4 to 6 times a day and pass 3 to 6 stools a day. Weight loss should be monitored and should not exceed 10% of birth weight without further evaluation. Mothers whose newborns are taken to the neonatal intensive care unit must be helped with pumping or hand expressing their breasts within the first hour after delivery. By encouraging initial and frequent expression of milk, a mother's milk supply can be established even when her newborn cannot directly nurse.

During the first 6 months after birth, the only supplement to breastfeeding that is needed is vitamin D 400 IU daily started in the first few days after birth to prevent rickets. Intramuscular vitamin K to prevent hemorrhagic disease of the newborn, application of ophthalmic antibiotic ointment or silver nitrate to prevent gonorrheal infections, and hepatitis B vaccination are administered to all newborns shortly after birth (see Chapter 23).

After hospital discharge, the breastfeeding newborn should be seen by the physician at day 3 to 5 of age and again at 2 weeks of age to support breastfeeding. Early assessment may prevent many breastfeeding problems and enables the physician to intervene early if problems arise, thereby helping to prevent discontinuation of breastfeeding. New mothers need encouragement and reassurance. At each visit, the neonate should be assessed for weight, feeding schedules, voiding and stooling patterns, and jaundice. The mother's breasts should be examined for fullness, engorgement, and nipple trauma. A feeding should be observed. Mothers who are giving formula supplementation in the first weeks need help improving milk transfer and weaning formula supplements. Referral to a lactation specialist and a follow-up appointment in several days is essential.

The infant should exclusively breastfeed until 6 months of age. At that time an iron source is needed, and iron-fortified cereal can be given with a gradual introduction of other pureed foods. The recommendation is that breastfeeding continue until at least 1 year of age or as long as the mother and infant desire.

If a mother plans to return to work, she should be counseled to initiate exclusive breastfeeding and wait until the infant is approximately 4 weeks of age before introducing a bottle of expressed milk. When the mother is separated from the infant, she should pump her breasts at regular intervals. The milk can be stored at room temperature for 4 hours, in the refrigerator for up to 4 days, or in the freezer for up to 6 months (ideal) or even 12 months (acceptable) for later use. Generally, milk should be stored in 2- to 4-ounce bags or containers that are labeled with the date of expression. When the mother is back with the infant, she should put the infant to breast at the usual interval rather than using the previously expressed milk. Many mothers can work and breastfeed well past a child's first birthday.

Sometimes pediatricians are consulted about weaning the breastfed infant. There is no age at which weaning must occur, and in many cultures toddlers nurse until age 3 to 4 years. Although some infants readily give up the breast, others are more reluctant to do so. Lactation consultants may be a valuable resource at this time.

Potential Problems

Attachment

Latching-on is the first step that is essential for successful breastfeeding. Getting some infants to latch may be difficult initially because of sleepiness or fussiness when attempts are made. It is best to start feedings when the infant exhibits early feeding cues, such as licking lips or bringing hands to the mouth. Placing the infant skin to skin in a vertical position on the mother's chest while she is leaning back can stimulate reflexive infant feeding behaviors. Infants can often maneuver themselves to the nipple with a little help if they are lying on top of their mother as she reclines in bed. The newborn should be positioned with 1 hand on each side of the breast and the chin touching the breast and the nipple near the baby's nose. This allows

the infant to get as much of the areola in the mouth as possible. Causes of poor latching include poor positioning, inverted or flat nipples, ankyloglossia (ie, tongue-tie), small mandible, engorgement, or nipple confusion (ie, preference for firm bottle nipples or pacifiers). Management may consist of help with positioning, frenotomy, or use of a supplemental nursing system at the breast. A supplemental nursing system is a small tube connected to a syringe or bottle that is slid into the infant's mouth after the infant is latched onto the breast to give a supplement of expressed milk or formula while the infant breastfeeds. This can provide flow to stimulate sucking in a sleepy infant. Occasionally nipple shields are used, but these may limit nipple stimulation and cause problems with milk supply. Thus, mothers who are given shields should be followed closely and encouraged to express milk after feedings to ensure a strong supply. In any instance of difficulty with attachment, hand expression or a pump should be used to ensure frequent effective breast emptying so that milk production continues.

Sore Nipples

Breastfeeding should not be painful. If the mother is experiencing pain, the neonate is probably not latching correctly and may be crushing the nipple with his or her gums. This may cause cracked and even bleeding nipples. If the nipple is being compressed the ducts are compressed as well, resulting in poor milk transfer. The nipple may appear flat or pinched after the feeding. Pediatricians can learn a great deal about the status of breastfeeding by checking a mother's breasts for fullness and trauma. With a correct latch, neonates have the nipple and a significant portion of the areola in their mouth with their lips flanged outward. If a mother experiences pain, the newborn should be removed from the nipple and attached again. If pain persists, a medical professional should evaluate the mother-infant dyad for problems. Cracked nipples can be treated with lanolin or hydrogel pads and repositioning. Mothers should express their milk if the latch is shallow to avoid engorgement and decreased supply. Expressed milk left to dry on cracked or bleeding nipples has healing properties. In the setting of significant injury, the mother may need to pump the affected breast for 24 hours while the nipple heals. Occasionally sore nipples are secondary to a candidal or bacterial infection, atopic dermatitis, or Raynaud phenomenon (ie, vasospasm). Raynaud phenomenon can be secondary to trauma, tends to be worse when nipples get cold, and often is improved with several days of low heat.

Engorgement/Mastitis

Engorgement may occur in the setting of milk stasis for any reason. The breast appears full, firm, lumpy, and tender. Treatment is to empty the breast, and the newborn or infant is the most effective breast pump. Gentle manual compression along the posterior edge of the glandular tissue may improve emptying. Application of warm packs or taking a hot shower before feeding can be helpful. Sometimes an electric breast pump expedites emptying, softens the breast, and facilitates baby latching. If it is not possible to empty an area of the breast, such as in cases of a prior surgery that has severed some ducts, feedback inhibitor of lactation will decrease and stop milk production in this area. Postpartum engorgement may also be caused in part by interstitial edema and improved by gentle massage toward the axillary lymph nodes.

Left untreated, engorgement may result in *mastitis*, which is breast inflammation with signs of systemic infection, frequently including fever and body aches. If a mother develops mastitis, she should continue to breastfeed. Emptying the breast is important, but treatment also consists of oral antibiotics and rest. Ineffective treatment of mastitis may result in progression to a breast abscess requiring more invasive treatments, such as serial needle aspiration, drain placement, or incision and drainage. Incisions should be made parallel to ducts to avoid severing them and away from the areola so the baby can continue to latch. In cases of frank pus coming from the nipple, the baby should not breastfeed until the discharge has resolved. The mother should pump the affected breast to empty the milk and support her supply.

Low Supply

The most common reason for early cessation of breastfeeding is perceived low milk supply. Although 95% of women from developed countries are physiologically able to produce sufficient milk, many supplement with formula when it is not medically necessary. Supplementation may be done because of difficulty with latch or unrealistic expectations of newborn behavior causing a lack of confidence. Formula supplementation leads to decreased frequency of breastfeeding, and in time, milk supply decreases if the breasts are not emptied by the baby, a pump, or hand expression.

To encourage exclusive breastfeeding, medical professionals must be able to support a mother's confidence and ability to breastfeed. They must be able to assess milk transfer as well as baby hydration and weight gain. When supplementation is necessary, medical professionals must enable mothers to express their breasts; often, this milk is the only supplement necessary. Any formula supplements given in the first few days should be of limited volume and should be stopped when mothers experience lactogenesis stage 2. At office visits, if babies have been given formula unnecessarily, physicians must help families by addressing breastfeeding problems and closely following the baby's weight as supplements are decreased and eliminated. In later months, mothers may express concern over shorter feeding times, thinking that they have less milk when, in fact, infants have become more efficient eaters.

In the baby with poor weight gain, a thorough investigation must be undertaken to determine whether the difficulty stems from a problem with the baby, mother's milk supply, milk transfer, or some combination of these. It is critical to provide the baby with sufficient calories and protect the mother's supply with pumping during this time. For mothers who do lack sufficient milk, more frequent and effective emptying of the breast may solve the problem; however, if this is unsuccessful, galactagogues (ie, human milk stimulants) may be useful in some cases.

Hyperbilirubinemia/Dehydration

Ten percent of exclusively breastfed infants born via vaginal delivery and 25% of infants born via cesarean section lose more than 10% of their birth weight. Too often, infants are started on formula supplements just as mothers have increasing milk volume. For this reason, it is important to check a mother's breasts at each

visit and encourage expression of milk at each feeding if an infant requires supplementation. Neonates who lose more than 10% to 12% of their birth weight are at risk for becoming dehydrated and have an increased likelihood of significant jaundice. Increased intake is necessary, and the frequency of feeds should be increased. If a newborn is not latching on well, expressed milk can be given by syringe. Neonates should be closely monitored, and formula can be offered after human milk if milk supply is insufficient. If insufficient supply is the problem, the mother should be assisted in increasing her milk supply. Using a breast pump will increase supply because of increased demand. If the newborn appears significantly jaundiced, serum levels of bilirubin should be obtained. Physiologic jaundice is related to hepatic immaturity with decreased conjugation of bilirubin as well as decreased excretion. Breastfeeding babies tend to have increased levels of unconjugated bilirubin. Increased feeding frequently resolves the problem as hydration status improves and frequency of stooling increases. Occasionally, especially in late preterm neonates, treatment with phototherapy is necessary. Interrupting breastfeeding is neither necessary nor helpful. For a more extensive discussion of jaundice, see Chapter 126.

Resources for the Breastfeeding Mother

Many hospitals and health care organizations have lactation specialists who can assist nursing mothers and answer questions related to lactation. Health facilities may loan or rent electric breast pumps to new mothers to help establish a good supply of milk. Some mothers may choose to purchase such pumps, especially if they are planning to continue to breastfeed after returning to work. Breast pumps usually are covered by health insurance.

Access to information can also be obtained through the internet, community agencies, or international and national organizations such as La Leche League International (www.lalecheleague.org) and the Special Supplemental Nutrition Program for Women, Infants, and Children. Such agencies provide a resource to the health care professional in assisting mothers with breastfeeding.

CASE RESOLUTION

In the case presented, the mother is aware of the many benefits of breastfeeding. You examine her breasts and note normal anatomy and easily expressed colostrum. The mother should be encouraged to breastfeed and reassured that she should be able to make adequate milk with early effective breast emptying. You recommend she stop cigarette smoking completely for her own health as well as the baby's; if she is unable to do so, however, she should be advised that breastfeeding is still superior to formula. In the hospital, she should request that her newborn be placed skin to skin with her in the delivery room and continue rooming-in to breastfeed on demand. If this is not possible, she should initiate hand expression in the first hour after the birth. Reassure her that the hospital and your office will give her support and guidance with breastfeeding. Even though she is anticipating returning to work, she should initially nurse exclusively. She can begin to introduce the bottle with pumped milk at 1 to 2 months of age. Her workplace should provide an area for nursing mothers to pump and refrigerate the milk. You encourage her to explore the lactation policies at her workplace and to seek out nursing support groups.

CHAPTER 30

Sleep: Normal Patterns and Common Disorders

Geeta Grover, MD, FAAP, and Thusa Sabapathy, MD

CASE STUDY

During a routine 6-month health maintenance visit, a mother states that although her 6-month-old son falls asleep very easily at approximately 10:00 pm every night while breastfeeding, he wakes every 2 to 3 hours and cries until she nurses him back to sleep. A review of the dietary history reveals that the infant is breastfed approximately every 3 hours and was begun on rice cereal 2 weeks prior to this clinic visit. His immunizations are current. The boy has no medical problems, and his physical examination is normal.

Questions

1. How old are most infants when they can begin to sleep through the night (≥5 hours at a time) without a feeding?
2. What factors contribute to frequent nighttime awaking during infancy?
3. What advice can be given to parents to facilitate an infant's sleeping through the night?
4. What are sleep disturbances experienced by older children and adolescents?
5. What advice can you give parents about helping children develop good sleep hygiene?

Sleep disorders are common during infancy, childhood, and adolescence. Getting children to go to bed, fall asleep, stay asleep, and stay in bed can be no small challenge. Parents frequently ask pediatricians about sleep-related problems at routine health maintenance visits. Age-appropriate suggestions on how to help children sleep well are usually welcomed by parents.

Epidemiology

Sleep problems occur in 20% to 30% of typically developing children and are among the most common concerns encountered in pediatric practice. Behavioral sleep problems, including bedtime refusal or resistance, delayed sleep onset, and prolonged night awaking requiring parental intervention, are the most common reasons for sleep concerns. Inadequate sleep in children negatively affects the quality of life of both the children themselves and their parents. Increased risk for obesity, mood and behavior problems, as well as impaired concentration and academic failure are some of the consequences associated with insufficient sleep in children.

Higher than normal rates of sleep disturbances are seen in children with medical, neurodevelopmental, and psychiatric disorders, such as obstructive sleep apnea (OSA), autism spectrum disorder (ASD), attention-deficit/hyperactivity disorder (ADHD), intellectual disability, anxiety, and depression. An estimated 25% to 50% of children with ADHD have sleep problems, especially difficulties in initiating and maintaining sleep. The relationship of ADHD and sleep problems is often complex and multidirectional. Children with ADHD have significant symptoms of impulsivity and hyperactivity that can make settling down for bed difficult. In addition, psychostimulant use has been associated with disturbed sleep; interestingly, however, it also has been shown to have the paradoxical effect of regulating children with ADHD and getting them ready for sleep.

An estimated 50% to 80% of children with ASD experience sleep-related difficulties. In typically developing children, behavioral reasons are the most common causes of insomnia. In children with ASD, however, insomnia is multifactorial. In these children, insomnia is the result of behavioral issues; medical, neurologic, and psychiatric comorbidities; and the secondary effects of medications used to manage the symptoms of ASD and the associated comorbidities.

In most Western countries, children are expected to sleep in their own beds. In many cultures, however, it is not uncommon for newborns, infants, and young children to sleep in their parents' bed (ie, the "family bed"). Bedsharing with newborns and infants younger than 10 to 12 weeks is associated with a higher incidence of sudden unexpected infant death, especially if the mother smokes. Accidental asphyxia from overlaying or the presence of soft bedding or overheating may contribute to bedsharing–related deaths. Parents should always be advised about safe sleeping practices (see Chapter 72). In older infants and children, co-sleeping is not a problem in and of itself, and the decision to co-sleep, like the decision to breast- or bottle-feed, is an entirely personal one. Most newborns and infants who share a bed with their parents have sleep-onset associations that facilitate falling asleep. Therefore, parents who share a

bed with their young children commonly must lie down with them for 20 to 30 minutes to get them to fall asleep. Several studies have shown that co-sleeping infants are 2 to 3 times more likely to experience night awaking than those who sleep alone. Furthermore, newborns and infants who are breastfeeding and bedsharing sleep the shortest periods before awaking. Parents who plan to co-sleep with their newborns and infants for only a limited period must develop a clear transition plan, such as ending this practice by 5 to 6 months of age, before infants are old enough to object excessively. For children with sleep problems, bedsharing is not a good solution. In the absence of preexisting sleep problems or psychological concerns, however, co-sleeping as a lifestyle choice has not been associated with any long-term developmental, behavioral, or psychological problems in the co-sleeping children.

Clinical Presentation

Parents may raise concerns about their child's sleep pattern during a routine health maintenance visit. However, many parents may not volunteer information about their children's sleep or may not appreciate the potential relationship between sleep problems and daytime behaviors, learning, attention, or overall health. Thus, it is important for health professionals to routinely screen children for sleep disorders.

Pathophysiology

To understand disturbances associated with sleep, it is necessary to understand the physiology of normal sleep and the development of normal sleep behavior in children.

Sleep States

Normal sleep has 2 distinct states—rapid eye movement (REM) and non–rapid eye movement (NREM) sleep. Rapid eye movement sleep develops at approximately 29 weeks of gestation and persists throughout life. It is an active, lighter stage of sleep that occurs in association with rapid eye movements. Other features of REM sleep include suppression of muscle tone; rapid, irregular pulse and respiratory rate; and body twitches. Dreams occur during REM sleep. The pattern of REM sleep noted on electroencephalography (EEG) is very similar to stage 1 NREM sleep.

Non–rapid eye movement sleep begins at approximately 32 to 35 weeks of gestation. During NREM sleep, pulse and respiratory rates are slower and more regular and body movements are minimal. Most of the restorative functions of sleep occur during this state. After the first several months after birth, NREM sleep may be divided into 3 stages. Stage 1 includes drowsiness and the beginning of sleep with slow eye movement. Stage 2 is sleep without eye movement. Stage 3 is deep sleep (also called slow-wave sleep). Each stage represents a progressively deeper state of sleep and has a characteristic EEG tracing.

The Sleep Cycle

Rapid eye movement and NREM sleep together make up the sleep cycle. Typically, the deepest sleep takes place during the first several hours of the night, with lighter stages of NREM and REM sleep occurring during most of the rest of the night. Although sleep stages are the same in infants and adults, several differences exist between the onset and duration of REM and NREM sleep in infants and adults. First, the sleep cycle is shorter in infants than in adults (50–60 minutes and 90–100 minutes, respectively), which means that infants have more periods of active REM sleep than adults. Second, the total amount of time spent in REM sleep decreases with increasing age. Full-term newborns spend approximately 50% of their total sleep time in REM sleep, whereas for preterm newborns up to 80% of total sleep time is spent in REM sleep; this decreases to approximately 30% by 3 years of age and to 20% by adulthood. Third, infants may have very little REM latency, entering their first REM cycle very shortly after falling asleep. Adults, in comparison, generally enter their first REM period approximately 90 minutes after the onset of sleep.

Melatonin, a hormone released by the pineal gland, regulates the sleep-wake cycle. It is often called the "Dracula of hormones" because peak levels occur at night. It has both hypnotic (ie, sleep promoting) and chronobiotic (ie, sleep phase-shifting) effects on the sleep-wake cycle. After melatonin is released into the bloodstream, it is taken into tissues expressing the receptors specific for melatonin and signals the body to prepare for nighttime. The pineal gland is under the control of the suprachiasmatic nucleus, which resides in the hypothalamus. When humans are exposed to light, a signal from the retina is sent to the suprachiasmatic nucleus and subsequently to the pineal gland, thereby suppressing release of melatonin.

Sleep-Wake Patterns

Sleep patterns follow a normal developmental sequence in children, and the amount of sleep children need changes with maturation (Table 30.1). Through age 12 months, infants sleep 12 to 16 hours a day. Many infants can sleep through the night (≥5 hours uninterrupted) by age 3 months, and most infants are capable of this by age 4 months. Brief arousals are a normal part of the sleep cycle at all ages, but children should be able to return to sleep on their own without requiring parental attention. Children should be able to fall asleep on their own by age 4 to 6 months. Otherwise, parental participation to fall asleep becomes required at every awaking throughout the night.

Table 30.1. Total Recommended Amount of Sleep in a 24-Hour Period by Age

Age	*Total Number of Hours*
Newborn–12 months	12–16
1–2 years	11–14
3–5 years	10–13
6–12 years	9–12
13–18 years	8–10

Adapted with permission from Paruthi S, Brooks LJ, D'Ambrosio C, et al. Recommended amount of sleep for pediatric populations: a consensus statement of the American Academy of Sleep Medicine. *J Clin Sleep Med*. 2016;12(6):785–786.

One- to 2-year-olds sleep 11 to 14 hours per day, and by age 3 to 5 years, children sleep a total of 10 to 13 hours per day. One-year-olds take 2 naps per day. This typically decreases to 1 afternoon nap by 18 to 24 months of age. Most children take an afternoon nap until 3 years of age, and some children continue this until 5 years of age. The amount of nighttime sleep children need continues to gradually decline, decreasing from approximately 12 hours during the preschool years to approximately 8 to 10 hours during adolescence.

Adolescents are often chronically sleep deprived because of a combination of biologically driven processes and modern lifestyle demands (eg, digital media use, excessive extracurricular activities). Biologically, around the time of pubertal onset, adolescents begin to experience changes in their circadian rhythm, with delay of sleep onset and wake times by up to 2 hours (ie, sleep-wake phase delay). It has been suggested that this occurs because of delayed melatonin secretion, as well as slower accumulation of sleep drive, resulting in inability to fall asleep at an appropriate bedtime. In addition, teenagers have more demands and expectations in the late afternoon, including homework and extracurricular activities, that push their bedtime later. Ultimately, adolescents are not getting the recommended 8 to 10 hours of sleep per night, which can have serious consequences, including impaired driving, academic decline, and depression. Emerging studies have demonstrated that early middle school and high school start times can interfere with total nighttime sleep in adolescents. The American Academy of Pediatrics supports delaying start times in middle schools and high schools to relieve sleep deprivation in adolescents and its associated effects. Discussion of the pathophysiology of sleep is incomplete without inclusion of the effect of electronic media. Use of electronic media in the evening hours can disrupt sleep-wake patterns because of several reasons. Media use may directly displace sleep time. Media content may cause physiologic arousal, making it difficult to fall asleep and negatively affecting overall quality of sleep. Additionally, the light emitted by the devices themselves may disrupt circadian rhythms by suppressing endogenous melatonin secretion, making it difficult to fall asleep at the desired bedtime.

Sleep Abnormalities

The etiology of sleep disorders can be complex, involving the interaction of children's temperamental characteristics, psychosocial stressors in the home, parental child-rearing philosophies, and the developmental nature of normal sleep states and sleep cycles.

Differential Diagnosis

The differential diagnosis of sleep disorders may be distinguished by problems associated with falling asleep or maintaining sleep (eg, frequent night awaking) (Box 30.1). Falling asleep may present 2 types of difficulties: problems associated with settling children to sleep and bedtime refusal.

Inappropriate sleep-onset associations and poor or inconsistent parental limit-setting are the most common reasons for difficulty settling infants and children to sleep. Inappropriate sleep-onset associations in infants are characterized by prolonged night awaking

Box 30.1. Practical Approach to the Differential Diagnosis of Sleep Disorders in Children

Difficulty Falling Asleep

Circadian and Sleep Schedule Disturbances

- Irregular sleep-wake patterns
- Advanced sleep phase
- Delayed sleep phase
- Time in bed exceeds sleep requirement
- Regular but inappropriate sleep schedules without phase shifts (eg, late evening naps)

Habits, Associations, and Expectations

- Inappropriate sleep-onset associations
- Bedtime refusal/struggles
- Poor or inconsistent limit setting

Overstimulation

Psychosocial

- Separation anxiety
- Nighttime fears (eg, of the dark, of monsters)
- Family and social stresses

Medical

- Acute illness
- Underlying medical problems
- Medications (eg, antihistamines, stimulants, codeine, anticonvulsant agents)

Difficulty Maintaining Sleep/Nighttime Awaking

Normal Variation (eg, Breastfed Infant)

Habits, Associations, and Expectations

- Inappropriate sleep-onset associations (eg, age-inappropriate night awaking for feeding)

Psychosocial

- Nighttime fears
- Family and social stresses

Medical

- Acute illness
- Underlying medical problem
- Medications

Nightmares

Arousal Disorders

- Night terrors
- Sleepwalking
- Sleep talking

Miscellaneous Sleep Disorders

Intrinsic Sleep Disorders

- Narcolepsy
- Sleep apnea (obstructive or central)
- Restless legs syndrome
- Periodic leg movements

Sleep-Wake Transition Disorders

- Head banging
- Rocking

episodes that require parental participation (eg, holding, rocking, feeding) to fall asleep. They have not learned the critical skills of self-calming and initiating sleep on their own. Because these infants do not have the self-soothing behaviors necessary to fall back to sleep after normal nighttime arousals, they also may experience nighttime awaking. Brief arousals are a normal component of sleep. Nighttime awaking is different because of the need for parental participation to resettle the infant. The problem is the difficulty that infants experience falling back to sleep on their own, not the awaking itself.

An example of an inappropriate sleep-onset association is the infant or child who needs to be breast- or bottle-fed to fall asleep. These children need to be fed before going back to sleep after normal nighttime awaking. Although they are developmentally old enough to receive all nutrition during the day, they have become conditioned to require nighttime feedings. These children are often breast- or bottle-fed until they fall asleep and only then placed in the crib. They are conditioned to require feeding to initiate sleep, and when they experience normal nighttime arousals, they require the breast or bottle to go back to sleep. Similarly, children who lack the self-comforting and self-initiating skills necessary to fall asleep on their own will awake, cry, and want to be held, comforted, or entertained before they can go back to sleep. Behavioral insomnia resulting from poor or inconsistent parental limit-setting is most common in preschool-age and older children. These children actively resist going to bed with verbal protests and multiple or repeat demands at bedtime ("curtain calls"). These children may also have difficulty settling back to sleep at night, especially if nighttime fears or anxiety contributed to their resistance to going to bed.

Acute illness also may be a cause of sleep disturbances. Children with otitis media may awake at night because of pain. They may continue to experience awaking after the infection has resolved, however, and require comforting or some sort of attention to fall asleep again.

In infants and children between the ages of 9 and 18 months, separation and separation anxiety may also affect sleep patterns. Children may cry when parents leave the room and have difficulty settling to sleep. Ability to climb out of the crib or bed can be associated with nighttime awaking in older toddlers. The transition from a crib to a bed is usually made between 2 and 3 years of age. Children who can climb out of their cribs or beds may come out of their rooms repeatedly for drinks of water, trips to the bathroom, or to sleep in the parent's or parents' bed. Such factors as nighttime fears of the dark influence sleep behaviors during the preschool years (3–5 years of age). Children's growing needs for autonomy and control over their environment may result in bedtime refusals during the toddler and preschool years.

Disorders of the sleep-wake cycle may contribute to sleep schedule irregularities. Circadian rhythms govern the regularity and degree of wakefulness and sleepiness. The circadian clock inherent in humans is not an exact 24-hour pattern but can be modified or entrained onto one by environmental cues. Parents must provide regular and consistent structure, because development of children's sleep-wake rhythms is dependent on an interaction between the child's inherent biological rhythms and the environment. Entrainment requires predictable occurrence of time cues, such as light and dark, mealtime, and bedtime. A consistent awaking time in the morning is among the most important of these cues. Time in bed exceeding actual sleep requirement is a common cause of insomnia at any age and occurs when children are expected to sleep more than is necessary.

Irregular sleep-wake cycles may occur in children living in chaotic environments with irregular mealtimes and sleep-wake schedules. A delayed sleep phase and regular but inappropriate sleep-wake schedule are the most common forms of sleep rhythm disturbance. Children with delayed sleep phase have a resetting of their circadian rhythm; they are not sleepy at bedtime and have excessive morning sleepiness. This is a common problem, because the inherent circadian clock has a cycle closer to 25, not 24, hours. This clock has not been entrained to a 24-hour schedule in these children.

One example of a regular but inappropriate sleep-wake schedule is napping at the "wrong" time (eg, a child who regularly naps at 7:00 pm for 1 hour and then has trouble going to bed at 9:00 pm). Another is seeming confusion between day and night in some infants, who sleep most of the day and stay up most of the night.

Night terrors (pavor nocturnus), sleepwalking (somnambulism), and sleep talking (somniloquism) are all forms of partial awaking that occur during deep or stage 4 NREM sleep, most often during the transition from stage 4 NREM sleep to the first REM sleep period. Sleepwalking and sleep talking usually occur during the school-age years, whereas night terrors begin during the preschool years.

Night terrors and nightmares may begin during the preschool years and may continue throughout childhood. Night terrors are different from nightmares and occur during a different stage of the sleep cycle (Table 30.2). With night terrors, children usually sit up in bed and cry or scream inconsolably for up to 15 minutes. They may appear dazed and have signs of autonomic arousal, such as tachycardia, tachypnea, and sweating. These children cannot be consoled. When they finally go back to sleep, they do not remember the event in the morning. Because parents are often frightened by the experience, they may think the child is having a seizure or is having

Table 30.2. Nightmares Versus Night Terrors

Characteristic	*Nightmare*	*Night Terror*
Time of night	Late	Early, usually within 4 hours of bedtime
Sleep stage	Rapid eye movement sleep	Partial arousal from deep non–rapid eye movement sleep
State of child	Scared but consolable	Disoriented, confused, and inconsolable
Memory of event	Clear recall of dream	Usually none
Return to sleep	Reluctant because of fear	Easily, unless fully awake
Management	Reassure child	Reassure parents

an emotional disturbance and may seek medical advice. Although attacks may be precipitated by stressful events or fatiguing daytime activities, night terrors do not indicate excessive stress or emotional disturbance in children's lives unless they recur.

Nightmares usually occur during the last third of the night during REM sleep, whereas night terrors more often take place during the early part of the night. Nightmares are scary dreams that may awaken children, who can often remember them. Children usually can be consoled by parents but are reluctant to go back to sleep because of their fears.

Excessive daytime sleepiness can be a symptom of medical problems, such as illness, narcolepsy, sleep apnea, and depression. Viral illness is perhaps the most common medical cause of such sleepiness in children. Inadequate sleep at night is another potential cause of sleepiness during the day. Screening for daytime impairments (eg, decline in academic performance, inattention) is important in children suspected of having sleep disorders. Primary sleep disorders, such as OSA, have been shown to be associated not only with excessive daytime sleepiness but also with cognitive deficits and impaired attentional capacity.

Narcolepsy, a disorder of excessive sleepiness, is characterized by an overwhelming desire to sleep during the daytime despite adequate sleep at night. Symptoms include excessive daytime sleepiness, cataplexy, sleep paralysis, and hypnagogic hallucination. *Cataplexy* is an abrupt loss of muscle tone that usually is precipitated by an emotional reaction, such as laughter or anger. *Sleep paralysis* is an inability to move or speak that occurs as individuals fall asleep or awaken. Hypnagogic hallucination, which can be visual or auditory, occurs while falling asleep. Narcolepsy affects approximately 0.05% to 0.1% of the general population. The prevalence increases to 50% of family members with a positive family history for the condition. The exact genetic basis of inheritance is unknown. The age of onset is usually between 10 and 20 years. Diagnosis is often delayed or missed for months to years in some cases because not all symptoms may be present initially. Diagnosis is important, because pharmacologic therapy with central nervous system stimulants may provide some symptomatic relief.

Sleep-related breathing disorders (SRBDs) occur on a spectrum, with habitual snoring the least severe form and OSA the most severe form. Risk factors associated with the development of SRBDs include obesity, presence of chronic sinus problems, recurrent wheezing, nasal allergies, family history of OSA, and certain genetic disorders (eg, Down syndrome, Prader-Willi syndrome). *Obstructive sleep apnea in children* is a disorder of breathing during sleep that is characterized by prolonged partial upper airway obstruction or intermittent complete obstruction (ie, obstructive apnea) that disrupts normal gas exchange and sleep patterns. Risk factors for OSA include adenotonsillar hypertrophy, obesity, craniofacial anomalies, and neuromuscular disorders. Obstructive sleep apnea syndrome (OSAS) is thought to be secondary to a combination of adenotonsillar hypertrophy and reduced neuromuscular tone of the upper airway during sleep. Large tonsils and adenoid alone are not necessarily diagnostic for OSA. Symptoms include nightly snoring, often with intermittent pauses or gasps; disturbed sleep; and daytime neurobehavioral problems. Obstructive sleep apnea syndrome should be distinguished from *primary snoring*, which is defined as snoring without obstructive apnea, arousals from sleep, or abnormalities in gas exchange. Obstructive sleep apnea syndrome not only has the potential to disturb the quality of sleep but also can cause potentially serious complications, such as failure to thrive and, in severe cases, cor pulmonale.

Restless legs syndrome, or *periodic leg movements*, is characterized by uncomfortable creeping or crawling feelings, mainly occurring in the lower extremities, when the child is resting or inactive and is relieved by movement. The condition may be attributed to growing pains in younger children (see Chapter 116) and can be associated with delayed sleep onset.

Evaluation

History

Evaluation of children with sleep difficulties begins with a thorough, detailed sleep history taken from parents and, if old enough, children themselves (Box 30.2). A thorough history includes information about total daily sleep in 24 hours; daytime sleep and nighttime

Box 30.2. What to Ask

Detailed Sleep History

- Does the child have regular nap times and bedtimes, or do these depend on changing parental schedules?
- What time does the child go to bed?
- What does the child do in the hour before bedtime? Is there a consistent bedtime routine, even on weekends?
- Does the child watch television, play video games, or use the internet or mobile telephone in the hour before bed?
- Where does the child sleep (eg, ask about co-sleeping, noise, temperature)?
- Can the child fall asleep without parental participation?
- Does the child require feeding or fluids at night?
- Can you provide a detailed explanation of when the sleep problem occurs relative to bedtime and what the child does?
- How often does the sleep problem occur?
- How long has the child been having sleep problems?
- How does the parent respond?
- Does the child snore?
- When does the child wake up in the morning? Is the child difficult to awake?
- Is the child sleepy during the day?
- How much caffeine does the child consume, for example, in coffee, tea, soda, or chocolate?
- Is the child taking any medications?
- Is there a family history of sleep disturbances?
- Is there any stress within the home resulting from marital or financial difficulties that may affect the home environment and cause the child to be anxious or stressed?

sleep; the sleep environment; bedtime rituals and routines; weekday versus weekend schedules; snoring; and evening routines, including screen time. The use of a specific screening questionnaire, such as the Children's Sleep Habits Questionnaire, may facilitate the evaluation. This questionnaire is designed to screen for the most common sleep problems in children aged 4 to 12 years. It is not intended to be used to diagnose specific sleep disorders but rather to identify children who may require further evaluation. The simple screening acronym BEARS (bedtime resistance/sleep-onset delay; excessive daytime sleepiness; awaking at night; regularity, patterns, and duration of sleep; and snoring and other symptoms) can be useful as an initial screening tool to determine whether further assessment is necessary. Evaluation should also include an assessment of the child's temperament, psychological well-being, and developmental status. Children with neurodevelopmental or psychological concerns have increased rates of sleep disturbances.

Asking about evening screen time is an important component of the sleep history, because electronic media use can disrupt sleep. Increased viewing of media on mobile electronic devices, such as tablet devices and smartphones, near bedtime has been reported. Seventy-five percent of children have at least 1 technological device in their bedroom. Approximately 1 in 10 children 13 to 18 years of age is awakened after going to bed every night or almost every night by a telephone call, text message, or email. Emerging data indicate that screen time in the evening is associated with delayed sleep onset, later bedtime, shorter sleep duration, and poor overall sleep quality.

The intake of caffeinated substances in the form of coffee and energy drinks is another component of the history to consider in adolescents experiencing sleep disturbances. Between 30% and 50% of adolescents have reported consuming energy drinks, which contain not only large amounts of caffeine but also large amounts of sugar and legal stimulants that can have dangerous side effects (eg, irregular heartbeat, heart failure, anxiety, dehydration, insomnia). The recommended maximum daily caffeine intake for adolescents aged 12 through 18 years is 100 mg, that is, the amount of caffeine in a single cup of coffee.

Physical Examination

A thorough physical examination is important to rule out organic causes of sleep difficulties. Special attention should be paid to the airway and nervous system. Conditions that may alter the sleep-wake cycle include acute illness (eg, otitis media), OSA (eg, resulting from adenoidal or tonsillar hypertrophy), colic, gastroesophageal reflux, and any central nervous system disease or abnormality.

Laboratory Tests

In most cases, a detailed history and physical examination are sufficient to establish the reason for sleep disturbance; laboratory assessment is rarely necessary. If further evaluation is warranted, it should be individualized to the child's clinical presentation. Electroencephalography may be useful if a central abnormality, such as a seizure disorder, is suspected. *Polysomnography*, which is the simultaneous monitoring of EEG, electrocardiography, chin muscle tone, eye movements, and respirations during a night of sleep in a sleep laboratory, may be useful in certain children when significant sleep disturbances, such as nocturnal seizures, narcolepsy, or OSAS, are suspected. Any child with suspected SRBD (eg, history of snoring, abnormal breathing during sleep) should be evaluated for OSAS.

The use of consumer sleep technology in the form of wearable devices and downloadable programs on mobile devices for tracking sleep cycles and overall sleep quality have become increasingly popular. The accuracy of the collected data and the relation of the data to sleep disorders is unclear, however. It would be advantageous for health care professionals to be aware of the types of available consumer sleep technology applications to further the discussion of sleep-related problems. However, it does not replace a full clinical evaluation.

Management

The goal of management is to help children develop a healthy pattern of sleeping, not simply to eliminate the immediate problem. Healthy sleep associations include providing a consistent schedule of naps and bedtime, along with a pleasant bedtime routine. It is important to put newborns and infants in their crib while they are relaxed and drowsy but not already asleep. This gives them the opportunity to develop skills to put themselves to sleep. If they become accustomed to being fed or rocked until they fall asleep, they will seek the same means of falling asleep every time they normally awaken during the night. In addition, overstimulation in the evening may make settling to sleep difficult for toddlers or young children. Instead, a routine such as a bath followed by a story in the child's bedroom with a clearly defined end point when the parent leaves the child in the crib or bed sleepy but awake may help facilitate sleep. Children must learn to fall asleep on their own.

The mainstays of treatment of infants and children with inappropriate sleep-onset associations is to put them in their crib or bed when they are sleepy but awake followed by systematic ignoring (ie, "extinction") when they awake at night. Their last memory before falling asleep should not be of a parent holding or feeding them. If the crying persists, parental contact with the newborn or infant should be brief and boring (ie, nonstimulating). *Scheduled awaking* is a technique in which the infant is slightly aroused by the parent 15 to 60 minutes before an expected spontaneous awaking in an effort to prevent spontaneous awaking. Scheduled awaking may be an effective treatment alternative for some infants who awake, cry, and require parental soothing to fall back to sleep. If an infant awakes for a feeding, the parent should try to stretch the interval between waking and feeding so that the infant has an opportunity to practice self-calming techniques.

Implementation of good sleep hygiene practices is an important first step for school-age children and adolescents who are experiencing sleep problems, especially sleep-onset problems. *Sleep hygiene* refers to the establishment and maintenance of schedules and conditions conducive to healthy, restorative sleep. Good sleep hygiene practices are listed in Box 30.3. Limiting screen time, especially in the evening, is an important component of good sleep hygiene practices.

Box 30.3. Good Sleep Hygiene Practices

Environment

- Dark.
- Quiet.
- Comfortably cool.

Schedule

- Regular bedtime.
- Regular awaking time.
- Naps, if needed, should be early in the day and of a consistent time and duration.

General

- No frightening/stimulating television, video games, or stories and no vigorous physical activities in the hour before bedtime.
- Unplug and charge technology devices outside children's bedrooms to avoid surreptitious access during sleep hours.
- Limit caffeine, especially after lunchtime.
- Consistent and calming bedtime routine.
- Consistent soothing methods.
- Children put to bed drowsy but awake.

The SPOIL System (social, play, outdoor, independent work, literacy; www.screenfreeparenting.com) may be helpful in guiding parents on how to fill their child's time with activities other than screen time. The SPOIL System was developed to provide families healthier options than viewing a screen and includes opportunities for socialization, child-led free play, time in nature, helping with age-appropriate chores, and education.

Specific sleep disorders can be addressed individually. Older toddlers and preschoolers who delay going to bed or refuse to stay in their rooms at night need clear, firm limits. These children need consistent bedtime routines and nighttime interventions for when they awake. It may be necessary to install a gate in the bedroom doorway to prevent children who refuse to stay in their rooms at night from moving about the house and potentially hurting themselves or disturbing others. Parents of children who have night terrors may require reassurance that their children are not having significant emotional problems or stressors. A night-light may help alleviate the anxieties of preschoolers who are unable to sleep at night because of their fears of darkness. Disturbances of the sleep-wake schedule can be corrected over time by gradually shifting children's schedules in the desired direction. For example, in the case of a child with a delayed sleep phase who goes to bed very late, the morning wake-up time can be progressively advanced approximately 15 minutes per day, after which bedtime is progressively advance until the desired schedule is achieved.

Pharmacologic interventions should be considered only after appropriate behavior interventions have been attempted. Medications for insomnia should be used in combination with a behavioral plan that addresses sleep hygiene and unhealthy sleep practices. It may be necessary to partner with subspecialists when treating children with underlying medical, neurodevelopmental, or psychiatric disorders. It is important to carefully review the potential effects of psychotropic medications with regard to the child's sleep. Commonly used psychotropic medications in children that may affect sleep include psychostimulants, selective serotonin reuptake inhibitors, and atypical antipsychotic medications.

Medications to manage insomnia include over-the-counter preparations and prescription medications. Antihistamines, melatonin, and herbal supplements are common over-the-counter options. Antihistamines are generally well tolerated because of their rapid onset of action and relatively short half-life. However, potential adverse reactions include "paradoxical" stimulation or disinhibition, anticholinergic effects, and development of tolerance to sedation. Antihistamines are best for short-term situational use in younger children. Melatonin, which is considered a nutritional supplement by the US Food and Drug Administration (FDA), has both hypnotic and chronobiotic properties. When used as a hypnotic agent to shorten sleep-onset latency, a larger dose is given 30 to 60 minutes before bedtime, whereas when used as a chronobiotic agent, a smaller dose is given 3 to 4 hours before bedtime in an effort to shift the circadian rhythm. Currently, the long-term side effects of melatonin, including its potential for hypothalamic-gonadal axis suppression, are unclear. The FDA does not monitor over-the-counter preparations of melatonin, and the actual dose of melatonin may not be the same as listed on the label. Thus, parents may want to consider using a pharmaceutical-grade formulation of melatonin to ensure that the tablet contains the stated amount of melatonin.

Some children may require referral to a sleep specialist, especially those children in whom significant sleep disturbances, such as narcolepsy, nocturnal seizures, or OSAS, are suspected.

Prognosis

It is to parents' advantage to help their children develop healthy sleep habits rather than ignore the problems and hope that children outgrow them. Children with sleep problems in early childhood are at increased risk for sleep problems later in life.

Sleep has an important influence on mood. Emerging data indicate an association between difficulty initiating and/or maintaining sleep with depression in children and adolescents. Additionally, sleeping less than 8 hours at night seems to be associated with an increased risk for suicide attempts after controlling for confounding variables.

CASE RESOLUTION

The 6-month-old has disordered sleep associations. He has been conditioned to nighttime feedings, although he is old enough not to require them for nutrition. The physician suggests several steps the mother can take to try to solve her son's sleep problem. She can begin by gradually lengthening the interval between daytime feedings to 4 to 5 hours. When the baby cries at night, she can wait progressively longer before feeding him and then eventually eliminate the feedings altogether. He will learn to fall asleep on his own without requiring feeding.

CHAPTER 31

Oral Health and Dental Disorders

Charlotte W. Lewis, MD, MPH, FAAP

CASE STUDY

The parents of a 9-month-old girl bring her to the office because they are concerned that their daughter has no teeth yet. Growth and development have proceeded normally, and the physical examination is unremarkable.

Questions

1. What is the typical first tooth to erupt, and at approximately what age does that occur?
2. What is meant by "mixed dentition"?
3. When should oral hygiene using a toothbrush and fluoride toothpaste begin?
4. What groups of children are at high risk for dental caries?
5. What are the indications for the application of fluoride varnish?

Healthy teeth allow us to consume a variety of foods, from which we obtain essential nutrients. Although physicians receive limited training about teeth, given the common nature of dental problems in children it is important that pediatricians and other pediatric primary care physicians understand and can not only recognize normal and abnormal dental conditions but can implement primary and secondary prevention of dental caries and dental injuries in their practice. Well-child care visits begin in the neonatal period and continue through the end of adolescence, and at every visit opportunities exist to promote oral health and examine oral structures for timely identification of dental problems. Infancy and early childhood are critical times for the establishment of habits, both good and bad, that have the potential to affect lifelong oral health.

Epidemiology

Both dental trauma and dental caries are common in childhood. Approximately one-third of toddlers and preschool-age children and 20% of teenagers experience dental trauma—in young children typically as the result of a fall and in older children most often the result of contact sports. Occlusal abnormalities are also common in children. At least 30% of children are estimated to have moderate to severe orthodontic needs.

Dental caries is the most common chronic disease of childhood. Even so, dental decay disproportionately affects low-income individuals, resulting in earlier onset of caries, more teeth affected, more caries-related complications, and ultimately more tooth loss during adulthood because of caries. Population-based data collected from 2011 through 2014 indicate that 36% of children age 2 through 8 years in the United States had experienced caries in their primary dentition, and 57% of US children age 12 through 19 years had experienced caries in their permanent dentition. Poverty is the most important risk factor for caries, and it also affects access to professional dental care. In 2015 to 2016, the prevalence of dental caries in children age 2 through 19 years in the United States increased as family income decreased (Figure 31.1). Among youth from families living below the federal poverty level, 56.3% had any caries, compared with 34.8% for youth from families with income levels greater than 300% of the federal poverty level. Likewise, the prevalence of untreated dental caries affected 18.6% of youth from families living below the federal poverty level, compared with 7.0% of youth from families with incomes greater than 300% of the federal poverty level.

Alaska Native/American Indian (AI/AN) children have a markedly higher prevalence of caries relative to other populations in the United States. In 2014, 76% of AI/AN children age 2 to 5 years had experienced at least 1 instance of dental caries, with 47% of all AI/AN children in this age group having untreated caries. In contrast, during 2011 to 2014, 24% of all US children between 2 and 5 years of age experienced caries and approximately 11% of children in this age group had untreated caries.

Toothache, a complication of dental caries, afflicts millions of US children. In 2007, 14% of 6- to 12-year-olds had experienced a toothache within the previous 6 months. Toothache disproportionately affects children who are poor or of minority status, or who have special health care needs.

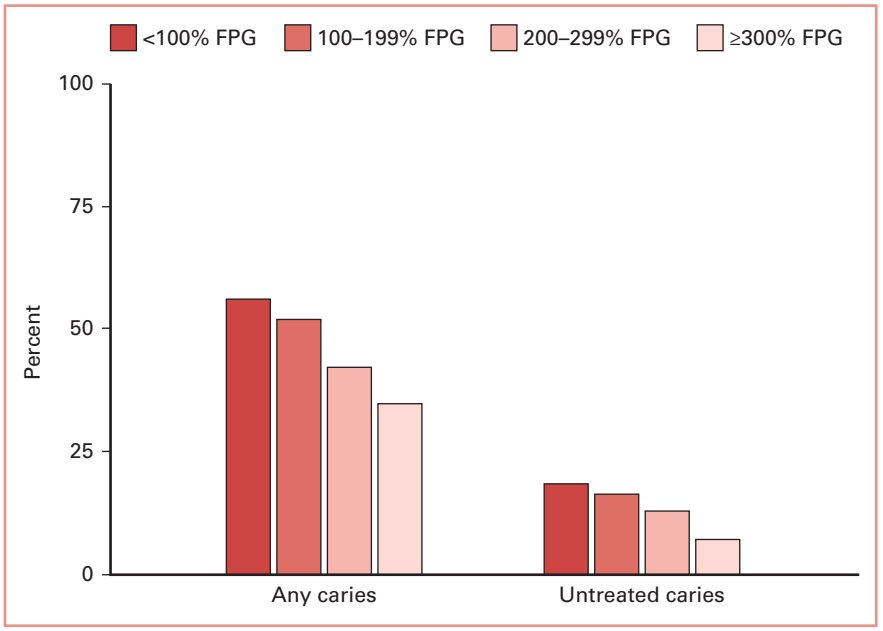

Figure 31.1. Percentage of US children, 2 to 19 years of age, with any caries and untreated caries by family income relative to Federal Poverty Guideline (FPG), 2015–2016.
Adapted from Fleming E, Afful J. Prevalence of total and untreated dental caries among youth: United States, 2015-2016. *NCHS Data Brief.* 2018;(307):1–8.

Clinical Presentation

Dental development begins in utero. Subsequently, the teeth erupt into the lower (ie, mandibular) portion of the jaw and into the upper (ie, maxillary) jaw. Teeth have a crown and root section (Figure 31.2). The crown is the visible portion of the tooth. The root is that part contained within the socket of the alveolar bone. The outer hard coating of the crown is the enamel. Beneath the enamel is the dentin, which is composed of microtubules for transport of nutrients from the pulp to the outer portions of the tooth. The pulp contains nerves and vascular structures critical for the health and viability of the tooth. Teeth are anchored to the jaw by periodontal ligaments.

Humans have 20 primary or deciduous teeth, which erupt sequentially between approximately 6 and 34 months of age (Figure 31.3A). The first primary teeth to erupt typically are the lower central incisors. These teeth erupt on average at approximately 8 months of age (±1 standard deviation: 6–10 months), after which approximately 1 tooth erupts per month until all primary teeth have erupted, by approximately 24 to 34 months of age. In each quadrant of the mouth, the normal pattern of primary tooth eruption is that the incisors erupt first, after which the first molars, the canines (ie, cuspids), and finally the second molars erupt (Table 31.1). There is variation in the timing of tooth eruption, and normal tooth eruption can vary by 6 months or more from the average age. Occasionally, the eruption process may be preceded by a bluish discoloration to the gum, called an *eruption hematoma*, which is a benign process. More often, eruption of the primary teeth is associated with more generalized symptoms, such as fussiness and drooling. These symptoms are commonly referred to as *teething*. Teething does not cause

Table 31.1. Approximate Ages of Primary Teeth Eruption and Exfoliation in the Upper and Lower Jaws

	Erupt		*Exfoliate*	
Primary Tooth Name	*Upper*[a]	*Lower*[b]	*Upper*	*Lower*
Central incisor	8–12 months	6–10 months	6–7 years	6–7 years
Lateral incisor	9–13 months	10–16 months	7–8 years	7–8 years
Canine	16–22 months	17–23 months	10–12 years	9–12 years
First year molar	13–19 months	14–18 months	9–11 years	9–11 years
Second year molar	25–33 months	23–31 months	10–12 years	10–12 years

[a] Upper: Maxillary.
[b] Lower: Mandibular.

diarrhea, respiratory infections, or true fever, although these conditions may be present coincidentally with tooth eruption in infants.

The primary teeth are replaced by the permanent teeth (Figure 31.3B), which begin erupting at approximately 6 years of age. Permanent and primary teeth are present during the mixed dentition phase, which occurs between 6 and 13 years of age (Table 31.2). During early mixed dentition, the permanent dentition looks large and awkward relative to the remaining primary teeth, and transient malpositioning of the teeth may occur. Normally, the adult mouth has 32 permanent teeth; the last teeth to erupt are the third molars, commonly referred to as "wisdom teeth," which emerge at approximately 17 to 21 years of age.

Variations from normal in number of teeth are not uncommon. *Hypodontia* refers to the presence of fewer than normal teeth. The most common teeth to be congenitally absent are the third molars, second premolars, and maxillary lateral incisors. Congenital absence of a central incisor is distinctly uncommon and should raise concern for the presence of other midline defects. Several teeth may be missing in disorders such as Down syndrome or ectodermal dysplasia. *Anodontia* is the congenital absence of teeth. Extra teeth are called *supernumerary teeth*. Children may be born with teeth already

Table 31.2. Approximate Ages of Permanent Tooth Eruption in the Upper and Lower Jaws

	Erupt	
Permanent Tooth Name	*Upper*[a]	*Lower*[b]
Central incisor	7–8 years	6–7 years
Lateral incisor	8–9 years	7–8 years
Canine	11–12 years	9–10 years
First premolar	10–11 years	10–12 years
Second premolar	10–12 years	11–12 years
First molar	6–7 years	6–7 years
Second molar	12–13 years	11–13 years
Third molar	17–21 years	17–21 years

[a] Upper: Maxillary.
[b] Lower: Mandibular.

erupted, known as *natal teeth*. Teeth that erupt shortly after birth are referred to as *neonatal teeth* if their eruption occurs in the first month after birth. These teeth are usually incisors, and at least 90% represent normal dentition rather than supernumerary teeth. The

presence of natal or neonatal teeth may be familial and, rarely, may be suggestive of an underlying syndrome. In addition to variations in number, teeth may also demonstrate variations in color and structure resulting from abnormalities in tooth development, trauma, or extrinsic factors.

The relationship of the maxillary to the mandibular dentition has functional and aesthetic implications. *Malocclusion* is an abnormal relationship between the upper and lower teeth and may be developmental, genetic, or environmental in etiology. Children with craniofacial disorders often have significant occlusal problems and facial asymmetries necessitating early referral for care by a craniofacial team. Other children may have milder malocclusion requiring orthodontic care. Normal occlusion, or *class I occlusion*, occurs when the maxillary incisors are slightly in front of the mandibular incisors and the posterior molars interdigitate (Figure 31.4). *Class II occlusion* occurs when the maxillary teeth project too far anteriorly from the mandibular teeth. This may be associated with an overjet, commonly known as "buck teeth," which can predispose to dental injury when children fall. *Class III occlusion*, or *underbite*, occurs when the mandibular teeth are anterior to the maxillary teeth. Other common forms of malocclusion include an *anterior open bite*, whereby the posterior teeth come together but an opening exists between the top and bottom anterior teeth, and a *crossbite*, which occurs when some of the upper molars are located inside the lower molars during occlusion.

Dental injuries can be classified into tooth concussion, subluxation, luxation, avulsion, and fracture. A *concussed tooth* follows a blow that leaves the tooth tender but not displaced or mobile. *Subluxation* is loosening of a tooth after injury without displacement. With *luxation*, or displacement of the tooth from its normal position, the tooth is dislodged from its usual location; the tooth may not be mobile at all if it has been forced into adjacent bone. Luxation injuries usually result in damage to the periodontal ligament, threatening the future viability of the tooth. *Intrusion* is a form of luxation; it occurs when a tooth is driven into the bone, fracturing the alveolar socket. An intruded tooth may not be visible at all; alternatively, only the very distal aspect of the crown may emerge from the gingiva. Complete loss of the tooth from the socket is referred to as an *avulsion*.

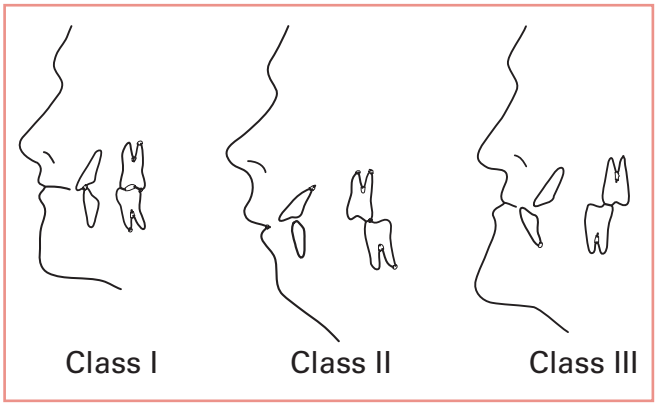

Figure 31.4. Classes of occlusion. Class I is considered most desirable from a functional and aesthetic perspective.

Dental fractures may affect the tooth crown, tooth root, and/or the alveolar bone. Fracture of the crown with no loss of tooth structure—that is, a crack exists in the tooth but no piece of tooth has broken off—is a *dental infraction*. Usually, these are initially asymptomatic. Dental follow up is needed for an infraction because the crack may allow passage of bacteria into the pulp, which can result in pulpal necrosis. Fractures involving the tooth crown, with loss of tooth structure, are classified depending on the site of the fracture. Fractures through the enamel (Ellis class I) or dentin (Ellis class II) are considered *uncomplicated dental fractures*. Fractures that involve the pulp (Ellis class 3), the root, or the alveolar bone are classified as *complicated dental fractures*.

Caries may occur any time after eruption of the teeth. *Early childhood caries* (ECC), a more general term referring to what in the past was called "baby bottle tooth decay" or "nursing bottle caries," disproportionately affects children of low socioeconomic status. The pattern of decay seen in ECC is different from that seen in the teeth of older children and adults. Typically, ECC first affects the maxillary incisors and spares the lower incisors. This pattern of decay is hypothesized to result from prolonged and frequent exposure of the teeth to sweet liquids, such as falling asleep with a juice bottle in the mouth, whereby the beverage pools around the upper incisors but the lower teeth are protected by the overlying tongue. In its earliest stages, ECC appears on physical examination as white, chalky, opaque areas at the gum line (ie, *white spot lesions*). At this early stage, the lesion is potentially reversible if remineralization can occur, such as by applying fluoride varnish to the white spots.

In older children, the pit and fissure surfaces of the molars are the likely sites of dental decay. Fermentable carbohydrates, particularly those of a sticky nature, become embedded in these surfaces and are not easily reached by the bristles of a toothbrush. This allows for prolonged action of acid-producing bacteria and subsequent caries formation. As decay invades through the layers of the tooth, it eventually reaches the pulp, resulting in inflammation and necrosis. The infection may then spread around the tooth apex, forming a periapical abscess or fistula. Dental infection can progress to involve the maxilla or mandible and then move into the fascial planes of the head and neck, producing abscess, facial cellulitis, or less commonly, airway obstruction.

Pathophysiology

Hypodontia may be familial or occur secondary to an underlying syndrome. However, failure of 1 tooth to erupt is more commonly caused by another tooth in the path of eruption or insufficient space in the dental arch. Defects of tooth structure have a variety of causes. Development of the primary teeth is predominantly subject to prenatal influences. The permanent teeth begin to develop in utero and mineralize after birth, making them susceptible to prenatal and postnatal exposures. Medications, infection, jaundice, metabolic disorders, and irradiation may adversely affect normal tooth formation or mineralization. Intrauterine infection, for example, with rubella, cytomegalovirus, or syphilis, may adversely affect tooth structure. A dental infection involving a primary tooth (eg, a periapical abscess)

can damage the developing permanent tooth bud, resulting in a malformed permanent tooth.

Discolored teeth may be the result of intrinsic or extrinsic factors. Fetal or early childhood (ie, before age 8 years) exposure to tetracycline can cause intrinsic staining of the permanent teeth. Exposure to high levels of fluoride during early childhood can cause fluorosis of the permanent dentition. Fluorosis, when it occurs in the United States, is usually mild, characterized by white striations on the permanent teeth. Children with mild fluorosis have teeth that are more resistant to dental decay. Teeth more severely affected by fluorosis may display hypoplastic enamel that is prone to staining; however, moderate and severe dental fluorosis is rare in the United States.

Inherited enamel or dentin defects may cause abnormal color of the teeth. These conditions may be isolated to the teeth, as in the case of dentinogenesis imperfecta, or as part of a systemic disorder, such as congenital erythropoietic porphyria. A single dark tooth is usually nonvital or has bled within the tooth structure after dental trauma. Extrinsic staining is superficial and is usually the result of poor oral hygiene; smoking; chewing tobacco or betel nuts; certain beverages such as coffee, tea, or wine; or medications, such as liquid iron supplements.

Malocclusion can be caused by tooth crowding, an underlying craniofacial condition, abnormal jaw growth relationship, or malpositioning of the teeth. One of the more common causes of malocclusion results from prolonged sucking of a digit (usually the thumb) or pacifier. The most common types of malocclusion associated with digit sucking are anterior open bite, overjet, and posterior crossbite.

Dental decay results from bacterial action on teeth. *Streptococcus mutans* and *Lactobacillus* species, among other bacteria, produce acids as end products of carbohydrate metabolism. These acids dissolve the calcium-phosphate mineral of a tooth's enamel during the process of demineralization. If not reversed through remineralization, the tooth's structure continues to break down until part of it collapses, resulting in a cavity. A balance of caries-promoting and caries-inhibiting factors is constantly in play. Intraoral factors that inhibit caries include normal salivary production and regular fluoride exposure; those that promote caries are frequent intake of carbohydrates, particularly simple sugars, and xerostomia (ie, dry mouth).

A variety of caries risk factors exist, some of which deserve specific mention. On a population level, children in families with low income and AN/AI children are at high risk for caries (Box 31.1). Children with developmental disabilities are also at higher risk than the general population, in part because of limited access to qualified dentists. On a family level, several genes have recently been discovered that influence caries risk. Parental oral hygiene habits, specifically less than twice daily toothbrushing by parents as well as recent maternal tooth loss from caries, increase caries risk in offspring. On an individual level, inadequate exposure to fluoride, frequent ingestion of sweetened beverages and food, use of medications that cause xerostomia, a history of caries in the previous 3 years, and visible plaque seen on oral examination are all associated with an increased risk of caries.

Box 31.1. Population and Individual Risk Factors for Dental Decay

Population Risk Factors

- Alaska Native or American Indian
- Low socioeconomic status
- Limited access to professional dental care

Family Risk Factors

- Family history of caries
- Recent maternal loss of teeth because of caries
- Parents brush teeth less than twice daily

Individual Risk Factors

- Currently active decay or personal history of caries
- Frequent and/or prolonged intake of foods containing fermentable carbohydrates (or frequent/ongoing use of liquid medications prepared with sucrose)
- Presence of visible plaque on the teeth
- Exposed root surfaces
- Having a special health care need that increases the risk for caries (eg, cleft lip), interferes with home oral hygiene (eg, oral aversiveness), or affects ability to obtain regular professional dental care (eg, behavioral difficulties associated with autism spectrum disorder)
- Inadequate exposure to fluoride
- Reduced salivary flow or xerostomia
- History of radiation therapy to head or neck
- Wearing of orthodontic appliances or prostheses

Differential Diagnosis

It can be difficult to differentiate tooth staining from a carious lesion, particularly in the tooth with small areas of discoloration on the pit and fissure surfaces. If the lesion disappears with cleaning, staining is the etiology. Staining is not always readily removed, however, and examination by a dentist and radiography can help evaluate such lesions. White spots on the teeth also can have multiple etiologies. When the white spot is chalky in appearance and located along the gingival margin, a diagnosis of demineralization should be considered. This is the earliest stage of dental decay. Small intrinsic defects of the enamel may also appear as white spots; however, these are usually located throughout the crown and not only along the gingival margin, and they usually reflect light like the rest of the tooth (ie, appearance is not chalky).

Evaluation

History

Dental pathology is diagnosed mainly through history and physical examination. The history is most important when evaluating risk for dental caries, a serious dental infection is suspected, or dental trauma has occurred. Symptoms may differentiate the degree and depth of dental injury or caries involvement of a tooth; however, young children often have difficulty localizing dental pain. A lesion

involving the dentin may produce intermittent pain, especially on exposure to temperature change or pressure on the affected tooth. After the pulp is involved, pain in the affected tooth may be severe and persistent, possibly awaking the child from sleep. In cases in which the neurovascular bundle supplying a tooth is disrupted, however, either as the result of trauma or pulpal necrosis from advanced dental caries, the pain may disappear; treatment is still necessary in these cases.

In the patient with dental injury, the history should address the mechanism of injury, the nature of other injuries, whether teeth are missing, perceived quality of pain, changes in occlusion, and tetanus immunization status.

Physical Examination

Many physicians have not traditionally included the teeth and supporting structures as part of their routine physical examination. However, pediatricians and other health professionals caring for children are generally the first, and often the only, health professionals to examine a child during the early years of life and therefore play a key role in identification of dental pathology. This is particularly true in settings in which access to routine professional dental care is limited. Early diagnosis ideally facilitates timely referral to dental specialists who provide definitive management. Additionally, children may first present to their primary care physician or an emergency department when a dental injury has occurred or an advanced odontogenic infection is present.

During each well-child care visit, the clinician should closely assess the mouth and adjacent structures for the pattern of eruption and dental development; the presence of caries, plaque, gingivitis, and other oral lesions (see Chapter 86); and malocclusion. In addition to looking for gingivitis, physicians also should examine the gingiva of children—particularly those with dental decay or toothache—to assess for evidence of periapical fistula or abscess, which typically requires antibiotic therapy or incision and drainage, followed by a root canal.

The oral cavity of a young child can be examined most easily with the caregiver and examiner in a knee-to-knee position, with the child's head in the examiner's lap and the legs wrapped around the caregiver's waist. Older children can be examined on the examination table or while seated in a chair. It is useful to have a disposable mouth mirror and a good light source. A toothbrush can be used to prop the mouth open to allow for examination of the teeth and oral cavity. The toothbrush can later be used to demonstrate good toothbrushing techniques.

In a child, occlusion is best examined by looking at the child's face from the anterior and lateral perspective and watching the child's front and back teeth as the child opens and then bites down. Having the child bite down on a tongue depressor placed horizontally between the child's upper and lower teeth demonstrates whether a cant or asymmetry of the occlusion exists. The lateral profile of a child's face can be particularly revealing. Constructing an imaginary line between the bridge of the nose, the base of the nose, and the tip of the chin defines the shape of the lateral profile. In preschool-age and older children, a slightly convex profile is preferable from functional and aesthetic perspectives. A concave profile is never normal and may be caused by midface underdevelopment or protrusion of the mandible. These children usually have a class III malocclusion. An overly convex profile may be caused by an overjet or mandibular retrusion. These children usually have a class II malocclusion.

When dental trauma occurs, the mouth and adjacent structures should first be gently cleaned. On examination, clinicians should look for facial swelling or tenderness; loose, missing, or fractured teeth; bleeding from the teeth or surrounding gums; and soft tissue injuries affecting the tongue, frena, mucosa, or palate. The presence of any of these findings suggests the need for further evaluation and treatment.

Laboratory Tests

A complete blood cell count and a blood culture should be obtained for an ill-appearing child with a dental abscess or facial cellulitis of odontogenic etiology.

Imaging Studies

Dental radiographs are useful in evaluating dental trauma and for the presence and extent of dental decay. They can also aid in determining whether an unexpectedly unerupted tooth is congenitally absent or has been prevented from erupting. If pathology is suspected, imaging, particularly panoramic radiography or computed tomography, can be useful in evaluating the facial skeleton. If a tooth or tooth fragment is missing following dental trauma, radiographic evaluation is necessary because the missing tooth or fragment may have been aspirated or swallowed; alternatively, it may have lodged in the lip or intruded into the alveolar socket, nasopharynx, or sinus cavity.

Management

Most dental disorders are definitively managed by dentists. Dental professionals are also experts in prevention of dental caries. The American Dental Association recommends that the first dental visit occur by 12 months of age. However, pediatric primary care physicians have an important role to play in identifying early and more advanced signs of dental disease and facilitating timely referral for professional dental care. Pediatric physicians may also provide initial management for odontogenic infections and dental trauma and, in cases in which access to dental care is limited, can provide treatment to halt caries progression. Some dental conditions commonly fall into the realm of the pediatric primary care physician. For example, teething symptoms can be alleviated by giving the child a cold teething toy to suck on or with acetaminophen or ibuprofen given orally. The US Food and Drug Administration has issued warnings against the use of benzocaine, viscous lidocaine, and homeopathic teething tablets for teething because these have been associated with serious or fatal side effects in young children.

Physicians and dentists can apply fluoride varnish to children at high risk for caries. Fluoride varnish is both a preventive modality and an agent used to reverse early decay in the form of white

spot lesions. Application of fluoride varnish (22,600 ppm fluoride) to the teeth can help remineralize enamel and reverse early caries lesions. Another product, silver diamine fluoride, which became available in the United States in 2015, is a solution of silver, amine, fluoride, and water that is painted onto a caries lesion to arrest more advanced active decay before it can progress to a serious infection or abscess. At 38% fluoride (44,800 ppm), it is the most concentrated fluoride product currently available for caries management. Silver diamine fluoride offers a nonsurgical alternative to traditional dental restorative surgery, and, as such, is appropriate for individuals with untreated caries who are unable to access professional dental care and others who may not be able to tolerate more extensive professional dental treatment, such as young children and special needs populations.

In most cases, advanced untreated caries in a child warrants prompt referral to a dental professional. Pulpal involvement and abscess formation may result if a carious lesion is ignored. In situations of serious dental infection in which dental care is not immediately available, antibiotics (ie, penicillin V, clindamycin) and analgesics (eg, ibuprofen) may alleviate symptoms temporarily; however, more definitive treatment (ie, root canal, extraction) is necessary to remove the source of infection and prevent resurgence of symptoms and further complications. Admission to the hospital for intravenous antibiotics and surgical drainage is usually indicated in cases in which an abscess has spread to involve the cheek, face, or neck.

Often, injuries to permanent dentition are treated differently from those to primary teeth. When permanent teeth are injured, emphasis is placed on maintaining tooth viability and prevention of complications. Even when optimal dental treatment is provided for an injured permanent tooth, however, the tooth may not survive. Blows to the teeth can result in damage to the periodontal ligament, resulting in potential neurovascular disruption, pulp necrosis, abscess formation, or root resorption. Even with prompt management of a displaced permanent tooth, a root canal may ultimately be necessary. During a root canal, the pulp is removed and the inside of the tooth is cleaned, shaped, filled, and sealed. In contrast, when a primary tooth is damaged, protecting the underlying developing permanent tooth is prioritized. For this reason, in some cases, injured or decayed primary teeth may be extracted rather than restored.

All dental injuries should be evaluated by a dental professional, but certain dental injuries, including Ellis class III fractures, root fractures, permanent tooth avulsions, and luxations, require urgent dental evaluation and management. Alveolar fractures and more complex facial fractures also require urgent consultation, usually with an oral surgeon, otolaryngologist, or plastic surgeon. It is important that pediatricians, coaches, school nurses, and parents or guardians know how to manage an avulsed permanent tooth, because survival of the tooth depends on immediate and appropriate care in the field. Primary teeth should not be reimplanted, because doing so risks damaging the underlying developing permanent dentition. A permanent tooth, however, *should* be replaced into the socket, ideally within 5 minutes of the injury, as long as the child is alert and cooperative.

The shorter the time between tooth avulsion and replacement into the socket, the better the chance for survival of the tooth. Holding the tooth by the crown (not the root, to avoid damaging the periodontal ligament fibers), an avulsed permanent tooth should be quickly rinsed with cold tap water to remove dirt and debris and then manually reimplanted in the socket. The tooth can be held in place either by the child's finger or by having the child bite onto a gauze pad or cloth until a dentist is seen. If the avulsed tooth cannot be immediately replaced into the socket, it should be stored in saline, cold milk, or a commercially available tooth-preserving system (eg, those usually stocked by paramedics and emergency departments) until definitive care is rendered. Water is not a desirable transport medium for an avulsed tooth because its low osmolality can result in cellular damage, decreasing the chance that the tooth will survive. A child with an avulsed permanent tooth should be seen urgently by a dentist for additional management, which typically involves splinting the tooth in place.

Prevention

Primary care physicians play an important role in helping families prevent dental problems (Box 31.2). Depending on the child's

Box 31.2. Caries Prevention

Standard Caries Primary Prevention for All Children

- Encourage consumption of optimally fluoridated water (0.7 ppm of fluoride).
- Initiate toothbrushing with fluoride toothpaste at first tooth eruption. Use a rice grain–size amount of toothpaste before age 2 years and a pea-size amount after 2 years. Brush twice daily and do not rinse afterward.
- Primary care physician should examine teeth and oral structures at every well-child care visit.
- Regular dental visits. The American Dental Association recommends that the first dental visit occur by 12 months of age.
- Anticipatory guidance should include the following information:
  - Frequently consuming sugar-sweetened foods and drinks (including 100% juice) increases caries.
  - Taking a bottle/sippy cup with any kind of juice or sugar-sweetened beverage to bed increases caries.
  - Regularly drinking optimally fluoridated water reduces caries.
  - Twice daily brushing with fluoride toothpaste of at least 1,000 ppm, which is all that is commercially available in the United States, reduces caries.

Intensive Caries Primary Prevention for Children With a High Risk of Caries

Includes all the standard recommendations as well as the following:

- Twice-yearly fluoride varnish application beginning at first tooth eruption.
- Initiation of regular professional dental care before 12 months of age.
- For children 5 years and older, chew polyol-sweetened gum for 10–20 minutes after meals.

age, anticipatory guidance should focus on limiting cariogenic food and beverages, toothbrushing twice daily with fluoride toothpaste, flossing, avoiding all tobacco products, preventing injury, drinking optimally fluoridated water (where available), and stressing the importance of regular professional dental care visits. Toothbrushing with fluoride toothpaste has largely supplanted fluoride drops, because fluoride toothpaste is less expensive, more readily available, and most importantly, more effective throughout the entire life span. Many aspects of oral health anticipatory guidance are also relevant to obesity prevention and promotion of overall health.

Fluoride is the single most important dental decay preventive modality. Fluoride strengthens teeth and reverses early carious lesions through enhancement of tooth mineralization. The composition of the fluoride-containing enamel, fluoride apatite, is harder and less acid soluble than the original enamel that it replaces. Increased availability of fluoridated water and fluoride-containing toothpaste has dramatically decreased the prevalence of dental caries in the United States and other countries over the past 50 years. Nevertheless, for some in the lay public, fluoride evokes controversy and concerns about adverse health effects, even though a large amount of robust research evidence attests to the safety and efficacy of fluoride for caries prevention. Pediatricians and other health professionals have an important role to play in countering misinformation and educating families about the benefits of community water fluoridation and the use of fluoride toothpaste and professionally applied fluoride products.

Caries preventive practices should begin in infancy and continue as lifelong habits; these include twice daily fluoride toothpaste for toothbrushing beginning at first tooth eruption (using a rice grain–size amount of toothpaste until age 2 years and a pea-size amount after age 2 years); drinking optimally fluoridated water where available (0.7 ppm is the recommended level of fluoride in drinking water in the United States); sound dietary practices, including avoiding frequent or prolonged exposure to fermentable carbohydrates, especially sucrose; and routine professional dental care. By the age of approximately 7 years, most children have developed sufficient fine motor skills to begin brushing their teeth independently. Until then, parents and guardians should help their children. It is also at approximately 7 years of age that children learn to spit out after toothbrushing. Some parents and guardians worry about the risks of their child swallowing fluoride toothpaste before they learn to spit. However, by applying the toothpaste to a dry toothbrush, using the appropriate amount of toothpaste, and not rinsing the mouth with water after brushing, only a small amount of fluoride is swallowed–an amount smaller than of prescription fluoride drops. There is no benefit to using a "training toothpaste" that does not contain fluoride.

It is not necessary to floss while spaces still exist between a child's teeth, as is the usual case in young children who have only primary teeth. As additional teeth erupt and teeth become closely approximated, flossing is important to remove plaque between the teeth that can contribute to caries, gingivitis, and later to periodontal disease. Sealants placed on the pit and fissure surfaces of permanent molars can also be an important defense against caries in these surfaces. Children should be seen by a dentist for evaluation for sealant placement within 6 to 12 months of eruption of their first and second permanent molars, typically occurring at approximately 6 and 12 years of age, respectively. School-based sealant programs offer an important caries preventive modality; such programs are usually provided in areas with high caries prevalence and limited availability of professional dental care. Regular use of chewing gum sweetened with polyols, also known as sugar alcohols (eg, xylitol, sorbitol, erythritol), decreases caries incidence, particularly in populations with high levels of caries. Polyols reduce caries risk through a variety of mechanisms, including stimulating saliva when chewing gum or sucking on a lozenge, substituting for sugar, and disrupting bacterial metabolism as well as biofilm organization and adherence to the teeth. The American Dental Association recommends that healthy children 5 years of age and older who are at high risk for caries chew polyol-sweetened chewing gum for 10 to 20 minutes after meals.

Certain types of malocclusion are preventable. For example, caries and dental trauma can result in premature tooth loss and subsequent loss of spacing and overcrowding, which then increase the need for orthodontic treatment. During the first year after birth, nonnutritive sucking on a digit or pacifier helps promote oral-motor development and self-soothing. Nonnutritive sucking behavior need not be discouraged up to age 1 year. However, prolonged digit or pacifier sucking contributes to malocclusion. By age 1 year, the bottle and pacifier should be discontinued, and by age 2 years, efforts should have begun to discourage digit sucking. If children can discontinue these practices before age 4 to 6 years, the malocclusion usually spontaneously reverses. Dentists can use specific devices and treatment to help stop digit sucking if other methods, including behavior modification, are unsuccessful (see Chapter 54).

Dental injuries can be prevented with appropriate vehicle restraint systems, environmental precautions when children are learning to walk and run, and use of mouthguards during certain sports. The National Federation of State High School Associations recommends mandatory mouth guards in high school football, lacrosse, ice hockey, field hockey, and wrestling. In the case of wrestling, a mouth guard is required only if the wrestler has braces. The American Dental Association recommends mouth guard use for several other sports.

Prognosis

Many dental disorders are preventable either on a primary or secondary level. Dentists can restore and repair more advanced dental disease and significant dental trauma, assuming a child has access to dental care, and ideally, has a dental home, in which an ongoing relationship exists involving the dentist, child, and parents or guardians.

Pediatric primary care physicians play an essential role in optimizing their patients' lifelong oral health by incorporating an examination of the teeth and oral structures into every physical examination, making timely referrals for prevention and in cases in which pathology is identified, including oral health prevention as part of each well-child care visit, and advocating for quality professional dental care for all patients.

CASE RESOLUTION

The parents of the infant should be reassured that the absence of teeth in their 9-month-old daughter is normal. Her first tooth may not appear for a few months. Provided she is growing and developing normally, there is no cause for concern.

CHAPTER 32

Normal Development and Developmental Surveillance, Screening, and Evaluation

Geeta Grover, MD, FAAP, and Jeanne Anne Carriere, PhD

CASE STUDY

The parents of a 12-month-old girl are concerned that she is not yet walking. They report that she sat independently at 7 months and began crawling at 8 months. She can pull herself up to stand while holding on to furniture but is not cruising. Her birth and medical history are unremarkable. The physical examination is within normal limits, and review of your records reveals no concerns on a developmental screening test administered at 9 months of age.

Questions

1. How is developmental delay in children defined?
2. What are the 5 major domains in which development is assessed?
3. How should you advise the parents in the case study about the acquisition of gross motor skills, such as walking?
4. What developmental screening tests could you administer to further assess her development?
5. What is the appropriate next step for the child with suspected developmental delay?

Development refers to the acquisition of functional skills during childhood. Monitoring the growth and development of children is an integral part of the assessment of pediatric patients. Recording the acquisition of developmental milestones provides a systematic approach by which to observe the progress of children over time. For ease of monitoring, these developmental milestones may be divided into 5 major domains or areas: gross motor, fine motor, language, social-emotional, and cognitive.

Four principles apply to all aspects of development. First, motor development is a continuous process that proceeds in the cephalocaudal direction and parallels neuronal myelination; therefore, developmental milestones reflect the maturation of the nervous system. Second, the sequence of development is the same in all children, but the rate of development may vary from child to child; for example, all children must walk before they run, but the age at which a child walks or runs varies from child to child. Third, the rate of attainment of milestones in 1 area may not parallel that in another. Fourth, certain primitive reflexes must be lost before corresponding voluntary movements can be attained (eg, the asymmetric tonic neck reflex must disappear before a child can roll over).

Pathophysiology

Development is influenced by biologic and environmental factors. Biologic factors, such as genetics, preterm birth, exposure to drugs in utero, or the presence of chronic disease, may place a child at increased risk for developmental problems and delays. Environmental factors that influence development include parental attitudes and actions, sociodemographic factors, and cultural and societal influences. The quality of parental stimulation may influence the rate of acquisition of certain skills, especially cognitive and language abilities in preschool-age children. Poverty and other socioeconomic factors may make it difficult for parents to provide their children with an optimal environment for growth and development. For example, research has found significant disparities in vocabulary and language processing between infants from families of higher– and lower–socioeconomic status (SES) as early as 18 months. Children from families of higher SES tend to have larger vocabularies at 2 years of age and score higher on language and cognition testing in elementary school. Processing speed is critical to language and cognitive development, because the faster children process (ie, understand) a word they have heard, the more cognitive energy they can put

into other parts of communication. Fortunately, regardless of SES, parents who consistently engage in language-rich activities with their infants and young children can help their children learn more quickly.

Development in Newborns and Infants

Normal, full-term newborns enter the world capable of responding to visual, auditory, olfactory, oral, and tactile stimuli. They can be quieted and can even soothe themselves. Newborns can signal needs (eg, crying when hungry or wet), but they have a limited ability to respond to caregivers, primarily exhibiting disorganized and seemingly purposeless movements when stimulated. The newborn's reflexive generalized symmetric movements (eg, arm waving and kicking) in response to environmental stimuli are eventually replaced by cortically mediated voluntary actions in older infants and children. Additionally, in newborns, certain primitive reflexes can be elicited by appropriate peripheral stimuli. Eventually, primitive reflexes are replaced by reactions that allow children to maintain postural stability in response to a variety of sensory inputs (ie, proprioceptive, visual, vestibular).

Primitive reflexes are mediated by the brain stem; they are involuntary motor responses that are elicited by appropriate peripheral stimuli and are present at birth but disappear during the first 6 months after birth. Normal motor development seems to be related to the suppression of these reflexes (Figure 32.1). Persistence or reappearance of these reflexes may indicate the presence of brain damage. Postural reactions, which are ultimately smoothly integrated into adult motor function (Figure 32.1), appear between 2 and 9 months of age. *Postural reactions* help maintain the orientation of the body in space and the interrelationship of 1 body part to another. The 3 major categories of postural reactions are righting, protection, and equilibrium.

The profile generated by combining primitive reflexes and postural reactions can be used to monitor the course of normal development and identify cases of problematic development. Persistence of primitive reflexes or failure of development of postural reactions can signal developmental problems. Authorities estimate that more than 70 primitive reflexes and postural reactions exist. Researchers do not agree on which of these reflexes or reactions are the most useful in the monitoring of development. The 7 most commonly used primitive reflexes are described in Box 32.1, and select postural reactions are presented in Box 32.2.

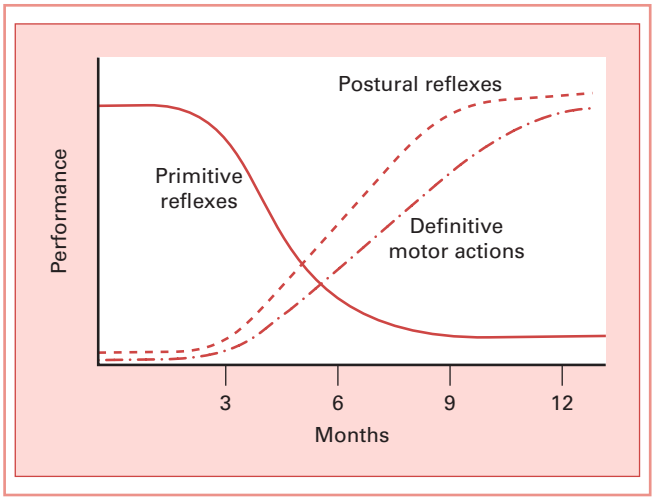

Figure 32.1. Primitive reflex profile.

Normal Development

A developmental assessment should include an evaluation of milestones in each of the 5 major domains. *Gross motor skills* are overall movements of large muscles (eg, sitting, walking, running). *Fine motor skills* involve use of the small muscles of the hands, the ability to manipulate small objects, and eye-hand coordination. *Language skills* involve hearing and include understanding and use of language as well as nonverbal communication skills. *Social-emotional skills*

Box 32.1. The 7 Most Commonly Used Primitive Reflexes

Moro Reflex
- Allowing the baby's head to drop back suddenly results in abduction and upward movement of the arms, followed by adduction and flexion. This reflex disappears by 3–6 months of age.

Rooting Reflex
- Touching the corner of the baby's mouth results in lowering of the lower lip on the same side and movement of the tongue toward the stimulus. This reflex disappears by 3–4 months of age.

Sucking Reflex
- Placing an object in a baby's mouth causes vigorous sucking. This reflex disappears at approximately 3 months of age.

Grasp Reflex
- Placing a finger in a baby's palm causes the baby to grasp it; the baby reinforces the grip as the finger is drawn upward. A similar response is seen in the foot grasp. The palmar grasp reflex disappears by age 3–4 months and is replaced by intentional grasping by age 4–6 months; plantar grasp may be present up to 9–12 months of age.

Placing Reflex
- Stroking the anterior aspect of the tibia against the edge of a table results in the lifting of the baby's leg to step onto the table. This reflex disappears by 2 months of age.

Stepping Reflex
- Holding the baby upright and slightly leaning forward produces alternating flexion and extension movements of the legs that simulate walking. This reflex disappears by 2 months of age.

Asymmetric Tonic Neck Reflex
- With the baby lying supine, turning the head to 1 side results in extension of the extremities on that side and flexion of the opposite extremities (ie, fencing position). This reflex disappears by 3–4 months of age and allows for rolling.

Box 32.2. Select Postural Reactions

Righting Reactions

- These allow the body to maintain normal postural relationships of the head, trunk, and extremities during all activities. The different reactions appear at different ages, beginning shortly after birth and occurring up to 12 months of age.

Protection and Equilibrium Reactions

Protective Equilibrium Response

- When gently pushed toward one side while in a sitting position, infants increase trunk flexor tone toward that side to regain their center of gravity and extend the arm on the same side to protect against falling. This response usually emerges at about 4–6 months of age.

Parachute Reactions

- When held in ventral suspension and suddenly lowered (downward parachute), infants extend their arms as if to protect themselves from a fall; similar reactions are seen with forward and backward stimulation. These reactions appear at 8–9 months of age.

involve attachment, socialization, and the ability to regulate emotions. *Cognitive skills* involve the ability to use higher mental processes, including comprehension, memory, problem-solving skills, critical thinking, and logical reasoning.

Table 32.1 outlines the normal pattern of development for each of these domains. The table lists the average age of attainment of these skills as well as the normal ranges as available. Development is an orderly and sequential process, and children must proceed through several stages before any given milestone is attained. Therefore, the physician should document not only *what* a child can do but *how* the child does it. For example, to sit without support, children first achieve head control. Several stages later they can sit in a "tripod" position with arms extended in front for support, and finally, they sit with the head steady and back straight without support (Figure 32.2).

Gross Motor Skills

During the first year after birth, the ultimate goal of gross motor development is walking. The first developmental skill toward this goal is head control; by 4 months of age there should be no head lag when a child is pulled to sitting from a supine position. By 6 months of age, children can sit without support for a few seconds. At 9 to 10 months of age, children can pull themselves to a standing position, and by 12 to 18 months of age, they can walk. Children then learn to run, use stairs, hop on 1 foot, and skip—in that order.

Fine Motor

Development of the 2-finger pincer grasp is the major goal of fine motor development during the first year (Figure 32.3). The hands primarily remain in a fisted position until 3 months of age. Infants also discover the midline at this age, and shortly thereafter they may play with their hands in the midline. At age 4 months, children begin reaching for desired objects; by 6 months of age, they can transfer an object from 1 hand to the other. By 7 months, they have a 3-finger pincer grasp, and by 9 to 10 months, they have developed the 2-finger grasp, which allows them to manipulate small objects, such as raisins. By 14 months, they begin to scribble, and by 3 to 5 years, they can copy geometric shapes. Children with early preference for the use of 1 hand over another, especially before approximately 18 months of age, should be assessed for the presence of paresis or other neuromuscular problems. Handedness may manifest by 3 years but often is not firmly established until 4 to 5 years of age.

Language Skills

The development of normal speech and language skills is discussed in Chapter 33.

Social-Emotional Skills

These skills enable children to interact and respond to the surrounding world. Deficits in the development of age-appropriate social skills/social relatedness (eg, social orienting, social referencing, joint attention, pretend play) are a defining feature of autism spectrum disorder (ASD; see Chapter 132). For children on this spectrum, the development of social skills is characteristically "out of sync" with their overall level of functioning. Joint attention is the inclination to share enjoyment, interests, or achievement with other people, and like other developmental skills, it seems to manifest in graduated stages. Early skills include reciprocal smiling at the sight of a familiar person, followed by later emerging skills, such as the ability to isolate one's index finger and point with a coordinated gaze by 12 to 15 months of age. Lack of joint attention is a core deficit of ASD.

Cognitive Skills

These abilities allow children to think, reason, problem-solve, and understand the surrounding environment. *Information processing theories* address how individuals acquire, interpret, and remember information and how these abilities develop. Cognitive development involves gradual changes in these processes. Infants are born with some sensory and perceptual capabilities. Newborns are drawn to both novel and social stimuli, especially from their caregiver; these stimuli support further sensory and perception development as well as social and language development. As children develop, their attention span increases, they more efficiently process information, and they are better able to plan and direct their actions toward goals. Additionally, their knowledge base grows and becomes more integrated. These developments allow them to be more efficient learners as they age.

A child's perception and understanding of the world, including the understanding of pain, disease, and illness, are guided by the child's stage of cognitive development. The concept of object permanence or object constancy, the realization that objects may exist even if they cannot be seen, develops at approximately 7 to 9 months of age. The understanding of time comes much later. Children develop the concept of "today" at 24 months of age, "tomorrow" at 30 months, and "yesterday" at 36 months.

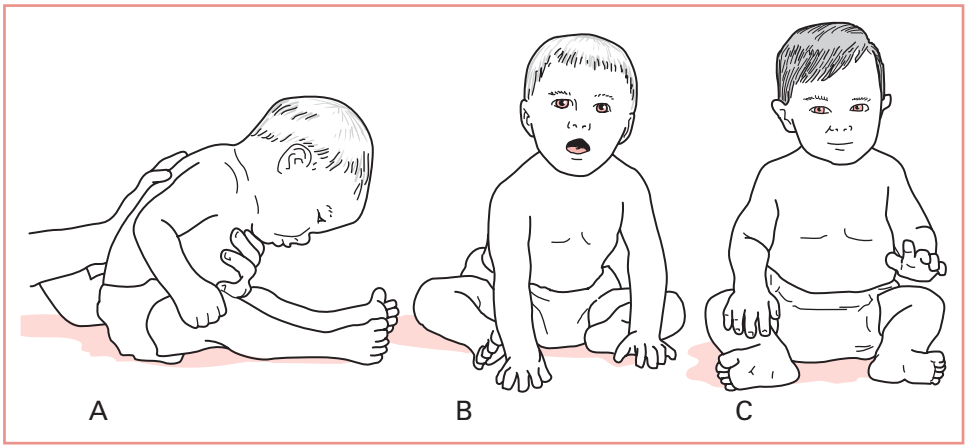

Figure 32.2. Stages in the development of sitting. A, Head control. B, "Tripod sitting." C, Head steady and back straight without support.

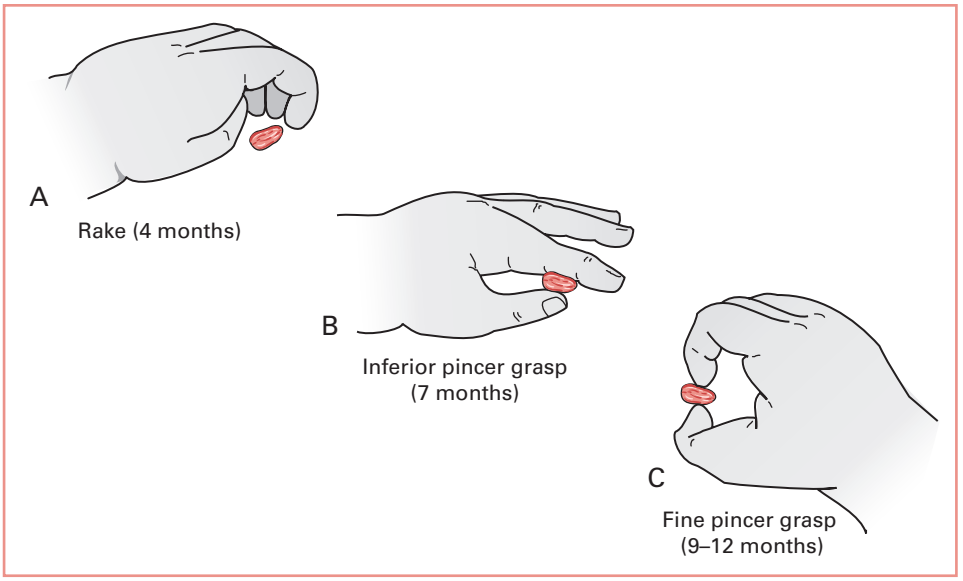

Figure 32.3. Development of the pincer grasp. A, Rake (4 months). B, Inferior pincer grasp (7 months). C, Fine pincer grasp (9–12 months).

Table 32.1. Normal Pattern of Development

Domain	*Description*	*Mean Age*	*Normal Range*
Gross motor skills	Reflex head turn; moves head side to side	Newborn	0–3 months
	Lifts head when prone	1 month	1–4 months
	Lifts shoulders up when prone	2 months	1–4 months
	Lifts up on elbows; head steady when upright	3 months	2–5 months
	Lifts up on extended hands; rolls front to back; no head lag when pulled to sitting from supine position	4 months	3–6 months
	Rolls back to front	5 months	4–7 months
	Sits independently	6 months	5–9 months
	Crawls on hands and knees	8 months	6–11 months
	Pulls to stand	9 months	6–12 months
	Cruises	11 months	9–14 months

Table 32.1. Normal Pattern of Development *(continued)*

Domain	*Description*	*Mean Age*	*Normal Range*
Gross motor skills (*continued*)	Walks	12 months	9–17 months
	Walks backward	15 months	13–17 months
	Runs	15 months	13–20 months
	Kicks a ball	24 months	18–30 months
	Walks up and down stairs using railing and putting both feet on each step; jumps with both feet off the ground; throws a ball overhand	24 months	—
	Pedals a tricycle; goes up stairs alternating feet without using the railing; balances on 1 foot for 3 seconds	3 years	30–48 months
	Hops on 1 foot 2–3 times; gallops	4 years	—
	Skips; walks down stairs using the railing and alternating feet	5 years	—
	Tandem walks	6 years	—
Fine motor	Tracks horizontally to midline	1 month	—
	Tracks past midline; tracks vertically	2 months	1–3 months
	Not fisted for >50% of the time; tracks 180°; visual threat; discovers midline	3 months	3–4 months
	Reaches for bright object; brings object to mouth	4 months	—
	Transfers object from 1 hand to the other	6 months	4–7 months
	3-finger pincer grasp	7 months	6–10 months
	Neat pincer grasp	9 months	7–12 months
	Bangs cubes in midline	9 months	7–11 months
	Tower of 2 cubes; scribbles spontaneously	14 months	14–20 months
	Drinks from a cup	15 months	10–18 months
	Uses a spoon, spilling a little	15 months	12–18 months
	Tower of 4 cubes	18 months	17–24 months
	Copies vertical and horizontal line; tower of 6 cubes	2 years	—
	Copies circle; strings beads; imitates a bridge of cubes	3 years	—
	Copies square; ties single knot; cuts basic shapes with scissors	4 years	—
	Copies triangle; draws person with 3 parts; writes first name	5 years	—
	Draws diamonds; draws person with 6 parts; forms letters correctly; creates and writes short sentences	6 years	—
Language skills[a]	Alerts to sound	Newborn	—
	Searches with eyes for sound	2 months	—
	Cooing (vowel sounds)	3 months	1–4 months
	Orients to sound/turns to voice; laughs	4 months	3–6 months
	Responds to name	4 months	4–9 months
	Babbles (consonants added to vowel sounds)	6 months	5–9 months
	Dada/Mama nonspecific	8 months	6–10 months
	Understands the word "no"	10 months	9–18 months
	Dada/Mama specific	10 months	9–14 months
	Follows 1-step command with gesture	12 months	10–16 months
	3–5–word vocabulary	12 months	—
	Follows 1-step command without gesture	15 months	12–20 months
	Points to several body parts; points to self	18 months	12–24 months
	≥50-word vocabulary (50–300 words); refers to self by name	2 years	—

(continued)

Table 32.1. Normal Pattern of Development *(continued)*

Domain	*Description*	*Mean Age*	*Normal Range*
Language skills[a] (*continued*)	2-word phrases; uses pronouns indiscriminately; follows 2-step command with gesture	2 years	20–30 months
	≥200-word vocabulary (200–1,000 words); uses 3-word sentences; speech intelligible to strangers 75% of time; uses pronouns appropriately	3 years	—
	Complex sentences using more than 1 action word (eg, "I lost my balloon because I let go"); 100% intelligible speech to strangers although may have articulation errors; points to several colors, letters and numbers when named; rote counts to 4	4 years	—
	Retells short stories with clear beginning, middle, and end; uses ≥2,000 words; produces rhyming words; rote counts to 10	5 years	—
	Knows days of the week; describes events in order	6 years	—
Social-emotional skills[b]	Regards face	Newborn	—
	Spontaneous social smile	6 weeks	1–3 months
	Discriminates social smile; relates to parent with real joy	6 months	—
	Displays stranger anxiety; plays peek-a-boo	7 months	6–9 months
	Gaze monitoring (follows adult gaze shift when adult looks away)	8 months	—
	Uses pointing to draw attention to (ie, protodeclarative) or request (ie, protoimperative) an object of interest	—	9-12 months
	Joint attention (uses 3-point gaze shifts and follows the gaze of another)	—	12–15 months
	Shows empathy (eg, looks sad when someone else cries); seeks help from adults	15 months	—
	Simple pretend play (eg, feeding doll)	18 months	17–22 months
	Helps with undressing; washes and dries hands; parallel play	2 years	22–30 months
	Undresses self; beginning to take turns	3 years	30–40 months
	Toilet training	—	24–36 months
	Imagines self as different characters; cooperative play	—	3–4 years
	Dresses without assistance; has a group of friends	5 years	—
Cognitive skills: infancy[c]	Approaches world through sensations and motor actions; attention drawn to complex or novel stimuli; growing awareness of cause and effect; development of *object permanence* (ie, awareness that object exists when removed from view); emergence of symbolic thought	—	Newborn–2 years
Cognitive Skills: early childhood	Rapidly developing language skills; limited perspective taking ability; increases in social play; ability to recall past events; growing ability to sustain attention to preferred activities	—	2–6 years
Cognitive skills: middle childhood	Able to understand that personal thoughts and feeling may differ from those of others; conservation of mass, volume, and number (eg, realization that amount stays the same if nothing is added or taken away); ability to perform mental operations if they relate to real objects; begins formal automatization of basic academic skills (eg, math facts, sight-word recognition); increased ability to focus on important information and ignore irrelevant information; use of rehearsal as the primary learning strategy	—	6–10 years
Cognitive skills: early adolescence	Able to attend to a task for an hour or more; beginning ability to engage in abstract thought and symbolic reasoning; emerging ability to use intentional learning strategies	—	10–14 years
Cognitive skills: late adolescence	Able to attend to a single task of interest for long periods; extensive and moderately integrated knowledge; more sophisticated ability to engage in abstract thought and symbolic reasoning; increasing use of self-regulatory learning strategies (eg, goal setting)	—	14–18 years
Miscellaneous cognitive milestones	Concept of today	24 months	—
	Concept of tomorrow	30 months	—
	Concept of yesterday	36 months	—
	Concept of right and left	7 years	—

[a] Detailed language milestones are presented in Chapter 33, Table 33.1.

[b] For play and social pragmatic milestones, refer to Chapter 33.

[c] Cognitive milestones adapted from constructivist theories of Jean Piaget, Lev Vygotsky, and information processing theorists.

Developmental Delay

Children are said to be developmentally delayed if they do not reach developmental milestones within the expected age range. The age ranges for these milestones are broad because of the wide variation among typically developing children. Children with global developmental delays have delays in multiple domains. Children can also have a specific delay in 1 area, such as expressive language or gross motor. Development across domains is often intertwined. Delays in 1 area can affect development in other domains. For example, a child with an expressive language delay may also demonstrate delays in social development because of limited communicative interaction with peers.

Differential Diagnosis

Three factors are involved in the differential diagnosis of children with developmental delays: determination of the area or areas of development in which delay is apparent; if motor delay is evident, determination of whether the condition is progressive or nonprogressive; and assessment for whether developmental milestones previously achieved are lost or if age-appropriate milestones were achieved at all.

The child with an early history of normal development who subsequently experiences a slowing of developmental progression, often associated with cognitive delays or seizures, may have a metabolic defect. The child who attains developmental milestones and subsequently loses them may have a neurodegenerative disease (eg, multiple sclerosis, adrenoleukodystrophy) or a lesion of the spinal cord or brain. The presence of habitual rhythmic body movements (eg, body rocking, head banging) may be a sign of a pervasive developmental disorder, such as ASD.

Cerebral palsy, the classic example of nonprogressive motor abnormality, is a form of static encephalopathy that is characterized by abnormal movement and posture. The type of cerebral palsy depends on which area of the brain is injured. Spastic cerebral palsy, which is the most common type, is secondary to upper motor neuron injury. The ataxic form of the disease is related to lesions of the cerebellum or its pathways. *Dyskinetic cerebral palsy* manifests as uncontrolled and purposeless movements that often result from a basal ganglia lesion (eg, athetosis after bilirubin deposition in the basal ganglia). Onset of symptoms is in infancy or early childhood. The key factor in making the diagnosis is establishing that the motor deficits are static and not progressing.

Evaluation

When evaluating children for possible delays in development, it is important to remember that a great deal of variation exists in the age of attainment of milestones. Additionally, the rate of acquisition of milestones in 1 area of development may not parallel that in another. Routine and ongoing assessment of a child's level of development at all periodic health maintenance visits through observation, history, physical examination, and screening tests allows the physician to form a longitudinal view of the child. The physician is thus able to identify and differentiate true deficits and delays from temporary setbacks.

History

Evaluation of children for suspected delays in development includes a complete history (Box 32.3). Family history of birth defects, childhood deaths, intellectual disability, speech delay, learning disability, and known genetic conditions (eg, fragile X syndrome) should be obtained. Perinatal factors that place children at high risk for developmental difficulties include a history of maternal drug or alcohol use during pregnancy, preterm birth of the child, and congenital infections. Preterm infants are at increased risk for developmental, behavioral, and learning disorders compared with children born at term. Although no formal guideline exists about the specific duration of time that gestational age correction should be performed for preterm infants for attainment of developmental milestone relative to term infants, most experts recommend correcting for preterm status for the first 24 months after birth. Other historical risk factors for developmental delay include history of seizures, sepsis, or meningitis; exposure to lead or other toxins; and poor feeding or growth. Environmental factors, such as stressful home conditions, history of abuse or neglect, and lack of stimulation, may also contribute to delayed development.

Physical Examination

Height and weight should be checked. Abnormal growth (ie, height or weight <5th percentile or head circumference <5th percentile or >90th percentile) may be a marker for developmental delay. The presence of congenital anomalies (eg, cataracts, hypertelorism, spina bifida) or neurocutaneous lesions (eg, café au lait spots) may be suggestive of chromosomal anomalies or other genetic diseases. Neuromuscular examination should emphasize age-appropriate milestones. Abnormalities in muscle tone (eg, hypotonia, hypertonia), bulk, or strength may be clues to the presence of neuromuscular disease (eg, muscular dystrophy), cerebral palsy, or Down syndrome.

Box 32.3. What to Ask

Normal Development in the Pediatric Patient

- Has anyone in the child's family had developmental problems or delays, or been diagnosed with learning disability, intellectual disability, or a known genetic condition?
- Did the mother use any drugs (illicit or prescription) or alcohol during pregnancy?
- Did the mother or father use illicit drugs or prescription medications prior to conception?
- Was the child born preterm?
- Does the child have a history of seizures?
- Has the child had meningitis or sepsis?
- Does the child have any history of not feeding well or of poor growth?
- Is the child's home environment characterized by any stressors (eg, new sibling, divorce, limited financial resources, homelessness)?

Laboratory Tests

Age-appropriate assessment of the child's vision and hearing should be performed if signs of motor, cognitive, or language delays are apparent. Chromosomal studies may be conducted if dysmorphic features are noted on the physical examination. Evidence of cognitive or motor delays may warrant metabolic studies (eg, organic and amino acids). Imaging studies of the head, such as magnetic resonance imaging or electroencephalography, may be necessary if the child has a history of seizures or an abnormal neurologic examination.

Developmental Surveillance, Screening, and Evaluation

Early detection of developmental delays is a responsibility of all pediatric health care professionals. Unfortunately, current detection rates of developmental disorders are lower than their actual prevalence. Approximately 20% of children between the ages of 3 and 17 years will have 1 or more developmental, learning, or emotional disorder, with 4% to 5% having developmental delays. Without the use of specific developmental screening tools, only approximately 30% of developmental disabilities are identified; however, with the use of screening tools this identification rate increases to 70% to 80%.

Developmental surveillance, the ongoing process of monitoring an individual child's developmental status, should be incorporated at each health maintenance visit. Surveillance involves eliciting and attending to parental concerns about the child's development and usually involves age-specific queries, such as whether the child is walking, talking, or pointing. Surveillance has been referred to as a sort of developmental growth chart. Recognition of the child who may be at risk of developmental delays is the goal of developmental surveillance.

Developmental screening is the administration of a brief standardized tool to identify the child at risk of a developmental disorder. Table 32.2 lists frequently used developmental screening tools. Screening is based on either parental report or direct observation and interaction with the child, and use of screening tools can increase the accuracy of clinical judgement. Developmental screening tools are not diagnostic; rather, they serve as a quick and effective means of identifying children who need further evaluation. A formal developmental screening should be performed when developmental surveillance elicits a risk factor for developmental delay; in the absence of established risk factors or parental concerns, the American Academy of Pediatrics (AAP) recommends that health professionals screen children for general development using standardized, validated tools at the 9-, 18-, and 24- or 30-month health maintenance visits. These instruments can be administered at other times if there are clinical concerns. The AAP further recommends that in addition to a general developmental screening tool, an ASD-specific screening tool should also be administered at the 18- and 24-month visits. Periodic screening is necessary to detect emerging disabilities as children grow. Screening instruments should have a broad developmental focus and be brief, inexpensive, valid, and reliable. A failed screening test should result in a referral for further developmental evaluation.

Developmental evaluation (ie, developmental assessment) is performed when surveillance or screening identifies a child as being at high risk for a developmental disorder. The aim is to identify the specific developmental disorder or disorders affecting the child. Developmental evaluation is performed by trained examiners. Unlike developmental screening, developmental evaluation is diagnostic.

The *Bayley Scales of Infant and Toddler Development®, 3rd Edition* (*Bayley-III®*), first published in 1933 by Nancy Bayley, is among the most commonly used developmental evaluation tools. It has 5 distinct scales yielding scores for 5 developmental domains: cognitive, language, motor, social-emotional, and adaptive behavior. The *Bayley-III* may be used for children 1 to 42 months of age. Especially before age 24 to 30 months, developmental tests such as the *Bayley-III*, which emphasize sensorimotor-based skills, have a poor correlation with later measures of intelligence, which emphasize language and abstract reasoning. Thus, developmental tests are best used as measures of current developmental functioning rather than as predictors of future functioning.

Intelligence tests, achievement tests, adaptive skills assessment (ie, age-appropriate skills necessary to take care of oneself and to interact with others), and behavior rating scales exist that may be used for preschool- and school-age children with suspected behavioral concerns, social-emotional concerns, learning disorders, or developmental disabilities, including intellectual disability. Delays in both cognitive skills and adaptive functioning must be present during the developmental period to make a diagnosis of *intellectual disability*.

Typical, or normal, development varies significantly; however, certain red flags, or warning signs, of developmental delay exist that warrant further monitoring or evaluation. Early detection can result in early intervention, which improves a child's chances of healthy or positive outcomes. Language development is discussed in more detail in Chapter 33, but it is important to note some red flags of language development that necessitate referral for a full evaluation, which include no babbling, no response to name, or no reciprocal gestures (eg, showing, reaching, waving) by 12 months of age; no single words by 16 months of age; and vocabulary of 50 words or less or no non-echolalic 2-word phrases by 24 months. Social-emotional development typically correlates with language development. A lack of sharing of vocalizations, back-and-forth smiles, or other facial expressions at 9 months of age; a lack of pointing to desired objects by 15 months of age; a lack of imitating actions by 2 years; or a lack of engagement in pretend play by 3 years warrants further evaluation. Motor development red flags include an inability to sit by 9 months of age, an inability to stand or bear weight at 12 months, an inability to independently walk by 18 months, frequent falling at 3 years, or poor balance at 5 years. Developmental skill regression or marked stagnation in any of the domains is a red flag and warrants further evaluation.

Management

The child with identified developmental delay in 1 or more areas should be referred to the appropriate specialist, agency, state program, or public school district (≥3 years of age) for further testing and assessment. Detailed neurologic examination may be necessary

Table 32.2. Frequently Used Developmental Screening Instruments

Assessment Type	*Instrument*	*Patient Age on Administration*	*Languages*
Parent report	Ages & Stages Questionnaire, Third Edition (ASQ-3)	1 month–5.5 years	English Spanish French Arabic Korean Vietnamese
	Child Development Inventory (CDI)	15–72 months	English Spanish
	Infant Development Inventory	Birth–18 months	English Spanish
	Parents' Evaluation of Developmental Status (PEDS)	Birth–96 months	English Spanish Vietnamese
	Parents' Evaluation of Developmental Status, Developmental Milestones (PEDS:DM)	Birth–84-132 months	English Spanish Vietnamese
	Modified Checklist for Autism in Toddlers (M-CHAT)	16–48 months	Translations in >50 languages
Direct observation and interaction with the child	Battelle Developmental Inventory, 2nd Edition (BDI-2)	Birth–95 months	English Spanish
	Bayley Infant Neurodevelopmental Screener (BINS)	3–24 months	English Spanish Portuguese
	Bayley Scales of Infant and Toddler Development®, Third Edition (Bayley-III®)	1–42 months	English
	Brigance® Infant & Toddler Screen	Birth–23 months	English Spanish

if gross motor delays are identified. Language delays may warrant formal hearing and speech-language assessment by an audiologist or a speech language pathologist. Cognitive impairment requires formal psychological assessment. The child aged 3 years or older and with developmental delay may qualify for special education support and services through the child's public school (see Chapter 36).

Prognosis

The pediatrician plays a key role in identifying developmental delay. When delays are observed, the pediatrician should refer for further evaluation early. Early identification of children with developmental delays is critical because it allows for early intervention. The prognosis for children with specific or global developmental delays can be greatly improved with participation in early intervention stimulation programs. Identification and management of underlying disease (eg, hypothyroidism, infection) also prevents further damage. Referring families to their state's early intervention programs can greatly stimulate the developmental potential of the child. The pediatrician can ensure that children with specific or global developmental delays receive timely support and intervention by performing developmental surveillance at each health visit and encouraging parents or caregivers to monitor milestones between visits.

CASE RESOLUTION

The parents of the child may be reassured that their child is developing normally for her age. Although most children begin walking at approximately 12 months of age, commencement of walking anytime up to age 18 months is considered to be within normal limits. The AAP recommends that standardized developmental screening be performed when developmental surveillance identifies high-risk factors for developmental delay and routinely at the 9-, 18-, and 24- or 30-month health maintenance visits. Administration of a formal screening tool is likely not necessary at this visit but can be considered again at the 15-month visit if lack of progression in the child's gross motor skills is noted or if any other risk factor is identified at that time.

CHAPTER 33

Speech and Language Development: Normal Patterns and Common Disorders

Geeta Grover, MD, FAAP, and Michelle L. Wahlquist, CCC-SLP

CASE STUDY

The parents of a 3-year-old girl bring her to see you. They are concerned because their daughter has only an 8- to 10-word vocabulary, and she does not put words together into phrases or sentences. They report that she seems to have no hearing problems; she responds to her name and follows directions well.

In general, she has been in good health. Aside from delayed speech, her development is normal. During the physical examination, which is also normal, the girl does not speak.

Questions

1. What expressive language skills should a child have by age 3 years?
2. Approximately how many words should 3-year-olds have in their vocabulary?
3. By what age should children's speech be intelligible to strangers at least 75% of the time?
4. What factors may be associated with delayed speech development?
5. What tests are used to assess children's hearing, speech, and language development?

The ability to communicate through language is a uniquely human skill. It develops in a predictable, orderly sequence, beginning in infancy with nonverbal forms and eventually progressing to the use of verbal language. When discussing the development of a child's communication skills, professionals often use the terms "speech" and "language." *Speech* refers to the articulation and production of speech sounds within the mouth, whereas *language* involves comprehension and expression; language is the understanding and use of words, phrases, and gestures to convey intent. Normal hearing is essential to the development of both speech and language.

Language is often thought of as encompassing 2 components: receptive language and expressive language. *Receptive language* refers to the ability to understand others, whereas *expressive language* is the ability to produce communication to convey meaning to others. Although most people think of language simply in terms of only receptive and expressive language, several other critical components of language development must be present for a child to develop effective communication. These include joint attention, play, and social-pragmatic language.

The development of normal speech and language skills is an important developmental milestone that is eagerly awaited by parents. Normal patterns of language development should be as familiar to pediatricians as all other aspects of child development (see Chapter 32), thereby allowing for early identification and referral for suspected delays.

The development of language skills in a normal sequence but at a slower pace than normal is referred to as *language delay;* language delays may affect only expressive language or both receptive and expressive language (eg, a mixed receptive-expressive language delay). An atypical sequence of language skill acquisition is referred to as a *language disorder*. Children with developmental language disorders have persistent and significant limitation in their ability to receive or express language.

Epidemiology

The prevalence of specific language impairment in school-age children with no hearing loss or obvious genetic or neurologic condition is approximately 7%. Speech and language disorders are more common in boys than girls and in children with a family history of language, speech, or reading disorders. Good evidence exists that early language impairment is associated with later difficulties learning to read.

Clinical Presentation

Lack of response to sound at any age, difficulty following directions, failure to achieve age-appropriate expressive language skills, reduced eye gaze or gesture, and parental concern about a child's hearing are the most important signs of hearing or language impairment. Deaf infants coo normally and may even babble; thus, an infant's vocalizing does not preclude hearing loss.

Pathophysiology

The left hemisphere of the brain is responsible for language skills in 94% of right-handed adults and in approximately 75% of left-handed adults. Peripheral auditory stimuli are transmitted to the primary auditory areas in both temporal lobes. Sounds then undergo a series of analyses, primarily in 3 main areas in the left cerebral cortex: the Wernicke area (ie, auditory association area), which is responsible for language comprehension; the Broca motor speech (ie, motor encoding) area, which is responsible for the preliminary conversion of language into motor activity; and the primary and supplementary motor cortices, which control the movements necessary for speech. This complex process is responsible for the comprehension and production of language.

For children to be successful communicators, they must be competent in all 5 critical domains of language development—joint attention, play, receptive language, expressive language, and social-pragmatic language—which are discussed herein in order of developmental progression by timing of acquisition (Figure 33.1). Additionally, a brief description of speech sound production, which also is important for successful communication, is provided.

The foundation of language development begins with eye contact, social smiling, and the ability to share attention with others, that is, *joint attention*. Use of eye gaze provides children with their first experiences with shared meaning, which is crucial to language development. Each time children look at their parent, they are provided with language learning opportunities. While looking at their parents, children begin to recognize and understand the meaning of nonverbal communication, including facial expressions and gestures. While watching a parent's mouth, they observe how speech sounds are formed. In using eye gaze, children begin to build a relationship and attachment to their parents, providing future motivation to want to communicate. Joint attention is a more advanced form of eye gaze that develops by 12 to 15 months of age. It includes sharing attention by alternating eye gaze between an object of interest, a communication partner, and back to the object. It also involves following the attention of another (eg, following the eye gaze or point of another person). Without a strong foundation in joint attention, a child will have challenges in all other language learning.

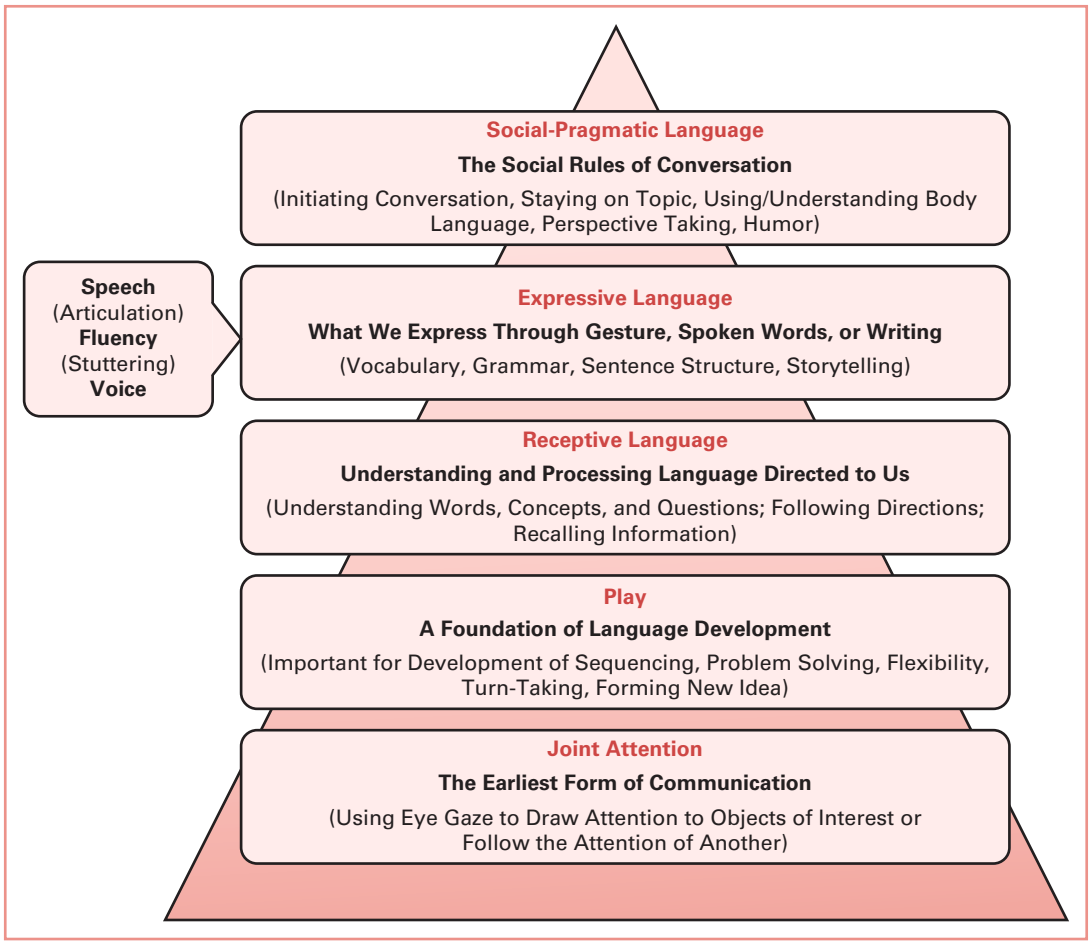

Figure 33.1. Progression of language development through the 5 domains: joint attention, play, receptive language, expressive language, and social-pragmatic language.

Children's language skills evolve primarily through parent-child interactions such as singing, reading, and play. It is within play that children learn early vocabulary, language concepts (eg, big, little, fast, slow), problem solving, organization, turn-taking, and sequencing, all of which are required for successful language use.

The ability to understand the communication of others is called *receptive language*. Early receptive milestones refer to ability to hear and respond to sound (eg, look toward a rattle being shaken), whereas later milestones reflect ability to understand spoken words, follow directions, recall spoken information, and understand questions. In typical language development, receptive language is more advanced than expressive language. Children must understand a concept before they can verbally express that same concept.

The means by which children express their thoughts and ideas through gesture, spoken words, and written communication is called *expressive language.* Early expressive milestones relate to speech production of vowels and simple consonants (eg, cooing, babbling); later, children begin to express themselves with gesture. Eventually, children use expressive language to convey their intent to others through single words; short phrases; simple sentences, including grammatical structures (eg, past tense ["-ed"]); and eventually in organized storytelling.

Social-pragmatic language refers to the way in which language is understood and used in a social context. It is the "unspoken," social rules of conversation. Development of social-pragmatic language is a long-term process that begins in infancy with a child's use of eye gaze, gesture, vocalizations, and single words to communicate with others for a variety of reasons (eg, to request, to comment, to protest, to show off, to share information). Important early milestones presenting between 9 and 12 months of age include protoimperative pointing (to request) and protodeclarative pointing (to show). Social-pragmatic language skills continue to develop and become more refined into late adolescence. Later developing skills include understanding and use of appropriate body language, initiating and maintaining conversation, staying on topic, taking the perspective of others, and using humor. Social-pragmatic language deficits are a core feature of autism spectrum disorder (ASD). Because ASD currently affects 1 in 59 children, all health professionals should be mindful of social-pragmatic language development and deficits (see Chapter 132).

For children to use language to communicate effectively, they must be intelligible to others. *Speech sound production*, which often is called "articulation," refers to how a child uses the structures of the mouth to produce speech sounds. Like language, speech sounds follow a developmental progression. Speech disorders include problems in the production of speech sounds. Speech disorders may affect articulation (ie, phonologic disorders), motor planning (ie, childhood apraxia of speech), motor strength (ie, dysarthria), fluency (ie, stuttering), or voice (ie, quality, tone, pitch, volume). By 3 years of age, a child should be at least 75% intelligible to strangers. By 4 years of age, a child should be 100% intelligible, although speech production errors (eg, "wabbit" for *rabbit*) may persist. This reflects the "rule of 4s," that is, 50% intelligible by age 2 years, 75% by age 3 years, and 100% by age 4 years.

Early language exposure through caregiver-child interaction is vital for the development of communication, cognitive, and academic skills. Earlier research reported that by the time a child is 4 years of age, a difference in word exposure of up to 30 million words may exist between children living in higher socioeconomic environments compared with those living in lower socioeconomic environments. Newer data support this finding when comparing families from socioeconomic extremes (ie, top and bottom 2% of families), although they suggest that the gap may be closer to 4 million words for families in less extreme poverty. Regardless the size, a gap exists between children living in more privileged environments and those living in more impoverished environments. Research also suggests that expressive language vocabulary at age 3 years is predictive of language and reading achievement up to 9 to 10 years of age (see Chapter 34). Knowledge of normal play as well as social-pragmatic, receptive, and expressive language skills is essential to recognition and identification of developmental delays (Table 33.1). Box 33.1 lists "danger signals" that indicate possible delays and serves as a guide for referral to specialists. The American Academy of Pediatrics reports that by age 18 months children should have an expressive vocabulary of 10 to 25 words and at age 24 months children should be using a vocabulary of at least 50 words. It is important to recognize that a vocabulary of 50 words at 24 months is not an average vocabulary size, with some children producing fewer words and some producing more words. Rather, the use of 50 words at 24 months is a minimum single word vocabulary for a child of that age. Literature in the field of speech-language pathology suggests that, on average, children 24 months of age are able to produce 200 to 300 words, with vocabulary expanding to 1,000 words by age 3 years. Thus, if a health professional sees a 24-month-old child who appears to be "struggling" to reach the 50-word milestone, language development should be monitored closely. The presence of additional language concerns or risk factors for language delay or hearing impairment warrants referral to a pediatric audiologist and pediatric speech pathologist. Children must be able to understand and express at least 50 words before they can begin combining words into 2-word combinations. It is important to remember that by age 3 years, 75% of children's speech should be intelligible to strangers.

Differential Diagnosis

The various causes of delayed language development include hearing loss, disorders of central nervous system processing, anatomic abnormalities, and environmental deprivation (Box 33.2). Although birth order (eg, the belief that younger children speak later than firstborn children because older siblings speak for them), laziness (eg, "Don't give him what he wants when he points. Make him ask for it"), and bilingualism are commonly believed to result in speech and language delay, these factors have never been proved to have a contributory role in such delay. For a complete discussion of hearing loss, refer to Chapter 88.

Disorders of central nervous system processing include global developmental delay, intellectual disability, ASD (see Chapter 132),

Table 33.1. Receptive, Expressive, Play and Social-Pragmatic Language Milestones (Birth to 5 Years)

Milestone Type	*Skill*	*Mean Age*	*Normal Range*
Receptive	Alerts to sound	Newborn	N/A
	Orients to sound/turns to voice	4 months	3–6 months
	Responds to name	4 months	4–9 months
	Understands "no"	10 months	9–18 months
	Follows 1-step command with gesture	12 months	10–16 months
	Follows 1-step command without gesture	15 months	12–20 months
	Points to several body parts	18 months	12–24 months
	Follows 2-step command with gesture	24 months	22–30 months
	Understands basic spatial terms (eg, in, on, under)	28 months	27–30 months
	Follows 3-step, unrelated directions	34 months	33–36 months
	Understands basic colors and shapes	42 months	36–48 months
Expressive	Cooing (vowel sounds)	3 months	1–4 months
	Laughs	4 months	3–6 months
	Babbling (consonants added to vowel sounds)	6 months	5–9 months
	Dada/Mama nonspecifically	8 months	6–10 months
	Dada/Mama specifically	10 months	9–14 months
	3- to 5-word vocabulary	12 months	—
	Immature jargoning (ie, gibberish with inflection)	13 months	10–18 months
	Mature jargoning (ie, gibberish with the occasional word)	18 months	16–24 months
	10- to 25-word vocabulary	18 months	—
	≥50-word vocabulary (50–300 words)	24 months (minimum)	—
	2-word phrases	24 months	20–30 months
	Uses pronouns indiscriminately	24 months	22–30 months
	States first name	34 months	30–40 months
	Uses pronouns appropriately (ie, I, you, we, me, they)	36 months	30–42 months
	≥200-word vocabulary (200–1,000 words)	3 years	—
	75% of speech intelligible to strangers	3 years	—
	3-word sentences	3 years	—
	Answers simple "WH" questions (Who, What, Where)	—	3–4 years
	Complex sentences using >1 action word (eg, "I lost my balloon because I let go")	4 years	—
	100% intelligible to strangers but may still have articulation errors	4 years	—
	Names letters or numbers	—	4–5 years
	Says rhyming words	—	4–5 years
	Tells short stories	—	4–5 years
Play[a]	Exploratory play (mouthing, shaking, banging, tapping, and squeezing toys)	—	4–10 months
	Object permanence (finds object completely hidden under blanket) and means-end behavior (pulls string to obtain desired toy)	10 months	9–12 months
	1-step pretend play (eg, pretends to drink from a cup or feed doll with bottle)	18 months	17–22 months
	Imitates housework activities	—	18–21 months
	Parallel play (ie, sharing play space with another child but not necessarily interacting)	24 months	—

Table 33.1. Receptive, Expressive, Play and Social-Pragmatic Language Milestones (Birth to 5 Years) *(continued)*

Milestone Type	*Skill*	*Mean Age*	*Normal Range*
Play[a] (*continued*)	Symbolic object use (pretend 1 object is another [eg, a banana becomes a telephone])	—	24–30 months
	Multiple-step play (eg, mix cake, bake cake, eat, and wash dishes) and imagines self as different characters (eg, firefighter, mom/dad)	—	36–42 months
	Cooperative play (ie, works together with other children for a common play goal)	—	3–4 years
Social-pragmatic[a]	Spontaneous social smile	6 weeks	1–3 months
	Dyadic joint attention (ie, infant and adult take turns exchanging looks, noises, and mouth movements)	8 weeks	6–10 weeks
	Joint attention (ie, uses 3-point gaze shifts and follows the gaze of another)	—	12–15 months
	Takes 2 turns in conversation	27 months	24–30 months
	Verbally expresses emotional and physical feelings (eg, happy, sad, sleepy, hurt)	30 months	25–36 months
	Takes 4–5 turns in conversation	40 months	36–42 months
	Theory of mind (ie, understanding another person's knowledge, beliefs, intentions, and emotions)	4 years	—
	Changes topics appropriately	—	4–5 years

Abbreviation: N/A, not applicable.

[a] Derived from Westby CE. A scale for assessing development of children's play. In: Gitlin-Weiner K, Sandgrund A, Schaefer CE, eds. *Play Diagnosis and Assessment*. 2nd ed. New York, NY: John Wiley & Sons; 2000:15–57.

Box 33.1. Danger Signals in Language Development

- Inconsistent or lack of response to auditory stimuli at any age
- Regression in language or social skills at any age
- No babbling by age 9 months
- No pointing or gesturing by age 12 months
- No intelligible single words by age 16 months
- No joint attention (ie, following the eye gaze of others) by age 15 months
- No 2-word spontaneous phrases by age 24 months
- Inability to respond to simple directions or commands (eg, "sit down," "come here") by age 24 months
- Speech predominantly unintelligible at age 36 months
- Dysfluency (ie, stuttering) of speech noticeable after age 5 years
- Hypernasality at any age
- Inappropriate vocal quality, pitch, or intensity at any age

Box 33.2. Causes of Delayed Language Development

- Hearing impairment
- Perinatal risk factors resulting in hearing impairment
- Disorders of central nervous system processing
  - Global developmental delay
  - Intellectual disability
  - Autism spectrum disorder
- Developmental language disorders
- Disorders of speech production
  - Articulation disorder
  - Dysarthria
  - Verbal apraxia
- Presence of anatomic abnormalities (eg, cleft lip, cleft palate)
- Environmental deprivation

and developmental language problems. Developmental language disorders produce speech or language delays in children in the absence of hearing loss, anatomic abnormalities of the vocal tract, intellectual disability, or global developmental delay. "Late talkers," that is, children with normal comprehension but who simply begin speaking late, have mild developmental language problems. Children who are completely nonverbal have more severe problems.

Anatomic abnormalities may also result in speech and language delays. Cleft palate is the abnormality most commonly associated with difficulties in speech production. Children with cleft palate characteristically have hypernasal speech secondary to velopharyngeal incompetence (eg, dysfunction of the soft palate). Speech sound production can also be affected as children attempt to compensate for their inability to achieve appropriate velopharyngeal closure while speaking. In addition, conductive hearing loss may result from chronic serous otitis media, which is common in children with cleft palate. The presence of a submucosal cleft palate, which is characterized by a bifid uvula, diastasis of the muscles in the midline of the soft palate with intact mucosa, and notching of the posterior

border of the hard palate, should be considered in children without an overt cleft palate who have recurrent symptomatic serous otitis media, hypernasality, and difficulties of speech production.

Environmental deprivation is another cause of delayed language development, especially in families in which children are not spoken or read to. Sometimes additional historical or physical evidence exists of deprivation (eg, profound failure to thrive, physical or sexual abuse) or emotional trauma (eg, domestic violence).

Evaluation

History

When evaluating children younger than 3 years, pediatricians must rely primarily on parental reports of children's language capabilities (Box 33.3). Children age 3 years and older usually can be engaged in conversation during the visit, but younger children are more likely to be uncooperative or remain silent when confronted by strangers or new situations. Historical factors, such as a family history of childhood deafness or speech and language delays, exposure to ototoxic agents (eg, aminoglycoside antibiotics), neonatal asphyxia or neonatal intensive care unit stay of more than 5 days, hyperbilirubinemia, maternal cocaine abuse, and low birth weight, provide valuable information in the identification of infants at high risk for delayed speech and language development (see Boxes 33.1 and 33.4).

Physical Examination

The physical examination includes a thorough assessment of the head and neck region, including examination of the hard and soft palate, to assess for the presence of overt or submucous cleft palate. Microcephaly may be an indicator for intellectual disability or structural abnormalities. Abnormalities of the external ear (eg, microtia) may be associated with sensorineural hearing loss. Otoscopic examination of the ear is an essential aspect of the examination. A middle ear effusion may be associated with conductive hearing loss. The tympanic membrane is examined for evidence of scarring or perforation, which often occurs secondary to recurrent otitis media.

Box 33.3. What to Ask

Language Development

- Are the child's language capabilities age-appropriate?
- Does the parent or do the parents feel that their child has difficulty hearing?
- Is there any family history of childhood deafness?
- Is there a family history of speech and language delays?
- Has the child been exposed to any ototoxic agents (eg, aminoglycoside antibiotics)?
- Is there a history of neonatal asphyxia, hyperbilirubinemia, or low birth weight?
- Has the child ever had bacterial meningitis?
- Did the mother have a TORCHS (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex, syphilis) infection during pregnancy?

Box 33.4. High-Risk Indicators for Hearing Loss in Children (Birth to 24 Months)

Neonatal Period (Birth–28 days)

- Family history of sensorineural hearing loss (SNHL)
- In utero infection associated with SNHL (eg, TORCHS [toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex, syphilis] infections)
- Anatomic malformations of the head and neck region
- Hyperbilirubinemia at a level requiring exchange transfusion
- Low birth weight (≤1,500 g [3.3 lb])
- Bacterial meningitis
- Low Apgar scores
- Respiratory distress (eg, meconium aspiration)
- Mechanical ventilation for ≥10 days
- Exposure to ototoxic medications (eg, aminoglycoside antibiotics) for >5 days or in combination with loop diuretics
- Stigmata of syndromes known to be associated with hearing loss (eg, Down syndrome)

Infants and Children (29 days–24 months)

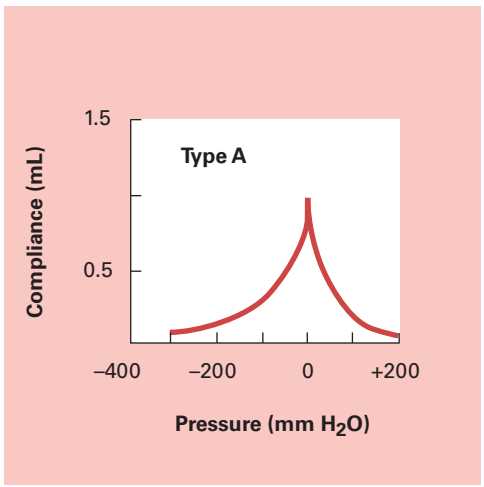
- Parental concern about hearing, speech, language, or developmental delay
- Recurrent or persistent otitis media with effusion for ≥3 months
- Severe head trauma (associated with fracture of the temporal bone)
- Infections associated with SNHL (eg, bacterial meningitis, mumps, measles)
- Neurodegenerative disorders or demyelinating diseases
- Any of the newborn risk factors listed previously

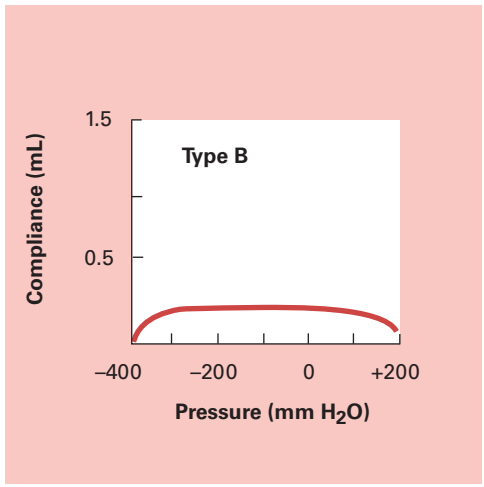
Adapted with permission from Muse C, Harrison J, Yoshinaga-Itano C, et al; American Academy of Pediatrics Joint Committee on Infant Hearing. Supplement to the JCIH 2007 position statement: principles and guidelines for early intervention after confirmation that a child is deaf or hard of hearing. *Pediatrics.* 2013;131(4):e1324–e1349 and Harlor AD Jr, Bower C; American Academy of Pediatrics Committee on Practice and Ambulatory Medicine, Section on Otolaryngology-Head and Neck Surgery. Hearing assessment in infants and children: recommendations beyond neonatal screening. *Pediatrics.* 2009;124(4):1252–1263.

Pneumatic otoscopy is a subjective assessment of tympanic membrane mobility (eg, compliance) when the membrane is subjected to a pulse of air. Tympanometry (eg, impedance audiometry) performed in the office can provide objective information about the mobility of the tympanic membrane and the presence of middle ear effusions (Figure 33.2). *Tympanometry* is not a hearing test; rather, it is an assessment of middle ear functioning that uses sound energy to determine the compliance of the tympanic membrane and pressure in the middle ear. Physical stigmata of any syndromes that may be associated with deafness are noted (Box 33.5).

Laboratory Tests

The advantages of early identification of hearing loss cannot be overemphasized. The Joint Committee on Infant Hearing "Year 2007 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs" recommends that the hearing of all newborns should be evaluated at no later than 1 month of age. Newborns who do not pass the screening should undergo





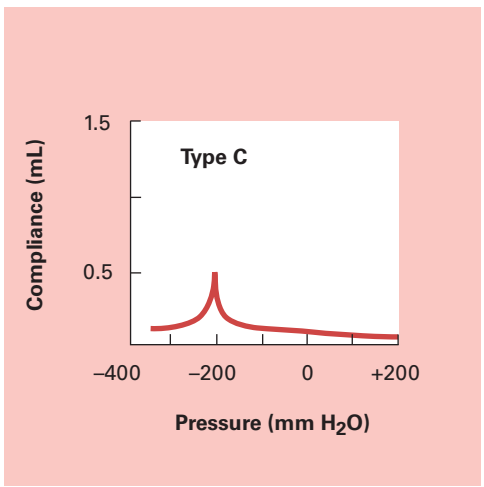


Figure 33.2. Basic tympanometry curves. The Type A curve indicates a normally compliant tympanic membrane (TM). The Type B curve indicates little or no motion of the TM and can be seen with middle ear effusion, a scarred TM, or a cholesteatoma. The Type C curve indicates negative middle ear pressure and may be seen with a resolving middle ear effusion or eustachian tube dysfunction. Other variations can occur in these basic curves that are not illustrated here.

Box 33.5. Syndromes Commonly Associated With Hearing Impairment

Autosomal-dominant Conditions

- Branchio-oto-renal syndrome
- Goldenhar syndrome (ie, oculoauriculovertebral dysplasia)
- Stickler syndrome
- Treacher Collins syndrome
- Waardenburg syndrome

Autosomal-recessive Conditions

- Alport syndrome
- Jervell and Lange-Nielsen syndrome
- Pendred syndrome
- Usher syndrome

Chromosomal Disorders

- Trisomy 13 syndrome
- Trisomy 18 syndrome

Miscellaneous Disorders

- CHARGE (coloboma, heart disease, atresia choanae, growth and intellectual disability, genitourinary tract anomalies, and ear anomalies) syndrome
- TORCHS (toxoplasmosis, rubella, cytomegalovirus, herpes simplex, syphilis) syndrome

a comprehensive audiologic evaluation at no later than 3 months of age. High-risk indicators for hearing loss serve 2 purposes (see Box 33.4). First, in areas in which universal newborn hearing screening is not yet available, these indicators help physicians identify newborns who should undergo audiologic evaluation. Second, these risk indicators help physicians identify neonates who require ongoing medical and audiologic monitoring; normal hearing at birth in these children may not preclude the development of later hearing loss (eg, delayed onset).

Speech and language evaluation begins in the pediatrician's office, where parent report inventories may be used to validate parental concerns and office-based language assessment may be aided by the use of screening tests such as the *Clinical Linguistic and Auditory Milestone Scale* or the *Early Language Milestone Scale*. These tests are used to supplement the clinical history of a child's language abilities.

Children with suspected language delays or disorders should be referred to specialists as early as possible. The first referral should be to a pediatric audiologist to assess the child's hearing. Normal hearing is essential to the development of speech and language; thus, if any concerns exist related to the development of either, hearing loss must be ruled out. An additional referral should be made to a speech-language pathologist (SLP) for a complete speech, language, and communication assessment (eg, assessment of pragmatic language skills) (Box 33.6). An abundance of research supports the benefit of early intervention in the development of speech and language skills. If any suspicion or concern exists regarding communication development, it is best to have an SLP explore these concerns further. Taking a "wait and see" approach with families wastes valuable

Box 33.6. Role of the Speech-Language Pathologist in the Evaluation and Management of Disorder

- Speech disorders affecting intelligibility (eg, difficulty producing speech sounds, deficits in motor-planning for speech production, dysfluency or stuttering, voice disorders, resonance disorders).
- Language disorders affecting the ability to understand language or express oneself verbally or in writing.
- Social communication disorders affecting the ability to communicate for social purposes. Evaluation and treatment also may address use of eye gaze, joint attention, and play.
- Cognitive-communication disorders, including problems organizing thoughts and ideas, problem solving, planning, and remembering information.
- Swallowing disorders, including difficulty with feeding and swallowing.

time that could be used to provide intervention services to remediate speech and language deficits. It is not necessary for a child to be using any language expressively to be evaluated or treated by an SLP. Children with speech or language impairments who also exhibit signs of possible cognitive or social skills impairment should undergo a comprehensive, multidisciplinary developmental assessment conducted by experts in developmental-behavioral pediatrics, psychology, speech-language pathology, and occupational therapy.

Management

The first 3 years after birth are crucial to language development. Hearing impairment is an important cause of delayed language development in young children; thus, the Joint Committee on Infant Hearing 2007 position statement recommends that infants with confirmed hearing loss should receive appropriate interventions by 6 months of age. The history, physical examination, and initial screening can be used to suggest referral to various specialists (eg, audiologists, SLPs, child psychologists, otolaryngologists) for further clarification of hearing, speech, or language deficits and treatment. Early identification of hearing impairment and the degree of severity enable early intervention in the form of amplification of sound, special education classes for affected children, and counseling and support services for the families of affected children (see Chapter 88).

Language learning occurs best in interactive and responsive environments. Parents of infants and young children should be encouraged to have fun speaking, singing, playing with toys, and reading with their children. These reciprocal parent-child interactions, along with high verbal parental responsiveness, stimulate children cognitively and foster language development.

For bilingual children, the home language should be preserved whenever possible. Bilingualism is associated with increased cognitive control in the form of improved executive function skills and mental flexibility. Evidence indicates that bilingualism itself does not cause language delays; however, the risk for language delays exists for bilingual children as it does for monolingual children.

Special education is of prime importance in the management of children with language difficulties. The Education for All Handicapped Persons Act, which was enacted by the US Congress in 1975, and the subsequent comprehensive reauthorization of it in 1990 and revision of it in 2004 as the Individuals with Disabilities Education Act, requires that public schools provide individualized and appropriate education for all children with disabilities. Knowledge of available community resources (eg, special schools) can aid pediatricians in providing support services, such as special community agencies and support groups for children with disability and their parents. Children with language delay in the context of global developmental delay, cognitive delay, or ASD require prompt referral to early intervention services.

Prognosis

Children with a history of speech and language delays should be monitored carefully for the emergence of reading difficulties. Reading is a language-based skill that requires the appreciation of subtle differences among speech sounds (eg, phonologic awareness) and the ability to link these sounds to written symbols. The emergent literacy model of reading development assumes that reading, writing, and oral language develop concurrently based on interactions in social contexts.

Children with speech and language delays require long-term monitoring of academic, emotional, and behavioral functioning. Treated early, speech and language delays and disorders generally improve over time. The final prognosis is dependent on the nature and severity of the underlying cause and the interventions provided.

CASE RESOLUTION

The child described in the case history has delayed development of expressive language skills. At the age of 3 years, she should have a 250-word vocabulary and speak in 3-word sentences; in addition, her speech should be primarily intelligible to strangers. Because of the delay, she should be immediately referred for a hearing assessment and speech and language evaluation. Hearing loss is an important diagnosis to rule out. Simply because her parents report no hearing problems does not mean she does not have a deficit. She may have learned to respond to nonverbal cues, or she may hear only some things.

CHAPTER 34

Literacy Promotion in Pediatric Practice

Wendy Miyares, RN, PNP

CASE STUDY

You are seeing a 9-month-old boy for the first time for a well-child visit. The child has a completely negative history and seems to be thriving. The patient's mother works part-time as a housekeeper, and his father is a seasonal worker in agriculture. The infant is up-to-date on his immunizations. The family history is noncontributory, but his mother mentions that her 6-year-old daughter needs to repeat kindergarten. Teachers have advised the mother that her eldest daughter is cooperative, but she has not yet mastered letters and early reading. Mother says she is not concerned because the teacher said with "a little more time" her daughter will be fine.

Questions

1. How are reading and language developmentally related?
2. What are the consequences of low literacy when children get older?
3. How are literacy and health outcomes related?
4. What are the components of the Reach Out and Read model?
5. What can pediatricians do to promote literacy in families?

Early literacy promotion in the office setting is now recognized as an essential part of pediatric primary care. The American Academy of Pediatrics (AAP) and the Canadian Paediatric Society encourage health professionals to include literacy promotion in the routine clinical care of toddlers and young children. It is known from the ever-expanding evidence of early brain development that reading aloud, speaking to babies, singing, and sharing books can permanently change neuronal connections in the brain. These connections forged by reciprocal attention and spoken language are important for learning during the school years as well as for the emotional health of the child.

Literacy promotion can begin even before a baby learns to speak and long before a child is ready to learn to read. Eventual mastery of reading will depend on skills such as language ability, imagination, and familiarity with books and the reading process. Children develop many of these skills in the first few years after birth, even before they go to preschool. In fact, a child's language ability by 3 years of age is strongly correlated with later academic performance. Parent-child interactions are crucial, and guidance for parents on literacy promotion activities at home should begin within the first year after birth.

Reading aloud to children on a regular basis is among the most effective means of promoting early literacy and language development. Language skills are the foundation for later reading ability and are largely dependent on the amount and quality of language exposure. The architecture of a developing brain is physically altered by experiences during infancy. At birth, a baby's brain contains 100 billion neurons, which go on to form trillions more connections. Those connections that are stimulated by frequent use persist, and less-used synapses are eliminated as the brain matures. Reading aloud and book sharing may help ensure the preservation of brain connections associated with skills such as memory, creativity, comprehension, and language. Reading aloud is also a positive nurturing activity which in itself promotes other important neuronal connections and healthy development. The AAP recommends avoiding television or other electronic media for children younger than 2 years, because young children learn best by interacting with people.

Reading aloud exposes children to vocabulary they do not hear in daily conversations (eg, 3 bears, beanstalks). Reading aloud also stimulates the imagination (eg, cows jumping over the moon). In time, children learn that the abstract letters on the page represent words, and they become aware of different, smaller sounds that make up words. All these experiences result in reading readiness.

Consequences of Low Literacy

Low literacy has significant consequences as children age. Poor academic skills are consistently linked with higher dropout rates, entrance into the juvenile justice system, and unemployment. One-third of all juvenile offenders are reported to read below the fourth-grade level, and more than 80% of adult prison inmates are high school dropouts.

Literacy level and health outcomes are also intimately related. *Health literacy* is defined as the degree to which individuals can obtain, process, and understand the basic information they need to make appropriate health decisions. Multiple studies have demonstrated that a low literacy level negatively affects health and well-being. Compared with average or above-average health literacy, individuals with limited health literacy have a higher number of visits to emergency departments and hospitalizations, and increased morbidity.

Adolescents with low reading ability are more likely to smoke, use alcohol, carry a weapon, and be in a physical fight that results in the need for medical treatment. Conversely, higher levels of literacy are associated with positive health outcomes, such as appropriate use of inhaled asthma medication or choosing to breastfeed a baby.

Promoting literacy is good medicine not only for the individual but also for society. Aside from the societal effect of school failure, individuals with limited literacy incur medical expenses that are up to 4 times greater than patients with adequate literacy skills. Low literacy carries a high financial cost, with billions of dollars spent in the United States each year on preventable emergency department visits and hospital stays.

Literacy Promotion in the Medical Office

The AAP endorses the Reach Out and Read model of early literacy promotion, and this model is incorporated in the official AAP Bright Futures guidelines for pediatric health professionals.

The Reach Out and Read model has 3 main components:

1. Anticipatory guidance: During regular well-child visits, health professionals encourage parents to read aloud to their young children at home. The advice is age-appropriate, and concrete examples are provided or modeled by the physician (Table 34.1).
2. Books: A new developmentally and culturally appropriate book is given by the physician to patients and parents at each well-child visit so that parents have the tools to follow the physician's advice.

Table 34.1. Developmental Milestones of Early Literacy

Patient Age	*Motor Development*	*Cognition*	*What Parents Can Do*
6–12 Months	Reaches for books Book to mouth Sits in lap; holds head steady Turns pages with adult help	Looks at pictures Vocalizes, pats pictures Prefers pictures of faces	Hold the child comfortably; face-to-face gaze. Follow the baby's cues for "more" and "stop." Point to and name pictures.
12–18 Months	Sits without support May carry the book Holds the book with help Turns board pages (several at a time)	No longer mouths right away Points at pictures with 1 finger May make the same sound for a particular picture (labels) Points when asked, "Where's...?" Turns the book right side up Gives the book to an adult to read	Respond to the child's prompting to read. Let the child control the book. Be comfortable with the toddler's short attention span. Ask, "Where's the...?" and let the child point.
18–24 Months	Turns board pages easily, 1 at a time Carries the book around the house May use a book as a transitional object	Names familiar pictures Fills in words in familiar stories "Reads" to dolls or stuffed animals Recites parts of well-known stories Attention span is highly variable	Relate books to the child's experiences. Use books in routines, including bedtime. Ask the child, "What's that?" and let the child answer. Pause and let the child complete the sentence.
24–36 Months	Learns to handle paper pages Goes back and forth in books to find favorite pictures	Recites whole phrases and sometimes whole stories Coordinates text with picture Protests when the adult gets a word wrong in a familiar story Reads familiar books to self	Keep using books in routines. Read at bedtime. Be willing to read the same story over and over. Ask, "What's that?" Relate books to the child's experiences. Provide crayons and paper.
≥3 Years	Competent book handling Turns paper pages 1 at a time	Listens to longer stories Can retell familiar story Moves finger along text "Writes" own name Moves toward letter recognition	Ask, "What's happening?" Encourage writing and drawing. Let the child tell the story.

Adapted from Reach Out and Read. Milestones of early literacy development. www.reachoutandread.org/resources. Accessed February 19, 2020. Used with permission.

3. Waiting rooms: Literacy-rich waiting rooms contribute to the literacy message. Gently used books for parents to read to their child while waiting and displays or information about local libraries are encouraged. Where appropriate and feasible, community volunteers read aloud in waiting rooms, modeling for parents the pleasures and techniques of reading aloud to very young children.

Reach Out and Read had its origins in an urban clinic that served a high proportion of low-income families and has always had a special focus on children growing up in poverty. For complex reasons, poverty is a powerful predictor of children's exposure to language. Children in low-income homes are 40% less likely to be read to on a daily basis than children in higher-income households. Pioneer researchers Hart and Risley estimate that by age 4 years, children living below the poverty line hear 30 million fewer words in total than those who grow up in higher-income households.

Providing advice to parents is easiest and most effective when a book is brought in at the beginning of a visit. That way, physicians can naturally weave in guidance that is appropriate to the age of the child (Box 34.1 and Table 34.1). Advice should be brief and to the point, supportive, and part of a general conversation about the child's development and behavior.

Another advantage of presenting the book early in the visit is the amount of developmental and relationship information that can be observed by the health professional. The book is a tool that can speed informal developmental surveillance. If a 2-year-old exclaims, "Doggie says bow-wow!" there is no doubt she is putting 2 words together. If a 1-year-old uses an index finger to point and looks to see if his mother is watching, the physician can gain information about fine motor ability and the child's social interaction in only a few moments.

Children benefit from storytelling and book time in whatever fashion is most comfortable for the parent. Ideally books should be either in the family's preferred language or bilingual. It is best for parents to use the language that is easiest for them, because it is more important for children to hear a language with rich vocabulary and complex sentences than to learn English first. If no book is available in the family's native language or parents are not confident with their own reading skills, the primary care physician should encourage parents to look at books, name pictures, and talk about what is going on in the pictures with their children. Physician knowledge of local programs for adult literacy and English as a second language is often useful, because parents may ask for resources when literacy is discussed in the examination room.

Box 34.1. Anticipatory Guidance for Parents[a]

- *Newborns and very young babies* need to hear a parent's voice as much as possible: talking, singing, and telling stories are all good.
- *6-month-olds* may put books in their mouths; this is developmentally normal and appropriate and is why we give them chewable board books. It is not in any way an indication that the child is too young for a book!
- *12-month-olds* may point with 1 finger to indicate interest in a picture; parents should see this as developmental progress.
- *18-month-olds* may turn board book pages and may insist on turning back again and again to a favorite picture.
- *2-year-olds* may not sit still to listen to a whole book but will still enjoy looking at individual pages or having parents read them stories bit by bit.
- *3-year-olds* may retell familiar stories and may memorize their favorite book.
- *4- and 5-year-olds* may start to recognize letters or their sounds. They can understand and follow longer stories.
- *School-age children* will start to be able to read to you—but do not stop reading to them—and enjoy taking turns.

[a] Specific guidance can help parents with age-appropriate expectations for how their children will physically handle and interact with books, and respond to stories.

Primary Care Physicians Can Make a Difference

The primary care setting is the ideal venue for literacy promotion. Almost all parents will bring in their child for routine examinations or urgent visits, which provides an opportunity to reach a broad group, not just those seeking learning experiences for their children. In fact, 96% of all children younger than 6 years see their physician at least once annually. Each child is seen for multiple visits from a very young age, providing repeat opportunities to discuss reading aloud during the critical first years. Suggestions in support of literacy-focused activities are a logical extension of the advice about growth and development that parents are already receiving at these visits. Those who provide primary care can review daily activities in which reading aloud can be incorporated, such as reading traffic signs, store names, or simple food labels. When parents trust and value advice from their primary care physician, early literacy messages assume greater credibility.

The effectiveness of this primary care model to promote reading aloud to young children has been demonstrated in multiple research studies. Parents who received even 1 book were much more likely to read aloud to their children and report reading as a favorite activity of their child. The effect was greatest for the poorest families, which is an important finding for children who may need this intervention the most. The outcome was similar for non-English-speaking families, and the findings held even if the provided book was written in English. Finally, and most encouraging, toddlers and preschoolers who had received care in clinics in which the Reach Out and Read model was used had higher scores on language and vocabulary assessments than children who had not been not served by the program.

Medical professionals who promote literacy and use the Reach Out and Read model of providing books and advice will help build stronger bonds between health professional and family. Using clinic visits as an opportunity to tailor age-appropriate advice for parents and emphasize the importance of reading aloud and the beneficial effects is favorable for all.

CASE RESOLUTION

You speak to the mother about the benefits of reading aloud to her children. You give the 9-month-old a board book with pictures of baby faces. You demonstrate, showing how the 9-month-old is interested in the pictures and engages with vocalizations as you describe each page. At the end of the visit you also find a gently used rhyming book that the mother can take home for her 6-year-old daughter.

CHAPTER 35

Gifted Children

Calla R. Brown, MD, FAAP, and Iris Wagman Borowsky, MD, PhD, FAAP

CASE STUDY

A 3-year-old girl is brought to your office for well-child care. Her parents believe that she may be gifted, because she is much more advanced than her sister was at the same age. The parents report that their younger daughter walked at 11 months of age and was speaking in 2-word sentences by 18 months. She is very "verbal," has a precocious vocabulary, and constantly asks difficult questions such as, "How do voices come over a radio?" The girl stays at home with her mother during the day but recently began attending a preschool program 2 mornings a week. She enjoys preschool and plays well with children her own age. She also likes to play with her sister's friends from school.

The girl is engaging and talkative. She asks questions about what you are doing during the examination and demonstrates impressive knowledge of anatomy. The physical examination is normal.

Questions

1. How are gifted children identified?
2. What characteristics are associated with giftedness?
3. What are the best approaches for optimizing the education of gifted children?
4. What is the role of the pediatrician in the care of gifted children?

Addressing caregiver concerns about giftedness provides an exciting intersection of strengths-based pediatric medicine with the educational system. Because several definitions of giftedness exist, prevalence rates vary. Identification of gifted children coupled with advocacy can promote an optimal educational match for the child; however, identification systems currently in use may result in an underrepresentation of children from socioeconomically disadvantaged backgrounds. Pediatricians can help counsel families in the creation of a supportive environment for their children and can advocate on behalf of children and families within the educational system.

Giftedness has been defined in several ways. The psychometric definition of giftedness is based on scores obtained on standardized intelligence tests. The 2 most frequently used cutoff points are 2 standard deviations above the mean (intelligence quotient [IQ] of 130–135) and 3 standard deviations above the mean (IQ of 145–150). Children with these scores are in the upper 2% and 0.1% of the IQ distribution, respectively. Intelligence quotient, which is considered to be fairly stable after 3 or 4 years of age, is the best single predictor of scholastic achievement at all levels, from elementary school through college.

A second definition of giftedness is based on real-life achievements or performance of exceptional skills rather than test scores. Children with special talents (other than general intelligence) in areas such as music, mathematics, ice skating, chess, or drama fit this description. Other definitions of giftedness recognize motivation, commitment, perseverance, high self-esteem, and creativity as personality traits that allow children with above-average ability to develop exceptional talents. This collective group of traits is often referred to as the "potential to achieve" academic or other success.

Epidemiology

The prevalence of giftedness depends on the somewhat arbitrary definitions of giftedness and the varied approaches to the identification of gifted children. Traditional screening systems identify 3% to 5% of students for participation in gifted programs in schools. Some schools use an alternative system in which 10% to 15% of children are recognized as above average. With the goal of fostering giftedness in these children, schools offer them enriched programs.

Intellectual giftedness in children has been associated with the social, economic, and educational background of their families. Factors that correlate with higher IQ scores in children are more years of parental education, higher IQ scores of mothers, increased family income, smaller family size, and longer intervals between siblings. Children from low-income and minority backgrounds are less likely to be identified as gifted than other children. Black, Hispanic, and Native American students are underrepresented by 30% to 70% in gifted programs in the United States. In particular, when single intelligence testing is used to identify gifted children, students from diverse cultural backgrounds are more likely to be excluded from programming opportunities. Some studies have also found that teacher referral–based systems may be more likely to underidentify students from diverse backgrounds if most of the teachers have cultural or ethnic discordance with the student.

Although research indicates that, as a group, children who are academically gifted begin to walk, verbalize, and read earlier, this area of research is still in its infancy, and conflicting results have been reported. Thus, these factors are not useful for predicting giftedness in individual children.

Evaluation

One of the primary goals of child health promotion is developmental monitoring. The early identification of developmental delays, which allows for prompt intervention, is among the primary purposes of such monitoring. Techniques for developmental assessment include review of developmental milestones with parents and discussion of parental concerns, informal observation of children in the office, and formal screening with standardized tests, such as the Ages and Stages Questionnaires.

Identification of Gifted Children

Although parents' first concern is usually to confirm that their child is developing normally, it is not uncommon for parents to ask if their child is gifted. Such questions are typically motivated by parents' desire to optimally encourage their child's development. Sharing information and observations with parents during developmental monitoring may facilitate parent-child interaction and child development. In a competitive society, the pediatrician should look for signs that above-average abilities are the result of undue pressures placed on children, such as incessant teaching or overscheduling of time.

Infancy and early childhood may not be the best time to determine whether a child is gifted. Age of attainment of developmental milestones and performance on standardized tests (eg, *Bayley Scales of Infant and Toddler Development*) during the first 2 years after birth are unreliable predictors of intellectual giftedness. Reasons for this lack of reliability may include weaknesses in the tests and variable rates of child development that result in transient precocity or delay. Tests that focus on visual memory tasks in infants may be better predictors of later academic intelligence, although additional research is required on the efficacy of such tests. Additionally, many special talents that comprise giftedness, such as creativity or artistic or musical ability, may not manifest until children are older.

The determination of giftedness in older children may involve several factors (Box 35.1). The early identification of giftedness allows for the development of an appropriate educational program that is optimally matched to a particular child's ability to learn. Without early identification and intervention, children who are intellectually gifted may become disillusioned with school, lose interest in learning, fail to develop study skills because they are never challenged to think and work hard, and develop a pattern of underachievement that may be difficult to reverse by the middle grades.

Box 35.1. Factors Used in the Identification of Giftedness in Children

- Intelligence tests
- Standardized achievement tests
- Grades
- Classroom observations
- Parent and teacher rating scales
- Evaluation of creative work in a specific field (eg, poems, drawings, science projects)

Special Groups of Gifted Children

Giftedness is harder to identify in some children. In the child with physical disability, giftedness is often obscured by the obvious physical disability, which demands attention. Such children may participate in special programs in which their physical needs are the major concern, to the detriment of their academic or artistic potential. In addition, poor self-esteem associated with the disability may prevent these children from realizing their potential. To identify giftedness in the child with physical disability, parents and teachers must make a concerted effort to search for potential and encourage its development. Strengthening a child's capacities may involve training in the use of a wheelchair or computer or taking frequent breaks to prevent fatigue.

Giftedness also commonly goes unnoticed in children with learning disabilities. Exceptional and poor abilities can coexist in a child. In fact, an estimated 10% of gifted children have a reading problem, reading 2 or more years below grade level. Albert Einstein, Auguste Rodin, and John D. Rockefeller are famous examples of brilliant individuals who had challenges with reading and writing. An extreme example of the occurrence of extraordinary and deficient abilities together in 1 individual is the child savant. Affected children possess amazing abilities in 1 area (eg, music, drawing, mathematics, memory), but they exhibit delays in other respects. In addition, they have behavioral problems that resemble autism, such as repetitive behavior, little use of language, and social withdrawal. Learning disabilities may obscure children's talents, thus preventing fulfillment of their potential.

Conversely, children's giftedness may mask their weaknesses, depriving them of needed help. Worst of all, gifted children with learning disabilities may manage to barely "get by" in the regular classroom setting and fail to receive recognition for strengths or weaknesses. Large differences on intelligence and achievement tests between scores in different areas, such as language and spatial abilities, may indicate both giftedness and a learning disability. Research suggests that programs that focus on strengths, not deficits, enhance self-esteem in gifted children with learning disabilities and can be extremely beneficial in their academic development.

The identification of giftedness is also difficult in children who underachieve. Parents may approach the pediatrician with the following frustrating problem: Their child is doing poorly at school, although they believe that the child is bright because of the child's abilities and participation in advanced activities at home. Underachievement may result from a learning disability; poor self-esteem; lack of motivation; or the absence of rewards, at home or at school, for succeeding in academics.

As previously stated, giftedness is less likely to be recognized in children from families of low income or who are ethnically diverse. For school districts that request privately obtained testing for entry into advanced educational programming, the costs may be prohibitive for some families. Additionally, many of the tests used to identify giftedness have been "normed" on white, English-speaking,

middle-class children. Furthermore, studies have shown that relying on referrals from teachers who have not had additional training on recognizing giftedness are likely to result in students who do not match typical cultural perceptions of the "gifted child" being overlooked. Students who are learning English as a second language are even more likely to be overlooked for placement into advanced educational programming. For new immigrant families, there may be different sociocultural expectations of behavior in school, cross-cultural stress, or symptoms such as posttraumatic stress or depression that may mask giftedness or academic potential. Validation of newer methods of assessment that are less fraught with cultural and socioeconomic bias is ongoing. Until validated tests are available that are sensitive to socioeconomic differences, a combination of other means of identifying giftedness should be stressed, such as assessment of creative work and teacher, student, and perhaps community nominations.

Management

At Home

Loving, responsive, stimulating parenting should be encouraged for all children, including those who are gifted. Parents of gifted children may feel inadequate, fearing that their child is smarter than they are. The pediatrician can provide parental reassurance by telling parents, "You must have been doing something right for your child to have been identified as gifted." Children's librarians, periodicals written for parents and teachers of gifted children (eg, *Gifted Child Today*), and the local chapter of the National Association for Gifted Children are good resources for parents.

Parents are often overwhelmed with complex questions from their precocious preschool-age children about issues ranging from homelessness and world hunger to theology and the creation of the universe. The pediatrician should tell parents that they should not be afraid to admit that they do not know all the answers and should work together with their child to find the answers.

The pediatrician may need to warn parents about putting too much pressure on their gifted children. For example, enrolling children in multiple classes often leaves little free time for unstructured play. Play affords many opportunities for self-learning, interaction with peers, and development of creativity and initiative. Parents of infants, toddlers, and preschoolers should be encouraged to take cues from their children. If children have a rich environment with plenty of objects and books to explore, diverse experiences, and stimulating interactions, they will develop their own interests. Other educational materials and special instruction can then be provided in a particular area of interest.

Children who are gifted are often mistakenly considered to fit the stereotype of troubled, socially awkward "nerds." With the exception of children at the genius extreme (IQ >180), gifted children are generally more sociable, well-liked, trustworthy, and emotionally stable than their peers, with lower rates of mental illness and delinquency. Nevertheless, they have the same emotional needs as other children. Gifted children may prefer to play with older children whose interests and abilities are closer to their own. This should be allowed as long as these relationships are healthy.

Parents should be encouraged to treat children who are gifted the same way they do their other children. For example, age-appropriate responsibilities and chores should be encouraged. Siblings of gifted children may become resentful if attention is centered on their gifted sibling. They may feel inferior, particularly if gifted children surpass them in school. Tensions may be magnified if gifted children become friends with their older siblings' friends. To preserve a sense of self-worth and competence in siblings, the pediatrician should recommend to parents that they set aside special time to spend with each of their children. Parents should encourage other talents (eg, musical abilities, athletic abilities) in siblings. Older siblings should receive the special privileges and responsibilities that come with age, such as staying up later or doing different chores. Any tensions within the family should be openly discussed and addressed.

At School

Parents often seek advice from their pediatrician about educational planning for children who are gifted. A learning environment with the optimal degree of challenge—hard enough to require new learning and stave off boredom, but not so hard as to be discouraging—is the goal for all children. Parents of young children should select a preschool with a flexible program and capable teachers to accommodate children with precocious skills. Parents of school-age children must decide whether *acceleration* (ie, starting school earlier or skipping grades) or *enrichment* (ie, staying in the same grade but supplementing the regular curriculum) is more appropriate (Table 35.1). The choice of approach is dependent on the particular child.

Table 35.1. Acceleration Versus Enrichment in Gifted Education

Strategy	*Advantages*	*Disadvantages*
Acceleration	May provide suitable academic challenge May have social benefits Can be offered by all schools Inexpensive	Difficult to reverse May have to skip more than 1 grade to be properly challenged
Enrichment	Classmates are the same age May expose children to subjects they would not otherwise learn Appropriate for children who are mildly gifted	May be expensive and inaccessible to many families because of tuition and transportation costs Inadequate for children who are highly gifted May isolate gifted from non-gifted children and encourage "elite" label Potential for excessive homework if children are required to make up the regular class work as well when they miss class to participate in an enrichment program

Parents and teachers of gifted children are usually concerned that children in accelerated programs may have problems with social adjustment if their classmates are older. Existing evidence suggests, however, that children who are gifted benefit socially from acceleration. Gifted children in accelerated programs participate in school activities (except contact sports) more often than gifted children placed with classmates of the same age. Even when children who are gifted are placed with children their own age, they tend to make friends with older children with whom they share more interests. Gifted children also make up any curricular content missed by grade skipping. Because the process may be difficult to reverse, acceleration may not be the best option if doubt exists whether doing so is in the child's best interest.

Enrichment involves keeping gifted children with same-age classmates but supplementing the regular curriculum. Regular class placement with a teacher who is willing to offer extra work (eg, special projects) in addition to grade-level assignments, part-time programs to supplement regular class work (eg, field trips, foreign language classes), honors classes that group bright children together for their basic curriculum, and independent study by the family at home are all examples of enrichment programs. These programs may work well for some children who are gifted, depending in large part on the resources and funding available and the experience, creativity, and enthusiasm of the teachers involved.

Some enrichment programs may isolate gifted from nongifted children, however, and encourage labeling of the gifted students as "elite." If children are required to make up the regular class work that they miss when they are involved in the enrichment program, they may find themselves overloaded with homework.

Often, a combination of acceleration and enrichment programs is the best option. Acceleration or enrichment alone may be inadequate for the brightest children. Acceleration may be insufficient for markedly advanced children who would have to skip 2 or 3 grades to be appropriately challenged. The pediatrician should recommend that parents work closely with teachers to achieve the best learning environment for their children. Some factors that should be considered are age, physical size, motor coordination, emotional maturity, personality, and particular areas and degrees of giftedness of the child. Acceleration may be a better option for a physically large, outgoing child than for a small one. Gifted children should be asked what they would like to do.

When evaluating the suitability of an educational situation for their gifted child, parents should watch for certain warning signs. Excessive homework should not be expected or tolerated, because it cuts into the child's time to play and develop socially. The emphasis in gifted education should be on broadening perspectives, not increasing busywork. If children who are gifted are developing a sense of elitism or peer animosity, the nature and philosophy of the program should be questioned. Boredom with schoolwork, not needing to study, signs of depression, or symptoms suggestive of school phobia, such as recurrent abdominal pain or headaches on school mornings, should prompt investigation into the suitability of the child's program.

Homeschooling, either part-time to complement classroom curricula or full-time, is an educational alternative. To decide if this is the best choice for the family and the child who is gifted, parents who are considering homeschooling are advised to gather as much information as possible, including talking to other parents who are homeschooling their children, reviewing sample curricular materials, and contacting school districts and state departments about requirements and specific steps.

Schools with students from low-income or minority backgrounds tend to use their limited resources to help students who are doing poorly in school, rather than gifted students. In addition, children from low-income or minority backgrounds may experience further barriers to academic achievement, including lack of informational materials about gifted programs in parents' native languages and difficulty meeting requirements because of parental employment responsibilities and lack of transportation. Research has shown that programs for gifted children from such backgrounds benefit all students by creating positive role models and promoting the school as a place for the cultivation of excellence. In addition to providing support for individual gifted children and their families, the pediatrician may choose to engage in an active advocacy role within the community by, for example, promoting diverse educational experiences for students of all backgrounds, helping policy makers discover and remove barriers to participation, and working with community organizations to educate families from minority or low-income backgrounds about educational opportunities for their children who are gifted.

Prognosis

Children who are gifted are a diverse group, comprising children with exceptional academic, artistic, or other abilities, combined with the creativity and commitment to achieve their potential. Children may be gifted in 1 area and average or even below average in another area. The purpose of identifying gifted children is to provide them with an educational environment to help maximize their potential. The pediatrician is poised to help children and their families recognize that other factors in addition to cognition, including social development, concepts of self-worth, self-discipline, and resilience, are also vitally important to the overall success and well-being of the child. Pediatricians can serve as a resource for parents in raising children who are gifted and helping children and families obtain appropriate evaluation, educational programs, and supportive resources. The prognosis for gifted children is excellent.

CASE RESOLUTION

The physician should reaffirm the parents' observations that their child is gifted. The parents should be encouraged to explore programs in which their daughter's talents may be fostered, but they also should be advised that even gifted children need time for play and unstructured activities.

CHAPTER 36

Children and School: A Primer for the Practitioner

Geeta Grover, MD, FAAP, and Jeanne Anne Carriere, PhD

CASE STUDY

An 8-year-old boy is brought in by his parents in early April because his third-grade teacher informed them that he is currently failing in school and may not be promoted to the fourth grade. Review of his medical, developmental, and school histories reveals that he was a colicky infant and continued to be difficult as a toddler. His language skills were somewhat delayed, although not enough to warrant a full evaluation. His preschool teacher felt that he was easily distracted when doing seat work. In kindergarten, he had some difficulty learning all his letters, numbers, and sounds. Early reading was difficult in kindergarten and first grade but improved by the end of the first-grade year. Second grade was fairly good, except for continued concerns about inattention and distractibility. By third grade he was struggling more, especially with writing, and not performing within grade level in several areas. He also continued to be inattentive and distractible in his classroom.

Examination reveals a well-developed and well-nourished boy whose growth parameters are within normal limits for his age. He appears somewhat anxious in the examination room, and when asked about school he tells you that he feels he is just not as smart as the other children in his class.

Questions

1. Should grade retention be considered when a child is failing in school?
2. What are the potential disadvantages of grade retention?
3. What are factors to consider when evaluating a child for school failure?
4. What steps should be taken at this time by the parents and the school for the boy in this case study?
5. How could early intervention have affected the boy's performance?

Pediatricians are the medical practitioners most knowledgeable of typical and atypical child development. Their routine contact with young children and their families, as well as their longitudinal perspective on their patients' lives, places pediatricians in a unique position to evaluate, diagnose, and manage not only children's medical needs but also their developmental, social-emotional, behavioral, and educational needs. Research has highlighted the importance of early experiences to optimize development and supported early intervention for children with developmental delays. Traditionally, the 5-year-old health maintenance visit has been regarded as the "school readiness" visit. However, waiting until this visit to address concerns or provide preventive guidance for educational readiness is too late. School readiness and the academic, behavioral, and social-emotional development it entails must be promoted from infancy through early childhood.

During the school-age years, pediatricians should continue to monitor children's educational progression by inquiring about academic, social-emotional, and behavioral development. Parents often turn to pediatricians for advice on their children's behavioral or academic difficulties at school. Early academic, behavioral, and social-emotional difficulties place children at risk for school disengagement and school failure. It is imperative that pediatricians have an understanding of the multiple facets, evaluation, and management of children's school readiness needs and the ways in which delays or deficits in academic, cognitive, physical, behavioral, and social-emotional development can affect a child's school engagement and long-term success. The evaluation and management of educational difficulties requires a multidisciplinary approach; however, the pediatrician should have a principal role in monitoring the critical elements supporting school readiness and providing ongoing guidance, support, and advocacy for patients and their families.

Epidemiology

Attempting to establish a set of determinants that result in successful learning or that place a child at risk for failure is an oversimplification of the complexities of school readiness, school engagement, and school failure. School readiness, school engagement, and school failure are nonlinear cumulative processes, not solitary events, and a multidisciplinary approach to assessment and management is required.

School readiness is the term used to describe those qualities and traits that are considered prerequisites for a child to be ready for

school success. When defining school readiness, parents tend to focus on the pre-academic skills their child has mastered (eg, identifying letters and sounds, counting, writing their name). Teachers' definitions of readiness regularly incorporate social skills and behavior as well. Factors identified in the literature as affecting school readiness include physical health, motor skill development, social and emotional development, language development, adaptive skills, and cognitive abilities. In addition, significant additional factors exist that readily affect school adjustment and success other than a child's skills and attributes, such as parent-child interactions, access to quality early childhood education, and both positive and negative life experiences (see Chapters 141 and 142).

Language deficiencies and problems with emotional maturity are cited most often as the factors that most restrict school readiness. Language development and school readiness are intertwined. Language proficiency provides a strong foundation for the cognitive and literacy skills required for school achievement. By providing a rich language environment from infancy, parents give children a head start on school success. Currently, however, more than 1 in 3 American children start kindergarten without the language skills necessary to learn to read. Similarly, with regard to emotional maturity, a recent study found that students who entered kindergarten lagging their peers in social-emotional skills were more likely to experience grade retention, receive special education services, and be suspended or expelled at least once by the fourth grade. *School engagement* can be broadly defined as meaningful student involvement throughout the learning environment. Research has shown that school engagement is associated with positive outcomes, including academic achievement and persistence, that is, staying in school until graduation. Within the school research literature, school engagement has 3 components: behavioral, emotional, and cognitive. *Behavioral engagement* is related to active participation, both in the classroom and the school community as a whole. It includes following classroom norms; demonstrating good conduct; and being involved in academic, social, and/or extracurricular activities. *Emotional engagement* refers to students' emotional reactions to teachers, peers, academics, and the school as a whole. Emotional engagement creates a sense of belonging and value to the school community. *Cognitive engagement* is related to students' investment in learning. It encompasses the problem-solving flexibility and coping skills students use as well as the hard work they do to understand and master the curriculum presented to them. School engagement is considered crucial to achieving positive academic outcomes and protecting students from school failure.

School failure is a multifaceted, epidemiologically complex issue. Research suggests that health and educational success are intricately connected. Compared with non-affected children, children with physical illnesses, mental health concerns, socio-emotional concerns, behavioral issues, and neurologic deficits are more likely to have difficulty learning throughout their school careers. They are at increased risk of poor attendance, poor achievement, academic decline, and failure to graduate from high school. Dropping out of school, which is commonly seen as an event, is in fact a process that often begins with early school failure.

Overall, high school completion rates in the United States have been slowing rising over the last decade, with 83% of all students graduating from high school. Graduation rates vary by state, however, and are lower for children from low-income families and for children with disabilities. The overall rate of high school completion is 76% for low-income students, with some states reporting rates as low as 63%. The high school completion rates for children with disabilities are even more concerning. In the United States, approximately 64% of students with disabilities graduate from high school, with rates as low as 29% for certain states.

Approximately 15% of children in the United States have a developmental disability. In the US public school population, 13% of children receive special education services under the Individuals with Disabilities Education Act (IDEA) of 2004. These services are provided to students with qualifying disabilities, if their disability affects their academic achievement or educational performance. Not all children with a diagnosed disability qualify for or require special education support (Box 36.1).

The number of children with diagnosed disabilities is significantly lower than the number of children who experience some level of adverse environmental, socioeconomic, or stress-inducing conditions that negatively affect their ability not only to get to school each day but be ready to learn on arrival (see Chapters 141 and 142). These children experience poor educational outcomes when they do not receive comprehensive support, intervention, and services. Youth who interface with the juvenile justice system have previously experienced increased rates of academic failure, disengagement from

Box 36.1. Special Education Eligibility Categories Under the Individuals with Disabilities Education Act of 2004 for Children and Youth Age 3 Through 21 Years[a]

- Autism
- Deafness
- Emotional disturbance
- Deaf-Blindness
- Hearing impairment
- Intellectual disability
- Multiple disabilities
- Other health impairment
- Orthopedic impairment
- Specific learning disability
- Speech or language impairment
- Traumatic brain injury
- Visual impairment, including blindness
- Developmental delays[b]

[a] To fully meet the definition and eligibility for special education and related services as a "child with a disability," a child's educational performance must be adversely affected as the result of 1 of the 14 categories listed here.

[b] The Individuals with Disabilities Education Act of 2004 allows each state to determine whether to use this eligibility category for student age 3 through 9 years.

school, and/or school disciplinary problems. More than half of such students perform academically below grade level. This population meets eligibility for special education services at 3 to 7 times the rate of their nonincarcerated peers. Approximately 85% of incarcerated juveniles are functionally illiterate (ie, lacking the literacy skills to manage daily living and employment tasks that require reading) or low literate. High school dropouts are 3.5 times more likely than high school graduates to be arrested in their lifetime and 63% more likely to be incarcerated than their peers with 4-year college degrees.

Research has not supported retention as an effective remediation strategy for poor school performance, and many studies have linked retention to future school failure. Grade retention rates in the United States have declined in the past decade, and currently, approximately 10% of students are retained each school year. Most retentions occur in kindergarten, with retention rates between 1st and 12th grade of 3% to 5%. However, retention rates as high as almost 9% in these grades have been reported for students of color, students of parents without a high school diploma, students whose families receive public assistance, and students living in the Southern states. Children receiving special education services experience retention at a significantly higher rate, with 32% being retained at some point in their school career.

Considering that the average child in the United States spends approximately 50% of the waking day in a school or a similar learning situation for approximately 12 or 13 years, it follows that a lack of success in these settings will lead to difficulties for much, or all, of adult life. School difficulties that go undetected, untreated, and undertreated can result in establishing a lifelong pattern of frustration and failure. For example, children with attention-deficit/hyperactivity disorder (ADHD) are 2 to 3 times more likely to drop out of high school than their peers without ADHD, and those who attend college are less likely to graduate than their peers without ADHD (see Chapter 133).

Clinical Presentation

Defining school readiness is not an easy task, because the intellectual, physical, social, and emotional development among children of kindergarten age varies tremendously. To confound the concept of readiness, kindergarten expectations and standards have changed significantly in the past 2 decades, becoming less socially play based and more academically focused. School readiness involves far more than adequate pre-academic skills (Box 36.2). Early childhood educators also emphasize the importance of sufficient physical, cognitive, language, social-emotional, and behavioral skills to children's success in the formal schooling environment. Current research emphasizes the importance of children's "learning to learn behaviors," highlighting the role that abilities such as sustained attention, engaging in goal-directed tasks, impulse control, and emotional regulation have on children's engagement in learning activities and academic achievement. Children who can control impulses, consider options, and demonstrate flexible thinking and creativity are better able to actively engage in learning opportunities than their peers who lack those skills. As conceptualized by the National Education Goals Panel, school readiness encompasses 5 dimensions: physical well-being and motor development; social and emotional development; approaches to learning; language development (including early literacy); and cognition and general knowledge.

Lack of specificity of children's presenting signs and symptoms and of parental concerns make it challenging to determine a specific etiology for school failure. For example, parental concern about a child's inability to focus may be suggestive of an attention disorder, a learning disability, a mood disorder, or perhaps all 3. Parental concerns can be categorized into 3 broad areas: learning (eg, learning disability; problems with higher-order cognition, including intellectual disability), attention (eg, ADHD), and emotional/behavioral (eg, anxiety, depression, serious emotional disturbance). Signs of school difficulties are presented in Box 36.3. It is important to look not only at academic skills but also at other components of the educational experience, such as social and emotional experiences. Additionally, it is important to ascertain the basis for the perception that a child is failing. It is necessary to determine whether the problem exists in the eyes of the student, parent, teachers, or everyone involved. Academic achievement across subjects must be assessed, especially in the areas of reading, mathematics, and writing. It is also important to evaluate students with good skills who fail to perform satisfactorily in the areas of writing, planning, organization, project completion, test taking, or classroom participation. Difficulty with academic performance may result in school failure despite satisfactory academic skills. In addition to academic skills and performance, the development of good social skills and peer relations is equally important. Some students have difficulties "fitting in," which results in a disappointing educational experience despite academic excellence.

Pathophysiology

Developmentally, support exists for promoting school readiness from a young age. Research highlights the effect of nurturing relationships and positive experiences on early brain development. Strong neural connections are created and modified by positive reciprocal interactions, creating a solid foundation for learning. Conversely, adverse environments can have harmful effects on healthy brain development.

The developing brain continues to make new synaptic connections and discard underused connections from birth to approximately age 5 years, well before formal schooling begins. For example, it is known that children who grow up without being read to and with little exposure to books or printed language during their first 5 years are at increased risk for developing reading failure and subsequent school failure (see Chapter 34). School readiness must be promoted from infancy throughout early childhood; waiting for the 4- to 5-year-old well visit to address school readiness is too late. Most children with learning disorders experience language, motor skills, and emotional or behavioral problems well before they encounter difficulties in the classroom. These deficits are noted by parents an average of 3 years before the disability is formally identified.

Box 36.2. Questions Related to General School Readiness and The Five Domains of School Readiness

General Readiness Questions

- Have they had any preschool or group child care experience, and how did they respond in these settings?
- Were any behavioral, developmental, or emotional concerns raised during those group care experiences?
- Have they been screened for developmental delays, and have any delays been addressed?

Self-regulation and Social-emotional Readiness[a]

- Are they able to both express and control their thoughts, feelings, and emotions?
- Are they able to understand that others have thoughts, feelings, and emotions that are different from their own, and can they express empathy or compassion?
- Can they take turns, share, and cooperate with others?
- Can they share and play with other children?
- Do they play well with age-appropriate peers, or do they seem to consistently prefer to play with younger or older children or adults?
- Can they self-soothe or are they easily calmed down when they are upset or frustrated?
- Are they able to separate from parents for several hours?

Physical Health and Motor Readiness[b]

- Do they come to school physically ready to learn (eg, well nourished, adequate sleep)?
- Are their vaccines current?
- Have vision and hearing been evaluated?
- Do they demonstrate developmentally appropriate fine motor skills (eg, can they manipulate a crayon/pencil with a correct grasp, turn pages 1 at a time in a book, or print some letters and numbers)?
- Do they demonstrate developmentally appropriate gross motor skills, such as balance on 1 foot, hop, or skip?

Language and Communication Readiness[c]

- Are articulation errors developmentally appropriate?
- Is speech understandable to strangers?
- Can they hold a back-and-forth conversation about everyday topics of interest?
- Do they use correct sentence structure and speak in complete sentences?
- Do they use appropriate tenses/pronouns?
- Can children use language to express their thoughts and feelings or to follow simple oral instructions?
- Do they use age-appropriate vocabulary?
- Do they have beginning literacy skills, such as basic book concepts, print awareness, and story sense?

Cognitive Readiness[d]

- Do they have general knowledge, such as reciting the alphabet and rote counting, colors, days of the week, letters and numbers names, and basic shapes?
- Do they have more complex understanding, such as letter-sound associations, spatial relations, number concepts, and 1-to-1 correspondence?
- Are they able to solve problems, follow the logic in a story, think, and make decisions?

Approaches to Learning[e]

- Are they able to focus and sustain attention for a developmentally appropriate amount of time?
- Are they able to work in a group, with a partner, and independently?
- Are they able to control their emotions and persist at challenging tasks?
- Do they demonstrate curiosity and enthusiasm for learning?
- Can they tend to basic needs independently, such as toileting, washing hands, and asking for help?

[a] This domain focuses on children's social and emotional development, including their interpersonal and intrapersonal skills.

[b] This domain covers such factors as health status, growth, and disabilities.

[c] This domain focuses on expressive and receptive language skills and literacy development.

[d] This domain includes general knowledge as well as gaining knowledge by making connections with objects, events, or people for similarities, differences, and associations. It also includes knowledge about societal conventions.

[e] This domain refers to the ability to use skills to actively engage in learning.

Adapted with permission from National Education Goals Panel. Ready schools. Washington, DC: U.S. Government Printing Office; 1998

Another critical period in brain development occurs during adolescence, when the brain again undergoes a process of synaptic pruning and myelination that is especially notable in the prefrontal lobe, the area responsible for the *executive function skills* of reasoning, impulse control, attention, and planning. These skills are higher-order cognitive tasks that enable attention, self-regulation, planning, organization, and completion of goal-oriented tasks, all of which are necessary to effectively engage in learning.

Interventions designed to improve children's school connectedness and prevent later academic problems are most effective when

Box 36.3. Factors Related to School Difficulties That May Result in School Failure[a]

Intrinsic

- Not able to follow directions, pay attention, or finish a task
- Not able to carry thoughts or ideas to paper
- Not able to read, write, or spell appropriate to age and educational level
- Requires excessive time to complete homework/excessive parental involvement with homework
- Previously tested but not eligible for special education (eg, child may be a "slow learner")
- Hates school/psychosomatic symptoms
- Has few, if any, friends or change of friends
- Sudden change in behavior
- Low cognitive skills (ie, intellect)
- Specific learning disabilities
- Attention-deficit/hyperactivity disorder
- Speech and language disorders
- Mood and anxiety disorders
- Low self-esteem, self-concept, and self-determination
- Social-emotional difficulties
- Neurodevelopmental delays
- Motor coordination disorders
- Chronic or serious medical illness (eg, seizure disorder, cystic fibrosis, asthma)
- Vision, hearing, or speech difficulties
- Poor nutrition
- Sleep problems
- Substance use/abuse
- Genetic history (eg, family history of school problems)

Extrinsic

- Serious psychosocial concerns (eg, parental depression, history of abuse or neglect)
- Disruption in the family (eg, many moves, divorce, death)
- Poor school readiness/absence of enrichment prior to school entry (eg, early literacy exposure)
- Parental or school expectations not commensurate with child's abilities
- School and/or classroom placement (poor "fit" or poor instruction)
- Grade retention
- Poor attendance, missed instruction
- Multiple school changes
- Language/cultural differences
- Adverse childhood experiences

[a] School failure is not a single event or a linear process. This list provides examples of factors within individual children and their environments, whether home or school, that could place them at increased risk for school difficulties and failure.

they are provided during the preschool years, before a child enters formal K-12 schooling. *School engagement* stems from learning theories demonstrating that learning improves when students are curious, interested, or energized by their schooling and that learning worsens when students are bored, indifferent, or disengaged from their school. Levels of student engagement can be seen on a spectrum from deeply engaged to resistant. For students with fluctuating engagement or true resistance to participation in school and learning activities, a multitiered system of support (MTSS) is often needed to improve student outcomes. School engagement is adaptable and is a function of not only the child but the context, that is, the school environment. This implies that behavioral, emotional, and cognitive engagement can be responsive to prevention and intervention.

School failure has a variety of causes. Both intrinsic (ie, child-related) and extrinsic (ie, environmental-related) causes relating to the home or school environment must be considered (Box 36.3). In most cases, school failure is the result of a complex interaction between child, family, and school-related variables rather than the result of a single factor (eg, ADHD). When evaluating for the etiology of learning disorders, medical problems should always be considered. Neurologic, psychological, social-emotional, and behavioral disorders based in the central nervous system may also be responsible for school failure. Unrecognized disorders may be causes of school failure. For example, children with ADHD often have significant academic underachievement, poor academic performance, and poor educational outcomes.

Learning disorders are a broad group of neurodevelopmental disorders affecting children's ability to learn, such as speech and language impairments, intellectual disability, specific learning disabilities, and ADHD. Learning disorders are among the most frequently diagnosed developmental disorders in childhood.

Learning disabilities comprise a subset of learning disorders and are neurologically based processing problems that interfere with learning basic skills, such as reading, writing, and/or math, as well as more complex skills, such as organization, planning, abstract reasoning, short- and long-term memory, and attention. Learning disabilities are the most common learning disorder. Approximately 10% to 15% of children have learning disabilities, and reading disabilities are the most common type. Children with learning disabilities are the largest group of students receiving special education services in schools; these disabilities vary in degree, nature, and complexity.

A formal definition of specific learning disability was first outlined in federal law in 1975 as part of the Education for All Handicapped Children Act, now the IDEA. A *specific learning disability* is "a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, that may manifest itself in the imperfect ability to listen, think, speak, read, write, spell, or to do mathematical calculations." The IDEA of 2004 expanded educators' options for determining whether a child has a learning disability by removing the requirement for use of a discrepancy model that identifies a learning disability as a significant difference between a child's intellectual ability (ie, intelligence quotient [IQ]) and academic achievement. That now-removed requirement was often called the "waiting to fail" model, because parents and schools had to wait until individual children's achievement fell significantly below their ability level before a learning disability could be identified. Currently, children can be identified with a learning disability if they do not exhibit adequate achievement when provided with age- or grade-appropriate learning experiences; do not make progress sufficient to meet age- or grade-level standards when provided research-based intervention (ie, response to intervention); or do exhibit a pattern of strengths and weaknesses in academic performance, achievement, or both, relative

to grade-level standards, or intellectual development. Specific learning disabilities do not include "learning problems that are primarily the result of visual, hearing, or motor disabilities; intellectual developmental disorders; of emotional disturbance; or of environmental, cultural, or economic disadvantage."

The criteria of learning disorders are listed in Box 36.4. For a more comprehensive list of diagnostic criteria and coding information, refer to *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*). Similar to IDEA, *DSM-5* removed the discrepancy between IQ and the affected learning area as a requirement for diagnosis. This change is based on research showing that children who meet and those who do not meet the IQ-discrepancy criterion do not differ in terms of symptomatology, underlying cognitive deficits, or response to effective intervention.

Although it is difficult to do, it is important to differentiate students with neurologically based learning problems from those with learning problems caused by other factors. For example, a student's disability may predispose the individual to learning problems even in highly accommodating environments, whereas inadequate environments can result in significant learning problems even in the absence of disability. This differentiation is vital to management or intervention success. An inadequate environment or a student disability are best addressed with evidence-based instruction in the deficit areas; focusing only on addressing the academic deficit will not alleviate comorbid negative social-emotional, behavioral, or environmental conditions. Before evaluating for child-related pathology or underlying dysfunction, such as specific learning disabilities, cognitive delays, language disorders, or mental health disorders, the physician should investigate external situations that may be causing or exacerbating the problem (eg, underperforming schools, lack of parental involvement, poor student-teacher relationship, mismatch between a child's ability/disability and the learning environment).

Evaluation

History

A thorough history is necessary to help the pediatrician assess a child's strengths and challenges and formulate a hypothesis for diagnosis. Research on prevention, resiliency, and social-emotional development demonstrates that the presence of assets or strengths is positively linked with improved outcomes in all domains of development. Incorporating educational and learning strengths assessment in the primary care setting can facilitate discussion of positive changes and prevention and can make the discussion of challenges and intervention more comfortable for parents and children.

Box 36.4. Criteria for Specific Learning Disorder

- Difficulties learning and using academic skills: word reading; meaning of what is read; spelling; written expression; number sense, facts, or calculation; mathematical reasoning
- Academic skills below expected for chronological age; interferes with academic/occupational performance/activities of daily living
- Learning difficulties begin during school-age years or when academic demands exceed the patient's capacities
- Learning difficulties are not secondary to intellectual, visual, auditory, mental, or neurological disorders

Derived from *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition.

School Readiness

Historically, pediatricians assessed school readiness during the 5-year-old health maintenance visit, but currently it is understood that the optimization of development and school readiness should be addressed beginning in infancy. The American Academy of Pediatrics (AAP) has highlighted 5 domains of school readiness, which are consistent with the 5 dimensions of school readiness from the National Education Goals Panel. These domains include self-regulation and social-emotional readiness, physical health and motor readiness, language and communication readiness, cognitive readiness, and approaches to learning (Box 36.2). The physician should interview the parent and observe the child to assess the acquisition or progression toward these readiness skills. Mastery of these skills is not necessary for social and academic competence and should never be used as exclusion criteria for a child beginning formal schooling, because public school kindergarten classrooms and curricula are designed to accommodate a diversity of skill levels. Providing this information to families early in a child's development can help families make decisions about early childhood programs and, if necessary, early interventions. More than 50% of children younger than 5 years regularly attend some type of child care or preschool program; thus, including questions about the quality and experiences within these settings is an important part of the history.

School Engagement/School Failure

When evaluating for school engagement and/or school failure, the physician should elicit information from parents, teachers, and the children themselves (Box 36.5). A review of present and past report cards provides information not only on academic progress relative to the grade level standards but also on the child's behavioral, social-emotional, and classroom adaptive skills. Teacher behavior rating forms, school district and state academic evaluations, and results of any school-based psychoeducational evaluations also should be reviewed.

Box 36.5. What to Ask

School Engagement and/or School Failure

- Have the child tell you about experience at school. What classes or subjects does the child like or dislike and why? Does the child have friends? Does the child participate in any extracurricular activities?
- Have any behavioral, social, emotional, or attentional concerns been raised by the child or the classroom teacher?
- How is the child's academic achievement? Is the child having problems in all academic areas, or are particular subjects especially difficult whereas others are not?
- Do concerns exist about educational performance, such as test taking, project organization, or homework completion?
- Are there attendance issues? How many days of school has the child missed?
- Has any testing (eg, psychoeducational evaluation) been performed by the school district or privately?
- Is the child receiving any accommodations or special services (eg, intervention group, counseling, speech therapy) at school?

Clinical approaches to early identification of children at risk for school failure include risk assessments and developmental surveillance and screening. Children from economically disadvantaged backgrounds are at the highest risk for problems in school. Developmental surveillance and screening allow pediatricians to identify children with developmental, behavioral, and emotional delays and to provide appropriate guidance, as well as referral to early intervention programs (see Chapter 32). Historical factors associated with an increased risk of school-related problems include preterm birth, low birth weight, small for gestational age, and maternal history of tobacco, alcohol, or illicit substance use during pregnancy. Developmental risk factors include delays in the acquisition of skills, especially those involving language. Medical factors that may affect school readiness include lead poisoning, iron deficiency anemia, and failure to thrive. The presence of chronic medical conditions (eg, asthma, diabetes mellitus, seizure disorders) can also affect school performance directly or indirectly via absenteeism, medication effects, or self-esteem issues. Environmental risk factors include poverty and lower socioeconomic status, parental mental health issues, domestic violence, substance abuse, or a family history of school problems or learning disabilities.

Physical Examination

In terms of school readiness, the most important aspect of the 5-year-old health maintenance physical examination includes careful assessment of hearing, vision, speech, and language. Fine and gross motor skills, attention and listening skills, ability to follow rules and directions, social skills, and self-help skills (eg, asking for help when needed, independently using the restroom and washing hands) also should be assessed.

The physical examination has a limited but important role in the evaluation of school failure. Signs of short attention span, distractibility, overactivity, sadness, or anxiety all should be noted. Special attention should be paid to head circumference, minor congenital anomalies, abnormal facies, and skin lesions suggestive of neurocutaneous disorders (eg, multiple café au lait spots, ash leaf macules). The pediatrician should evaluate the child's vision, hearing, and speech and language and conduct any other appropriate evaluations as suggested by the history.

Neurodevelopmental Assessment

School readiness assessment begins with routine pediatric surveillance and screening (see Chapter 32). Several brief school readiness tests have been developed for use by pediatricians (eg, Pediatric Examination of Educational Readiness). However, because the reliability and ability of such tests to detect subtle learning disabilities or arrive at more complicated diagnoses has not been established, it is difficult to recommend any of them for routine use. If a specific school readiness evaluation is warranted, it is best to make a referral to the school district or an independent specialist (eg, developmental and behavioral pediatrician, educational psychologist) for a full evaluation.

Neurodevelopmental assessment can help identify the etiology of school failure. *Neurodevelopmental assessment* surveys a child's abilities across the different areas of development (ie, fine motor, language, visual-spatial, memory skills) and helps identify areas of strength and weakness. Such an assessment can be performed by a professional such as a developmental and behavioral pediatrician or a psychologist. Psychoeducational assessment is also critical in the evaluation of children with school failure. Such an assessment includes an evaluation of cognitive abilities, academic achievement across subjects (eg, reading, writing, mathematics), perceptual processing strengths and weaknesses, social and emotional functioning, and the way in which these areas affect a child's learning. This can be accomplished through the public school system via the Individualized Education Program (IEP) process, as mandated by federal law (ie, IDEA) or privately, by an educational psychologist.

Management

According to the AAP policy statement "The Pediatrician's Role in Optimizing School Readiness," helping children develop the physical, social-emotional, cognitive, adaptive, and language skills needed to learn should begin at birth. Pediatricians can create a medical home in which they provide for children's physical health while also working with families to address developmental, social, emotional, and behavioral components of school readiness. Empowering parents with knowledge can give them the confidence to interact positively with their children's schools and allow them to effectively advocate for their children's educational needs.

Often, an important role in management is facilitating open communication about a child's needs. Pediatricians must acknowledge the emotions and fear that often are associated with discussing a child's delays or disability and must demystify the process of accessing support, interventions, and treatment. For both parents and children, the process of demystification can include assurances that all people have strengths and challenges and that resources and support are available. It is important to use an optimistic tone in such discussions. In addition to addressing the needs of families and children, the physician can also serve an important advisory role for the school on the educational implications of chronic medical conditions and the potential academic, behavioral, and social-emotional effect of a child's disability (eg, side effects of medications, appropriate seizure or allergic reaction responses).

Early intervention is the key to success in children's school readiness. Pediatricians are in the most opportune role to help families recognize the importance of early brain and child development and how they are affected by a child's environment and experiences. Teaching parents that their child's learning begins at birth and occurs in all environments not only can support children in meeting developmental milestones but can help them successfully acquire the curiosity, emotional regulation, and problem-solving skills they will need when they begin school. It is important for pediatricians to promote community and home activities to enhance readiness skills, refer families to community resources, and support access to early childhood programs.

During routine well-child visits, the pediatrician should ask families what child care arrangements they have made for their children and educate them about the importance of high-quality child care. To maximize quality early learning experiences, pediatricians can provide resources through links such as AAP's *Quality Early*

Education and Child Care from Birth to Kindergarten. For many at-risk children, early childhood education programs such as Head Start and other preschool compensatory programs may come too late. Early intervention programs for younger children and their families that promote good parenting, language stimulation, and learning through play are valuable and available in many communities.

Reading aloud to children is among the most important parent-child interactions physicians can promote, and it builds the child's skills required for eventual success in reading (see Chapter 34). Reading promotes language mastery, which is critical to school readiness.

Children who are at increased risk for school readiness problems because of medical, social-emotional, behavioral, or environmental concerns should be monitored carefully. If these children do not appear to demonstrate age-appropriate skills, they should be referred for further evaluation. Despite early intervention, some children still may lack age-appropriate school readiness skills. Options for these children include delayed school entry or enrollment in special educational programs. Delaying school entry may not be the best solution if children remain in the same environment that failed to produce readiness in the first place. In addition, studies have shown that students who are older than their classmates because of delayed school entry have increased rates of behavior problems, substance abuse, and other health risk behaviors in adolescence. Instead, it may be best for these children to enter school along with their same-age peers and, if necessary, receive school-based support to address any difficulties.

The management of school failure requires a multidisciplinary approach. Information from the school, including school reports, teacher conferences and notes, testing that has been completed, and input from other school officials, if appropriate, should be requested. The primary care physician can assist the child and family in working with the school system to obtain appropriate services. The primary care physician may also refer the child to appropriate resources in the community (eg, educational psychologist, developmental and behavioral pediatrician). Not infrequently, external factors such as social, family, and school-based issues may be difficult to alter. Knowledge of the educational laws and community services, as well as ongoing developmental surveillance and screening by the primary care physician, are necessary to help prevent school failure.

Grade retention is often suggested as an intervention for school failure. However, disparities exist in rates of grade retention based on sex, race/ethnicity, geographic locale, and socioeconomic circumstances. Boys, minorities, children born outside the United States, and children from homes led by adults with lower levels of education are retained at the highest rates. Although grade retention has been a common educational practice in US schools, overall retention rates have decreased notably in the past 10 years. Nonetheless, parents and school personnel may consider retention as a viable intervention option for children who are struggling for academic, behavioral, or social-emotional reasons. Research does not support retention as an effective remediation strategy, however.

Data suggest that grade retention has an adverse effect on most students. In fact, grade retention can diminish the positive outcomes of early intervention programs and is a significant contributing factor to school disengagement. Retention is the number 1 predictor of student attrition. Retained students, regardless of race, socioeconomic status, attendance, English language status, or parental involvement, are more likely to drop out of school than similarly low-achieving students who were promoted to the next grade level. Many teachers report suggesting retention to allow a child to "mature" or "give the gift of time," although minimal evidence exists that it is beneficial to repeat a grade without making changes to the curriculum or environment, or directly addressing the reason for retention. Educational alternatives to retention include directly addressing the reason retention was considered. For academic delays, extra support can be implemented in the form of targeted academic interventions, differentiated instruction, classroom accommodations, and, in some cases, special education services. Equally as important as remediating the areas of weakness is recognizing the child's areas of strength (eg, the idea of using children's strengths to leverage their weaknesses).

The pediatrician can assist families with children who are demonstrating learning, behavioral, and/or social-emotional difficulties that are affecting their academic achievement and performance. Public school systems, as mandated by federal and state laws, have systems of support and services available for students through both general and special education. Pediatricians' awareness and understanding of these systems is an important part of management, because they are often the first professional to be made aware of these delays.

The Every Student Succeeds Act signed into federal law in 2015 is a reauthorization of the Elementary and Secondary Education Act. The law includes a number of provisions to support success for all students by requiring districts and schools to establish a MTSS promoting children's academic, behavioral and social-emotional learning regardless of their ethnicity, socioeconomic status, primary language, family history, strengths, challenges, or disability. The MTSS is a schoolwide, data-driven, prevention-based framework for improving learning outcomes for all students through a layered continuum of evidence-based practices and systems. Common school prevention frameworks, such as response to intervention and Positive Behavior Interventions & Supports, are imbedded into MTSS. Within this tiered system is the recognition that providing every student the same level of supports, regardless of the quality, will not meet every child's needs. Levels of support are typically divided by the intensity of the services and the number of students they are designed to serve. Tier 1 includes foundational universal supports, which are evidenced-based practices that support the academic, behavioral, and social-emotional success of all students. Examples of tier 1 supports include training all teachers in differentiated instruction, implementing a school-wide positive behavioral system, conducting mental health screening of the entire student body, and adopting an evidence-based language arts curriculum. Supplemental and intensified services are designed for students who require more academic, behavioral, or social-emotional support, with the most intensive level of support targeted to students with the greatest needs. Examples of Tier 2 support for students who have been identified as having academic, behavioral, or social-emotional struggles may include homework modifications, small group reading intervention, or participation in a social skills

group. Students who have been identified as needing the most support may receive the most intensive interventions, such as 1-to-1 counseling or an individualized behavior support plan. Special education services are typically viewed to be tier 2 service.

Students with disabilities have the same right to public education as students without disabilities. To receive and benefit from that education, students with disabilities may need special education and/or related aids and services. Pediatricians can help parents of children with neurodevelopmental disabilities (eg, intellectual disability, mental health disorders, cerebral palsy, learning disorders, autism spectrum disorder) gain access to these services. Special education, as mandated by the IDEA, is not a place to which students with disabilities are sent. Rather, special education is a broad group of specially designed instruction, services, and supports that address the unique educational needs of students age 3 through 21 years who have a disability. In *specially designed instruction*, the content, methodology, or delivery of instruction is adapted to address the unique needs of a student with a disability. *Related services* are developmental, corrective, and other supportive services that are required to assist a child with a disability to benefit from special education. Examples of related services include transportation, speech and language therapy, occupational therapy, nursing services, and behavioral support services.

The IDEA requires public schools to provide free and appropriate education in the least restrictive environment for all children with a qualifying disability. That is, special education is provided at no cost to parents and includes services designed to meet the individualized educational needs of the students so they can access their educational program. Students with disabilities must also be educated with students without disabilities to the maximum extent appropriate. Special education services differ for each child, regardless of disability, because services, supports, and accommodations are individualized to meet each child's unique educational needs.

The IEP process begins when the parent requests an evaluation for special education services (Figure 36.1). A multidisciplinary

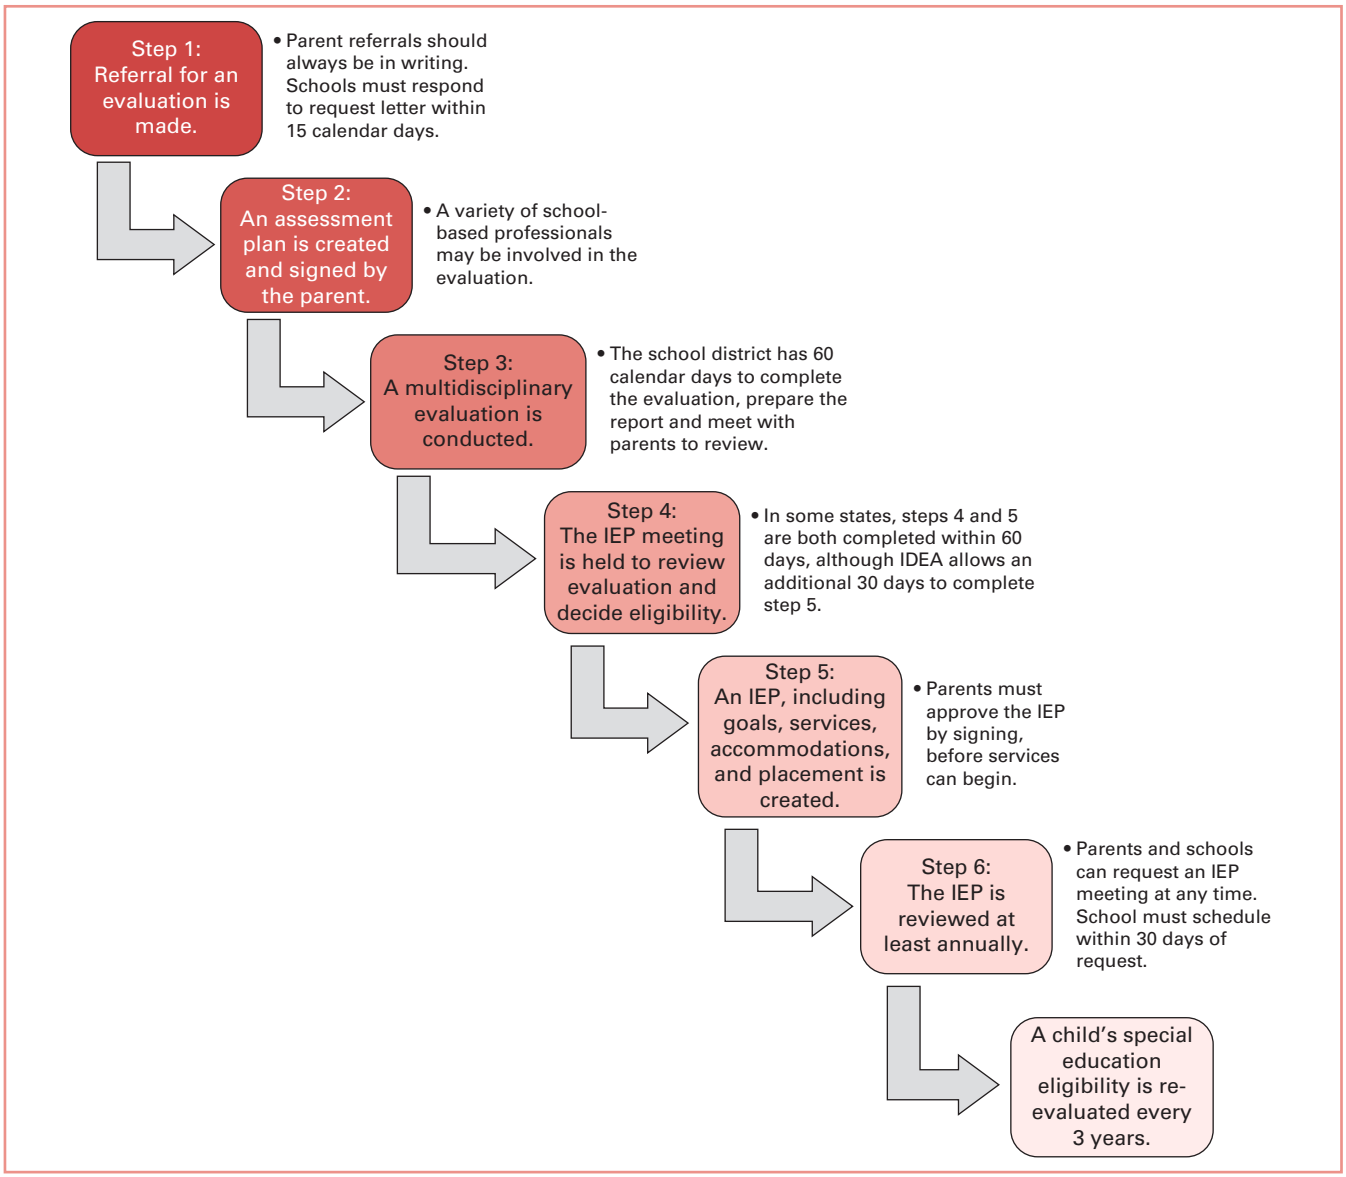

Figure 36.1. The Individualized Education Program process.

Abbreviations: IDEA, Individuals with Disabilities Education Act of 2004; IEP, Individualized Education Program.

evaluation designed to evaluate for special education eligibility and need is conducted. This evaluation may cover a broad range of areas depending on the referral concerns, including cognitive ability, academic achievement, social-emotional and behavioral functioning, adaptive behavior, language development, motor skills, and sensory processing. Eligibility for IDEA is dependent on meeting criteria for 1 of the 14 special education eligibility categories (Box 36.1). The IDEA and state educational codes provide operational definitions for these disability categories. It is important for the medical community to understand that educational systems do not use diagnostic criteria of the *DSM-5* or *International Classification of Diseases, Tenth Revision*. Rather, IDEA eligibility criteria use disability categories and focus on the ways in which a child's disability affects academic achievement or educational performance. A multidisciplinary team, including the child's parents, reviews and discusses evaluation results to decide on eligibility, identify educational needs, and create an IEP, including goals, services, accommodations, and placement. Should a child demonstrate behaviors that affect the child's or other students' learning, behavioral supports such as behavior goals or behavior intervention plans must be part of the IEP. The IEP is reviewed and revised regularly, with input from the IEP team members, including the parents and school-based professionals. A distinguishing component of IDEA is that the specific special education eligibility criteria used to qualify a child for special education services do not drive goals, services, and placement. Typically, within medical systems a child's diagnosis drives treatment; in the educational system, however, the child's unique educational needs, regardless of special education eligibility criteria, drive services. This is the individualized part of the IEP.

Special education services do have certain constraints. The purview of special education is the provision of educationally relevant services and supports. The purpose of special education is not to provide the full range of treatment options for a child with disability; rather, special education involves providing services and supports so that children with disabilities can gain access to and receive benefit from their education. For example, services such as occupational therapy and speech therapy need to relate to educational access and participation. Health professionals often view medical diagnoses and educational eligibility, as well as educationally related services and medically necessary services, as the same. They are not. Although these terms and services overlap, they are not interchangeable, and this can cause confusion and frustration for both medical providers and families. For example, a child with a medical diagnosis of autism spectrum disorder may not meet the special educational eligibility for a child with autism. However, this child may meet the educational eligibility for speech and language impairment and therefore would be eligible to receive special education supports and services to address the child's unique educational needs, regardless of the special education category in which the child was deemed to be eligible.

Section 504 of the Rehabilitation Act of 1973 (Section 504) is a civil rights statute that prohibits exclusion of individuals and discrimination against people with disabilities in federally funded programs and activities, including public schools and many after school programs. Students with a physical or neurologic impairment (eg, ADHD) that substantially restricts 1 or more major life activity are eligible for services under Section 504. Examples of school-based major life activities may include performing manual tasks, speaking, learning, working, thinking, and communicating. Students with disabilities who need only reasonable accommodations or modifications to be educationally successful within general education are frequently served under this law. The definition of disability and the way in which it affects a student at school is more broadly defined and has less stringent criteria in Section 504 than in the IDEA; thus, Section 504 provides for support and services for students with disabilities who do not require more comprehensive special education support.

The medical home concept of comprehensive, coordinated care is particularly useful for children with disabilities. Open communication among pediatricians, families, and schools can facilitate shared expertise and knowledge of the unique needs of children with special needs and can foster implementation of appropriate services to address those needs. Each state establishes its own special education code and regulations based on IDEA standards. Thus, pediatricians should be familiar with their state laws as well as the federal IDEA so that they can advocate for their patients at the time of school entry or whenever a child with a disability is not succeeding in school.

The pediatrician's role in advocacy on behalf of the child with a disability cannot be underestimated. Coordination of care, including educational services, for children and adolescents with chronic medical or disabling conditions should include the child's primary care physician. To effectively coordinate patient care, the pediatrician must be knowledgeable about federal and state education laws, establish linkages with early intervention services and parent support resources, and promote open communication with the child's family and school-based team. Additional examples of advocacy roles for physicians include involvement with assessment team processes at children's schools, consulting with local school districts, participation in local or state early intervention interagency councils, and serving as knowledgeable proponents for improved community and educational services.

Prognosis

Promotion of school readiness should be part of early pediatric visits. Children with daily exposure to reading, singing, and conversation have an enormous language and academic advantage over peers with fewer language and literacy experiences. Early literacy promotion through programs such as Reach Out and Read can educate parents about the importance of reading to their children and enhance children's exposure to early reading. Quality early childhood education programs also promote children's school readiness not only by introducing children to pre-academics but by introducing them to the social, emotional, and behavioral requirements for school success. Early academic success is the best predictor of later academic success. Children who begin school with the appropriate developmental skills, as well as family and community support, are prepared for learning. Pediatric primary care physicians

can serve an important role in improving educational and health outcomes for their patients by supporting coordinated care with children, families, and schools in the evaluation of and intervention for children who are not academically, socially, or behaviorally successful at school.

School failure results not from a single factor, but rather from a combination of risk factors. For children with neurologically based learning disorders or other neurodevelopmental disorders, the educational prognosis depends on the severity of the problems and the intensity and timing of the interventions the children receive. With coordinated support from educational, medical, family, and psychological sources, many of these students have successful school careers. Health impairments can contribute to school failure; however, social, behavioral, and emotional problems often contribute more significantly to academic difficulties. Students who may have endured major or chronic socioeconomic upheaval or environmental or familial trauma often continue to struggle unless they receive comprehensive changes in their support system.

The US Department of Education set a goal of having all students graduate from high school prepared for college or careers. The transition to college and career can have more challenges for students with disabilities. On average, students with disabilities who receive special education services earn fewer overall credits, have lower grade point averages, and fail more courses than their general education peers. Course failure and credit deficiency are highly predictive of failing to graduate from high school. Outcomes for those who do graduate are also affected. High school students with an IEP are less likely than their non-IEP peers to have experiences in high school (eg, managing their own bank or credit union account, driving, holding a part-time job) that are associated with success after high school. Additionally, their parents have lower expectations of them with regard to financial independence and independent living. Research has shown that students with intellectual disability, autism, deaf-blindness, multiple disabilities, and orthopedic impairments are at the greatest risk for not transitioning successfully beyond high school.

Regardless the cause, academic difficulties and school failure can have lifelong consequences if not properly diagnosed and addressed. Students with academic, behavioral, and social-emotional struggles are more likely than their peers to drop out of school or engage in behaviors that are dangerous to their health as adolescents. The pediatrician can make a significant difference in outcomes for their patients' educational and school success by helping families engage in healthy development practices and advocating for appropriate assessment of and intervention services for children who are struggling academically.

CASE RESOLUTION

The pediatrician should advise the family to request in writing a psychoeducational evaluation for special education eligibility from the school. The pediatrician can also institute an evaluation for ADHD by gathering information from the family.

CHAPTER 37

Immunizations

ChrisAnna M. Mink, MD, FAAP

CASE STUDY

A 20-month-old boy who emigrated with his family from Botswana because his mother is attending graduate school at a local university is brought to the office for a checkup. He has his World Health Organization Expanded Programme immunization card from his homeland showing that he received a BCG vaccine at birth; 3 doses of diphtheria, tetanus toxoids, and pertussis vaccine at 2, 4, and 6 months of age; 3 doses of live oral poliovirus vaccine at 2, 3, and 4 months of age; 3 doses of hepatitis B vaccine at birth and at 2 and 9 months of age; and a monovalent measles vaccine at 9 months of age. It is August, and his parents plan to enroll him in child care; they are eager for him to receive any needed vaccines. His parents report that he is a healthy boy with no immune problems. They report that they will be living with his uncle, who has HIV infection. The boy has had a 3-day history of a runny nose, cough, and tactile fever. His physical examination is normal other than mild clear coryza and a rectal temperature of 37.9°C (100.3°F). The physician must determine what vaccinations may be given to the patient.

Questions

1. What are the different kinds of vaccines?
2. What are the mechanisms of action for live and inactivated vaccines?
3. What are the routinely recommended immunizations for healthy pediatric populations?
4. What are the considerations for immunizing select pediatric populations, such as immunocompromised children?
5. What are reliable resources for up-to-date information about immunizations?
6. How can a pediatrician address parental vaccine refusal?

The Centers for Disease Control and Prevention (CDC) considered immunizations among the top 10 greatest health accomplishments of the 20th century, and vaccines continue to play a major role in the improvement of the health of the world's population. In the United States, the incidence of nearly all the pathogens for which there are routine vaccinations has decreased by 95% to 100% since the early 20th century. The only exception to this is pertussis, which has undergone an approximately 80% reduction. In 2017, the immunization rates for children in the United States remained high, with 84% to 94% of children aged 19 to 35 months immunized for the 4:3:1:3:3 series (4 diphtheria, tetanus toxoids, and acellular pertussis [DTaP]; 3 polio; 1 measles, mumps, and rubella [MMR]; 3 *Haemophilus influenzae* type b [Hib]; 3 hepatitis B virus [HBV]). Worldwide, the percentage of children immunized with 3 doses of diphtheria, tetanus toxoids, and pertussis (DTP) and oral polio vaccines (OPV) and a measles-containing vaccine is at a record high of nearly 85%. Since 1990 the mortality rate has declined for children younger than 5 years in every region in the world, which is directly related to increased rates of vaccinations. Generally, immunizations are safe, well tolerated, and cost-effective, with savings of $5 to $16.50 for every $1 spent.

Another less recognized benefit of vaccinations is that the schedule has essentially provided the backbone for routine pediatric care in the United States, with regular visits scheduled around the recommended intervals for immunizations. These visits have afforded health professionals opportunities for serial evaluation of newborns, infants, and young children as well as education and anticipatory guidance for parents. Increasing availability of new vaccines targeted for older children and adolescents should permit opportunities for improved health care delivery to these age groups. Additionally, health professionals who treat adults have a growing appreciation for the critical role of vaccinations in protecting their patients as well as all members of their patients' family.

General Principles

When planning immunizations for a patient, 2 important factors to consider are the health status of the recipient and the type of immunization to be given. The risks and benefits of using the vaccine in the specific host should be weighed carefully. Vaccines are intended for a host with the capacity for mounting an appropriate immune response, who will likely benefit from the protection provided, and, ideally, who is at little to no risk for adverse effects.

Types of Immunization: Passive and Active

The 2 major types of immunizations are passive and active.

Passive immunization refers to the delivery of preformed antibodies, usually as immune globulin (IG), which may be a general formulation or hyperimmune IG developed with high concentrations of antibodies against a specific disease, such as hepatitis B IG for hepatitis B.

Delivery of IG may be useful in any of the following 3 settings: in a host who cannot manufacture antibodies (eg, congenital immunodeficiency); as a preventive measure, either pre- or post-exposure, especially when the host may be unable to mount an antibody response (eg, immunocompromised naïve child with acute exposure to varicella); or for treatment, in which IG may be used to ameliorate symptoms in the patient in whom disease is already present (eg, intravenous IG for the management of Kawasaki disease).

With *active immunization* all, part, or a modified product (eg, toxoid, purified antigen) of a microorganism is given to the host to elicit an immune response. The intact organisms may be inactivated (ie, killed) or live-attenuated (ie, weakened). Usually, the elicited immune response mimics the response to natural infection and, ideally, poses little to no risk to the recipient.

Inactivated Vaccines

Inactivated vaccines may contain inactivated or killed organisms, purified components (ie, subunit), or inactivated toxins (ie, toxoids) of the organism. These vaccines are not capable of replication in the host. Most inactivated vaccines are delivered by intramuscular injection. Generally, inactivated vaccines may be administered simultaneously with other inactivated vaccines, as well as live viral vaccines.

The common viral vaccines that are inactivated include inactivated influenza vaccine (IIV), trivalent and quadrivalent formulations, hepatitis A vaccine (HAV), HBV, inactivated poliovirus vaccine (IPV), human papillomavirus (HPV), Japanese encephalitis, and rabies vaccines. Toxoid vaccines that are used routinely include tetanus and diphtheria toxoids alone or in combination with whole-cell or acellular pertussis components (eg, DTaP; DTP; tetanus and diphtheria toxoids; tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis [Tdap]). The acellular pertussis vaccines are composed of 1 or more purified antigens of *Bordetella pertussis*, in contrast with the whole-cell pertussis vaccines, which are made with killed, whole *B pertussis* organisms. Diphtheria and tetanus toxoids combined with whole-cell pertussis (ie, DTP) vaccines are no longer marketed in the United States but are used in many developing countries. Other inactivated bacterial vaccines include capsular polysaccharide (CPS) vaccines, such as the 23-valent pneumococcal polysaccharide vaccine and tetravalent meningococcal CPS vaccine.

Conjugate Vaccines

Capsular polysaccharide antigens are chemically linked to a protein carrier, which converts the T-cell independent polysaccharides to T-cell dependent antigens. These conjugate vaccines can elicit an immune response, even in young infants. The first CPS-protein conjugate vaccine available was for Hib. The Hib bacterium is covered with a CPS, polyribitol-phosphate. Children younger than 2 years of age are not efficient at mounting antibodies to the polyribitol-phosphate CPS; however, with linkage to a protein carrier the CPS is immunogenic. Since licensure for infants of the Hib conjugate vaccines in 1991, a more than 98% reduction in Hib disease has occurred. With the success of the Hib CPS-protein conjugate vaccines, conjugation techniques have been used for other CPS pathogens, including *Streptococcus pneumoniae* and *Neisseria meningitidis*.

Live-Attenuated Vaccines

Live-attenuated vaccines are infectious agents that replicate in the host to elicit an immune response. The administration is generally not intramuscular but by other delivery routes, such as oral, intranasal, or subcutaneous. Often the live vaccines are viral, including MMR, varicella-zoster virus (VZV), rotavirus, live-attenuated influenza virus (LAIV), OPV, and yellow fever vaccines. Two live bacterial vaccines are available: BCG used against *Mycobacterium tuberculosis* and oral typhoid (Ty21a) vaccine.

A transient suppression of T-cell immunity occurs 2 to 4 weeks after measles vaccination. Because of this, when vaccinating with live viral vaccines, 2 or more live vaccines should be administered at the same time or vaccine administrations should occur at least 4 weeks apart. This principle also holds true for tuberculosis skin testing; either the purified protein derivative should be placed at the same time as a live viral vaccine, or they should be administered at least 4 weeks apart to avoid a false-negative purified protein derivative result because of the transient T-cell suppression. Although this phenomenon has primarily been studied with measles vaccine, the same guidelines should be followed with other live viral vaccines.

Vaccination Schedule

Factors for developing the schedule include the host ability to respond (eg, lost maternal antibody), the need for multiple doses (eg, IPV), the minimal intervals needed between serial doses, and the available products (eg, combination vaccines). Each year, a synchronized immunization schedule is posted by the American Academy of Pediatrics (AAP), American College of Obstetricians and Gynecologists, American Academy of Family Physicians, and the CDC Advisory Committee on Immunization Practices. Separate immunization schedules are available for children from birth through 18 years as well as for adults 19 years and older. The schedules for the United States are posted each January at https://www.cdc.gov/vaccines/schedules. Schedules for countries worldwide are available from the World Health Organization.

Vaccine Recipients

Healthy Pediatric Populations

Routine immunizations on the synchronized schedule are targeted for healthy newborns, infants, children, and adolescents. All licensed vaccines have undergone review by the US Food and Drug Administration (FDA) and have proven safety and immunogenicity or efficacy for the target population. No vaccine is completely free of adverse events or provides 100% protection for every recipient, however. Every effort should be made to provide immunizations when the recipient is healthy and has the best chance to mount an optimal immune response without delaying vaccination or risking a missed opportunity.

Special-Risk Pediatric Populations

Although immune responses to vaccinations are likely most favorable in healthy recipients, a growing segment of the pediatric population has underlying health problems. Because of congenital or acquired immune dysfunctions, some individuals should not receive immunizations as directed by the routine schedules. Special accommodations need to be made for immunizing these individuals, such as adjusting the schedule or possibly not administering some agents. Administration of decreased or partial doses of vaccines is not indicated. Some of the select populations or circumstances that warrant special consideration include immunocompromised status, immunodeficiency, pregnancy, preterm birth status, low birth weight status, allergy to egg protein, planned international travel, patients from other countries, adolescence, and vaccines administered in other countries.

Immunocompromised Child

The vaccination plan for the immunocompromised child should be determined by the nature and degree of immunosuppression. The health professional should weigh risks and benefits for each child individually, with consideration for some general principles. For example, live vaccines should not be given to severely compromised individuals because of the possible risks. In general, inactivated vaccines may be safely administered to nearly all recipients; however, immunocompromised individuals may not mount an optimal immune response. In this setting, the health professional should attempt to adjust timing of vaccination to optimize the chance of a good immune response. Guidelines for immunizing immunocompromised children and adults have been established by the Infectious Diseases Society of America in conjunction with the AAP, CDC, and other professional groups and are posted at www.idsociety.org/Templates/Content.aspx?id=32212256011.

Types of Immunodeficiency

Newborns, infants, and children may have abnormalities of any aspect of the immune system, which may affect their ability to receive vaccinations. Weighing the risks of both the disease and the vaccine and the benefits of protection is essential. A reasonable approach to developing a vaccination plan for children with immune abnormalities is to consider the mechanism of immune defense against the vaccine agents; if the needed defense mechanism is deficient, immunizing with that agent may not be appropriate. For example, cellular immunity is essential in defending against viral agents. Thus, children with abnormalities of cell-mediated immunity, whether primary or acquired, may not be candidates for live viral vaccines.

Primary immunodeficiencies are generally inherited, and secondary immunodeficiencies are acquired. Examples of acquired immunodeficiencies include HIV infection, malignancy, and illnesses (eg, malnutrition, uremia) as well as those caused by medications (eg, chemotherapy, immunosuppressive agents). The OPV is contraindicated for individuals with primary humoral immunity abnormalities (ie, those who cannot make antibodies); however, MMR vaccine may be indicated for some of these individuals because of the potential risks of natural infection. Receipt of all vaccines, including live viral vaccines, is acceptable for most individuals with complement deficiencies. For abnormal phagocytic function, live bacterial vaccines should not be given. For individuals with traumatic or surgical asplenia, vaccination with pneumococcal, meningococcal, and Hib vaccines is indicated and should be considered emergently in the case of trauma. Chemoprophylaxis also may have a role in protection for compromised individuals.

For children with immunocompromised household contacts, it is generally acceptable for them to receive MMR, VZV, and oral rotavirus vaccines. However, the live viral vaccines of OPV and LAIV should not be given in some settings. In contrast, use of some vaccines, such as IIV, is encouraged to protect the vaccinated individuals as well as their compromised contacts.

Pregnancy

Pregnancy is associated with some impairment of cell-mediated immunity. With this decreased immunity, pregnant women may not mount protective immune responses to some infectious agents. Thus, in general, live vaccines should not be administered to pregnant women; however, the risks and benefits should be weighed for each individual patient. Live-attenuated influenza virus should not be given to pregnant women. Neither should rubella vaccine be given to pregnant women, although no cases of rubella embryopathy following inadvertent immunization of a pregnant woman have been reported.

Both IIV and Tdap are recommended during pregnancy to provide protection for the mother and the fetus. These vaccines may be given anytime during pregnancy, although the preferred timing for Tdap administration is 27 through 36 weeks to optimize transfer of pertussis antibodies to the fetus. Pediatricians are often asked whether administration of live viral vaccines is contraindicated for children residing with a pregnant household contact; generally, such administration is not contraindicated.

Preterm and Low Birth Weight Infants

In general, medically stable preterm (<37 weeks of gestation) and low birth weight infants (<2,500 g [<5 lb 5 oz]) may be immunized at the same dose, schedule, and postnatal age as full-term and normal birth weight infants.

Special consideration should be given to use of HBV vaccine in newborns weighing less than 2,000 g (<4 lb 4 oz) as follows. For the hepatitis B surface antigen (HBsAg)-positive mother or mother whose status cannot be determined within 12 hours, monovalent hepatitis B vaccine and hepatitis B IG should be administered within 12 hours of birth. The birth dose of vaccine does not count as part of the series; thus, the infant requires 3 additional vaccine doses starting at 1 month of age. The HBsAg and antibodies should be checked after completing the vaccine series, usually at the 9- or 12-month check-up. For the HBsAg-negative mother, monovalent hepatitis B vaccine is administered to the newborn at 1 month of age (sooner if the newborn is stable for discharge), after which the usual schedule

is followed, such that the infant receives a total of 3 doses. Serologic testing is not necessary.

Other Conditions Affecting Immunization Schedule

Allergy to Egg

Children with allergic reactions to egg protein—including severe hypersensitivity—are at low risk for anaphylactic reactions to measles, mumps, and influenza (both IIV and LAIV) vaccines. Special precautions for immunizing children with egg allergy are no longer routinely recommended.

Yellow fever vaccine may contain egg protein in higher concentrations than in influenza vaccines and may rarely induce an immediate allergic reaction. Guidelines for skin testing and graded vaccine dosing are provided in the vaccine package insert.

International Adoptees, Travelers, Immigrants, and Refugees

Travel is not restricted to persons of any particular socioeconomic status; thus, physicians should inquire about foreign travel in all routine clinical visits. In preparing patients for travel, the health professional should review the child's record to ensure that all routine vaccines are up-to-date. The child should receive vaccinations and other preventive measures (eg, malaria prophylaxis) targeted for his or her destination. An accelerated schedule may be necessary, for example, early administration of MMR for infants 6 to 12 months of age traveling to a measles-endemic area. Use of IG prophylaxis to prevent HAV is recommended for susceptible individuals who are not candidates for active immunization (eg, too young to receive the HAV vaccine, immunocompromised status) traveling to areas with elevated risk of hepatitis A. To help ensure healthy travel, the health professional should check the current recommendations for the traveler's destination at the CDC Travelers' Health website (https://wwwnc.cdc.gov/travel) and the World Health Organization International Travel and Health website (www.who.int/ith/en).

Immigrants, refugees, and international adoptees often have health care issues. Immunization status, underlying health, and possible intercurrent illnesses should be evaluated soon after arrival. Many of these children have been in poor living conditions and exposed to health hazards of environments such as refugee camps and orphanages. The United States requires proof of the first dose of vaccines for entry into the country, although exemptions exist for refugees and adoptees younger than 10 years of age. Often these high-risk children have not been immunized or their records are missing. Written, dated, and appropriate records (ie, patient age, dates, interval, number of doses) may be considered valid, and subsequent immunization may resume according to the US schedule. Another option, especially in cases in which documentation is questionable, is to perform serologic studies for antibodies to vaccine antigens with available valid testing.

Adolescents

The AAP recommends a routine health visit at 11 to 12 years of age, including receipt of immunizations needed for adolescents. One of these vaccines is Tdap for use as a single booster dose at 11 to 18 years of age. Currently, Tdap is licensed only for a single booster dose. Off-label use of additional doses is recommended in special situations, however, such as during pregnancy and for close contacts of infants. With recognition of waning vaccine-induced immunity to pertussis, additional Tdap doses may be routinely recommended in the future.

Meningococcal vaccine and HPV are also indicated for adolescents at the 11- to 12-year-old visit. Four meningococcal vaccines are available in the United States: 2 CPS-protein conjugate vaccine (meningococcal conjugate vaccine [MenACWY]), and 2 B meningococcal (MenB) vaccines. The CPS vaccines contain 4 serotypes (A, C, Y, and W-135). The MenACWY-D vaccine (Menactra) is licensed for use in persons age 9 months to 55 years. The MenACWY-CRM vaccine (Menveo) is licensed for use in persons age 2 months to 55 years. Routine immunization with MenACWY is recommended at age 11 to 12 years, with a booster dose at age 16 years. For adolescents who received the first dose between age 13 and 15 years, the second dose may be given at ages 16 to 18 years (up to 5 years after the first dose); however, no booster dose is needed for teenagers who receive their first dose at age 16 years or older. The MenACWY vaccine is also recommended for catch-up dosing for older adolescents who have not been immunized, as well as for individuals 9 months to 55 years of age who are at increased risk of meningococcal diseases. The 2 MenB vaccines (Bexsero and Trumenba) are prepared using different virulence factors of the bacteria. The vaccines are licensed for individuals 10 through 25 years of age and recommended for those at increased risk of meningococcal infection. The vaccines may also be used during MenB outbreaks. The MenB vaccines are not routinely recommended at the 11- to 12-year-old visit.

The only HPV vaccine available in the United States is 9-valent (9vHPV) and is recommended for routine use in adolescents at 11 to 12 years of age. The vaccine is composed of virus-like particles prepared from recombinant L1 capsid protein. The 9vHPV vaccine (Gardasil 9), contains serotypes 6, 11, 16, 18, 31, 33, 45, 52, and 58 and it is licensed for females and males age 9 through 26 years to protect against cancers caused by HPV infections. For individuals younger than 15 years, 9vHPV is administered in a 2-dose regimen, with the second dose given 6 to 12 months after the first dose. For those age 15 years and older, 9vHPV is given in a 3-dose regimen at day 0, 1 to 2 months, and 6 months.

In addition, at adolescent visits (including precollege visits), health professionals should review the patient's records to ensure that all recommended vaccines have been received, inquire about household contacts of infants or compromised hosts, and provide anticipatory guidance for safe and healthy living for the adolescent and parent.

Immunizations Received in Other Countries

Most vaccines used worldwide are produced with adequate quality control and may be considered reliable. Healthy immigrants immunized in countries outside the United States should receive vaccines according to the recommended schedule for age in the

United States. Only written documentation should be accepted as proof of previous vaccination. Written, dated, and appropriate records (ie, correct age, dates, interval, number of doses) may be considered as valid, and immunizations may resume according to the US schedule.

Although most globally prepared vaccines are acceptable, concern may exist for vaccine potency because of unsuitable storage and handling. Other concerns include inaccurate documentation and inadequate immune response in some children resulting from other factors (eg, malnutrition, underlying illness). If vaccination status is uncertain, options include vaccinating with the antigen in question or, if available, serologic testing. Generally, receipt of additional doses of diphtheria and tetanus toxoids alone or in combination with a pertussis-containing vaccine (ie, DTP, DTaP, tetanus and diphtheria toxoids, Tdap) may result in an increase in reactions (especially injection site reactions), and checking antibody titers against diphtheria and tetanus toxoids is encouraged. Currently, commercially available assays for pertussis antibodies are of unknown clinically accuracy and testing is not recommended. A serological assay developed by the CDC and FDA has been used to confirm the diagnosis of pertussis, especially during outbreaks. For other vaccines, if the status is unknown, vaccination may be performed because extra doses are generally well tolerated. Additionally, extra doses are less expensive and more time efficient than performing serology. Most developing countries do not have VZV, conjugated pneumococcal, or Hib vaccines; thus, these should be given as indicated per the US schedule.

Adverse Events and Vaccine Information

Adverse Events

As noted previously, no vaccine is completely free of adverse events, and known adverse events should be discussed with non-minor vaccine recipients or the parent(s)/legal guardian(s) of the minor vaccine recipient. In addition to discussing the risks and benefits of vaccination, health professionals should include education about the risks associated with the natural disease. This is especially important today, because many individuals have not seen the diseases that vaccines have been successful in controlling or eradicating.

In addition to safety information from the AAP and CDC, the manufacturer's package insert provides information about the rates of adverse events and contraindications for the specific vaccine. Most adverse events observed following routine immunizations are local injection site reactions (eg, erythema, swelling, pain) and systemic reactions (eg, fever, fussiness). Although most of these adverse events are mild and self-limiting, some may be associated with significant dysfunction for the child (eg, not using a limb because of pain).

Rarely, serious adverse events may occur following immunization, and these may be associated with permanent disability or life-threatening illness. The occurrence of an adverse event after immunization does not prove a cause-and-effect relationship of the vaccine and the event but a temporal relationship. If a vaccine recipient experiences a serious adverse event, a complete evaluation for all plausible causes, including the role of the vaccine antigen, should be performed. Additionally, all clinically significant adverse events should be reported to the Vaccine Adverse Event Reporting System (https://vaers.hhs.gov), which is maintained by the CDC and FDA. Adverse event reporting is important because it helps identify possible unexpected events that were not observed in pre-licensure clinical trials.

Precautions and Contraindications

The Vaccine Information Statement (VIS) and package insert provide information for health professionals, the non-minor vaccinated individual, and the parent(s)/legal guardian(s) of minor vaccinated individuals about the precautions and contraindications for specific products.

A *precaution* suggests that careful analysis of risks and benefits of the vaccine should be performed; if benefits outweigh risks, the vaccine may be given. A *contraindication* means that a vaccine should not be administered. An example of a contraindication is known anaphylaxis to any component of the vaccine. Breastfeeding does not interfere with oral immunization with rotavirus or OPV vaccines and is not a contraindication.

Minor illness without fever (temperature ≤38°C [≤100.4°F]) should not be considered a contraindication to vaccination. Temperature above 38°C (>100.4°F) may not be a contraindication, depending on the physician's assessment of the child, the illness, and the particular vaccine. If the child is evaluated early in the disease process and the course is not predictable or the illness is moderate to severe, delaying immunization is reasonable. Deferring immunization without appropriate justification can cause a missed opportunity and may result in inadequate immunization of the child.

Informing Vaccine Recipients and Parents and Vaccine Refusal

Vaccine recipients and parents should be informed about the risks and benefits of vaccination and the disease the vaccine is designed to prevent. The National Childhood Vaccine Injury Act of 1986 requires that parents receive a VIS each time a child receives a vaccine covered under this legislation, whether the vaccine was purchased with public or private funds. The VISs are available from the CDC (www.cdc.gov/vaccines/hcp/vis/index.html). Health professionals should document in the patient's chart the vaccine manufacturer, lot number, and date of administration and that VISs were provided and discussed with the non-minor vaccinated individual and the parent or legal guardian of the minor vaccinated individual.

In the United States, proof of immunization is required for entry into elementary and secondary school. In addition, some child care centers and colleges also require vaccines for entry. All states permit medical exemptions (eg, immunocompromised child), and most states have provision for religious or philosophic exemption for individuals whose beliefs prohibit immunizations. Three states—California, Mississippi, and West Virginia—do not permit personal belief exemptions for children attending child care or schools. Less than 1% of US children are from families who refuse all vaccines. An increasing number of parents decline some

immunizations for their child, however, despite best efforts to educate parents about the effectiveness of vaccines and the realistic chances of vaccine-associated adverse events. At times, parents have a genuine fear of the risks of vaccines without fear of the natural disease, because many parents have not seen the diseases in the current, post-vaccine era. For others, their exaggerated fear of vaccine risks results from deeply held family beliefs, or their fears are fueled by biased anti-vaccine information presented in the media without scientific support.

A reasonable approach for the health professional is to address the concerns of parents or guardians in a non-condescending fashion, provide education about the known risks and benefits of immunization, and initiate a candid discussion of the risks of the natural infections. The discussion should be documented in the child's chart and the topic revisited at future encounters. The AAP encourages a presumptive rather than a participatory approach in counseling about vaccinations. With the *presumptive approach*, instead of asking the parents or guardians whether they want the vaccines to be administered, the pediatrician informs them that shots are due. Researchers have shown that parents with whom this strategy is used are more likely to accept vaccines. Because of strong convictions that immunization benefits outweigh risks, some health professionals choose not to provide care for children of families who refuse vaccines.

Vaccine Information

Information about current immunizations for health professionals and laypersons is available from many resources, including the CDC, AAP, FDA, and World Health Organization (Table 37.1). Multiple web-based applications with vaccine information are available for smart devices from the AAP and US Department of Health and Human Services (ie, CDC, FDA, National Institutes of Health), as well as other professional organizations.

CASE RESOLUTION

The boy was appropriately immunized for Botswana recommendations through the age of 9 months; however, his immunizations are considered delayed according to the US schedule. He is past due for the fourth dose of DTaP and the first dose of MMR and VZV vaccines. Additionally, he has not received HAV or any conjugate vaccines. The dose of monovalent measles vaccine does not change his need to receive 2 doses of MMR and VZV vaccines after age 12 months in the United States. His uncle's immune status does not affect his receipt of MMR or VZV vaccines. His current respiratory illness is considered mild, and he does not have significant fever (<38°C [<100.4°F]); thus, his illness does not preclude him from receiving immunizations.

During this visit, he may receive DTaP, the first dose of MMR plus VZV (alone or as a combination MMRV); 1 dose of Hib conjugate vaccine; dose 1 of 2 of conjugate pneumococcal vaccine, which should be administered 2 months apart; and dose 1 of 2 of HAV, which should be administered at least 6 months apart. He is too old to receive the oral rotavirus vaccine. All VISs should be provided. The patient is scheduled to return in 2 months (ie, in October) for his next dose of conjugate pneumococcal vaccine and dose 1 of 2 of IIV. He will need a fourth dose of inactivated poliovirus vaccine before school age.

CHAPTER 38

Health Maintenance in Older Children and Adolescents

Monica Sifuentes, MD

CASE STUDY

Before a 13-year-old girl enters a new school, she is required to undergo a physical examination. She has not seen a primary care physician in many years and has been healthy. Currently she has no medical complaints. Her examination is completely normal.

Questions

1. What are the important components of the history and physical examination in healthy older children and adolescents?
2. What immunizations are recommended for older children and adolescents?
3. What laboratory tests should be performed at health maintenance visits? Why?
4. What are significant topics to cover for anticipatory guidance in this age group?

Older children and adolescents are generally healthy individuals who infrequently visit physicians. If they are seen by a doctor, the visits are often for acute complaints, such as upper respiratory infections or sports-related injuries, and are, therefore, generally problem oriented. Statistics on health maintenance visits in this age group are not readily available because patients may go to several different sites for health care and often do not receive consistent comprehensive care at any of these places for a variety of reasons. Older children and adolescents seek treatment for acute and chronic conditions in private offices, urgent care centers, public health clinics, community and school health clinics, hospitals, and emergency departments. It has been reported that fewer than 50% of adolescents consistently receive a preventive health care visit during any given year, and the same percentage probably applies to older children as well.

This all-too-common practice of inconsistent health care contributes to missed opportunities for anticipatory guidance, health education, and screening for preventable conditions. Screening tests also can be used to identify treatable conditions such as hypertension, anemia, and tuberculosis. Ideally, older children and adolescents should receive recommended immunizations beginning at 11 to 12 years of age; screening for depression; counseling concerning sexual activity, contraception, and sexually transmitted infections (STIs), including HIV; reassurance to address their emotional well-being; guidelines for adequate nutrition, sleep hygiene, and screen time; education about tobacco, e-cigarettes and vaping, illicit drugs, and alcohol; and information about physical fitness and exercise as well as violence and injury prevention.

Guidelines for preventive child and adolescent health care have been published by the American Academy of Pediatrics (AAP) in conjunction with the Maternal and Child Health Bureau, US Child Health and Disability Prevention Program, AAP Section on Adolescent Health, and American Medical Association. Box 38.1 is a brief summary of these guidelines for older children and adolescents.

Health Maintenance Visit

The purpose of the health maintenance visit for an older child or adolescent is to assess their general physical health, mental and psychological health, and overall well-being and establish an independent relationship between the patient and health professional for open communication and trust for future visits. Initial questions asked during this visit should be simple and focused on how the patient feels in general about his or her health, physical growth and development, and existing relationships with family and friends. More specific questions can then be formulated depending on the patient's responses. In healthy patients, the medical history can be obtained using a questionnaire that parents and children complete in the waiting room. If this method is used, a separate form should be given to the adolescent if they are accompanied by a parent or guardian. The information is then reviewed at the start of the interview. Chronic medical conditions should be addressed at this time.

Medical History

Older children and adolescents should always be questioned directly about their medical history (Box 38.2). The parent or guardian should be encouraged to participate only after the child or adolescent

Box 38.1. Guidelines for Adolescent Health Maintenance Evaluation

Screening History

- Eating disorders
- Gender identification
- Sexual orientation
- Sexual activity (consensual and nonconsensual)
- Tobacco, e-cigarettes, or vaping use
- Alcohol use/abuse
- Drug use/abuse (CRAFFT questionnaire[a])
- School performance
- Depression
- Risk for suicide

Physical Examination

- BMI
- Blood pressure
- Comprehensive examination
- Genital examination
- Pelvic examination[b]

Universal and Selective Screening Laboratory Tests/Studies

- Snellen test
- Audiometry
- Hemoglobin or hematocrit
- Tuberculin skin test or blood test (IGRA)
- Cholesterol (If the patient is obese or there is a significant family history of hyperlipidemia, consider other laboratory tests, such as fasting glucose and lipid panel.)
- If sexually active
  - Urine hCG
  - Urine or vaginal NAAT for gonorrhea/chlamydia
  - Serum HIV, RPR, hepatitis C[c]
  - Papanicolaou test[b]

Anticipatory Guidance and Counseling

- Parenting/communication
- Pubertal development
- Diet/nutrition, including calcium and vitamin D supplementation
- Exercise
- Injury prevention
- Screen time/social media
- Educational or vocational plans/goals
- Lifestyle modifications
  - Gender and sexual identity
  - Abstinence
  - Safe sexual activity
  - Other reproductive health issues
  - Contraception
  - Avoidance of tobacco, e-cigarettes, vaping, alcohol, and prescription and illicit drugs
  - Identifying feelings of sadness/anger

Abbreviations: BMI, body mass index; CRAFFT, car, relax, alone, forget, friends/family, trouble; hCG, human chorionic gonadotropin; HIV, human immunodeficiency virus; IGRA, interferon gamma release assay; NAAT, nucleic acid amplification test; RPR, rapid plasma reagin.

[a] See Chapter 63 for information about the CRAFFT questionnaire.

[b] A pelvic examination with a Papanicolaou test is recommended within 3 years of the onset of sexual activity (American Cancer Society) or age 21 years (American Congress of Obstetricians and Gynecologists). For indications for a pelvic examination, see Chapter 58.

[c] If patient engaged in injection drug use or young man having sex with men.

Box 38.2. What to Ask

Screening in Older Children and Adolescents

Questions for Patient and Parent

- How has the child or adolescent been doing lately? Does the parent have any complaints or concerns?
- How does the child or adolescent like school? How is he or she doing academically and socially? What are his or her future goals?
- What activities does the child or adolescent currently participate in, including work?
- Does he or she have any hobbies?
- With whom does the child or adolescent live?
- Are there any significant illnesses in the immediate or extended family, such as hypertension, diabetes, or cancer?
- Does the child or adolescent take any medications, herbs, or supplements (prescribed or over-the-counter) regularly?

Questions for Child or Adolescent Alone

- Do you have any questions or concerns?
- How are things at home? Are there any problems with parents or siblings? Do you feel safe at home and school?
- Are you attending school?
- Do you like school? Who do you hang out with at school?
- Have you ever been truant, suspended, or expelled?
- What do you like to do for fun?

(See Chapter 4 for the rest of the interview.)

has responded to questions or if invited by the child or adolescent to assist with the interview. The degree of parental participation also is influenced by the current cognitive and developmental stage of the patient.

Psychosocial History

The psychosocial component of the interview should be conducted with older children or adolescents alone as well as together with parents or guardians after the issue of confidentiality has been reviewed (see Box 38.2). General questions about school, outside activities or hobbies, and family are often less threatening than inquiries about friends and high-risk behavior such as tobacco use. More sensitive topics relating to drug use, sexuality, gender identification, sexual orientation, and sexual activity should be addressed confidentially after parents or guardians have left the room. Subjects initially discussed with parents should be reviewed once again with teenagers alone.

A useful tool for conducting the psychosocial interview has been developed and refined by physicians who specialize in pediatrics and adolescent medicine. Known by the acronym HEADSS, it reviews the essential components of the psychosocial history: *h*ome, *e*mployment and *e*ducation, *a*ctivities, *d*rugs, sexuality, and *s*uicide/depression (see Chapter 4). Additional inquiries should be made about social media usage, including its influence on sleep hygiene. Some authors have suggested that this should be the third S in the HEADSS acronym.

Dietary History

A general dietary history should be obtained, with particular focus on eating habits, level of physical activity, and body image. Dietary restrictions, if any, should be investigated to assess for possible deficiencies in minerals and vitamins as well as the presence of disordered eating. Daily calcium, vitamin D, and iron intake should be reviewed, especially in adolescent females. Adolescent males should be asked about nutritional supplements.

Family History

Significant illnesses, such as hypertension, hyperlipidemia, obesity, and diabetes, in first- and second-degree family members should be reviewed. Family use of alcohol, tobacco, and illegal as well as prescribed substances also should be determined. Age and cause of death in immediate family members should be recorded.

Medications and Allergies

Prescription as well as nonprescription (over-the-counter) medications, herbs, and supplements should be reviewed along with the indications and frequency of usage.

Physical Examination

The height and weight of patients should be plotted on a growth curve, with particular attention paid to the velocity of growth and body mass index (weight [kg]/(height [m])^2). Blood pressure also should be noted and compared with age- and height-related reference values.

Aspects of the physical examination that are influenced by puberty should be emphasized. The skin should be carefully inspected for acne and hirsutism; clinicians should offer treatment whether or not patients acknowledge that they have skin problems. Tattoos, piercings, and signs of abuse or self-inflicted injury (ie, cutting) also should be noted. The oropharynx should be examined for any evidence of gingivitis or other signs of poor dental hygiene or malocclusion. The neck should be palpated for adenopathy and the thyroid gland for hypertrophy or nodules, especially in adolescent females. The back should be examined for any evidence of scoliosis, which is important to diagnose during this time of rapid growth.

Assessment of the pubertal development of the breasts and genitalia in preadolescent or adolescent females and the genitalia, including presence of pubic hair, in adolescent males is essential. The sexual maturity rating (SMR) (ie, Tanner stage) can then be correlated with other signs of puberty, such as the appearance of acne and body odor. For example, the adolescent female with SMR 4 breasts and immature pubic hair distribution may have an underlying problem, such as complete androgen insensitivity syndrome (also called testicular feminization syndrome).

The abdomen should be palpated for organomegaly and the testicles for masses, hydroceles, hernias, or varicoceles. Lesions such as warts or vesicles also should be documented. The external female genitalia should be inspected for similar lesions and to document Tanner stage development. A speculum examination should be performed in females who are sexually active and report vaginal discharge, unexplained vaginal bleeding, or lower abdominal pain. (See Chapter 58 for additional indications for a pelvic examination.) A speculum examination is otherwise not indicated in an asymptomatic sexually active female. In general, virginal girls with normal pubertal development do not require a speculum examination; gentle inspection of the external genitalia is adequate in most cases, with special attention to the SMR and hymenal patency. A rectal examination is generally reserved for patients with chronic abdominal pain or other specific acute gastrointestinal symptoms.

Immunizations

Many recent modifications have been made to the preadolescent/adolescent vaccination schedule (Table 38.1). As always, health professionals should verify that patients have completed the primary immunization series. If not, they should be given catch-up doses according to the most recent Advisory Committee on Immunization Practices and Centers for Disease Control and Prevention recommendations. The tetanus and diphtheria toxoids and acellular pertussis (Tdap) (eg, Adacel, Boostrix), human papillomavirus (HPV) (eg, Gardasil 9), and meningococcal conjugate (MCV4) (eg, Menactra, Menveo) vaccines should be given to preteens at the 11- to-12-year visit. The Tdap vaccine has replaced the tetanus/diphtheria booster previously given at this age. Pertussis was added to the booster because immunity to pertussis has been noted to wane 5 to 8 years after vaccination, and there has been an increasing prevalence of pertussis detected in adolescents and adults with chronic cough in many communities. A conjugate vaccine against *Neisseria meningitidis* (MCV4) was approved by the US Food and Drug Administration in 2005. The Advisory Committee on Immunization Practices recommends that MCV4 be given to all 11- to 18-year-olds. Although there are 3 different vaccines (ie, Gardasil, Cervarix, and Gardasil 9) available that include protection against 2 of the HPV types that

Table 38.1. Recommended Immunization Schedule Affecting Adolescents

	Recommended Age (years)	
Vaccine Type	*11–12*	*13–18*
Tetanus, diphtheria, pertussis	Tdap	Tdap (catch-up)
HPV	HPV (2 doses)	HPV (catch-up) (2 or 3 doses)[a]
Meningococcal Meningococcal serogroup B	MCV4	MCV4 (booster at 16 years) Individual clinical decision at age 16–23 years if not at increased risk
Varicella	Varicella 2-dose series	
Influenza	Influenza annually	

Abbreviations: HPV, human papillomavirus; MCV4, meningococcal conjugate vaccine; Tdap, tetanus and diphtheria toxoids and acellular pertussis.

[a] 2- or 3-dose series depending on age at initial vaccination (see Chapter 37).

Modified from Centers for Disease Control and Prevention. Child and adolescent immunization schedule (birth through 18 years). https://www.cdc.gov/vaccines/schedules. Reviewed February 5, 2019. Accessed September 2, 2019.

cause most cervical cancers (oncogenic types 16 and 18), only the 9-valent product is currently used in the United States. Licensed in 2015, Gardasil 9 protects against 5 additional HPV types that cause an additional 10% of HPV-associated cancers in the United States. While there has been much publicity and some controversy surrounding the HPV vaccine, current recommendations state that all adolescents should begin the HPV vaccination series routinely at 11 to 12 years of age with the goal of completing the series by age 13 years. The vaccine is approved for patients as young as 9 years. For those who initiate the series at 9 to 14 years of age, a 2-dose series is administered rather than the 3-dose series for those who begin vaccination at age 15. Gardasil 9 also should be routinely administered to young adults through the age of 26 years who have not received the vaccine. Ideally, the vaccine should be administered before the initiation of sexual activity because Gardasil 9 is only preventive and does not treat or cure HPV infection, dysplasia, or cancer that has already developed in response to HPV exposure. However, regardless of previous sexual exposure, the HPV vaccine should be administered to all adolescents, even if they are already sexually active.

Recommendations concerning some of the older, traditional vaccines have changed, as have the catch-up schedules. The adolescent (13 years and older) with no evidence of immunity to varicella should receive 2 doses of the vaccine at least 4 weeks apart. If an adolescent or preadolescent has received only 1 dose of the varicella vaccine, a second dose should be administered. Routine vaccination against hepatitis B also is recommended, regardless of sexual activity, if it has not been administered previously. The 2-dose hepatitis A series should be given to all teenagers not previously vaccinated if they reside in high-incidence communities. Influenza vaccine should be given annually to all infants 6 months and older, children, and adolescents and to those who come into close contact with individuals with high-risk conditions. Two meningococcal serogroup B vaccines (ie, Bexsero, Trumenba) are currently licensed for use among persons aged 10 to 25 years in the United States and are used routinely for individuals 10 years and older who are at high risk for serogroup B meningococcal disease, such as those with anatomical or functional asplenia or persistent complement deficiencies. Adolescents and young adults aged 16 to 23 years also may be vaccinated to provide short-term protection during serogroup B meningococcal disease outbreaks. Pneumococcal vaccine should be offered to high-risk groups, such as those with chronic lung disease, cyanotic congenital heart disease, and diabetes mellitus. In addition, a Mantoux skin test for tuberculosis should be performed if the adolescent resides in a high-risk environment. A tuberculosis blood test (also called an interferon gamma release assay) is preferred if the patient has received the tuberculosis or BCG vaccine or has a difficult time returning for a second appointment to look for a reaction to the Mantoux skin test. (For complete recommendations, see Chapter 37.)

Laboratory Tests

A hemoglobin level should be obtained to evaluate for anemia. Although previously included in laboratory screening, a urinalysis is no longer recommended to assess for protein, blood, and pyuria because most abnormal findings resolve spontaneously. Other suggested screening tests include hearing and vision tests and a cholesterol and lipid profile, once between 9 and 11 years and a second time between 17 and 21 years of age.

In addition to these laboratory tests, sexually active adolescents should be screened for STIs. If a pelvic examination is performed, an endocervical specimen should be obtained for nucleic acid amplification testing for gonorrhea and chlamydia. However, if a pelvic examination is not indicated, routine screening for gonorrhea and chlamydia may be performed with a urine or vaginal sample alone using nucleic acid amplification testing methods. The 2015 recommendations from the Centers for Disease Control and Prevention state that all sexually active women younger than 25 years should be screened annually. Males should be screened in high-prevalence clinical settings, such as adolescent clinics, correctional facilities, or STI clinics; if they are symptomatic; if they have a history of multiple partners and unprotected intercourse; or if they are having sex with men. In addition, a rapid plasma reagin test for syphilis and an HIV test should be obtained, especially if another STI is suspected or confirmed. All these tests should be offered in the clinically appropriate setting after patients have received adequate education on STIs, with a follow-up visit scheduled to discuss the results.

Patient Education

At the conclusion of the health maintenance visit, positive as well as negative findings should be reviewed with patients and their parents or guardians. Depending on the nature of these findings and the age of the patient, the health professional may initially choose to address these findings with the patient alone, keeping in mind issues of confidentiality. All recommended screening laboratory studies and immunizations should be reviewed before their administration, including the need for further follow-up. Subsequent vaccine doses must be outlined for patients and parents or guardians. The timing of the next visit and reasons for this visit should be discussed.

The remainder of the health maintenance visit should be spent addressing any specific concerns of patients and parents or guardians,

highlighting health care problems (eg, obesity, high blood pressure), and identifying any factors that may be contributing to high-risk behavior, such as drug or alcohol use. Older children or adolescents who are not participating in any deleterious activities should be praised for their positive behavior as well as provided with educational information such as materials addressing injury prevention and sleep hygiene.

Preparticipation Physical Evaluation for School-age and Adolescent Athletes

The preparticipation physical evaluation (PPE) is essentially the "sports physical" that many schools require for participation in organized athletic programs. The primary objective of the PPE is to assess the athlete's readiness to compete safely and effectively in training and competition. Ideally, it also should identify athletes at risk of injury, reinjury, or sudden death, as well as those with an underlying medical condition that may preclude safe athletic participation.

Historically, controversy existed about the appropriate location for performance of the PPE. Community physicians were often asked to perform limited en masse examinations at schools, or a group of clinicians was asked to perform the examinations in the gymnasium using "stations." Either way, the patient did not truly receive a complete physical examination or assessment, and neither approach lent itself to privacy. In addition, parents had a false sense of security and believed that their children had received adequate medical care. The AAP, in conjunction with other professional organizations, has developed a monograph that includes guidelines for the PPE. Ideally, primary care physicians should perform the PPE annually in their office during a scheduled visit at least 4 to 6 weeks before the beginning of the athletic season. Pediatricians can also use this required visit as an opportunity to perform an annual comprehensive health maintenance examination on older children and adolescents, including providing important anticipatory guidance, administering catch-up immunizations, and performing the various screening tests recommended for this age group.

History

The most challenging aspect of the PPE is reviewing the past medical and family history with the athlete to uncover previously unrecognized abnormalities of the cardiovascular system that warrant further investigation by a cardiologist prior to participating in a given sport. Red flags include a history of congenital heart disease, cardiac channelopathies (eg, long QT syndrome), a history of Kawasaki disease and associated coronary artery anomalies, and a history of myocarditis. The rest of the medical history for the PPE should focus on previous athletic participation and any current or past injuries that have required immediate evaluation and subsequent bracing, casting, surgery, or missed practice or play (Box 38.3). A standard questionnaire codeveloped by the AAP for this purpose may be used in the office setting. In addition, many health professionals record the results of the physical examination as well as their recommendations for the degree of athletic participation on this standard form (Figures 38.1 through 38.4). A review of systems should specifically include an inquiry about a history of syncope, near-syncope, chest pain, palpitations, and excessive shortness of breath or fatigue with exertion.

Box 38.3. What to Ask

Preparticipation Physical Evaluation

- What sport(s) does the child or adolescent wish to participate in? Has he or she participated in this sport in the past?
- Has the child or adolescent ever experienced a sports injury? If so, how much time did the athlete refrain from sports activities as a result of this injury?
- Has the athlete ever experienced a lapse of consciousness or concussion?
- Does the child or adolescent have a significant underlying health problem?
- Is the child or adolescent taking any prescribed or over-the-counter medications, supplements, or caffeine?
- Does the child or adolescent have any allergies?
- Has the child or adolescent ever had syncope or near-syncope, palpitations, chest pain, discomfort, or shortness of breath during exercise or at rest?
- Does the child or adolescent have a family history of sudden, early, nontraumatic deaths in a first- or second-degree relative younger than 50 years?

Physical Examination

A complete physical examination should be performed. If circumstances preclude this, specific attention should be paid to the eyes, heart, abdomen, skin, and musculoskeletal system. Height, weight, blood pressure, and visual acuity also should be measured. Examination of the eyes is essential to document physiological *anisocoria* (different papillary diameters). A thorough cardiac evaluation for murmurs, abnormal heart sounds, or arrhythmias should be performed with the patient supine and again standing or straining during the Valsalva maneuver. The abdomen should be palpated for an enlarged liver or spleen, especially in the adolescent with a recent viral illness that could suggest mononucleosis. In males, the genitalia should be examined for sexual maturity in addition to assessing for abnormalities, such as atrophy, absence of a testis, or presence of a testicular mass or inguinal hernia. The skin should be inspected for lesions, such as tinea corporis, molluscum contagiosum, scabies, impetigo, or herpes simplex infection.

The 2-minute orthopedic examination consists of a head-to-toe assessment of all muscle groups and joints; any deformities, anomalies, or evidence of previous injuries should be noted (Table 38.2). Recent studies suggest expanding this examination to include a more detailed evaluation of areas at high risk of injury, such as the knee, ankle, and shoulder.

Laboratory Tests

Routine laboratory screening tests, except for those performed during the general health maintenance visit, are not recommended for the PPE. Screening young athletes for anemia or proteinuria has not been found to be particularly helpful. Such screening may be useful with highly competitive professional athletes, however. Although controversial, some groups believe that electrocardiography and echocardiography should be routine components of the PPE as well.

■ PREPARTICIPATION PHYSICAL EVALUATION

HISTORY FORM

Note: Complete and sign this form (with your parents if younger than 18) before your appointment.

Name: _____ Date of birth: _____

Date of examination: _____ Sport(s): _____

Sex assigned at birth (F, M, or intersex): _____ How do you identify your gender? (F, M, or other): _____

List past and current medical conditions. _____

_____

Have you ever had surgery? If yes, list all past surgical procedures. _____

_____

Medicines and supplements: List all current prescriptions, over-the-counter medicines, and supplements (herbal and nutritional).

_____

_____

Do you have any allergies? If yes, please list all your allergies (ie, medicines, pollens, food, stinging insects).

_____

_____

Patient Health Questionnaire Version 4 (PHQ-4)

Over the last 2 weeks, how often have you been bothered by any of the following problems? (Circle response.)

	Not at all	Several days	Over half the days	Nearly every day
Feeling nervous, anxious, or on edge	0	1	2	3
Not being able to stop or control worrying	0	1	2	3
Little interest or pleasure in doing things	0	1	2	3
Feeling down, depressed, or hopeless	0	1	2	3

(A sum of ≥3 is considered positive on either subscale [questions 1 and 2, or questions 3 and 4] for screening purposes.)

GENERAL QUESTIONS (Explain "Yes" answers at the end of this form. Circle questions if you don't know the answer.)	Yes	No
1. Do you have any concerns that you would like to discuss with your provider?		
2. Has a provider ever denied or restricted your participation in sports for any reason?		
3. Do you have any ongoing medical issues or recent illness?		
HEART HEALTH QUESTIONS ABOUT YOU	**Yes**	**No**
4. Have you ever passed out or nearly passed out during or after exercise?		
5. Have you ever had discomfort, pain, tightness, or pressure in your chest during exercise?		
6. Does your heart ever race, flutter in your chest, or skip beats (irregular beats) during exercise?		
7. Has a doctor ever told you that you have any heart problems?		
8. Has a doctor ever requested a test for your heart? For example, electrocardiography (ECG) or echocardiography.		

HEART HEALTH QUESTIONS ABOUT YOU (*CONTINUED*)	Yes	No
9. Do you get light-headed or feel shorter of breath than your friends during exercise?		
10. Have you ever had a seizure?		
HEART HEALTH QUESTIONS ABOUT YOUR FAMILY	**Yes**	**No**
11. Has any family member or relative died of heart problems or had an unexpected or unexplained sudden death before age 35 years (including drowning or unexplained car crash)?		
12. Does anyone in your family have a genetic heart problem such as hypertrophic cardiomyopathy (HCM), Marfan syndrome, arrhythmogenic right ventricular cardiomyopathy (ARVC), long QT syndrome (LQTS), short QT syndrome (SQTS), Brugada syndrome, or catecholaminergic polymorphic ventricular tachycardia (CPVT)?		
13. Has anyone in your family had a pacemaker or an implanted defibrillator before age 35?		

Figure 38.1. Preparticipation Physical Evaluation: History Form.

BONE AND JOINT QUESTIONS	Yes	No
14. Have you ever had a stress fracture or an injury to a bone, muscle, ligament, joint, or tendon that caused you to miss a practice or game?		
15. Do you have a bone, muscle, ligament, or joint injury that bothers you?		
MEDICAL QUESTIONS	**Yes**	**No**
16. Do you cough, wheeze, or have difficulty breathing during or after exercise?		
17. Are you missing a kidney, an eye, a testicle (males), your spleen, or any other organ?		
18. Do you have groin or testicle pain or a painful bulge or hernia in the groin area?		
19. Do you have any recurring skin rashes or rashes that come and go, including herpes or methicillin-resistant *Staphylococcus aureus* (MRSA)?		
20. Have you had a concussion or head injury that caused confusion, a prolonged headache, or memory problems?		
21. Have you ever had numbness, had tingling, had weakness in your arms or legs, or been unable to move your arms or legs after being hit or falling?		
22. Have you ever become ill while exercising in the heat?		
23. Do you or does someone in your family have sickle cell trait or disease?		
24. Have you ever had or do you have any problems with your eyes or vision?		

MEDICAL QUESTIONS (*CONTINUED*)	Yes	No
25. Do you worry about your weight?		
26. Are you trying to or has anyone recommended that you gain or lose weight?		
27. Are you on a special diet or do you avoid certain types of foods or food groups?		
28. Have you ever had an eating disorder?		
FEMALES ONLY	**Yes**	**No**
29. Have you ever had a menstrual period?		
30. How old were you when you had your first menstrual period?		
31. When was your most recent menstrual period?		
32. How many periods have you had in the past 12 months?		

Explain "Yes" answers here.

I hereby state that, to the best of my knowledge, my answers to the questions on this form are complete and correct.

ATHLETES WITH DISABILITIES FORM: SUPPLEMENT TO THE ATHLETE HISTORY

Name: _____ Date of birth: _____

1. Type of disability:	
2. Date of disability:	
3. Classification (if available):	
4. Cause of disability (birth, disease, injury, or other):	
5. List the sports you are playing:	

	Yes	No
6. Do you regularly use a brace, an assistive device, or a prosthetic device for daily activities?		
7. Do you use any special brace or assistive device for sports?		
8. Do you have any rashes, pressure sores, or other skin problems?		
9. Do you have a hearing loss? Do you use a hearing aid?		
10. Do you have a visual impairment?		
11. Do you use any special devices for bowel or bladder function?		
12. Do you have burning or discomfort when urinating?		
13. Have you had autonomic dysreflexia?		
14. Have you ever been diagnosed as having a heat-related (hyperthermia) or cold-related (hypothermia) illness?		
15. Do you have muscle spasticity?		
16. Do you have frequent seizures that cannot be controlled by medication?		

Explain "Yes" answers here.

_____

_____

_____

Please indicate whether you have ever had any of the following conditions:

	Yes	No
Atlantoaxial instability		
Radiographic (x-ray) evaluation for atlantoaxial instability		
Dislocated joints (more than one)		
Easy bleeding		
Enlarged spleen		
Hepatitis		
Osteopenia or osteoporosis		
Difficulty controlling bowel		
Difficulty controlling bladder		
Numbness or tingling in arms or hands		
Numbness or tingling in legs or feet		
Weakness in arms or hands		
Weakness in legs or feet		
Recent change in coordination		
Recent change in ability to walk		
Spina bifida		
Latex allergy

I have examined the student named on this form and completed the preparticipation physical evaluation. The athlete does not have apparent clinical contraindications to practice and can participate in the sport(s) as outlined on this form. A copy of the physical examination findings are on record in my office and can be made available to the school at the request of the parents. If conditions arise after the athlete has been cleared for participation, the physician may rescind the medical eligibility until the problem is resolved and the potential consequences are completely explained to the athlete (and parents or guardians).

Instructions	*Points of Observation*
Stand facing examiner.	Acromioclavicular joints, general habitus
Look at ceiling, floor, over both shoulders; touch ears to shoulders.	Cervical spinal motion
Shrug shoulders (examiner resists).	Trapezius strength
Abduct shoulders 90°.	Deltoid strength
Full external rotation of arms.	Shoulder motion
Flex and extend elbows.	Elbow motion
Arms at sides, elbows flexed to 90°; pronate and supinate wrists.	Elbow and wrist motion
Spread fingers; make fist.	Hand or finger motion and deformities
Tighten (contract) quadriceps; relax quadriceps.	Symmetry and knee effusion; ankle effusion
Duckwalk 4 steps (away from examiner with buttocks on heels).	Hip, knee, and ankle motion
Back to examiner.	Shoulder symmetry, scoliosis
Knees straight, touch toes.	Scoliosis, hip motion, hamstring tightness
Raise up on toes, raise heels.	Calf symmetry, leg strength

Exclusion Criteria

The most common causes of unexpected death during athletics include undiagnosed cardiomyopathies, anomalous coronary arteries, heart valve defects, primary cardiac rhythm disorders, and pulmonary hypertension. Although most assessments are within reference range, an important part of the PPE is geared toward determining if a patient has risk factors for any of these conditions. Medical exclusion criteria for athletic participation are based on information obtained in the medical as well as family history. Significant historical clues include a family history of sudden, nontraumatic death; premature coronary artery disease in a first- or second-degree relative; a history of palpitations, chest discomfort, or syncope during exercise; and recent, documented infection with Epstein-Barr virus. Controversy exists concerning when athletes can return to collision sports after infectious mononucleosis. A history of a recent or suspected sport-related concussion also requires close monitoring to address when the athlete is cleared to return to participate in a given sport. Current clinical experience and neurocognitive research on adolescents and concussions support the mantra, "When in doubt, sit them out!" In other words, the athlete should not be pressured to continue to play through injuries or return to play on the same day as the injury. Patients with concussions should rest, physically and cognitively, until their symptoms have improved at rest and with exertion, according to the AAP Council on Sports Medicine and Fitness. The exact amount and duration of rest should follow an individualized course because each athlete recovers at a different pace. A stepwise graduated return-to-sport program that was recently updated by the Berlin Concussion in Sport Group allows the athlete to gradually progress through 5 stages a day provided there is no increase in symptoms during exercise. Contrary to previous reports, prolonged inactivity is known to result in a higher symptom level and prolonged recovery. Athletes with more significant injuries, however, may require several weeks to completely recover if the concussion is severe. The short- and long-term effects of sports-related concussions and repetitive head impacts over the life span of athletes of all ages are still under intense investigation in an effort to create appropriate return-to-play criteria and to reduce cognitive, emotional, behavioral, and neurologic consequences.

Findings discovered during the physical examination, such as severe myopia, strabismus, lens subluxation and stature consistent with Marfan syndrome, a cardiac arrhythmia, or the midsystolic click of mitral valve prolapse, could preclude the adolescent from participation in a particular sport. Specific conditions, such as the athlete with 1 kidney, should be evaluated on an individual basis by a physician qualified to assess the safety of the particular sport for the athlete (ie, contact/collision sport vs limited contact sport).

Special circumstances to consider during the PPE are amenorrhea and the female athlete, exercise-induced bronchospasm, anabolic steroid use, and eating disorders that may be associated with certain activities, such as gymnastics, ballet, and wrestling.

CASE RESOLUTION

The young adolescent should first be interviewed with the parent and then alone. Her medical and psychosocial history should be reviewed. A complete physical examination should be performed as well as a pelvic examination if she is sexually active and has a history of lower abdominal pain, abnormal vaginal bleeding, or vaginal discharge. If she is sexually active and asymptomatic or not sexually active, only general laboratory screening tests should be performed and the results reviewed with the patient. The remainder of the visit should be spent discussing issues such as nutrition, exercise, illicit substance use, sexuality and sexual activity, and safety. Results of the physical examination and screening tests should then be discussed with the parent or guardian who accompanied her to the office. If necessary, a follow-up visit should be scheduled. Otherwise, the adolescent should be seen annually.

CHAPTER 39

Health Care for International Adoptees

ChrisAnna M. Mink, MD, FAAP

CASE STUDY

Jaxon is a 14-month-old boy adopted from Thailand. His biological mother was a 26-year-old commercial sex worker who entered a maternity house during her pregnancy to receive care and relinquish the baby for adoption. His mother reported that she was physically and sexually abused as a child and became a street child at age 14 years. She used illicit drugs 5 years previously but none since. She identifies the father as a European customer but has no other information. Jaxon was born at 32 weeks' gestational age and was placed in an incubator but did not have any respiratory problems. He has been in foster care in the home of a Thai family with his care supervised by an internationally respected adoption organization. He was selected by his parents at the age of 4 months, and they have received monthly progress reports on his growth, development, and medical status. Reportedly, he has had several "colds" and 1 ear infection but otherwise has been growing and developing well. Before departure to pick up Jaxon, his adoptive parents met with you to prepare for his arrival.

The parents placed a call to you from the Bangkok airport because Jaxon would not stop crying. They report that on the morning his foster mother left him with them, he cried quite a bit but had settled by bedtime and seemed to be adjusting well during the week. Over the 12 hours preceding the telephone consultation, however, he had not stopped crying, and he refuses to eat. He has been drooling, and they question if his discomfort is related to teething; they have not noticed any other symptoms of teething, however. They are gravely concerned that he does not like them and is having attachment difficulties.

Questions

1. What factors influence the prevalence of international adoption?
2. What are some of the potential health problems of the international adoptee?
3. What is an appropriate medical evaluation for the international adoptee?
4. What is the role of the pediatrician in caring for the child and newly formed family?

Although internationally adopted children come from a wide range of birth countries, many of their health-related issues are similar. Many of the children have lived in orphanages in impoverished areas of the developing world and have incurred the maladies associated with poverty and deprivation.

Epidemiology

From 1999 to 2012, 242,602 children were adopted internationally into the United States; this is nearly the same number as the previous 30 years combined. Through the first decade of the 21st century, 90% of such children were from Asia, most commonly China and South Korea; Eastern Europe; and South America (Guatemala and Colombia). From 2009 to 2012, China, Ethiopia, and Russia were the 3 leading countries of origin for children adopted into the United States. The number of international adoptions has been declining since 2009, with a nadir in 2017 of only 4,714 adoptees entering the United States. This decline is the result of multiple factors, including economic uncertainty in the United States; changing geopolitical landscapes in birth countries; and stricter policies governing adoption in an attempt to curb corruption, including The Hague Convention on the Protection of Children and Co-operation in Respect of Intercountry Adoption, which is an international agreement for standardizing intercountry practices to promote protection of children available for adoption.

Many factors influence the choice of international adoption. In the United States, delays in childbearing and associated infertility have increased the demand for adoptable children. Simultaneously, more readily available birth control and growing acceptance of single motherhood have resulted in a decreased number of infants available for adoption. In addition to the shortage of adoptable children in the United States, other factors in the decision to pursue international adoption include real and perceived risks of domestic adoption (eg, failure of birth parents to relinquish rights), reluctance to adopt a child with special needs or with in utero drug exposure, and limited availability of children with desired traits (eg, specific age and ethnicity [often white infants]). The prompt termination of rights of birth parents in international adoption is also cited as a factor in this decision.

The advent of intercountry adoption in the United States occurred in conjunction with World War II and the large number of orphaned children in Europe, many of whom were fathered by American soldiers. The second—and more formalized—wave of intercountry adoption occurred with the Korean War. Because of the need to care for unwanted orphans, primarily of mixed ethnicities and fathered by American soldiers, South Korea established a foster care system and the children became available for adoption to Americans. War and political turmoil remain factors in the availability of children for adoption. For example, the fall of communism was a significant factor in Russia and other states of the former Soviet Union becoming common birth countries for adoptees in the 1990s and the early part of the 21st century. Following a diplomatic rift, however, in 2013 the Russian government outlawed adoptions to the United States. Early in the 21st century, because of poverty and political strife, more children were being adopted from African countries, especially Ethiopia. Recently, adoptions from Ethiopia have been stopped, however, in part because of cultural pride, as well as a highly publicized death resulting from abuse of an Ethiopian child adopted into the United States.

Societal values also influence adoption practices. China was among the leading birth countries for adoptees because of the population control initiatives of the government mandating that families have only 1 child. With this practice and the desire for a male heir, some newborn girls were abandoned and became available for adoption. With the 2008 Summer Olympic Games, China had a surge in national pride and a realization that their future population may not include enough girls for the boys to marry. Subsequently, fewer infant girls became available for adoption. Currently, China mainly permits international adoption of children of both sexes with special medical or developmental needs.

Until 2016, most internationally adopted children were female (approximately 56%), in part reflecting the adoption of girls from China, as well as a preference among some adoptive parents (especially single women) to adopt a girl. Currently, most are male, mainly reflecting the changes in China's policies. International adoptees are young, with approximately 55% between the ages of 1 and 5 years.

The United States is the birth country of approximately 100 children annually adopted into other countries. Absolute statistics for US children adopted into other countries are not available because the US government does not routinely report the number of exit visas issued for adopted children. These adoptees are often males of African American or mixed ethnicity and are adopted by families in Canada and Western Europe. They are available purportedly because of the low desire for these infants by adoptive parents in the United States.

The status of the country of origin (eg, war, turmoil, poverty, societal values) aside, significant overlap exists in the reasons that children from foreign countries and from the United States become available for adoption. The common reasons include parental substance use, abandonment, chronic neglect, abuse, and domestic violence, all of which often are associated with underlying poverty.

Until the 1990s, most international adoptees were from South Korea, which had in place an excellent foster care system and health care. Since the 1990s, most adoptees come from institutions in poor nations without a developed foster care system, resulting in a significant decline in the health and well-being of adoptees.

Clinical Presentation

Preadoption

Some adoptees become known to the US health professional "only on paper" during the preadoption stage. The adoptive parent or parents may ask their physician for help in assessing the child's medical status. Often a parent receives a written health report (varying in the quantity and quality of information) and photos or videos of the child under consideration for adopting. The written documents may be in a foreign language or not translated by an experienced medical translator. Because some countries prohibit international adoption of healthy children, diagnoses may be embellished to improve the child's chances for adoption. Additionally, some medical records contain diagnoses that are nonsensical in US medicine but represent standard terms used in the country of origin. These inconsistencies are quite challenging when trying to evaluate the medical records of potential adoptees. Many physicians may not feel comfortable with reviewing medical records given so many limitations; however, even with all the caveats, review of the records may provide valuable insight into the health status of the adoptee.

During this stage, the physician may provide information for parents and families for preventive health measures to prepare for travel to a developing area of the world. The Centers for Disease Control and Prevention (CDC) Traveler's Health website (www.cdc.gov/travel) is a good resource for physicians and parents. Up-to-date information may also be obtained from the World Health Organization (WHO) and the US Department of State (Table 39.1). Prospective parents should be informed about the infections that may occur in international adoptees, and they should receive appropriate education and preventive measures, including vaccinations (eg, measles, hepatitis A, hepatitis B).

During the Adoption Trip

All internationally adopted children are required by the US Department of State to undergo a physical examination before admission into the country; however, this examination is limited in scope and performed mainly to rule out severe impairments or certain communicable diseases that may pose a public health threat (eg, active tuberculosis [TB]). This examination should not be considered a complete medical evaluation for an individual child.

Some health professionals can provide support for families during travel via e-mail, telephone, and the internet, similar to telephone consultations performed in general practice.

Postadoption

After the adoption, the health status of children on presentation to the US physician may be quite variable, ranging from well to severely

ill with acute infections or chronic diseases (eg, malnutrition, TB). The adopted child should be seen by the physician within 2 to 3 weeks of arrival in the United States, or sooner if the child has an acute illness. This 2-week period allows for the child (and parent or parents) to recover from jet lag and become more familiar with each other, permitting a better assessment at the visit. If an acute illness visit is required, a separate appointment for a comprehensive evaluation should be scheduled at a later time.

Health Care Issues

In addition to problems commonly related to poverty and deprivation, many health issues are specific to the country or region of origin (eg, increased risk of malaria and other parasites in children from the continent of Africa). Adoptees from South Korea have the lowest risk for infectious diseases.

Generally, health care issues for adoptees are extensive, including acute illness (eg, respiratory infections), chronic illness (eg, anemia, malnutrition, poor dental hygiene, TB, asthma, parasite infestation), delayed or unknown immunizations, psychosocial challenges, and impaired growth and development.

Some children have assigned birth dates (eg, abandoned infants and street children for whom birth dates are not known), and they may have small growth parameters, making it difficult to know their true age and expected development. Developmental delays, most commonly language delay, are frequently identified. Assessment of development may be even more difficult in infants and young children who are nonverbal and older children who speak their native language.

Growth delay is common for adoptees. Many children are malnourished or exhibit failure to thrive, and these conditions are often multifactorial in origin, including poor prenatal environment (eg, maternal stress, malnutrition, substance abuse), inadequate calories, inadequate nurturing, unrecognized genetic or congenital disorders (eg, fetal alcohol spectrum disorder; see Chapter 147), and untreated chronic illness (eg, TB, rickets). Institutionalized children may exhibit psychosocial dwarfism and may lose 1 month of linear growth for every 3 to 4 months spent in the orphanage. Delay in puberty may be observed in adolescents from deprived environments, such as orphanages. Precocious puberty may also be seen among international adoptees.

Immunization records may not be available, may be incomplete, or may be in a foreign language, which hinders assessment of the vaccination status of adoptees. Many vaccines available in the United States are not available in the developing world (eg, *Haemophilus influenzae* type b, pneumococcal conjugates) and, thus, children will not have had them. Adopted children immigrating to the United States who are younger than 10 years are exempt from the Immigration and Nationality Act regulations requiring proof of immunizations before arrival; however, adoptive parents are required to sign a waiver that they will comply with US recommended immunizations after arrival.

Psychosocial, emotional, and mental health disorders are some of the more challenging problems to assess. The spectrum of mental health problems is related to age and previous life experiences of the child. Children may have experienced physical or sexual abuse before placement in an institution, and they may also be subject to abuse by older children or adult caregivers while in institutional placement. Attachment disorders are among the most concerning abnormalities for adoptive parents, adoption professionals, and health professionals. The fundamentals for learning healthy attachments are greatly influenced by early infant-caregiver relationships. Thus, many international adoptees have difficulties bonding, in part because they have not had secure caregiver relationships. Issues of attachment and bonding may be especially problematic for children who have resided in an orphanage or had multiple caregivers from an early age. Children who have had multiple caregivers may be indiscriminately friendly, which may pose risks for their safety. Other common mental health problems include depression,

attention-deficit/hyperactivity disorder, posttraumatic stress disorder, abnormal behaviors (eg, self-stimulating behaviors, hoarding food, sleep disturbances), and oppositional defiant disorder. As mentioned previously, communication with the child may be difficult because of language barriers, causing another obstacle to assessing the child's mental health.

Sensory integration difficulties are increasingly recognized in adoptees. The children may have adverse responses to touch (eg, new clothing, hugs and kisses, bathing) or textures (eg, new foods). Individual senses or all of them (ie, hearing, vision, taste, smell) may be notably increased or decreased, and some children have decreased sensation to physical pain, resulting in an increased risk for injuries. Dyskinesia in the form of clumsiness or being prone to injury has also been observed.

The most common identified medical issues are infectious diseases, including acute illness (eg, upper respiratory infection, bronchitis, otitis, infectious diarrhea) and chronic infection (eg, TB, parasite infestations, with scabies and *Giardia lamblia* common manifestations of the latter. Because of the lifestyle of their biological mother and the children's time residing in institutions, many adoptees are at increased risk of exposure to infectious diseases, such as syphilis, HIV, and hepatitis B and C.

Preventive care that is considered routine in the United States is unlikely to have been part of the child's care and must be performed as appropriate for age. This includes newborn screening laboratory studies and assessments of hearing, vision, dental, and mental health. Anticipatory guidance for new parents should be incorporated into preadoption encounters and all subsequent visits.

Evaluation

The initial office visit with the physician should be scheduled for an extended period because of the complexity of the evaluation and additional time needed for parental education. If the physician's schedule does not permit extended visits, ancillary staff (eg, nurses, dietitians, therapists) may perform parts of the evaluation and education.

Observation of the child's behavior, development, and interactions with the adoptive parent or parents and physician is a critical element of the evaluation. Most physicians routinely include such observations in their visits, but particular attention to these factors is necessary for new adoptees. Items to notice include the child's demeanor and behavior, such as determining whether the child is easily engaged or is withdrawn, makes eye contact with the parent or physician, makes any vocalizations or words (depending on the child's age), plays with toys, is too friendly or is afraid of strangers, and seeks comfort from the new parent or parents.

History

Limited medical information is available from most birth countries, although some exceptions exist (eg, from foster care in South Korea). Family and birth history are rarely obtainable for adoptees. Immunization histories are becoming increasingly available. Previously, vaccine records were considered unreliable; however, in recent years, data have emerged to suggest that well-documented immunizations may be considered valid. Written records showing the age of the child when vaccinated, date of administration, dose given, and proper intervals between dosing that are consistent with WHO schedules or are comparable to US schedules may be considered acceptable for proof of immunization. (Guidelines for care in the absence of vaccine records is discussed in the Management section of this chapter.)

Dietary history is important for assessing the child's nutritional status. Questions to ask are listed in Box 39.1.

An interim medical history may be available, because many children are selected by their adoptive parent or parents several months before immigrating to the United States. The interim medical history may be provided from the orphanage or foster care provider through the adoption agency. Parents should be encouraged to solicit as much information as possible from the child's caregivers. At a minimum, this history should include serial growth parameters, known illnesses, hospitalizations, surgeries, allergies, and immunizations given while the child was under their care. Parents should also ask caregivers about any food preferences, special fears, toys, or friends from the placement prior to adoption. If the child has a special "lovey," the parent or parents should request to bring it with the child as a transitional object.

Physical Examination

A complete unclothed physical examination should be performed on infants and children of all ages. Because of previous trauma (eg, sexual abuse), however, it may be necessary to perform some parts of the examination over a series of visits to minimize the possibility of inflicting additional trauma from an examination. All aspects of the physical examination are essential. Accurate measurements of height, weight, and, depending on age and size, head circumference should be obtained. Plotting of parameters on the growth curves from WHO or the CDC (compared with birth country) should be used, with few exceptions. The child should be closely inspected for unusual scars or bruises, evidence of fractures (old or recent), rachitic changes, and genital or rectal scarring. The skin should be examined for rashes, lesions, and a bacille Calmette-Guérin (BCG) scar (typically on the upper deltoid). Developmental screening should be performed, and a more complete developmental assessment should be scheduled at a separate visit (when the child is not distressed or acutely ill). A dental examination should be included, and referral for a formal dental

Box 39.1. What to Ask

Dietary History of the International Adoptee

- What food and formula/milk is the child receiving?
- Has the child received adequate calories?
- Is there known or suspected food intolerance? (For example, lactose intolerance is more common in Asian ethnicities.)
- Are there abnormal behaviors associated with food or eating (eg, preoccupation with food, hoarding, food refusal, gorging)?

evaluation likely will be necessary. Screening evaluations of hearing and vision should be performed; formal testing may be necessary, depending on the age of the child and ability to cooperate.

Laboratory Testing

Laboratory studies should include complete blood cell count, lead levels, and thyroid function testing (iodine is not in many diets in Asia) (Box 39.2). Additionally, testing for illnesses associated with specific countries of origin, findings on examination (eg, comprehensive metabolic panel for malnourished child), and as directed by the child's age (eg, newborn screening for metabolic disorders in newborns and infants) should be performed. Screening tests, if initially negative, should be repeated in 3 to 6 months, especially for children for whom concerns exist about underlying malnutrition or of immunocompromised status.

Because of the increased risks of exposures, laboratory screening for infectious diseases should be undertaken. Serum samples should be tested for syphilis (nontreponemal and treponemal antibodies), hepatitis surface antigen B panel (HBsAg, HBsAg antibody [HBsAb], and hepatitis B core antibody), hepatitis C antibody, and HIV 1 and 2 antibodies. Human immunodeficiency virus polymerase chain reaction may be indicated in some children (eg, those who may not make specific antibodies because of malnutrition or immunocompromised status). Stool samples should be sent for ova and parasite examination and *Giardia* and *Cryptosporidium* antigen testing (Box 39.2). Stool for bacterial pathogens (eg, *Salmonella, Shigella*) should be sent from children from some regions, such as the Indian subcontinent. Because cytomegalovirus infection is ubiquitous, routine testing is not recommended. Testing for acute infection with hepatitis A virus (HAV) by measuring immunoglobulin M anti-HAV antibodies should be performed for adoptees from HAV-endemic areas, because infants and young children may be asymptomatic but contagious. Administering HAV vaccine, as recommended in the United States, is not problematic for children who may have had previous HAV infection.

Tuberculin skin testing (ie, purified protein derivative [PPD]) should be performed on all children; history of receipt of BCG is not a contraindication to skin testing. Bacille Calmette-Guérin vaccinations usually are given at birth in most developing nations, and its influence on skin test status is controversial. Generally, BCG given within the previous 1 to 2 years may contribute to a positive PPD skin test; however, a positive PPD test is more likely reflective of true infection with *Mycobacterium* with or without active disease and merits further evaluation. For children 5 years and older, interferon-γ release assays (eg, QuantiFERON-TB Gold) are an acceptable screening alternative to PPD testing. Latent TB infection has been reported in 0.6% to 30% of international adoptees, which is not surprising because most adoptees come from areas in which TB is endemic.

Box 39.2. Recommended Laboratory Testing for International Adoptees

- Hepatitis A IgM.
- Hepatitis B virus serologic testing.
  - Hepatitis B surface antigen
  - Antibody to hepatitis B surface antigen
  - Antibody to hepatitis B core antigen
- Hepatitis C virus serologic testing.
- Syphilis serologic testing.
  - Nontreponemal test: RPR, VDRL, or ART
  - Treponemal test (MHA-TP or FTA-ABS)
- HIV 1 and 2 serologic testing.
- Complete blood cell count with differential and red blood cell indices.
- Stool examination for ova and parasites (3 specimens).
- Stool examination for *Giardia intestinalis* and *Cryptosporidium* antigen (1–3 specimens).
- Additional parasite testing.[a]
  - *Trypanosoma cruzi* serology if child is from endemic area
  - If child has eosinophilia (eosinophil count >450 cells/mm^3 with negative ova and parasite stool testing): *Strongyloides* serology and *Schistosoma* serology if from endemic area
- Tuberculin skin test.[b]
- Consider antibody testing to select vaccine antigens (if written records are unreliable).[c]
- Additional testing: thyroid function tests, lead level, and others as directed by history and physical examination (see text).

Abbreviations: ART, automated reagin test; FTA-ABS, fluorescent treponemal antibody absorption; IgM, immunoglobulin M; MHA-TP, microhemagglutination test–*Treponema pallidum*; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratories.

[a] In conjunction with international adoption or infectious diseases specialist.

[b] Repeat at 6 months after initial testing.

[c] For children older than 6 months, may check diphtheria, tetanus, and polio; for children older than 12 months, may check measles antibodies.

Derived from the American Academy of Pediatrics and the Centers for Disease Control and Prevention.

Management

Counseling for the Transition

Education and preparation for the parent or parents and all family members is a priority. Generally, countries of origin for adoptees are in the developing world, and parents should prepare for healthy travel for themselves by receiving immunizations and following travel guidelines from the CDC and the US Department of State.

Parents should provide consistent structure and boundaries in a loving milieu for adoptees. A scheduled regimen may be especially important to previously institutionalized children because it has been their way of life, but even children who were not institutionalized benefit from a predictable routine. Parents should maximize their 1-on-1 interactions with their adoptee while still allowing time for themselves and other family members—not an easy task with multiple children. Initially, it may be necessary to temper physical contact and affection as directed by the child's tolerance. Parents should try to enhance bonding and attachment by frequently identifying themselves as "Mom" or "Dad." Other strategies to enhance attachment include initially limiting contact with individuals outside

the family and not "handing" the child to others, including non-household family members, because they are strangers to the child. Frequent verbal reassurances and talking to the child about the people and the new world around the child should be encouraged. In caring for the child, the parent or parents should be encouraged to meet the child at the child's developmental level rather than chronologic age.

Growth and Nutrition

When children are identified as malnourished or exhibiting failure to thrive, a multidisciplinary treatment plan is recommended, including the parent or parents, physician, nutritionist, and therapists (eg, occupational therapist for feeding difficulties). The child should be offered familiar foods, if that is the child's preference, and each meal may include a new, more nutritional offering. Children should be offered frequent meals and snacks, because they may not be able to eat much at a single sitting. Foods should be calorie dense and, depending on the child's age and previous dietary history, may include foods such as added butter, cheese, avocado, and peanut butter. Dietary supplements, such as PediaSure or Boost, may be indicated.

Precocious puberty has been observed more in female international adoptees than male international adoptees and is thought to be related to the rapid improvement of nutrition. If signs of precocious puberty are observed, evaluation by a pediatric endocrinologist is recommended.

Development

Because developmental delays are so common among international adoptees, most of them should undergo developmental assessment. Language delays, especially expressive delay, are common; when any such delay is identified, formal audiology testing should be included in the assessment. Performing developmental assessments of language poses difficulties, however, because most are conducted in English, which is rarely the child's primary language. Repeating the testing after a period of adjustment may be helpful. Language barriers do not preclude audiology testing.

Mental Health

Mental and emotional health problems are common and may manifest early or late or occur as relapses. Initial problems may include sleep disorders, fears and phobias, bizarre behaviors, and self-stimulating behaviors. Unless the behaviors pose a safety risk, parents should tolerate them because most dissipate with time in a secure environment. At times of emotional distress, parents may observe a relapse of behavior problems. For milder disorders, physicians may provide guidance to parents; however, moderate and severe disorders merit prompt referral to a mental health professional, ideally someone with expertise in adoption.

Immunizations

If vaccinations are considered valid, as described previously, resuming immunizations per the US schedule (see Chapter 37) is appropriate. If immunization status is unknown or incomplete, however, repeating immunizations or checking antibody concentrations to vaccine antigens is an acceptable option. Most areas of the world routinely administer BCG, polio (oral), and vaccines containing diphtheria and tetanus toxoids with pertussis (often whole-cell) components. Receipt of additional diphtheria, tetanus, and possible pertussis antigens may be associated with an increased risk of adverse events; measuring antibodies to diphtheria and tetanus is warranted to minimize the risk of adverse events. No US Food and Drug Administration–approved antibody tests are available commercially for pertussis antibodies. Receipt of additional doses of inactivated polio vaccine is not usually associated with adverse events. Testing for HBsAb should be performed on all adoptees, and planning for further immunizations will be based on these results. Hepatitis B vaccine will elicit only HBsAb responses; the presence of antibodies to other hepatitis B antigens is suggestive of natural infection. For measles, mumps, and rubella, various formulations and combinations (1- and 2-component more commonly than 3-component) vaccines are available worldwide. Checking antibodies to these antigens is possible, but it likely may be necessary to administer a US-licensed combination (eg, measles, mumps, and rubella) to ensure protection against all 3 antigens. Most of the other vaccines available in the United States are not available in the developing world (eg, *H influenzae* type b, pneumococcal conjugates, varicella, HAV), and the child should receive these vaccines as recommended for age per the US schedule.

Infectious Diseases

Any acute identified infectious disease (eg, scabies, otitis) should be managed following standard practice, bearing in mind the possibility that different antibiotic resistance patterns exist in other parts of the world. Thus, if the child does not have the predicted response to treatment, consultation with a pediatric infectious diseases specialist should be considered. For other infectious disease screening noted previously, additional evaluation and possible management should be initiated promptly (eg, penicillin therapy for syphilis) and pediatric infectious diseases consultation may be considered.

For TB evaluation, any positive PPD skin testing merits further investigation for true infection with *Mycobacterium tuberculosis.* A compounding problem is that some children may be anergic resulting from malnutrition, and a false-negative PPD test result may be obtained. If malnutrition is suspected, obtaining a chest radiograph should be considered even if the PPD is negative, and consideration should be given to repeating the PPD when the child's nutritional status has improved. Additionally, routinely repeating the PPD 6 months after the child's arrival is advisable if the child is from an endemic area, because late exposure to an infected individual is possible.

Prognosis

Being prepared for the complex needs related to international adoption has been identified as the best determinant for parents to consider the adoption experience as positive, regardless of the number or severity of the medical needs of the adoptee.

With improved nutrition and environment, most children have significant catch-up growth; however, up to one-third of adoptees may have unrecoverable loss in linear growth. In terms of intellectual development, by 1 year of age nearly all children in orphanages have 1 or more areas of delay. Their prognosis is generally good, however, with an increase in 2 developmental quotient points per month after arrival in the United States. For children who have been in an orphanage for the first 3 years after birth, the longer the time of subsequent institutionalization the greater the negative effect on IQ and development.

Many children have ongoing mental and psychosocial problems, and some disorders do not manifest until children are older, such as attention-deficit/hyperactivity disorder or learning disorders when the child is of school age. Ongoing attachment disorders seem to occur with greater frequency in children with lower IQs and more behavior problems than average as well as in adoptive families of a lower socioeconomic status.

Assessment of the overall outcome of children who spent 8 or more months in institutional care in Eastern Europe, when evaluated at least 3 years after adoption, showed that approximately one-third had multiple serious problems, including IQ less than or equal to 85, insecure attachment, and severe behavior problems; approximately one-third had a few serious problems but were thought to be making progress; and approximately one-third had progressed very well. The best predictors of major problems were greater length of time in the orphanage, increased number of children adopted at the same time, younger adoptive mother, lower socioeconomic status of mother, and father alone selected the child. Although the effect of these risk factors may not be identical for all birth countries, they do provide some insight. Reviewing these risk factors with adoptive parents during the preadoption period may aid in their decision making.

Role of the Pediatrician

The role of the pediatrician is not to tell the adoptive parent whom to adopt; parents are essentially choosing life partners, which is an individual decision. The pediatrician can, however, assist the parent or parents in reviewing available medical information, which may help the parent or parents make an informed decision about proceeding with an adoption.

During the adoption process, the physician must assume an active role as a child advocate as well as parental advocate and educator. This may be the first parenting experience for the adoptive parent or parents and, thus, education on the basics of child care is necessary, no matter the age of the adoptee. This might include feeding and routine care (eg, estimate the number of diapers needed if traveling to an area with no access to supplies), as well as discipline techniques for a traumatized child. It is necessary to be prepared to care for illnesses because many adoptees are ill at the time of the adoption and travel. The parent or parents may be isolated from their usual support systems while embarking on the new role of parent, and the pediatrician can facilitate emotional preparation for that experience.

After the family returns home, the pediatrician has a role as primary care provider and in serving as a referral source for specialty care, such as in medical subspecialties, mental health, postadoption support services, developmental intervention, and nutrition.

Counseling Adoptive Parents About Expectations

Parents should be informed that it is unlikely that an institutionalized child will emerge from such a situation unscathed. Bearing this in mind, parents may make preliminary preparations for treatment and rehabilitation for the child. Families should be counseled that it is acceptable to say "no" to a potential adoptee. No one benefits from adoption of children by families who do not have the necessary resources to care for them. Most importantly, parents should be reassured that optimism is appropriate. Being prepared matters!

CASE RESOLUTION

In the telephone consultation, the parents report that they have not observed any injuries and no areas seem tender when they examine Jaxon, per your suggestion. They elect to give him some diphenhydramine and fly home with the plan to make an office visit on arrival. Although they are exhausted, they travel directly to your office for an acute care visit. They report that Jaxon remained inconsolable and that the flight home was miserable for him and everyone around them. On entering the examination room, Jaxon was screaming and noticeably uncomfortable but trying to find comfort in his father's arms.

His temperature was 38.9°C (102°F) axillary, his pulse rate was 144 beats per minute, and his respiratory rate was 30 breaths per minute. His examination was notable for extensive oral and pharyngeal vesicular lesions with erythema, but he had no labial lesions. He had multiple shotty cervical nodes, and the rest of the examination was noncontributory. A diagnosis of herpangina was made. He was given a dose of ibuprofen, and 15 minutes later he was quiet, able to swallow electrolyte solution, and cuddling in his father's arms. His parents were reassured that this was an acute infection and not an indication of poor bonding; in fact, Jaxon was already seeking comfort from them. Additional testing for infections included obtaining antibodies to HIV, rapid plasma reagin for syphilis, and hepatitis C and hepatitis B panel, which was especially important because of his biological mother's history of being a commercial sex worker. Other testing included complete blood cell count, lead level, and thyroid function. An appointment was made for 2 weeks hence to complete the assessment, including a developmental assessment; this evaluation was deferred because he was acutely ill at the time of the initial office visit.

CHAPTER 40

Health Care Needs of Children in Foster Care

Kelly Callahan, MD, MPT; ChrisAnna M. Mink, MD, FAAP; and Sara T. Stewart, MD, MPH, FAAP

CASE STUDY

A 13-year-old girl is brought to your office by her foster parent for a general physical examination. The foster parent states that the girl has been living in her home for the past 2 weeks. When the child was initially brought by the social worker, she was wearing dirty clothes and smelled of cigarette smoke. Neither medical records nor immunization records are available for your review, and the teenager is not sure the last time she saw a doctor. The girl states that she often missed school to help care for her sick grandmother. She gets very quiet when you ask about her family. She states that she misses her younger sisters but does not mention anything about her mother. When asked about her mother, she states that she does not care to see her because her mother "cares more about her boyfriend than she does me and my sisters." The only history known by the foster parent is that the child was failing school because of frequent absences and that there were extensive amounts of pornography and drug paraphernalia found in the home at the time of removal. The social worker also told the foster mother that an expired albuterol inhaler was found in the home with the girl's name on it. The foster parent states that the teenager seems "sad" all the time, and 2 nights previously when asked about school, she began to cry and ran to her room.

On physical examination, the patient is sad appearing and quiet, but cooperative. Her weight is in the 25th percentile and her height is in the 50th percentile for her age. She has poor dentition with multiple dental caries. She has a few basilar wheezes on lung examination and has scattered bruises on her anterior shins; no other abnormalities were noted.

Questions

1. What are the medical, psychological, and behavioral issues that commonly affect children in the foster care system?
2. What is the role of the primary care pediatrician in providing a medical home for the child in foster care?
3. How does a child's legal status as a child in foster care affect how medical care can be delivered?
4. What are the appropriate health care referrals and community resources to access for a patient who is in foster care?

The term *foster care* refers to the temporary placement of a child in the home of another caregiver or foster parent because of a threat to the child's safety or well-being in the original home. Placement of a child in foster care results from an investigation of the child's home environment by child protective services (CPS) and may be arranged via voluntary agreement of the parent or through court sanction. The foster parent may be related to the child (also known as kinship care) or may be a nonrelative. For children in voluntary placement, the biological parent retains the right to terminate the placement at any time. For those placed by legal sanction, a series of court hearings give parents, the child, and the CPS agency the opportunity to present their perspectives on the circumstances surrounding the allegations as well as their respective views on interventions to ensure the child has the best home environment.

Children in foster care may present to the primary care pediatrician soon after placement in foster care or after living with a foster parent for a long time. In either scenario, children in foster care often have a significant number of unmet medical and mental health needs because of complex psychological trauma and limited access to health care. These children have rates of medical and mental health disorders that are higher than those of children from equivalent socioeconomic backgrounds who are not in foster care. Thus, foster children should be considered part of the special needs patient population.

At the time of initial removal, the CPS worker may not be able to obtain a medical history or essential information about current medications for the child. Changes in foster care placement may interrupt continuity of care with a health professional, and frequent changes in assigned social services caseworkers can create barriers to communication among biological parents, foster parents, health professionals, and caseworkers.

Traditionally, those in the general medical community have lacked an appreciation for the complexity of the needs of this patient population. Additionally, in part because of low payment rates, it

has been difficult to allot sufficient time in a "routine" office visit to complete the comprehensive evaluation these children require. For those children with identified mental health needs, often few psychiatric and psychological resources are available; this is particularly true for children younger than 5 years.

These unmet needs have long-lasting effects on the well-being of the children, even after exiting the foster care system, including into adulthood. Data have shown that the more adverse childhood experiences to which a child is exposed (eg, abuse, neglect, parental substance abuse, witnessing domestic violence; see Chapter 142), the higher the risk for heart disease, suicide, obesity, and other conditions in adulthood, including early death.

Because of their complex health care issues and vulnerability to fragmented care and adverse childhood experiences, foster children merit a medical home that provides comprehensive, multidisciplinary services and medical case management.

Epidemiology

At any point during a given year, 600,000 children in the United States spend time in foster care. Approximately 275,000 children enter the system annually. Reasons for placement, in descending order of prevalence, include neglect, physical abuse, psychological or emotional abuse, and sexual abuse. As a population, children in the foster care system come from home environments that experience high rates of poverty, parental mental illness, parental substance abuse, unemployment, adolescent parenthood, frequent involvement with the criminal justice system, and low levels of education. Foster children have high rates of exposure to domestic violence, and many are victims of neglect, physical abuse, and sexual abuse. Their biological parents often have limited parenting skills; the children experience inconsistent parenting behaviors along with minimal developmental stimulation and emotional support. All these factors combine to cause unpredictable, stressful, and unsafe home environments for these children, prompting their removal and placement into foster care. Children in foster care account for 25% to 41% of Medicaid expenditures despite representing less than 3% of all enrollees.

Foster children are of all ethnicities, but children of color are disproportionately represented. Children younger than 5 years comprise nearly one-half of the children in foster care, with those 11 to 15 years of age a distant second. In the past several decades, an increasing percentage of new entrants into foster care are infants younger than 1 year of age. Many of these infants are exposed to substances prenatally and are placed in foster care because of a combination of factors related to maternal drug use.

Approximately 70% of children leave foster care within 2 years of placement, with the average stay being 20 months. More than one-half of these children are reunited with their biological parent or primary caregiver. Six percent remain in foster care for more than 5 years, and approximately 35% of all children who leave foster care later reenter the system because of a new CPS report. Since the 1990s, the number of adoptions from foster care has increased to 20% of those leaving the child welfare system. An additional 8% of those leaving foster care emancipate out of the system by reaching 18 years of age without attaining permanent placement. Many of these teenagers later report being incarcerated or homeless at some point after emancipation. Twenty-five percent of the children in foster care will experience 3 or more placements, which results in further fragmentation of their health care and education. Multiple foster care placements are more common for those children with behavioral, emotional, or coping problems.

Clinical Presentation

Medical Issues

Children in the foster care system have been shown to have high rates of acute and chronic illness at the time of their initial medical evaluations after placement (Box 40.1). Thirty percent to 80% of children entering foster care have at least 1 medical concern, with one-third having a chronic illness. Common conditions include obesity, asthma, vision or hearing problems, neurologic disorders, gastrointestinal diseases, dental caries, and other inadequately managed chronic illnesses, such as eczema and anemia. Acute infections are also common, including respiratory tract infections, skin infections, otitis media, sexually transmitted infections (STIs), and intestinal infestations with parasites. Low immunization rates are a frequent occurrence.

Many children entering foster care have growth delay, with weight, height, or head circumference measurement less than the 5th percentile for their age. This may be caused by a combination of factors, including inadequate nutrition, environmental deprivation, prenatal alcohol exposure, genetic predisposition, and underlying illness (eg, HIV infection). Behaviors such as rumination and social withdrawal may manifest in children in environments that are chronically stressful or lack the necessary stimulation and support for a child. (For further discussion of failure to thrive, see Chapter 146.) Overweight (ie, body mass index [BMI] 85%–95% for age) and obesity (ie, BMI >95%

Box 40.1. Medical, Developmental, and Mental Health Issues Common to Children in Foster Care

- Acute infection
- Undiagnosed or inadequately treated chronic illness
- Dental caries
- Growth delay and failure to thrive
- Incomplete immunization history
- Prenatal or perinatal exposure to sexually transmitted infection
- Effects of prenatal substance exposure
- Physical sequelae of physical and sexual abuse
- Developmental delay
- Attention-deficit/hyperactivity disorder
- Posttraumatic stress disorder
- Anxiety
- Depression
- Conduct and oppositional defiant disorders
- Attachment disorders
- Educational disabilities

for age) are also common among children in foster care. Depression, dysfunctional coping skills, and lack of family connectedness also contribute to suboptimal health.

Many children placed in foster care have a history of prenatal exposure to illicit drugs, alcohol, and tobacco. These children have high rates of preterm birth and prenatal or perinatal exposure to infections such as hepatitis C, hepatitis B, HIV, syphilis, and herpes simplex. This risk of exposure to infectious agents is related to maternal drug use and its frequent association with prostitution, needle sharing, and drug use in sexual partners.

Children who have been placed in foster care may present with physical sequelae of prior physical or sexual abuse. Physical abuse may result in skin trauma, skeletal fracture, head trauma, abdominal trauma, and chest trauma. Sexual abuse may result in genital trauma or symptoms of STIs. Both can result in mental health needs related to toxic stress and/or complex trauma.

Developmental and Mental Health Issues

A high prevalence of developmental delay, behavioral disorders, and educational difficulties has been noted in foster children of all ages. These disorders are more common in children with a history of neglect or abandonment than in those who have experienced other forms of child maltreatment. Sixty percent of children younger than 5 years entering foster care have significant developmental delays, and 40% of school-age children (age 5 years and older) have school difficulties. Speech and language concerns, delayed fine motor skills, and poor social-adaptive skills are common. Foster children are more likely than their peers who are not in foster care to require special education, experience multiple school placements, and require grade retention. Approximately 30% of children in foster care have behavioral difficulties, and 17% take at least 1 psychotropic or antipsychotic medication, a percentage that is significantly higher than the national average of 5%. Of children taking any psychotropic or antipsychotic drug, a disproportionate number (29%) were children placed in foster care, group homes, or residential treatment centers.

Common mental health issues in the foster care population include attention-deficit/hyperactivity disorder, depression, anxiety, and suicidal ideation resulting from toxic stress. Posttraumatic stress disorder is common and more prevalent in those who have experienced or witnessed family violence. Adolescents in foster care may act out as a manifestation of mental health difficulties, resulting in sexual promiscuity, substance abuse, and truancy, as well as rates of conduct and oppositional defiant disorders that are higher than those in the general adolescent population.

Attachment disorders are more common in the foster care population than in the general pediatric population and account for a portion of the behavioral difficulties in children in foster care. A secure attachment to a primary caregiver is necessary to the development of emotional security and the sense that one's needs are important. Children who are removed from violent homes or who may have experienced abuse or neglect are likely to have never developed a secure attachment to a primary caregiver and therefore may have difficulty bonding with a foster parent. This problem is further compounded if the child is moved between multiple foster homes, prohibiting development of a healthy attachment to a caregiver. In addition to a lack of emotional reciprocity, these children may exhibit self-stimulatory behaviors or sleep disturbances.

The behavioral difficulties manifested in children in the foster care system are often the result of early childhood trauma and toxic stress. Toxic stress changes the neurobiology of the developing brain and can result in emotional dysregulation, impulsivity, and aggression. These children also may be predisposed to behavioral disorders from having been abused or neglected or from having experienced prenatal exposure to drugs or alcohol. Children often experience fear, sadness, and a feeling of guilt or responsibility for the family discord that resulted in their removal. Foster placements are invariably sudden and unexpected, involve the loss of a familiar caregiver, and are traumatic for children of all ages.

Evaluation

It is important for pediatricians to be familiar with the medical consent legalities concerning foster children in their geographic locales. Specifics vary by locality, but generally, foster parents have the authority to provide consent for routine medical care. The placement of a child in foster care does not supersede the right of a biological parent to participate in the medical decision making for his, her, or their child, and many biological parents retain the authority to consent for medical tests and procedures. Any medical procedure or test that requires specific written consent is likely to require authorization by the legally recognized parent (eg, child welfare agency, courts, biological parent). Two common clinical scenarios that frequently require consent beyond the foster parent's authority are HIV testing and the administration of psychotropic medications.

History

Children in foster care may be brought for medical evaluation by an authorized caregiver, who may be a foster parent, a relative of the foster parent, or the social service caseworker. Often the biological parent is absent from the visit and the child's medical records are not available at the time of the evaluation. Obtaining past medical records can be difficult, but the caseworker can be of assistance in this process. It is important to ascertain the circumstances that prompted a child's placement in foster care, because it may be necessary to modify portions of the evaluation accordingly.

Biological family history is useful to evaluate for the presence of genetic disorders and communicable diseases. A maternal history of drug use or STIs is helpful in identifying those children who may have experienced prenatal exposure to drugs or infectious agents.

Birth history should include any history of prenatal care and complications, such as preterm birth or drug withdrawal. Results of routine newborn screening (eg, hearing, inborn errors of metabolism, thyroid function, hemoglobinopathies) should also be obtained.

A complete medical and surgical history should be gathered, including the identification of a regular health professional if the child has one. Older children and adolescents may be able to provide some of their own histories. Known medications and allergies should be documented, and all available immunization records should be obtained. Documentation of a child's immunization history is frequently unavailable; thus, all possible sources of records, such as biological parents or school districts, should be identified. Feeding history and nutritional assessments should include the type and amount of formula or human milk for infants and types and quantities of foods for older children.

The psychosocial history includes a child's current and prior foster placements or living arrangements and whether the child was exposed to domestic violence, physical abuse, or sexual abuse (Box 40.2). Verbal children may also be able to discuss their feelings about their current foster placement. Adolescents should undergo a confidential screening (eg, home, education and employment, activities, drugs, sexuality, and suicide/depression [HEADSS]; see Chapter 4) to address drug, alcohol, and tobacco use; issues related to home and school; sexual activity; violence; and gang involvement.

The developmental history should include the results of prior developmental assessments as well as a listing of therapeutic or early intervention services received. The behavioral history should also include results of prior assessments, mental health services used, and any psychotropic medications prescribed. The foster parent, biological parent, or CPS caseworker may be able to provide useful observations of the child's developmental capabilities, behavioral patterns, and social interactions. The biological parent or CPS caseworker may also be able to assist in collecting records from prior assessments.

Educational history is often not available at the time of the medical evaluation. It is helpful, however, to know a child's history of prior evaluations by the school system, special education services provided, or prior therapeutic services (eg, physical, occupational, or speech therapy) received through the school district.

Box 40.2. What to Ask

Psychosocial Concerns

- When was the child placed in foster care?
- Why was the child placed in foster care?
- Has the child had prior foster placements? If so, when? Why did placement change?
- Was there prior exposure to domestic violence? To physical or sexual abuse?
- Does the child have siblings in foster care?
- How does the child feel about the current foster placement?
- How has the child integrated into the foster family?
- Has the child previously received mental health services or therapeutic services for developmental delay or educational difficulties?
- What is the child's social service plan (eg, parental visits, reunification, termination of parental rights)?
- Does the child have visitation with the biological parents? If so, are visits monitored or unmonitored?
- Do the parents have to participate in any classes or training?

Physical Examination

A complete, unclothed physical examination should be performed on each child. For children who are traumatized or particularly frightened, disrobing only the immediate area being examined may help ease their discomfort. For some traumatized children, more than 1 office visit may be necessary to complete the evaluation. Growth parameters, including height, weight, and occipitofrontal head circumference (for children younger than 2 years) or BMI (for children 2 years and older), should be plotted on a reference chart, and a close inspection should be performed for signs of prior trauma. The child should be assessed for dysmorphic features consistent with prenatal alcohol exposure or other genetic syndromes. In children of all ages, the physical examination should include a genital examination to assess for signs of trauma. Additionally, sexually active females should undergo a pelvic examination if there are any reports of abdominal pain, vaginal discharge, or other concerns. (See Chapters 144–146 for further descriptions of physical findings.)

Immunizations

Immunizations should be administered as appropriate for age, and if immunization records cannot be obtained in a timely fashion (eg, before the next scheduled visit), the child should be considered unimmunized. In this situation, options include restarting the vaccination series or checking antibody titers for selected vaccine antigens (see Chapter 37 for further information). Other possible sources for vaccine records include state or county registry, the child's previous health professional, or the school previously attended by the child. If available, the biological parent should be asked to assist with providing any vaccine record as well as other medical records.

All children should also undergo appropriate screening for tuberculosis, such as purified protein derivative skin testing or interferon-γ release assays.

Additional Assessments

All children should undergo mental health and developmental screenings and should be referred for comprehensive testing if abnormalities are noted. Dental screening should be incorporated in the physical examination of all children older than 6 months. Vision and hearing screenings should also be performed on all children old enough to cooperate. A referral for expert vision or hearing evaluation should be made if it is indicated by the history or physical examination or the patient cannot complete the screening procedure, such as infants and children with developmental delay.

Laboratory Tests

Routine screening laboratory tests should be performed on foster children just as they are indicated for the general pediatric population. For example, hemoglobin level should be checked annually in all infants, toddlers, and preschool-age children. Serum lead

levels should be checked according to local guidelines but should be checked at least once for a child during the toddler years. A urinalysis should be performed as indicated by the history and examination for the child younger than 2 years of age and at least once for the child 2 years of age or older.

For infants younger than 12 months, especially those with a history of prenatal drug exposure or other known risks for maternal STI, rapid plasma reagin, hepatitis C antibody, hepatitis B surface antigen and surface antibody, and HIV testing should be performed.

Adolescents who are considered to have at-risk behaviors, patients with signs or symptoms consistent with an STI, and children with a history of sexual abuse that could result in the transmission of infection should be tested for STIs. Often adolescents can sign their own consent forms for evaluations and treatment related to STIs; however, local statutes should be consulted.

Imaging Studies

If a child has a history or physical findings concerning for physical abuse, imaging such as a radiographic skeletal survey, computed tomography, and magnetic resonance imaging of the head or radionuclide bone scan may be indicated. (For more specific recommendations, see Chapter 17.)

Management

Given the breadth of health-related needs for this patient population and the frequency with which such patients change foster homes, close case management is an essential component of health care delivery to this population. Health professionals should maintain consistent communication with the child's caseworker to ensure that medical and mental health recommendations are incorporated into the child's social service plan. Ideally, a child should have a trauma-informed medical home and continuity with a primary care pediatrician over time. Unfortunately, changes in home placements often make this difficult. If continuity of care is broken, incorporation of the health care plan into a child's broader social service plan should ensure that medical history and medical and mental health recommendations are not lost. The use of electronic health records is a growing practice in many foster care systems and promotes continuity of care, even with logistical challenges.

Children and adolescents in foster care require frequent health visits. The American Academy of Pediatrics recommends a health screening within 72 hours of placement, a comprehensive medical evaluation within 30 days of placement, and a follow-up medical examination within 60 to 90 days after placement. Because of the prevalence of significant medical, social, and mental health issues affecting children in foster care, additional visits are often advisable. Anticipatory guidance should be provided to the caregiver, and age-appropriate issues should be discussed with older children and adolescents.

Children in foster care often need referral to medical subspecialists, dentists, dietitians, speech therapists, occupational therapists, mental health professionals, and other service providers. Case management is necessary to track these referrals and to contact the foster family or caseworker if an appointment is missed.

Prognosis

Children in foster care, spanning in age from newborns to adolescents emancipating from the system, have a spectrum of mental health and medical needs. Preliminary studies have documented improved physical health status, school performance, and adaptive functioning of young children after placement in foster care; however, these studies require replication. The strength of the bond between the foster parent and the child, as well as the consistency and predictability of the foster home environment, are significant to the development of the child's sense of safety and well-being.

To date, much of the research on the health status of children in foster care has focused on the delineation and description of the health-related issues that these children face. More limited evaluation has been done of the different models of health service delivery to the foster care population as well as of the subsequent medical, developmental, and emotional outcomes of the children in these different models.

Although a need exists for continued study of health care delivery to the foster care population, it is widely accepted that children in the foster care system benefit from the establishment of trauma-informed medical homes with case management capabilities and physicians who are well-versed in the complex medical and mental health issues that affect this vulnerable population.

CASE RESOLUTION

This case illustrates many of the common issues that affect children when they are placed in foster care. Medical and immunization records are frequently unavailable to the medical examiner, and chronic medical needs have often gone unmet. This child's poor hygiene and frequent school absences point to a history of parental neglect and, given the presence of drug paraphernalia, her mother likely was involved with substance abuse.

This child should undergo a thorough assessment for behavioral problems, developmental delays, and education-related disabilities. The child states that she does not want to return to her parents' care, but she still misses her family members. This may be remedied through her child welfare plan, for example, by arranging for her to remain in contact with her siblings throughout their foster placement. Because of her experiences in her prior home environment, she has depressive symptoms and is likely to have other unmet mental health needs, which require referral to a mental health provider. She also needs evaluation by her new school system to determine her specific educational needs and appropriate grade placement.

The girl has poor dentition, which is a common finding in the foster care population, and she requires a referral for dental care. The presence of mild wheezing in a child who states that she feels fine otherwise is a likely marker for untreated reactive airway disease and may be a reflection of poor continuity of medical care prior to her placement. Routine adolescent care should be initiated at this visit, including a thorough history of drug and alcohol use as well as reproductive history. Anticipatory guidance on menstruation, sexuality, and drug use should be considered. Her vaccines should be updated. She should be scheduled for a revisit in 2 months for the second human papillomavirus vaccine and to establish an ongoing relationship, monitor her asthma, and talk about any concerns she may have.

CHAPTER 41

Working With Immigrant Children and Their Families

Ismael Corral, MD, MBA, and Carol D. Berkowitz, MD, FAAP

CASE STUDY

A 7-year-old boy presents with vomiting and clinical signs of dehydration. The family thinks he has empacho (a Latin American folk illness). You tell the family that you suspect that he has viral gastroenteritis. You want to draw some blood samples for testing and give him fluids intravenously. The parents are skeptical; they refuse the blood work and want to leave, against medical advice.

Questions

1. What are the ways in which different immigrant families view illness and health?
2. What are barriers to accessing health care that children in immigrant families face?
3. What questions help the physician understand the health beliefs of immigrant families?
4. What are the considerations when interacting with parents who do not speak English?

The United States is described as a nation of immigrants. Out of a population of 326 million, current estimates are that about 43 million, or approximately 13.2% of the current US population, are foreign-born citizens or noncitizens. Half of these immigrants are Hispanic, and 65% of Hispanics are of Mexican descent. It is expected that by 2030, Hispanic children will account for most children living in the United States. During the 1990s, 70% of the overall US population growth was influenced by a wave of recent immigrants, mostly from Latin America and Asia, and by the children born to these newcomers. The vast growth in the population of children living in immigrant families, whether foreign born (first generation) or US born (second generation), poses a unique set of challenges. This is especially the case in 10 major metropolitan areas that are classified as traditional immigrant destinations, where approximately 48% of immigrant children reside. While this chapter focuses on immigrant children, children of migrant workers, and children living by the United States-Mexico border may face similar issues related to access to quality health care.

Households with immigrant children are more likely to live below the federal poverty level (FPL) and have at least 1 parent who did not graduate high school or is not fluent in English. An estimated 31% of mothers and a similar number of fathers in these families have not graduated from high school. In 2013, 26% of children in immigrant families lived below the FPL, compared with 19% of children whose parents were born in the United States. This has gradually increased since 2006, when 22% of children in immigrant families lived below the FPL. These children are also more likely to live in crowded housing (>1 person per room) and in a multigenerational household. Families of immigrant children tend to be larger, with 19% having 5 or more children, compared with families of children born in the United States, of which only 14% are of that size. While some immigrant children are citizens and eligible for safety net programs, their family's status directly influences whether these children will even access such care. Children of immigrant parents are twice as likely to be uninsured (15%) as children in nonimmigrant families (8%). There is also growing concern that the health status of some immigrant children, whether foreign born or first generation, actually declines after settling in the United States.

Demographics of Immigrant Children

There are 5 general categories of immigrants in the United States, each benefiting from specific entitlements and services and having certain legal rights: lawful permanent residents, naturalized citizens, refugees/asylees, nonimmigrants, and undocumented immigrants (Box 41.1).

In 2007, individuals who had become naturalized citizens included immigrants (32%), lawful permanent residents (29%), undocumented immigrants (29%), refugees (7%), and nonimmigrants (3%). From 1980 to 2000, the children of immigrants increased from 5% to 20% of school-age children, representing approximately 10 million of the estimated 60 million school-age children in the United States.

By far the largest category of immigrants is nonimmigrants or temporary visitors. Approximately 3 million children arrive each year, mostly from Asia, Western Europe, and parts of North America, typically accompanying their parents, who are seeking

Box 41.1. Categories of Immigrants in the United States

Lawful Permanent Residents

- Carry a green card.
- Noncitizens with permission to permanently live and work in the United States.
- May apply for naturalization after 5 years (or 3 years if they marry a citizen).
- Group with the most international adoptees.

Naturalized Citizens

- Born as noncitizens.
- Having met certain English literacy requirements and demonstrating a basic knowledge of civics and a desirable moral character, are granted the same rights as natural-born citizens.
- However, are not eligible to hold the office of president or vice president.

Refugees/Asylees

- Granted permission from the US government before entry.
- Fled their country of origin for fear of persecution because of their race, religion, social group, or political opinion.
- Many unable or unwilling to return to their country of origin.
- Those granted permission to remain are deemed *asylees*.
- After a year, both may apply to adjust their status to lawful permanent resident.

Nonimmigrants

- Carry a visa.
- Granted permission to enter for a specified time and specific purpose (usually to work or study).

Undocumented Immigrants

- Entered the country illegally or even legally but then violated the terms of their stay and remained after their visa expired.
- Lack proper papers and identification to live in the United States.

work. A smaller percentage are students or exchange visitors. While not technically immigrants, this special group may present for care with similarly unaddressed health issues depending on their country of origin.

The next largest group, almost a quarter-million children, enter the United States as lawful permanent residents, with most eventually becoming naturalized citizens. Although most arrive with or to meet family already residing in the United States, several thousand adolescents immigrate unaccompanied each year; most are female, and many are married to a naturalized citizen at the time of immigration. Included in this group are children of refugees or asylees. More than 75,000 individuals arrive each year, most recently from the countries of the former Yugoslavia and former Soviet Union, Vietnam, Somalia, and other war-torn regions. Numbers for the third-largest group, undocumented immigrants, are based primarily on estimates. Most are from Mexico or other Latin American states. Some entered the United States legally but have overstayed their visa or lost their status by committing a crime.

While most pediatricians are not in a position to assist families in their efforts to attain citizenship or legal status, programs such as the National Center for Medical-Legal Partnership (https://medical-legalpartnership.org) may provide necessary advice and services. There is also an Immigrant Child Health Toolkit available through the American Academy of Pediatrics (AAP) that provides primary care physicians with immigration-specific resources readily available within their area.

Health Care Needs of Immigrant Children

When the child of an immigrant family presents for care, primary concerns are about the presence of an infectious disease (from exposures and possible lack of vaccination) or of a hidden genetic or ethnic condition (eg, hemoglobinopathies, glucose-6-phosphate dehydrogenase deficiency). Investigating the health status of a child, especially from undocumented immigrant families, is paramount because these children likely have not seen a doctor prior to immigrating. Similarly, nonimmigrants, such as tourists and other temporary visitors, from many Western or Pacific Rim countries are not required to have a medical examination performed as part of their application. Only visas for permanent residency require a health examination to be performed by an approved physician, and even then, the focus of the examination is to exclude certain conditions, such as active tuberculosis (TB), HIV, and other severe physical or mental disabilities. In children, laboratory testing may be limited, and proof of vaccination status may be exempted for certain groups, such as international adoptees.

Lack of education and poverty, which results in relative food insecurity and inadequate, crowded housing conditions, poses an ominous threat to the health of these same children. Immigrant parents of children born in the United States may be reluctant to apply for Medicaid or the Children's Health Insurance Program for fear of being considered a public charge (ie, a person dependent on the government for expenses of living). The Patient Protection and Affordable Care Act of 2010 excluded undocumented immigrants from health care coverage. Noncitizen children who are lawful permanent residents must wait at least 5 years before they are able to apply for public assistance. While most refugee children may receive some form of subsidized care, such as Medicaid, many of these benefits are time-sensitive. Even US-born children of undocumented mothers, while legally eligible as US citizens for benefits such as nutritional assistance programs, may not receive these because of parental fears of detection and deportation.

Physicians should ascertain that the family has adequate housing and access to food, 2 basic human needs. The physician should take the following factors into consideration during health supervision visits (Box 41.2): Is the food available in the family's neighborhood consistent with the traditional food that the family desires? Is the food healthy, or does the family live in a food desert where there is a plethora of fast-food restaurants and a paucity of supermarkets or grocery stores? The ability to safely attend the local park, walk around the neighborhood, or even go outside the family's own

Box 41.2. Risk Factors Affecting the Health of Immigrant Children

Social and Economic
- Inadequate or crowded housing
- Environmental safety concerns
- Food insecurity
- Lack of insurance (because of ineligibility)
- Lack of access to insurance (eligible but unable or unwilling to apply)
- Educational level of household

Cultural
- Dietary preferences
- Lack of language fluency or literacy and translation/interpretation issues
- Disparate ideas about the causation and treatment of illness
- Expectations of the medical system
- Religious practices with a medical component
- Lack of access to traditional medical practitioners and treatments
- Importation of drugs not approved in the United States

Physical
- Carriage of infectious disease and the possibility for repeated exposure via travel or living within one's immigrant community
- Presence of ethnic or genetic variations
- Lack of vaccination
- Poor nutritional status

Mental Health
- Negative past living conditions, including exposure to violence or natural disaster
- Cultural adjustment (or the process of acculturation or enculturation)
- Traumatic separation

home should be determined, as any of these factors may interfere with treatment plans. In cases in which safety or access is an issue, information about local community centers should be provided during clinic visits. Often, families may not be aware of affordable, local, easily accessible resources.

It has traditionally been supposed that immigration itself imposes unique stresses on these children. Mental health challenges (eg, depression, anxiety, grief) may be related to the reasons for their migration as well as to the inevitable process of acculturation. Stress is compounded by the potential loss of the immigrant's identity, separation from home support systems, or traumatic separation from family members either in the United States or during travel; inadequate language and literacy skills in a society intolerant of linguistic weakness; disparities between one's country of origin and the United States in economic, social, and professional standards and status; and the psychological and emotional trauma of war, persecution, or exploitation in one's country of origin.

Despite these challenges, epidemiological studies indicate that children in immigrant families experience better outcomes than those in their native countries who did not immigrate, especially in some countries. The most striking example is the lower rate of low-birth-weight children born to foreign-born mothers, especially among Hispanic and non-Hispanic black immigrants, compared with women in their native countries who did not immigrate. This positive effect related to immigration has been studied less in older children because of limited availability of data samples from second-generation children that do not exclude first-generation children.

General Approach to the Initial Medical Evaluation of an Immigrant Child

Ascertaining the life history of an immigrant child, including any relevant travel history, will help determine the extent of the medical evaluation (Box 41.3).

In general, most immigrants from industrialized nations have received comprehensive medical care, and the only issues facing these children are routine, such as updating immunization status. In contrast, adoptees, refugees, and undocumented children often have received little or no care. While there is no single approach to the medical evaluation of all immigrant children, some general principles apply.

Any and all existing medical records should be reviewed. Previous growth parameters should be obtained, if available. While a complete translation is not always necessary, if an unusual diagnosis or a complicated history exists, use of clinical translational services or a nearby university's academic language department may facilitate the process. Sometimes, records suggest that a diagnosis was considered but not confirmed, and it may be appropriate to reevaluate the child for any suspected condition.

It is important to screen for certain infectious diseases. The most common among immigrants are TB, intestinal parasites, hepatitis B, syphilis, and HIV. In fact, the risk of TB is more than 100 times greater in immigrant children than in US children. Fifty percent of all newly identified cases of TB in the United States are diagnosed in immigrants, many within the first 5 years after birth. If TB is not clinically apparent (ie, in the incubation period), or test

Box 41.3. What to Ask

Evaluating Immigrant Children
- Are the parents present? Or is there a current guardian who may have personal knowledge of the child's social and medical history?
- In which countries has the child resided and under what circumstances?
- Have the child's living conditions changed dramatically (positively or negatively) recently?
- Are there verifiable birth and medical records to be reviewed? Vaccination status? What age is the child? What type of health care did the child receive in his or her home country?
- Has the child undergone any recent procedures or treatment?
- Was the child exposed to any potentially toxic occupational or environmental risks?
- What educational level did the child achieve?

results are negative but clinical suspicion exists, TB testing should be repeated in 6 months. The AAP *Red Book* can provide guidance on interpreting tuberculin skin tests in the setting of BCG vaccine as well as advice about alternative tests, if warranted. Intestinal parasitic infestations may be present without symptoms. Some clinics specializing in immigrant health advocate giving a single dose of albendazole as a more cost-effective approach than screening and diagnosis, but the safety and efficacy of this approach has not been substantiated in children.

Ethnic or genetic conditions should also be considered. Conditions such as glucose-6-phosphate dehydrogenase deficiency in immigrants from the Mediterranean, Africa, and Southeast Asia may affect the child's health in the short term. Others, such as hemoglobinopathies and thalassemia, while common among certain ethnic populations, such as those from Southeast Asia, may not be of immediate importance. Overall, anemia is extremely common among immigrant children, and the diagnostic workup of these children may uncover an underlying blood dyscrasia trait or lead intoxication. If iron therapy has been initiated empirically, repeat testing after treatment is paramount to ensure a response and confirm the diagnosis. Understanding the risk of nutritional deficiencies based on the country of origin is important. For instance, nutritional disorders, such as rickets and iodine deficiency, are common in children who are ethnic Chinese and children from the former Soviet Union.

Immunizations must be administered as appropriate, following the catch-up recommendations of the AAP and the Advisory Committee on Immunization Practices. Records of previous immunizations may be difficult to interpret. Shortened intervals or the administration of a vaccination at too early an age may not be readily apparent. Fraudulent records, especially among adoptees and children from institutional settings, often exist. In young children, it is generally considered safe and cost-effective to simply give missing vaccines; however, determining serum immunity through the use of titers may be more cost-effective in older children. It is also important to remember that children seeking asylum are not required to meet immunization requirements at time of entry; however, at time of permanent residency application they must show proof of immunization.

Cultural and Linguistic Sensitivity

Bridging language differences using professional interpreter services is required to provide adequate patient care. Such linguistic services are mandated by agencies such as the Centers for Medicare & Medicaid Services for payment from the federal government. The use of children or hospital maintenance or janitorial staff as interpreters is inadequate and potentially violates federal laws, including the Health Insurance Portability and Accountability Act of 1996. Professional interpreters are taught to interpret and not carry on additional conversations with the patient or expound on the questions the physician asks. The physician should address questions directly to and maintain eye contact with the patient, not the interpreter.

Communicating in a patient's native language serves to foster and enhance the physician-patient relationship. Patients often feel more relaxed, confident, and open to sharing their concerns with their physician. Treatment plans expand beyond a physician-directed plan to a dynamic interaction that empowers the patient to take control of the disease.

Providing culturally competent care that considers cultural practices and beliefs about child health or illness when devising a treatment plan is also critical. Questions to ask are provided in Box 41.4 and also include the following: Does the family access healers for medical problems? What are the family's views about medication use? Are there hierarchical structures that influence a parent's acceptance of a physician's advice (eg, father accepting advice from a female physician, parent accepting advice from a young resident)? Are there dietary restrictions? In addition, it is important to consider the influence of socioeconomic status and environmental hazards during the development and implementation of a treatment plan. Failure to take all these factors into account may lead to undesired health outcomes and incorrectly labeling the family or patient as noncompliant.

Conclusion

There are numerous barriers that potentially interfere with achieving optimal health status for immigrant children. Many of these barriers are societal and relate to funding for medical services. Trust is a core component of the physician-patient relationship, and establishing trust may be more difficult when the physician and family have different cultural values and expectations. It has been stated that in medicine, the sacred trust that develops between a patient and his or her doctor should never be taken for granted. The development of trust forms the foundation of the therapeutic relationship. It provides credibility to the practitioner. The practitioner must act in a manner that elicits and fosters trust, and being knowledgeable and nonjudgmental about the beliefs and practices of patients is pivotal.

Box 41.4. What to Ask

Understanding Cultural Concepts of the Symptoms of Illness

- What do you call the problem? What is your understanding of the problem?
- What do you think caused it?
- Why do you think it started when it did?
- What do you think the sickness does? How does it work?
- How severe is it? How long will it last?
- What are the chief problems the illness has caused?
- What kind of treatment do you think the child should receive? What are the most important results you expect from this treatment?
- What do you fear most about the illness? Do you fear the treatment or medication?

Adapted from Kleinman A. *Patients and Healers in the Context of Culture: An Exploration of the Borderland Between Anthropology, Medicine, and Psychiatry*. Berkeley, CA: University of California Press; 1981.

Health professionals must work toward creating an atmosphere of trust so that parents feel comfortable revealing their beliefs, concerns, and fears. The threat of deportation should be considered when taking into account whether the patient or family will follow up or adhere to medical recommendations.

It is unwise not to acknowledge the cultural divide that exists between most pediatric practitioners and the families they serve. Therefore, pediatricians who are less familiar with the enrichment provided by a multicultural patient population may be less inclined to advocate for social reforms that may prove beneficial. Physicians must approach families with an open mind, respect, and a sense of humility if they are to gain families' trust, close the gaps that separate, and promote the well-being of children.

Children are better served when their families receive information about federal, state, and community programs that provide resources to immigrant families. In addition to health care, pediatricians can provide families with information about educational programs, such as Head Start, that are not restricted by immigration status. All children, regardless of their immigration or socioeconomic status, should receive compassionate, culturally competent, and linguistically effective care services. Such care requires that health professionals incorporate knowledge, attitudes, and skills in cultural and linguistic competence within their professional agenda.

The well-being of all children can be advanced through advocacy, especially on behalf of vulnerable children. Such advocacy addresses outreach efforts to children who are potentially eligible for Medicaid and the Children's Health Insurance Program but are not enrolled, simplifies enrollment for both programs, and expands state funding for those who are not eligible. The medical community must collaborate with legislators, families, and organizations representing underserved populations to increase the effectiveness of one's own advocacy effort. All children should receive care in a medical home (ie, the establishment of comprehensive, coordinated, and continuous health care services). This is especially critical for immigrant children with chronic and mental health care needs.

CASE RESOLUTION

You reach an agreement with the family for a community healer to come and perform a therapeutic massage while allowing you to place an intravenous line and administer fluids. The patient is significantly improved after the massage and intravenous fluids. The family appreciates that you respected their beliefs and agrees to return for a routine health supervision visit in 2 weeks.

CHAPTER 42

Well-Child Care for Children With Trisomy 21 (Down Syndrome)

Moin Vera, MD, PhD, and Henry J. Lin, MD

CASE STUDY

A 6-month-old girl with trisomy 21 (ie, Down syndrome) whom you have known since birth is brought to your office for well-child care. She and her parents have been doing well, although she has had several episodes of upper respiratory infections. Her medical history is significant for a small ventricular septal defect, which has since closed spontaneously, as well as 1 episode of otitis media at 5 months of age. Her weight gain has been good—along the 25th percentile on the growth chart for children with Down syndrome. Currently, she sleeps through the night and has a bowel movement once a day. She has received all the recommended immunizations for her age without any problems.

The infant smiles appropriately, grasps and shakes hand toys, and has some head control but cannot roll from supine to prone position. Since 1 month of age, she has been enrolled in an early intervention program. An occupational therapist visits her at home twice a month.

On physical examination, she has typical facial features consistent with trisomy 21, a single palmar crease on each hand, and mild generalized hypotonia. Her eyes have symmetric movement, and her tympanic membranes are clear. She has no cardiac murmurs.

Questions

1. What is the prevalence of trisomy 21 (ie, Down syndrome) in the general population? What is the association of maternal age with trisomy 21?
2. What are the clinical manifestations of Down syndrome?
3. What medical conditions are associated with trisomy 21 in the newborn period, during childhood, and in adolescence? When should screening tests for these conditions be performed?
4. What is the role of early intervention services for patients with trisomy 21 and their families?
5. What specific psychosocial issues should be included in the anticipatory guidance and health education provided by the physician?
6. What is the prognosis for the child with trisomy 21?

Trisomy 21, or Down syndrome, is the most common genetic cause of intellectual disability in children. Primary care physicians are in a unique position to offer affected children specific health maintenance and anticipatory guidance, help manage intercurrent illness and chronic problems, and apply the latest recommendations for clinical screening based on risks for conditions associated with trisomy 21. Additionally, the general pediatrician has the opportunity to develop rapport with children and families, which is of particular importance because of the complex medical and social implications of raising a child with trisomy 21. An important goal of the well-child visit is to provide children with trisomy 21 and their families with counseling about educational, social, and financial resources and support to ensure a healthy and productive transition into adulthood.

Epidemiology

According to the Centers for Disease Control and Prevention, the prevalence of trisomy 21 is approximately 1 in 700 live births in the United States. It is estimated that trisomy 21 is responsible for up to one-third of all cases of moderate to severe intellectual disability. Trisomy 21 has a male-to-female ratio of 1.3:1.

Ninety-five percent of all cases of Down syndrome are caused by chromosomal nondisjunction, and most of these events occur in oocytes during meiosis. The probability of maternal chromosomal nondisjunction is determined by maternal age. A 25-year-old woman has a 1 in 1,240 risk for having a live baby with Down syndrome, and the risk increases to 1 in 340 at age 35 years and 1 in 98 at age 40 years. It is estimated that approximately one-half of

trisomy 21 embryos abort spontaneously. The risk of recurrence of the nondisjunction type of Down syndrome in subsequent pregnancies is 1 in 100 until age 35 years, after which the risk determined by age takes precedence. Other family members generally are not at increased risk of bearing children with this type of Down syndrome.

Recent advances in first and second trimester screening allow prenatal diagnosis of Down syndrome with a sensitivity of 80% to 90%. If a prenatal diagnosis of Down syndrome is made and the general pediatrician is asked to participate in counseling the family, the pediatrician should go over with the family the points listed in Box 42.1.

Clinical Presentation

Newborns, infants, and children with trisomy 21 have a characteristic appearance (Box 42.2). They may exhibit microcephaly, with flattening of the occiput and face. The eyes have an upward slant with prominent epicanthal folds, the ears are small and set low, the nasal bridge is flattened, and the tongue appears large. The feet, hands, and digits are small and stubby (ie, brachydactyly), and the fifth digit may be hypoplastic and turned in (ie, clinodactyly). A single palmar crease and wide spacing between the first and second toes may be evident. After the newborn period, diffuse hypotonia and developmental delay are universally seen.

Box 42.1. Counseling the Family After a Prenatal Diagnosis of Down Syndrome

- Review the data that established the diagnosis in the fetus.
- Explain the mechanism of occurrence and risks for recurrence.
- Review the manifestations of trisomy 21, commonly associated conditions, and the variable prognosis based on the presence of these conditions.
- Discuss other modalities that confirm the presence of associated anomalies, such as fetal echocardiography in the case of congenital heart disease.
- Explore treatment options and interventions for associated conditions.
- Offer resources to assist the family with decisions about completing or terminating the pregnancy.
- Refer the family to a clinical geneticist or genetic counselor.

Box 42.2. Diagnosis of Trisomy 21

- Microcephaly, with flattening of occiput and face
- Upward slant to the eyes with epicanthal folds
- Brushfield spots on the irises
- Small ears and mouth (tongue appears large in relation to the mouth)
- Low-set ears
- Flat nasal bridge
- Broad, stocky neck with loose skin folds at the nape
- Funnel-shaped or pigeon-breasted chest
- Small, stubby feet, hands, and digits (ie, brachydactyly); the fifth digit may be hypoplastic and turned in (ie, clinodactyly)
- Single transverse palmar crease on each hand
- Wide space between first and second toes
- Fair, mottled skin in newborns; dry skin in older children
- Hypotonia

Pathophysiology

Down syndrome is caused by trisomy 21 resulting from meiotic nondisjunction (approximately 95% of cases), translocation (3%–4% of cases), and mosaicism (1%–2% of cases). A small percentage of affected children have a chromosomal rearrangement resulting in 3 copies of a portion of chromosome 21.

Translocations in an affected child are unbalanced and usually occur between chromosome 21 and another acrocentric chromosome, most commonly chromosome 14 or 15. Approximately 75% of these translocations are de novo rearrangements, and 25% are the result of a familial translocation. In the latter case, a parent may be an unaffected carrier of a balanced translocation involving the long arms of chromosome 21 and another acrocentric chromosome (ie, robertsonian translocation). Thus, if a child is found to have a translocation, parental karyotypes must be assessed because balanced translocation carriers have an increased risk of Down syndrome in future children. Mosaicism implies the presence of 2 cell lines—1 normal and 1 with trisomy 21. As might be expected, children with mosaic Down syndrome are usually affected less severely than children with other types of Down syndrome.

Research has focused on the role of individual genes, such as *DYRK1A*, in the pathogenesis of Down syndrome. It is expected that in the near future, pharmacologic agents that mitigate the effects of excess expression of such genes will result in new treatments for patients with Down syndrome.

Evaluation

Routine health maintenance for newborns, infants, children, and adolescents with trisomy 21 should include discussion of the same issues of health education, prevention, and counseling that are discussed with other patients and their families. The schedule of health maintenance visits for newborns, infants, and young children with trisomy 21 is essentially the same as that recommended by the American Academy of Pediatrics for other children, whereas older children with Down syndrome should be evaluated annually. Surveillance and anticipatory guidance related to the additional medical and psychosocial conditions common among patients with trisomy 21 is tailored to the main periods in a child's life: newborn, infancy and early childhood, and older childhood and adolescence.

Newborn Period

Verification of the diagnosis of trisomy 21 is perhaps the single most important focus of the initial family visit. Sometimes the diagnosis has been suspected prenatally because of abnormal biochemical markers and sonographic findings and verified by chorionic villus sampling or amniocentesis (Box 42.1). If no prenatal testing data are available and the diagnosis is suspected based on clinical findings,

a karyotype test must be performed while in the nursery and the results reviewed at the 1- to 2-week visit. In some institutions, a fluorescence in situ hybridization test for trisomy 21 may provide a more rapid confirmation of the diagnosis (1–3 days).

Several conditions associated with trisomy 21 are important to identify in the newborn period, including hearing loss, congenital heart disease (most commonly endocardial cushion defect), duodenal atresia, Hirschsprung disease, congenital hypothyroidism, hip dislocation, and ocular anomalies (ie, cataracts, glaucoma, strabismus, nystagmus). Hematologic abnormalities include polycythemia, leukemoid reactions that resemble leukemia but resolve during the first month after birth, and, rarely, leukemia.

History

A feeding history is critical because hypotonia often results in difficulty swallowing (Table 42.1). A history of vomiting may be indicative of gastroesophageal reflux or, less commonly, gastrointestinal malformation. Constipation may be the first indication of Hirschsprung disease or hypothyroidism. A detailed family and social history should also be obtained if this was not done in the hospital.

Physical Examination

A detailed physical examination should reveal some common features of newborns with Down syndrome (Box 42.2). All growth parameters should be recorded and compared with those obtained at birth. The size of the fontanels should be evaluated because of the increased incidence of congenital hypothyroidism in this population. Bilateral red reflexes and conjugate gaze should be documented to exclude congenital cataracts or strabismus. A careful cardiac examination must be performed, noting any cyanosis, murmurs, irregular heart rates, abnormal heart sounds, or asymmetry of pulses. The abdomen should be palpated for organomegaly or any masses, and patency of the anus should be verified. Ortolani and Barlow maneuvers should be performed for hip laxity. Finally, the newborn should be evaluated for hypotonia.

Laboratory Tests

Karyotyping is an important tool in verifying the diagnosis and assessing the risk of recurrence. Newborn screening laboratory tests must be reviewed, especially hearing evaluations and thyroid screenings. Additionally, a cardiac evaluation for congenital heart disease should be performed, which may include electrocardiography, chest radiography, echocardiography, and formal cardiology referral. A complete blood cell count is indicated to assess for hematologic abnormalities, including leukemoid reaction, transient myeloproliferative disorder (ie, pancytopenia, hepatosplenomegaly, and immature white blood cells), and neonatal thrombocytopenia.

Management

The primary care physician should discuss the increased propensity for respiratory infections in children with Down syndrome. Other important issues to address include those pertaining to available resources for children and families, such as early intervention programs and Down syndrome support groups in the community.

Table 42.1. Health Supervision for Children With Down Syndrome

Evaluation Type	*Assessment*	*Age at Initial Evaluation*	*Timing of Subsequent Evaluations*
History and physical examination	Developmental Visual and hearing (subjective)	Newborn	Same as regular well-child care schedule until age 5 years, then annually.
Laboratory assessment	Karyotyping	Newborn	None.
	Thyroid screening	Newborn screening	6 months and 12 months, then annually thereafter.
	Complete blood cell count	Newborn	0–1 month, after which hemoglobin level is assessed annually.
	Celiac screening	2–3 years	Measure tissue transglutaminase IgA antibody levels.[a]
	Echocardiography	Newborn	Condition dependent.
	Neck radiography	3–5 years	Obtain in symptomatic individuals with pain or neurologic abnormalities. May be required for Special Olympics entry.[b]
Consultation	Genetics	Newborn	As needed.[c]
	Cardiology	Newborn	Condition dependent.
	Ophthalmology	6 months	Annually until age 5 years, then every 2 years until age 13 years, then every 3 years.
	Ear, nose, and throat	As needed	As needed.
	Dental	By 1 year	Twice per year.
	Pulmonary	As needed	As needed.

[a] Lack of expert consensus on evaluation. Some recommend testing every 5 years and others recommend testing only symptomatic individuals.

[b] Lack of expert consensus on evaluation.

[c] Depending on experience and comfort level of primary care physician.

Educational materials, such as pamphlets and books, may also be supplied at this time. Upcoming appointments with other physicians and allied health professionals should be reviewed.

Infancy and Early Childhood

History

Some additional history-related issues to address include a detailed developmental assessment focusing on progress made since the previous visit, because most affected children have motor and speech delays (see Table 42.1). It is important to review any ancillary services, such as physical, occupational, and speech therapy, in anticipation of school entry. The parent or parents should provide their assessment of the child's vision and hearing. A history of recurrent respiratory infections is concerning for recurrent otitis media with the associated risk of hearing loss. Many children with trisomy 21 experience constipation. A history of snoring and restless sleep may be indicative of obstructive sleep apnea, and a sleep study may be necessary. Finally, it is extremely important to document any history of neck pain, gait changes, increased clumsiness, or other neurologic symptoms that would be indicative of spinal cord compression resulting from atlantoaxial dislocation.

Physical Examination

All growth parameters should be plotted on growth charts specific to children with Down syndrome (Figures 42.1 and 42.2). Children with trisomy 21 are shorter than other children and may have poor weight gain in their first year. Later in life, obesity unrelated to the syndrome may become a problem. As with routine well-child visits in other infants and children, a complete physical examination should be performed at each patient encounter. Noteworthy aspects of the examination in infants and children with trisomy 21 are presented in Box 42.3. In particular, the ear canals of these children are easily collapsed, making it difficult to visualize the tympanic membrane. In some cases, referral to an otolaryngologist may be necessary for an adequate otoscopic examination. A complete neurologic examination should be performed at each visit, including an assessment of the severity of hypotonia.

Laboratory Tests

Hearing evaluation should be performed annually, starting with the newborn hearing screening. Developmentally appropriate gross visual screening should be performed at each visit in infants between 6 and 12 months of age, and a formal ophthalmologic examination is recommended starting at 6 months of age. Thyroid screening tests should be repeated at 6 and 12 months and then annually.

Children with congenital heart disease should be given antibiotic endocarditis prophylaxis for dental or other procedures. Additionally, these children should be considered for monoclonal antibody therapy against respiratory syncytial virus in the winter.

Children with Down syndrome are at increased risk for autoimmune disorders, such as celiac disease, Graves disease, and type 1 diabetes. Because the signs of celiac disease may be subtle, some pediatric gastroenterologists recommend measuring tissue transglutaminase immunoglobulin A antibodies as well as an immunoglobulin A level, at 2 to 3 years of age and every 5 years thereafter. Current American Academy of Pediatrics recommendations include screening only symptomatic children, however.

Children with Down syndrome have an increased incidence of atlantoaxial instability when screened with routine lateral cervical radiographs with flexion and extension views. Any patient with signs or symptoms of spinal cord compression should be evaluated on computed tomography or magnetic resonance imaging and referred to an orthopedic surgeon or neurosurgeon. The symptomatic child should be kept out of any sports that involve contact or neck extension, such as swimming, gymnastics, and soccer. Experts agree that careful neurologic screening at health supervision visits is a much better predictor of serious injury than cervical radiographs. The current recommendation is to screen only symptomatic children, unless a preparticipation radiograph is required for events, such as the Special Olympics.

Management

Infants with trisomy 21 should undergo all routine screening tests and immunizations. Growth and developmental progress should be reviewed with the parent or parents at the end of each visit, and any concerns or unmet expectations should be addressed at this time. Often the developmental delay associated with trisomy 21 is not apparent to families until an infant is 4 to 6 months of age and not achieving the expected milestones of rolling over or sitting. It should also be emphasized to families that the severity of intellectual disability in trisomy 21 is quite variable, ranging from mild to severe. Social function is not necessarily related to IQ, however. If the child is not already enrolled in an early intervention program, the physician should emphasize to the parent or parents the positive role of such an experience. The availability of support groups for parents and other family members should also be discussed. The role of support groups may be especially beneficial to the patient with both Down syndrome and autism spectrum disorder.

In the early childhood years, plans for preschool attendance and future educational opportunities should be reviewed with the family. The role of discipline and the presence of common behavioral problems, such as temper tantrums and biting, should be assessed in preparation for school entry and socialization. Nutrition should be reviewed, because children with Down syndrome have a reduced basal energy expenditure and are at increased risk for obesity. Nutritional supplements and other alternative medicines have not been proved to have any efficacy in the treatment of patients with Down syndrome.

As is recommended for all children, a dental referral should be made by 1 year of age.

Older Childhood and Adolescence

History

School-age children with Down syndrome should continue to visit their primary care physician at least annually. Educational issues should be discussed, including the Individualized Education Program and transition from school. Specific medical issues to

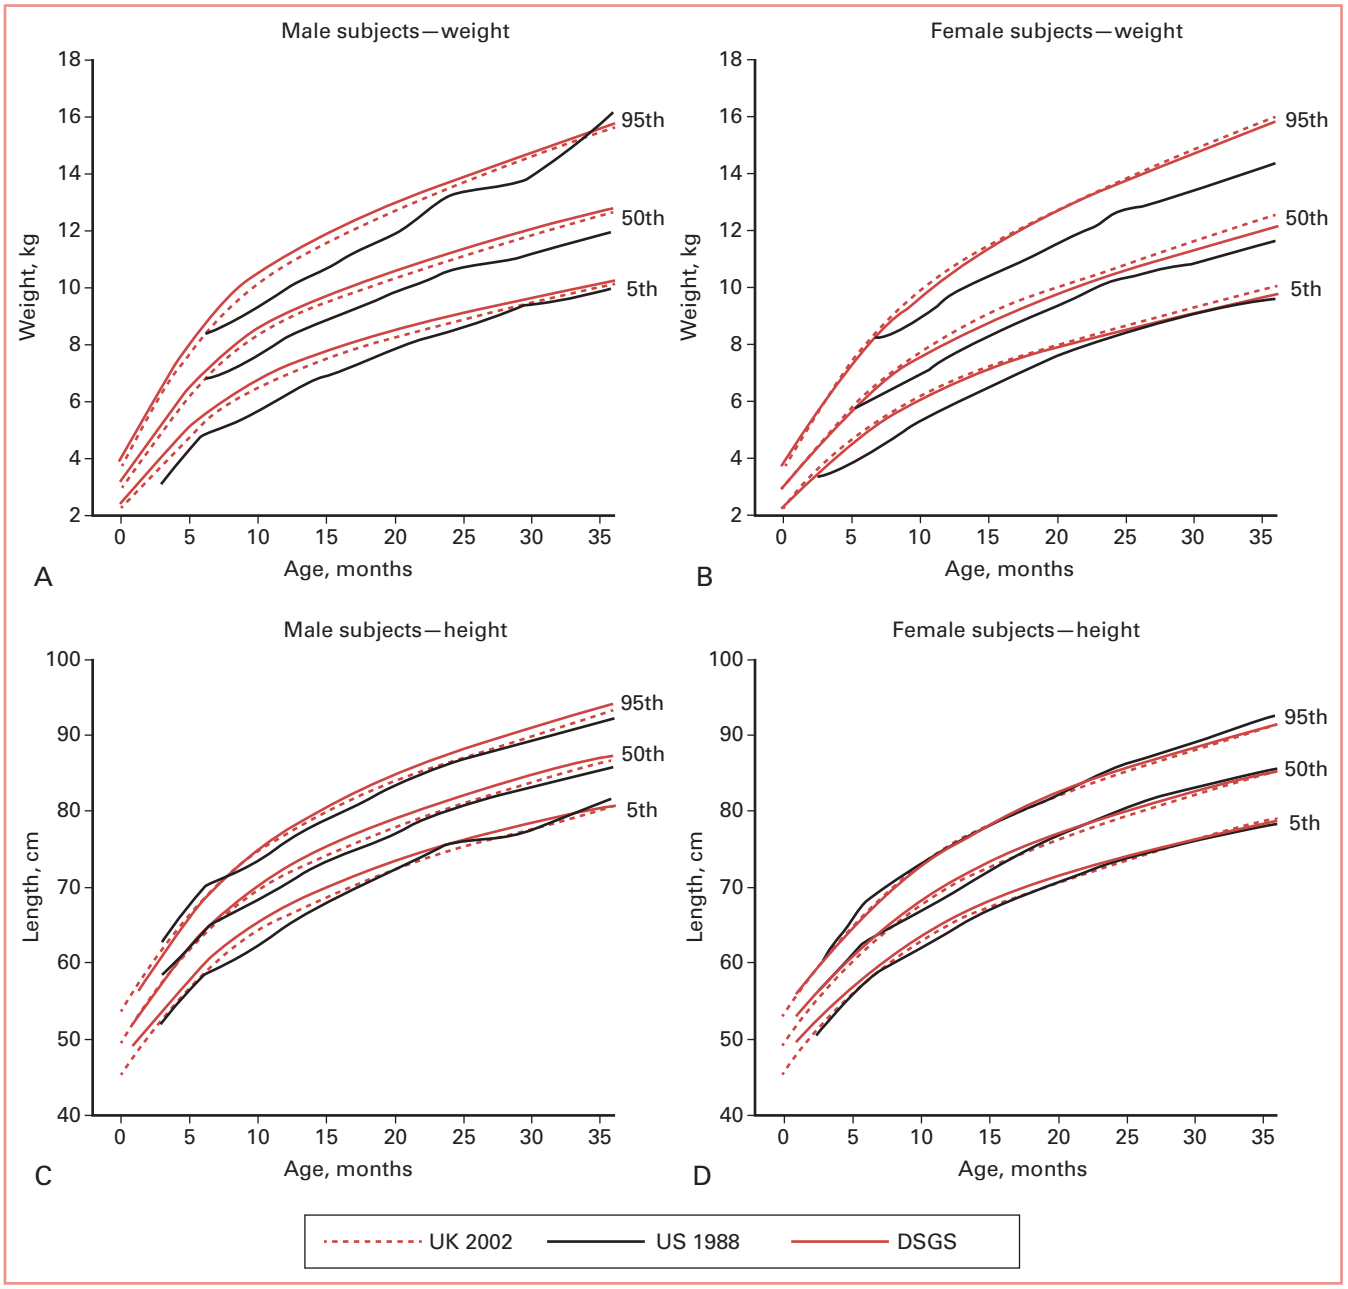

Figure 42.1. Curve comparisons for weight in kilograms and length in centimeters for male and female subjects, birth to 36 months of age. Contemporary curves from the Down Syndrome Growing Up Study (DSGS [solid line]) are compared with those from the US 1988 curves from Cronk et al (dotted line) and the UK 2002 curves from Styles et al (dashed line).

Reprinted with permission from Zemel BS, Pipan M, Stallings VA, et al. Growth charts for children with Down syndrome in the United States. *Pediatrics.* 2015;136(5):e1204–e1211.

address during the history include visual or hearing deficits; evidence of hypothyroidism (ie, decreased activity, coarse and dry hair, constipation); skin problems, including eczema; and dental problems. A careful nutritional history should also be obtained because of the propensity for obesity, and the child should be closely monitored for signs of obstructive sleep apnea.

Physical Examination

The physician should continue to plot height and weight measurements. The skin should be examined closely for xerosis, acne, or syringomas (ie, multiple papules, often present on the eyelids and upper cheeks) during adolescence. A cardiac examination is important because of an increased risk of mitral valve prolapse and valvular dysfunction. The sexual maturity rating (ie, Tanner stage) of all patients should be noted and discussed with the parent or parents. A pelvic examination is not indicated as a part of the routine visit unless concern exists for sexual abuse or a sexually transmitted infection; however, a testicular examination is important because of the increased risk for testicular cancer in patients with Down syndrome. Patients who participate in sports and other physical activities should undergo a complete neurologic examination to assess for signs of impending atlantoaxial dislocation.

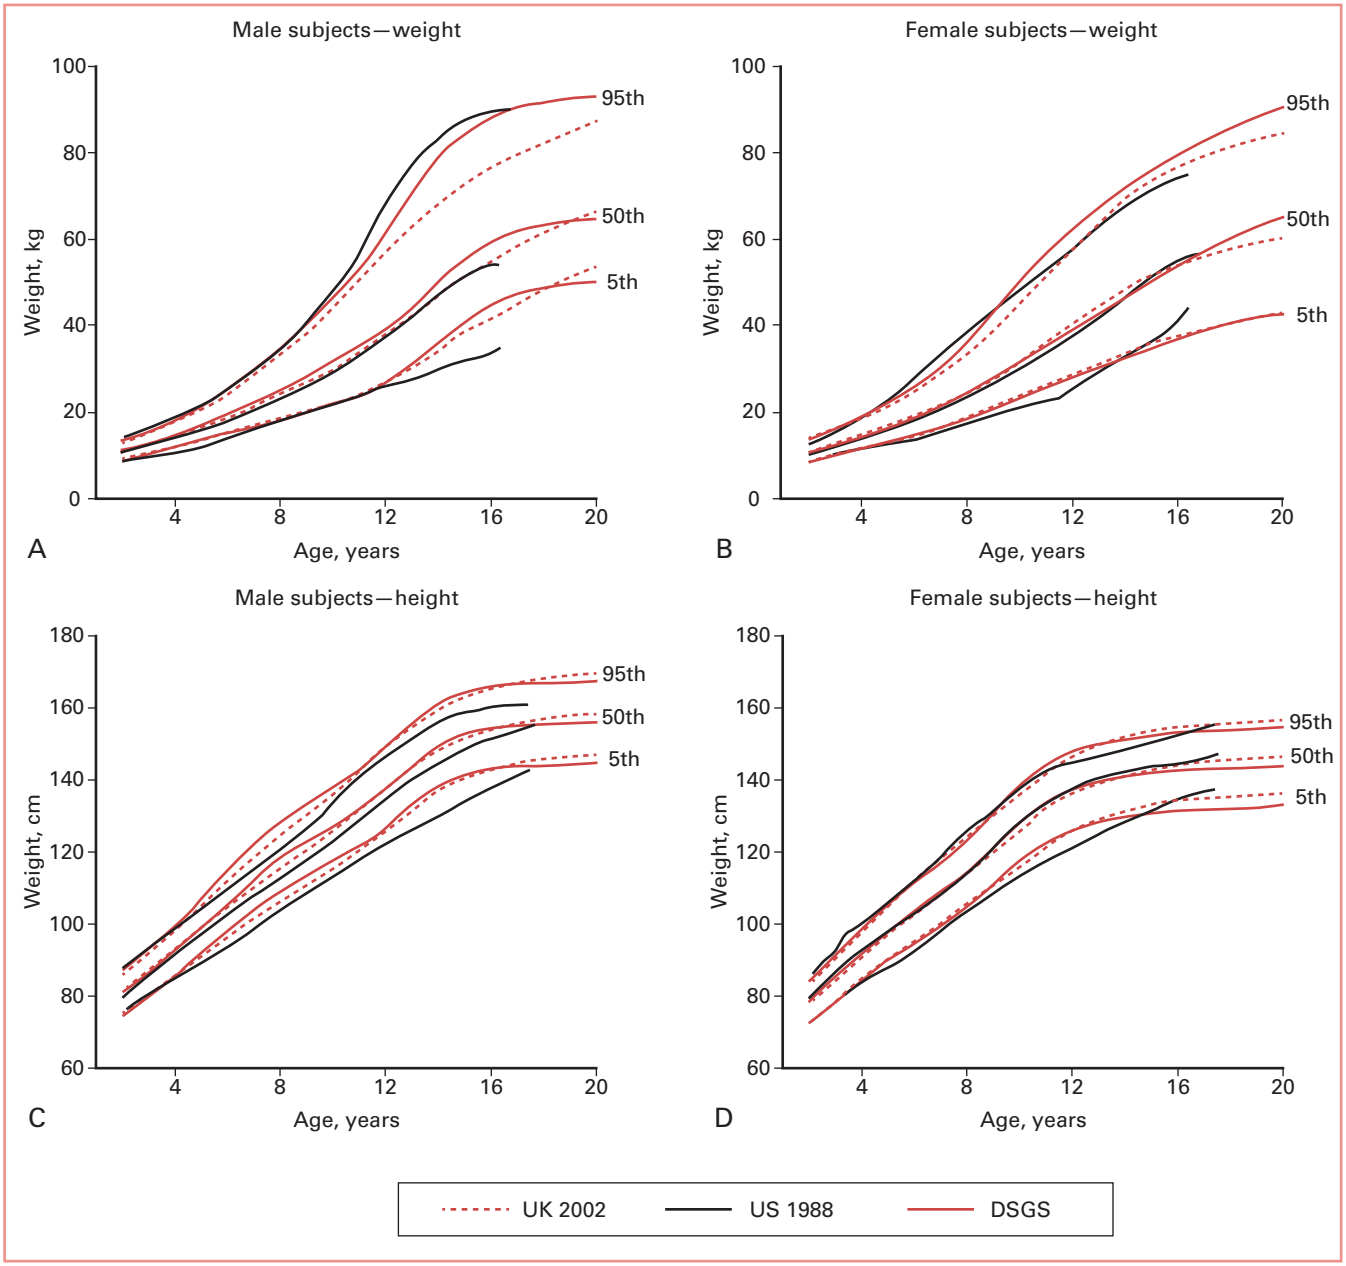

Figure 42.2. Curve comparisons for weight in kilograms and height in centimeters for male and female subjects, 2 to 20 years of age. Contemporary curves from the Down Syndrome Growing Up Study (DSGS [solid line]) are compared with those from the US 1988 curves from Cronk et al (dotted line) and the UK 2002 curves from Styles et al (dashed line).

Reprinted with permission from Zemel BS, Pipan M, Stallings VA, et al. Growth charts for children with Down syndrome in the United States. *Pediatrics.* 2015;136(5): e1204–e1211.

Laboratory Tests

Annual thyroid screening for thyroid-stimulating hormone and thyroxine levels is recommended for all school-age children and adolescents with trisomy 21, in addition to other routine screening tests. Hearing evaluation should also occur at least once in older children and annually thereafter. Because of the risk of keratoconus, an annual ophthalmologic consultation should be conducted after the age of 10 years. Additionally, the child with trisomy 21 should be encouraged to continue biannual dental visits, because gingivitis, periodontal disease, and bruxism (ie, teeth grinding) are common in these individuals.

Management

The major part of the visit with school-age and adolescent children should focus on developmental, educational, and vocational anticipatory guidance. Educational placement and future goals should be developmentally appropriate for the child and acceptable to the parent. Activities requiring socialization and development of

Box 42.3. Physical Examination of the Child With Trisomy 21

- Look for dry, sensitive skin and alopecia, which manifests in approximately 10% of children and resolves spontaneously.
- Monitor the size of the anterior and posterior fontanels, because delayed closure may be indicative of hypothyroidism.
- Check for visual abnormalities, such as strabismus, nystagmus, cataracts, refractive errors, and blepharitis.
- Document recurrent serous otitis media. It is estimated that 40%–60% of children with trisomy 21 have significant conductive hearing loss and 20%–30% have some degree of neurosensory loss.
- Examine the oropharynx carefully for delayed dentition, malocclusion, and caries.
- Auscultate for stridor, wheezing, or other abnormal breathing that may indicate airway anomalies.
- Perform a thorough cardiac examination and note any evidence of previously unrecognized congenital heart disease.
- Palpate the abdomen for distention or organomegaly. Children with trisomy 21 have a slightly increased risk of developing acute non-lymphoblastic or acute lymphoblastic leukemia.
- Perform a rectal examination in infants or children with a history of constipation.
- Evaluate any musculoskeletal abnormalities such as overall hypotonia and joint laxity (most commonly in the knees and hips) that might contribute to overall gross motor delay.

responsibility should continue to be encouraged; however, these events can be very stressful for parents and other family members. Injury prevention should be highlighted as well, especially because older children are becoming more independent. In early adolescence, prevocational and vocational training within the school curriculum should be reviewed. Additionally, brief discussions about independent living, group homes, transition of medical care, and financial resources (eg, community-supported employment for young adults) should begin during adolescence.

For older children and adolescents with trisomy 21, puberty, fertility, and contraception are extremely important issues to address with both the patients and their parents. The patient's psychosocial development and physical sexual maturation should be discussed, including menstrual hygiene and any foreseeable problems with its management. Contraception and the potential for victimization must be addressed as well, particularly with female patients. Males with trisomy 21 usually are sterile, but females have an approximately 50% chance of having children of their own with Down syndrome.

Prognosis

Individuals with trisomy 21 often can live well past the age of 50 years, unless they are born with a congenital heart lesion, which may limit life expectancy. One major cause of morbidity and mortality is the manifestation of symptomatic Alzheimer disease, which occurs in approximately 15% of adults after the fourth decade. Many adults with Down syndrome remain asymptomatic, however, despite histopathologic evidence of the disease.

CASE RESOLUTION

The family should be encouraged by the healthy progress of the patient. For this visit, anticipatory guidance should consist of a review of early intervention services, available resources, and general support services for the patient and her family. The increased risk for upper respiratory infections and otitis media should be reviewed. Medical screening should include thyroid screening, subjective hearing screening, and a formal evaluation by a pediatric ophthalmologist. If the results are normal, the next visit should take place 3 months hence.

CHAPTER 43

Well-Child Care for Preterm Infants

Soina Kaur Dargan, MD, FAAP, and Lynne M. Smith, MD, FAAP

CASE STUDY

A 10-week-old girl was discharged from the neonatal intensive care unit 2 weeks previously, where she had resided since birth. She was the 780 g (27.5 oz) product of a 26-week gestation born via spontaneous vaginal delivery to a 32-year-old primigravida. The perinatal course was complicated by premature rupture of membranes and maternal amnionitis. Several aspects of the neonatal course were significant, including respiratory distress that required surfactant therapy and 2 weeks of endotracheal intubation; a grade 2 intraventricular hemorrhage diagnosed at 1 week after birth; hyperbilirubinemia, which was treated with phototherapy; several episodes of apnea, presumably associated with the preterm birth; and a history of poor oral intake with slow weight gain.

The parents have a few questions about her feeding schedule and discontinuing the apnea monitor, but they feel relatively comfortable caring for their daughter at home. She is feeding well (2 oz of 22 cal/oz postdischarge formula for preterm infants every 2–3 hours) and, according to the family, is becoming progressively more alert. She sleeps on her back in a crib.

The infant's weight gain has averaged 25 g (0.9 oz) per day. The remainder of the physical examination is normal, with the exception of dolichocephaly and esotropia of the left eye.

Questions

1. What constitutes well-child care in preterm infants?
2. What are the nutritional requirements of preterm infants in the months after discharge from the hospital?
3. What information must be considered in the nutritional assessment and developmental screening of preterm infants?
4. What immunization schedule is appropriate for preterm infants? Do they require any special immunizations?
5. What specific conditions or illnesses are more likely to affect preterm infants than term infants?

Preterm birth is defined as birth before 37 completed weeks of gestation. However, the increased frequency of adverse neonatal outcomes in neonates born at 37 and 38 weeks' gestation led the American College of Obstetricians and Gynecologists to redefine *optimal delivery* as 39 weeks' gestation to eliminate nonmedically indicated deliveries prior to this time. Because advances in neonatal care have resulted in improved survival, an increased demand exists for skilled primary care physicians who can care for the preterm infant. Providing primary care for these infants is an important and challenging task and often requires coordination of medical, developmental, and social services for multiple chronic conditions. Because preterm infants are at increased risk for impaired growth and developmental delay, longer well-child visits may be necessary to evaluate their nutritional and developmental progress and assess how families have adjusted to caring for them at home. Primary care physicians must learn to manage these and many other complex issues while providing families with comprehensive anticipatory guidance. Providing a medical home in which care is accessible, comprehensive, continuous, culturally sensitive, and family oriented is essential to the optimal heath and developmental outcome of the patient who was born preterm.

Epidemiology

In the United States, the Centers for Disease Control and Prevention (CDC) reports that preterm birth rates decreased from 2007 to 2014, in part because of a decline in the number of births to teenagers and young mothers. However, since 2016, preterm births are once again on the rise, the cause of which is largely unknown.

The preterm delivery rate is highest for black women and lowest for white women (14% and 9%, respectively). The increase in preterm births has occurred among late preterm newborns (>34 weeks' gestation), who comprise 70% of preterm births. Reasons for the increased preterm delivery rates include increased use of artificial reproductive technologies (see Chapter 26), increased interest in elective cesarean section, and increased maternal age.

Although most preterm newborns are delivered at greater than 34 weeks' gestation, these neonates are at increased risk for morbidity and mortality compared with neonates born at term. Additionally,

many neonatologists routinely resuscitate neonates born at 23 weeks' gestation, a gestation with a survival rate of approximately 25%. Very low-birth-weight (VLBW, <1,500 g [<52.9 oz]) and extremely low-birth-weight (ELBW, <1,000 g [<35.3 oz]) newborns are at risk for cerebral palsy, respiratory disease, hearing and vision problems, and intellectual disabilities. Furthermore, learning disabilities, attention-deficit/hyperactivity disorder, borderline to low IQ scores, psychiatric disorders or abnormalities in executive function, and visuomotor integration occur in more than 50% of VLBW infants, thereby complicating post-discharge care for these children. In 2007, the Institute of Medicine (now the National Academy of Medicine) estimated the annual societal cost of preterm birth at $26 billion and individual family cost of $2 million.

Pathophysiology

In utero, the placenta serves several functions, including promoting and regulating fetal growth, providing nutrients, and preventing infection by acting as a barrier. Delivery before 39 weeks of gestation halts this process, and these immature organs have functional limitations. Causes of preterm delivery can be maternal, the most common of which is pregnancy-induced hypertension, or fetal, the most common of which is premature rupture of membranes resulting from chorioamnionitis. Regardless of cause, these infants have special needs that should be addressed at every primary care visit.

Evaluation

The purpose of the health maintenance visit for preterm infants is the same as for other healthy children: to provide consistent preventive health care and education for patients and their parents. Preterm status, however, places children at risk for additional medical and neurodevelopmental conditions. Compared with children born full term, children born preterm have an average of nearly 3 times the number of well-child visits in the first year after birth and more hospital readmissions.

History

Almost one-third of preterm newborns are not brought in for their first scheduled outpatient appointment. Because failure to attend follow-up appointments has been associated with a higher rate of developmental delay, discussions about the importance of follow-up appointments are ideally initiated with the parent or caregiver before the infant is discharged from the neonatal intensive care unit (NICU).

It is imperative to review the entire medical history and hospital course before the initial visit and then discuss it with the family at the appointment. Ideally, the NICU should provide a discharge summary that includes the information listed in Box 43.1.

Any significant complications or concerns should be discussed with parents or caregivers at the earliest opportunity to assess their understanding of these issues and their expectations for improvement. Specifically, growth, nutrition, and developmental issues should be addressed at each visit (Box 43.2). Adequate or desirable weight gain should be explained to caregivers in terms of the infant's current weight versus discharge weight. Infants younger than 6 months should gain an average of 20 to 40 g (0.7–1.4 oz) per day. To ensure continued weight gain, many preterm infants are discharged from the NICU on a 24-hour feeding schedule, which requires that they be fed at least every 3 hours. The necessity for this practice should be reevaluated during the first few weeks following discharge after infants have demonstrated adequate weight gain.

Box 43.1. Neonatal Intensive Care Unit Discharge Summary Information

1. Birth weight, gestational age, and significant prenatal and perinatal information, including delivery room details
2. Overview of the hospital course by system, including significant illnesses, events, surgical procedures, and pertinent radiographic and other diagnostic studies
3. Nutrition information and present feeding regimen
4. A list of current medications, including dosing intervals and, if appropriate, the latest serum drug levels
5. Immunizations administered during the hospitalization
6. Pertinent laboratory and diagnostic data, such as most recent hemoglobin level, newborn screening results, ophthalmologic and hearing screening information, neurosonography and magnetic resonance imaging results, and highest serum bilirubin level
7. Discharge physical examination, including most recent height, weight, and head circumference
8. Parental or other social concerns throughout patient's stay in the neonatal intensive care unit
9. Problems remaining at discharge
10. All follow-up appointments

Box 43.2. What to Ask

Well-Child Care for Preterm Infants

- How much did the infant weigh when discharged from the hospital?
- Is the infant fed mother's milk, or is the infant formula-fed? Is the infant on any special formula?
- How often and how much does the infant feed? How long do feedings take?
- Does the infant have any feeding problems (eg, pain, vomiting, gastroesophageal reflux)?
- Does the infant take dietary supplementation of vitamins and minerals?
- What developmental milestones has the infant reached? Does the infant roll over? Smile? Sit up?
- Does the infant seem to hear and see?
- Who cares for the infant? Is the primary caregiver getting enough rest?
- Does the infant have regional services and if so, which ones and how often?
- Where and in what position does the child sleep?
- Does the parent or caregiver have any concerns about growth, development, or nutrition?
- Is the infant on an apnea monitor and/or caffeine? Has the infant experienced any apneic episodes?

Developmental history is a critical component of the health maintenance visit. Parental expectations and observations should be noted, and any developmental concerns should be evaluated. The adjusted developmental age should be calculated by subtracting the number of weeks the infant was born preterm from the infant's current chronologic age in weeks. The adjusted age should then be used for all formal and informal developmental assessments. The importance of correcting for preterm status until children are 2 years of age must be emphasized when discussing developmental progress and giving anticipatory guidance to parents or caregivers. It is important to know if the patient is receiving any regional services, which ones, and how often so an accurate recommendation can be made if it is necessary to increase these services.

Physical Examination

A complete physical examination should be performed at each visit to monitor the status of associated medical conditions. All growth parameters (ie, weight, height, and head circumference) should be plotted on the growth chart for preterm newborns until approximately 50 weeks' postmenstrual age and adjusted for preterm status on standard growth charts until age 2 years. Because catch-up head growth generally precedes catch-up weight and length, preterm infants may appear to have disproportionally large heads. The onset of accelerated head growth may begin within a few weeks after birth (36 weeks' postconception) or as late as 8 months adjusted age. Average daily weight gain in grams per day should also be calculated and discussed with the parent or caregiver at every visit.

The size and shape of the head must be evaluated, especially if the infant has a history of intraventricular or intracranial hemorrhage or hydrocephalus. An increase in head circumference of more than 2 cm (0.8 in) per week should be cause for concern in these infants. In infants who have undergone neurosurgical treatment for hydrocephalus, ventriculoperitoneal shunt and tubing may be palpated. The head must also be evaluated for *positional plagiocephaly*, a condition caused by lying in the same position for prolonged periods of time. Visual abnormalities, such as strabismus, must be carefully ruled out by both physical examination and history because up to 20% of preterm infants may have an ophthalmologic problem (see Chapter 91). Oropharyngeal abnormalities, such as a palatal groove, high-arched palate, or abnormal tooth formation, may occur as a result of prolonged endotracheal intubation. Baseline intercostal, substernal, or subcostal retractions; wheezing; stridor; and tachypnea in former preterm babies with moderate to severe bronchopulmonary dysplasia (BPD), a form of chronic lung disease, should be documented. Infants with BPD have increased susceptibility to pulmonary infections leading to rehospitalization and may continue to exhibit poor lung function through adolescence.

Chest and back scars secondary to the placement of chest tubes or patent ductus arteriosus ligation should be noted. Adult female breasts may be affected if scarring occurs on or close to breast tissue. The umbilicus may appear hypoplastic as a result of umbilical catheter placement and suturing. Scars on the distal extremities from intravenous catheters and cutdowns may be evident.

The genitalia of all preterm infants should be examined closely for inguinal hernias. Inguinal hernia repair is often deferred until 60 weeks' corrected gestational age unless incarceration risk is deemed high or the family lives far from a pediatric surgeon. Surgery is deferred because of concerns about adverse neurodevelopmental outcomes in children exposed to general anesthesia in the first months after birth, the high rates of postoperative apnea, and the occasional spontaneous closure in the first year after birth without intervention. If a hernia is surgically repaired under general anesthesia, the infant should be monitored for apnea for up to 24 hours postoperatively. The male scrotum should be examined for cryptorchidism, because at term gestation only 25% of testes are in the scrotum of males born preterm. By 1 year of age, more than 90% of testes are intrascrotal. A careful evaluation for developmental dysplasia of the hip should be performed until children are ambulatory, and hip ultrasonography (US) should be performed at 6 weeks of age for all breech deliveries (see Chapter 113).

A thorough neuromuscular examination is essential in children born preterm. Increased muscular tone, asymmetry, and decreased bulk should be noted along with the presence of any clonus or asymmetry of deep tendon reflexes. Inappropriate reflexes, such as a persistent Moro reflex or fisting beyond 4 months of age, should also be documented. Other abnormalities (eg, scissoring, sustained clonus) in the neurologic examination may become more apparent with age. The detection of subtle early findings is important so appropriate intervention services can begin as soon as possible.

Laboratory Tests

In addition to the standard screening tests performed on all healthy infants and children during health maintenance visits, several laboratory studies are important for preterm infants. Such tests include a hemoglobin test and reticulocyte count to assess for anemia; electrolytes in infants with BPD on diuretics to detect abnormalities; and serum calcium, phosphorus, and alkaline phosphatase levels in infants with documented metabolic bone disease of prematurity.

Pulse oximetry is indicated for oxygen-dependent infants as well as those presenting with respiratory symptoms greater than baseline. Results from newborn screening tests, including auditory and ophthalmologic examinations, should be reviewed and repeated as indicated. Cranial US should be reviewed with caution, because nearly 40% of infants born weighing less than 1,000 g (35.3 oz) with normal head US findings develop cerebral palsy or developmental delay. Additionally, infants with grade 1 or 2 intracranial hemorrhage are at increased risk for developmental delay. Brain magnetic resonance imaging should be considered in infants born at less than 30 weeks' gestation or in any infant with a concerning abnormal neurologic examination or abnormal rate of head growth.

Management

Well-child care in relatively healthy preterm infants has 2 components. One is the provision of routine health care maintenance for infants and appropriate developmental anticipatory guidance for

parents or caregivers. The other component involves the incorporation into each visit of treatment for chronic conditions that are sequelae of preterm birth. Health care maintenance should include the psychosocial well-being of the family, nutrition counseling, developmental surveillance, immunizations, and assessment of vision and hearing in addition to standard screening tests discussed previously. Outside resources concerning developmental delay can be reviewed with parents or caregivers. Care related to chronic conditions includes adjusting medication doses, such as diuretic therapy; weaning from supplemental oxygen; and discontinuing the apnea monitor.

Anticipatory Guidance

Before hospital discharge, parents or guardians should be given anticipatory guidance that caring for a NICU graduate is challenging (Box 43.3). The American Academy of Pediatrics (AAP) recommends parental education as 1 of 6 critical components of discharge planning for any high-risk neonate and includes not only educating parents about the patient's care but also identifying an additional caregiver who can assist with the demands of caring for the child at home. Preterm newborns have poorly organized sleep-wake cycles, resulting in more frequent awaking than term newborns. Additionally, preterm newborns have immature suck-swallow coordination, causing them to feed more frequently and for longer periods. Colic is reported twice as frequently in VLBW infants compared with infants born at term, and many are described as having difficult temperament until past their first birthday. Preterm infants also develop gastroesophageal reflux more often than full-term infants, which presents with such symptoms as irritability, respiratory problems, and postprandial vomiting.

The medical costs associated with the care of preterm infants often strain the family finances at a time when many women reduce their work schedules. Additional stressors include uncertainty about the long-term outcome of the child, guilt many women feel after delivering prematurely, and anxiety about future pregnancies. The difficulty of caring for these complicated, challenging children results in significant parental stress and can interfere with parents' ability to properly bond with their babies. Health professionals should be alert to signs of a parent feeling overwhelmed, because a higher caregiving burden is associated with an increased incidence of child welfare reports, such as child neglect.

Box 43.3. Physician Support and Education of Parents of or Caregivers for Preterm Infants

- Understand parental/caregiver expectations.
- Legitimize parental/caregiver fears.
- Be a source of support and encouragement.
- Provide consistent, honest information.
- Assume the role of the overall coordinator of care.
- Provide referrals to outside resources, including respite care.

Nutrition

According to the AAP Committee on Nutrition, the average daily energy requirement for most hospitalized healthy preterm newborns and infants is 105 to 130 kcal/kg/day to achieve adequate growth. Energy requirements vary by individual infant depending on associated chronic conditions, such as BPD or malabsorption. Key nutrients, such as calcium, vitamin D, and phosphorus, are critical to the management of bone health in preterm infants. Growth is considered adequate in the newborn weighing more than 2,000 g (>70.5 oz) if weight gain is more than 20 g (>0.7 oz) per day and length and head circumference increase 0.7 to 1.0 cm (0.3–0.4 in) per week. Feeding difficulties are common in preterm infants and result in hospital readmission secondary to failure to thrive.

At 40 weeks' corrected age, preterm newborns usually are smaller than term newborns. Adequate nutrition in the first year after birth is critical, because catch-up weight gain is unlikely to occur after age 3 years. Because human milk is insufficient for providing adequate protein and micronutrients to preterm newborns, fortifier is added to human milk.

If they are not receiving human milk, children born at 34 weeks or sooner or weighing less than 1,500 g (<52.9 oz) usually are discharged home on a nutritionally enhanced transitional formula (eg, Similac Expert Care NeoSure, Enfamil EnfaCare). The calcium, phosphorous, and caloric content of these 22 cal/oz transitional formulas are between levels found in standard preterm and term formulas. Use of preterm enriched formulas usually is continued until the child reaches the 5th to 10th percentile on the growth chart or is 1 year of adjusted age. A meta-analysis showed limited evidence to demonstrate that nutrient-enriched formulas improve growth rates after discharge relative to standard term formula.

Formula-fed infants require multivitamin supplementation until 750 mL/day of formula is consumed. Preterm infants fed mother's milk may benefit from continuing multivitamin solution and supplementation of oral iron drops as long as human milk is the predominant source of nutrition. Vitamin D supplementation is recommended for all infants fed mother's milk. Because preterm newborns are at increased risk for metabolic bone disease of prematurity, soy formulas are to be avoided because of the low phosphate content.

The introduction of solid foods is appropriate after an infant has developed acceptable oral-motor skills for swallowing solids. Recent studies have suggested that 20% of parents of preterm infants report feeding problems at age 2 years. Cow's milk should not be introduced until 12 months' adjusted age.

Developmental Surveillance

Informal and formal developmental surveillance should include referral to an early intervention program, particularly for ELBW infants, because routine screening tests are not sensitive enough to detect subtle neurodevelopmental abnormalities (Box 43.4; see Chapter 32). The Individuals with Disabilities Education Act Part C guarantees early intervention programs for infants and

Box 43.4. Typical Speech, Play, and Physical Development

In addition to standardized tests, the following guidelines provide development milestones useful for early detection:

By 3 Months' Adjusted Age, the Infant

- Coos or vocalizes other than crying
- Visually tracks a moving toy from side to side
- Attempts to reach for a rattle held above chest
- Pushes up on arms
- Lifts and holds head up

At 6 Months' Adjusted Age, the Infant

- Begins to use consonant sounds in babbling and uses to get attention
- Reaches for a nearby toy while on tummy
- Transfers a toy from 1 hand to the other while lying on back
- Reaches both hands to play with feet while lying on back
- Uses hands to support self in sitting
- While standing with support, accepts entire weight with legs

At 9 Months' Adjusted Age, the Infant

- Increases variety of sounds and syllable combinations in babbling
- Looks at familiar objects and people when named
- Explores and examines an object using both hands
- Turns several pages of a chunky book at once
- Imitates others in simple play
- Sits and reaches for toys without falling

At 12 Months' Adjusted Age, the Child

- Meaningfully uses "mama" or "dada"
- Responds to simple commands (eg, "come here")
- Produces long strings of gibberish in social communication
- Finger feeds self
- Uses thumb and pointer finger to pick up tiny objects
- Pulls to stand and cruise along furniture
- Stands alone and takes several independent steps

At 15 Months' Adjusted Age, the Child

- Has a vocabulary consisting of 5–10 words
- Helps with getting undressed
- Walks independently and seldom falls
- Squats to pick up toy

At 24 Months' Adjusted Age, the Child

- Uses 2- to 4-word sentences
- Walks up and down stairs holding on for support
- Builds a tower of 4 blocks or more
- Identifies basic body parts

Derived from Pathways Awareness Foundation. *Assure the Best for your Baby's Physical Development.* https://pathways.org/topics-of-development/milestones/ as well as Centers for Disease Control and Prevention. Developmental milestones. CDC.gov website. http://www.cdc.gov/ncbddd/actearly/milestones/index.html. Accessed July 16, 2019.

toddlers with disabilities up to age 3 years. Children born weighing less than 1,200 g (<42.3 oz) are automatically eligible, but any child with suspected developmental delay is entitled to an evaluation to determine eligibility for services regardless of a family's ability to pay. Because many developmental issues do not manifest until school age, frequent developmental assessments and enrollment in preschool are especially important for infants born preterm.

The AAP recommends that autism spectrum disorder (ASD)–specific screenings be completed for all childrenat 18 to 24 months of age. The prevalence of ASD has been reported to be 8% in children born at less than 26 weeks, which is much higher than that for the general population. Preterm newborns have higher scores on the Modified Checklist for Autism in Toddlers, with greater social-communication difficulties and autistic-like behaviors. These increased scores may be reflective of the increased incidence of neurodevelopmental delays in individuals born preterm, making screening for ASD more challenging.

Immunizations

Routine immunization schedules recommended by the CDC Advisory Committee on Immunization Practices should be followed. The administration of any vaccine is determined by the patient's chronologic or postnatal age, not gestational age. Standard doses and intervals should also be used (see Chapter 37). Several studies have shown an adequate serologic response despite a history of prematurity. Absolute and relative contraindications to specific vaccine components or to live vaccines for preterm infants are identical to published guidelines for term infants and children. In addition to following the recommendation that all infants 6 months and older be vaccinated against influenza, the pediatrician should strongly urge that all household contacts of preterm newborns be vaccinated. Two doses of influenza vaccine are administered 1 month apart, with subsequent immunization the following year requiring only 1 dose. Because the rotavirus vaccination utilizes a live virus, it is recommended only for clinically stable preterm newborns if they are 6 to 14 weeks' chronologic age at the time of hospital discharge or have already been discharged from the NICU.

If adequate weight gain has been established, it is safe to administer hepatitis B vaccine to medically stable infants weighing less than 2,000 g (<70.5 oz) as early as 30 days of age or at hospital discharge, whichever comes first. All neonates born to mothers who are positive for hepatitis B surface antigen should receive hepatitis B vaccine and hepatitis B immunoglobulin (HBIG) within 12 hours of delivery. When maternal hepatitis B status is unknown, the neonate should be vaccinated for hepatitis B within 12 hours of birth. In this situation, if status remains unknown, the neonate weighing less than 2,000 g (<70.5 oz) should receive HBIG within 12 hours after birth and those weighing 2,000 g (70.5 oz) or more should receive HBIG within 7 days after birth.

The CDC recommends that all pregnant women receive the tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine to help protect their newborns against pertussis. Maternal vaccination results in higher concentrations of pertussis antibodies in newborns compared with unvaccinated mothers, possibly resulting in increased protection against pertussis during the critical period

between birth and the first diphtheria and tetanus toxoids and acellular pertussis vaccine dose.

Because respiratory syncytial virus (RSV) causes increased morbidity and mortality in NICU graduates and infants with congenital heart disease, administration of the RSV-specific immunoglobulin palivizumab (eg, Synagis) is recommended every month from November through March (Table 43.1). A documented infection with RSV is not an indication to discontinue passive immunization, because multiple strains may circulate during the RSV season.

Assessment of Vision and Hearing

Follow-up visits for visual and auditory sequelae of prematurity must be arranged at the health maintenance visit. An initial ophthalmologic screening examination should have been performed between 4 and 9 weeks of age in infants weighing less than 1,500 g (<52.9 oz) or born less than 30 weeks' gestation, irrespective of oxygen exposure. Infants between 1,500 and 2,000 g (52.9–70.5 oz) or greater than 30 weeks' gestation with an unstable clinical course should also be screened. The frequency and need for repeat examinations are determined based on initial findings. Regardless of the presence of retinopathy of prematurity, preterm infants are at increased risk for strabismus, myopia, amblyopia, and glaucoma and must undergo an ophthalmologic examination between 4 and 6 months of age. Because birth before 28 weeks' gestation is associated with an increased risk of retinal detachment later in childhood and early adult life, long-term follow-up to detect and manage late-onset retinal detachment should be considered.

Table 43.1. Indications for the Use of Palivizumab for Respiratory Syncytial Virus Prophylaxis

Indication	*Age at Onset of RSV Season*
Preterm infant with chronic lung disease requiring medical management with oxygen, a bronchodilator, diuretics, and corticosteroids	<24 months
Hemodynamically significant congenital heart disease with cyanosis and moderate to severe pulmonary hypertension	<24 months
Significant congenital abnormalities of the airway or neuromuscular disease that compromises handling of respiratory secretions	<12 months
Born ≤28 weeks of gestation	<12 months
Born 29–31 weeks 6 days of gestation	<6 months
Born 32–34 weeks 6 days of gestation with at least 1 of 2 risk factors, whether attending child care or with a sibling younger than 5 years of age in the home	<3 months

Abbreviation: RSV, respiratory syncytial virus.

The AAP recommends universal hearing screening for all newborns. Neonatal intensive care unit graduates account for approximately 50% of all newborn hearing screening failures, and severe sensorineural hearing loss occurs in up to 10% of ELBW infants. Screening is recommended immediately before discharge, and repeat testing is recommended if the child develops speech delays.

Other Potential Problems

Preterm infants exposed to mechanical ventilation and prolonged exposure to oxygen are at risk for BPD. These infants are at increased risk for respiratory illness, especially during the winter. Parents or caregivers should be informed of this risk and counseled about symptoms such as tachypnea and wheezing associated with a simple upper respiratory infection. Physicians should have a low threshold for considering a diagnosis of pneumonia in these infants even in the absence of classical symptoms.

The primary care physician should also keep in mind that preterm infants are at increased risk for sudden unexpected infant death (SUID; see Chapter 72). The AAP recommends that all infants sleep in the supine position. In the NICU, neonates often are placed on their stomach if they have respiratory difficulties and on their side if they have symptomatic gastroesophageal reflux. Neonatal intensive care unit personnel need to begin placing these babies on their backs in anticipation of discharge. The physician should counsel the parent or caregiver about safe sleep practices, that is, placed on the back in a crib without blankets, pillows, or other objects. Parents and caregivers should also be reminded that bedsharing is not recommended and is highly associated with SUID from accidental asphyxia.

Home apnea monitors are not associated with the prevention of SUID and should be reserved for infants who are considered to have extreme cardiorespiratory instability or are being discharged on oral caffeine. Discontinuation of caffeine and home monitoring may be considered at 42 weeks' postmenstrual age and when significant apneic events have ceased, whichever comes later.

Preterm survivors who were critically ill can be particularly at risk for developing vulnerable child syndrome because their parents may continue to perceive them to be fragile and vulnerable. Features of this syndrome include abnormal separation difficulties for mother and child, sleep difficulties, parental overprotectiveness and overindulgence, lack of appropriate discipline, tolerance of physical abusiveness by the child toward the parent, and excessive preoccupation with the child's health. Serious behavioral problems may arise as a result of such parent-child interactions, and recent studies suggest a correlation between higher parental perception of child vulnerability and worse developmental outcomes. Primary care physicians must be cognizant of early signs of this syndrome and should try to prevent its occurrence by reassuring parents or caregivers about the child's well-being. After vulnerable child syndrome is suspected, connecting the child's history of critical illness with ongoing parental concerns is important because many parents are unaware that current concerns may stem from their unresolved anxiety. Every effort should be made to normalize the family's schedule after the

infant is stable and to encourage parent-child interactions unrelated to health care.

Prognosis

Neurodevelopmental impairment is a concern for physicians who care for preterm infants. Risk factors for developmental delay include postnatal steroid exposure, necrotizing enterocolitis, BPD, small for gestational age status, and maternal pregnancy-induced hypertension. Chorioamnionitis is a risk factor for cerebral palsy in term infants and possibly in infants born preterm. Extremely low birth weight infants and those born between 20 and 25 weeks' gestation are at significant risk for developmental issues. Surviving infants born at less than 26 weeks' gestation in the United Kingdom in 1995 had median Bayley mental and psychomotor scores of 80 at 30 months of age, with comparable cognitive score deficits at age 6 years and a higher prevalence of learning difficulties, including lower reading and mathematics scores at 11 years.

During adolescence, 50% of former VLBW infants have an IQ in an abnormally low range, and 30% have attention-deficit/hyperactivity disorder. Although individuals born preterm experience higher rates of chronic medical and neurodevelopmental problems, their self-perception of health and well-being in adolescence has been found to be the same as those of their normal birth weight peers. Additionally, increased systolic blood pressure, insulin resistance, and impaired glucose tolerance have also been reported in VLBW adults. Parents should also understand that long-term follow-up information may not accurately reflect the outcome for their child because these adolescents were treated before subsequent advances in prenatal and neonatal care.

CASE RESOLUTION

The current feeding schedule for the infant should be continued because appropriate weight gain has occurred. Iron and multivitamin supplementation is recommended until the infant is consuming 750 mL/day of formula. Discontinuation of the apnea monitor can be considered after the infant reaches term gestation (40 weeks) and has been event-free. The first set of immunizations should be administered at this visit, and any questions the family has should be answered. A follow-up visit should be scheduled for 3 to 4 weeks hence. Formal developmental testing should be arranged to take place in 1 to 2 months, and the parents should be encouraged to continue placing the infant on her back alone in her crib to sleep.

CHAPTER 44

Care of Children With Special Health Care Needs

Clare Kasper, MD

CASE STUDY

A 5-year-old girl with a physical disability is brought to your office for her first visit for a routine physical examination for school entrance. She was the result of a full-term pregnancy complicated by an elevated screening α-fetoprotein and subsequent fetal ultrasonography that demonstrated a lumbar myelomeningocele and no hydrocephalus. Delivery was by elective cesarean section, with an Apgar score of 9 at both 1 minute and 5 minutes, to a 25-year-old gravida 1, para 0–1 mother. The mother used no illicit drugs, alcohol, or any other medications during pregnancy but was not on vitamins or folate supplementation at the time of conception. At delivery, a low lumbar spinal malformation was noted, with no other malformations. The quadriceps muscles were strong, but the feet demonstrated a rocker-bottom deformity.

Shortly after birth, the myelomeningocele malformation was closed by neurosurgery. Later, the girl underwent orthopedic surgical release of Achilles tendon contracture and currently is ambulatory with the use of ankle-foot orthoses. She has a neurogenic bladder and requires intermittent catheterization. She also has chronic constipation that is managed with a bowel regimen. Her cognitive function is age-appropriate.

She will be entering a school program for the first time since moving to this community and has not established care with any specialists.

Questions

1. Why is early identification and intervention important for newborns, infants, and children with special health care needs?
2. What role do primary care physicians play in the care of children with special health care needs?
3. What are the appropriate referrals and resources for families of children with special health care needs?
4. What specific psychosocial issues should be addressed whenever children with special health care needs visit their primary care physician?

Children and youth with special health care needs (SHCN) have physical, developmental, emotional, or behavioral conditions that require special health-related services. These conditions must last longer than 1 year and result in 1 of 5 consequences: the need for prescription medications; the need for increased medical care; compromised mental health or limited educational ability; the need for special therapy; or the need for counseling. Children with SHCN are defined by the International Classification of Functioning, Disability and Health as *disabled* if they are limited from doing what children of the same age can do. Most information on children with SHCN combines the group with and the group without disabilities. Conditions experienced by children with SHCN can range from mild to severe, depending on the nature and extent of them and their effect on daily living. Frequently, care requirements of families and health professionals for children with a diagnosis of SHCN are dramatically increased. For parents, the diagnosis of a condition in their child can be initially overwhelming and disappointing. Support of the parents is essential as they transition from disappointment to acceptance and assume the role of facilitator of their child's treatment plans.

Early identification of a health condition by a physician can result in appropriate, definitive treatment of many diagnoses. In some instances, early intervention may even prevent secondary conditions (eg, early management of hearing loss with hearing aids may minimize speech abnormalities). Even when such corrective treatment is not available, prompt identification improves children's long-term outcome and allows families to obtain appropriate resources for their children. Through early intervention, newborns, infants, and children with irreversible conditions can be introduced to medical, educational, and psychosocial services available in the community that serve to help these children maximize and reach their full potential.

Epidemiology

According to a national survey, an estimated 11.2 million children in the United States have SHCN, affecting 23% of households with children across all racial, ethnic, and socioeconomic groups. Approximately 65% of children with SHCN reportedly have more than 1 medical condition, including attention-deficit/hyperactivity

disorder, asthma, autism spectrum disorder (ASD), cerebral palsy, developmental delay, diabetes, and epilepsy. A single sensory disability, such as deafness, affects approximately 3.5% of children; blindness occurs in 1% of children. The prevalence of cerebral palsy is 1.5 to 2 per 1,000 live births. Advances in medical technology, as well as improved survival of low-birth-weight newborns and children with malformations, have increased the number of children living with such disabilities. Environmental exposures have increased the incidence of chronic medical conditions, such as asthma.

The presence of SHCN has a profound effect on the health and education of affected children. Studies show that children with SHCN have 1.5 times more doctor visits and spend 3.5 more days in the hospital than children without these conditions. Children with SHCN miss twice the number of school days and are twice as likely to repeat a grade compared with children without medical conditions.

In addition, numerous associated conditions occur more commonly in children with SHCN. These include intellectual developmental disorders, growth failure, and nutritional problems. Problems with dentition, respiratory infections, and bowel and bladder continence also may occur. Significant emotional disturbances may occur as children adapt to their condition.

Clinical Presentation

Children with SHCN can present in a variety of ways depending on their diagnosis. Many physical disabilities may be readily apparent at birth on the newborn examination or newborn screening. Some diagnoses, such as cerebral palsy, may be detected later, as the motor impairment becomes more evident. Following the child's development at routine health maintenance visits is essential for early detection of developmental delay. Implementing the Bright Futures program from the American Academy of Pediatrics (AAP) can help in early detection of many conditions. Children with SHCN also may present with chronic illness (eg, asthma, diabetes) or with specific complaints (eg, poor vision or hearing). Alternatively, they may present with a more general concern, such as growth failure (Box 44.1). Behavioral problems or difficulties in school may precipitate the initial visit.

Box 44.1. Diagnosis of Children With Physical and Sensory Disabilities[a]

- Growth failure
- Microcephaly
- Abnormal neurologic examination, including hypertonicity, spastic diplegia or quadriplegia, and brisk deep tendon reflexes
- Developmental delay
- Speech or hearing deficit
- Visual deficit
- Physical malformations

[a] May not be present in all children.

Pathophysiology

Pathophysiology of a medical condition is completely dependent on the specific diagnosis. Conditions may be secondary to an embryologic defect such as myelomeningocele, or to an infection such as congenital cytomegalovirus (CMV), which interferes with cochlear development and results in hearing loss. Etiologies are often multifactorial. For some conditions, such as ASD, the pathophysiology is unknown and may have several different etiologies.

Special health care needs may be classified as acquired or congenital and static or progressive. *Cerebral palsy*, for example, is a group of nonprogressive neuromotor disorders resulting from a central nervous system insult prenatally or within the first 2 years after birth. It is characterized by abnormal motor movements and posturing and may be accompanied by other problems as well. Causes of cerebral palsy include preterm birth, low birth weight, asphyxia, prenatal abnormalities (eg, placental insufficiency), congenital infections (eg, toxoplasmosis, CMV), and biochemical abnormalities (eg, severe hyperbilirubinemia). Other causes are environmental (eg, in utero exposure to alcohol) and genetic (eg, inborn errors of metabolism). Severe postnatal injuries or infections also may result in cerebral palsy (eg, abusive head trauma, meningitis). However, an estimated 25% to 50% of cases of cerebral palsy have no discernible cause.

Diagnosis

The term *SHCN* is used in a broad sense to include conditions that require additional medical care and supervision, as defined by the US Department of Health and Human Services Maternal and Child Health Bureau. As previously noted, children with SHCN may have significant physical, sensory, or developmental disabilities that may result from preterm birth, congenital infections (eg, CMV), or exposure in utero to alcohol or illicit substances. Some children are born with congenital malformations or inborn errors of metabolism that mandate special diets and occupational or physical therapy. Other children with SHCN include those with chronic medical conditions, such as asthma, obesity, and sickle cell anemia. All these medical conditions alter lifestyle, require increased medical care (including subspecialty care), increased medication usage, and increased use of community services compared with the general pediatric population.

Evaluation

History

When initially evaluating children with newly diagnosed SHCN, health professionals should first determine any specific parental concerns. A complete medical history should be obtained, including information about the pregnancy and birth. The history also should include any possible exposures as well as significant infections. General screening questions about development are important to ask to assess the child's developmental progress (Box 44.2). Specific questioning is warranted if parents are concerned about delayed development or if any of their responses

Box 44.2. What to Ask

Children With Special Health Care Needs

- Were there any perinatal complications, such as premature rupture of membranes or fetal distress?
- Was the child born prematurely? If so, how long did the child remain in the hospital and for what reasons?
- Was the child exposed to any toxins (eg, alcohol, illicit drugs) in utero?
- Is there any history of infection during the perinatal period or infancy?
- What developmental milestones has the child mastered?
- Is the child attending school or some type of early intervention program?
- How does the child get there?
- What does the child do on returning from school?
- Who feeds and bathes the child?
- Can the older child use the toilet without assistance?
- How is the child sleeping? Does the child take naps at school and home?
- Has respite care been arranged for the family?
- Does the caregiver seem overwhelmed or excessively tired, especially one who is caring for a child with multiple disabilities?
- Do other family members help care for the child?
- Is extended family available to help with siblings?
- Are there any other people with disabilities in the family?
- Does the family receive any financial assistance for care of the child?

indicate that their child is not attaining age-appropriate developmental milestones.

In cases of children with known sensory or physical disabilities, families should be asked directly at each visit about daily activities and the child's ability for self-help skills. Because many children with disabilities are also on daily medication for seizures or other chronic conditions, it is important to ask about the presence of any drug side effects.

Any behavioral or emotional problems in the child should be identified. Additionally, an overall assessment of family dynamics should be made. It is important to inquire about the relationships between children with SHCN and their siblings, as well as the effect these children have on the parents' marriage or relationship.

Physical Examination

In general, a complete physical examination, including an oral health assessment and a detailed neurologic assessment and neuromotor examination, should be performed at each visit. Height, weight, and head circumference should be plotted on the growth chart and compared with previous measurements. Failure of adequate growth as measured by any of these parameters should be examined closely. For example, microcephaly, nutritional problems, and growth failure are not uncommon in children with cerebral palsy. Depending on the specific diagnosis, the examination should focus on physical findings associated with the particular condition. For children with physical disabilities such as congenital or acquired amputations, for instance, assessment of the skin that comes in contact with prosthetic devices is a pertinent aspect of the physical examination. Pressure sores may be found in nonambulatory children with cerebral palsy. In children with sensory disabilities, such as unilateral hearing loss, the evaluation of middle ear effusion or infection in the unaffected ear should be prioritized. If a child has a tracheostomy or gastrostomy tube, inspection of the site is essential at each visit to look for erosions or skin infections.

Overall, for most children with SHCN, the neurologic examination is extremely important (Box 44.3). An age-appropriate developmental assessment is also an essential part of the examination at all health maintenance visits.

Laboratory Tests

Laboratory evaluation of newborns, infants, and children with physical or sensory disabilities depends on their specific conditions. Not all patients need a costly array of diagnostic procedures. A chromosomal karyotype or comparative genomic hybridization using peripheral blood is helpful in children with suspected genetic disorders (eg, abnormal facies, a major anomaly, developmental delay). Routine testing for fragile X syndrome should be strongly considered in all boys with intellectual and developmental disabilities and in girls with a family history of it. Other testing should be specific for the suspected diagnosis (see Chapter 84).

Metabolic screening for inborn errors of metabolism should be performed on children with intellectual and developmental disabilities and any of the following symptoms: intermittent vomiting or lethargy, loss of developmental milestones, or seizures. Such screening is not needed in the routine evaluation of children with developmental delay and no other symptoms.

A screening test for visual acuity (Snellen eye chart) and hearing (ie, audiogram) should be performed in all children with suspected sensory deficits, even mild ones. For infants and toddlers, a brain stem auditory evoked response or behavioral audiogram is a more appropriate screening test for hearing (see Chapter 88). A visual evoked response can be performed to test vision.

Psychometric testing may be helpful in certain school-age children to assess intellectual function. Electroencephalography is indicated in all patients with a history of seizures or seizure-like episodes.

Imaging Studies

Brain imaging studies, such as magnetic resonance imaging of the head, can be informative in the setting of suspected intrauterine infection, intraventricular hemorrhage, or genetic disorders with

Box 44.3. What to Ask

Neurologic Examination of the Child With Special Health Care Needs

- Are normal primitive reflexes (eg, Moro, rooting) present in neonates?
- Do newborns and infants appear to visualize and track objects appropriately?
- Are there any abnormal movements of the trunk or extremities at rest?
- Is muscle tone normal?
- Is any hypertonicity or hypotonicity evident?
- Is any asymmetry of the upper and lower extremities apparent?
- Are deep tendon reflexes normal and symmetrical?
- Have all primitive reflexes been extinguished in older children?
- Is the gait appropriate for age?

associated developmental delay and even isolated global developmental delay. Electromyography can be used to differentiate cerebral palsy from a congenital myopathy.

Management

Caring for children with SHCN can be rewarding yet challenging for primary care pediatricians. The pediatrician should be cognizant that these patients will take increased practice time and paperwork to ensure that they receive all services necessary. Case management services are an essential aid to their management. The primary care pediatrician must supervise acute and chronic medical care, provide anticipatory guidance, monitor growth and development, coordinate subspecialty involvement, make educational referrals, and offer community services. Sometimes a subspecialty physician will provide comprehensive care if the diagnosis (eg, cystic fibrosis) encompasses most of the child's health care needs. Although care should be individualized to each patient, general guidelines have been developed for the provision of pediatric services to newborns, infants, and children with SHCN. The guidelines include recommendations for establishing a medical home with the primary care pediatrician, medical services, suggestions for parental involvement, assistance from community agencies, and fulfillment of specific federal requirements for educational opportunities for children with disabilities. Pediatricians who care for children with SHCN should be familiar with the principles of care published by the AAP and should incorporate these principles into the overall treatment plan. Pediatricians also should be knowledgeable about the rights of such individuals as established by various legislation, including the Americans with Disabilities Act and the Individuals with Disabilities Education Act Part C. Coordination of intervention services and the use of adaptive or assistive technology are essential components of management.

General Considerations

The major role of primary care pediatricians who care for children with SHCN is 4-fold: provide primary medical care; serve as the patient and family advocate in evaluating therapeutic options; inform families of available community resources; and most important, serve as a proactive coordinator of care. The first task of the pediatrician is to establish the diagnosis and recognize any comorbidities. Whether the diagnosis is an obvious physical malformation or one that is not readily apparent, physicians are placed in the challenging position of breaking the news to families. Parents should be informed of the diagnosis as soon as possible, but care should be taken to refrain from discussing the prognosis, especially if it is still unknown. The cause of any disability and the possible complications of the condition should be reviewed with parents. *The primary goal is to help children with disabilities reach their full potential.*

Health professionals are in a unique position to establish a treatment plan with families that includes medical, psychosocial, and educational services. A multidisciplinary team should be assembled that includes the pediatrician, a member of the school system, a social worker, and a representative of an early intervention program. Federally funded, nonprofit, regional centers can provide an organized treatment plan and entry into an early intervention program to some children with disabilities. To qualify, children must be diagnosed with an eligible condition, such as cerebral palsy, epilepsy, ASD, or global developmental delay. In addition, newborns and infants considered to be at risk for developing disabilities qualify for assistance (eg, preterm newborns with bronchopulmonary dysplasia and intraventricular hemorrhage). For children who do not qualify, similar services can be coordinated on an individual basis by the physician's office or the school district.

Children with severe physical and sensory disabilities often are cared for by many medical subspecialists in addition to the primary care pediatrician. Referrals to pediatric orthopedic surgeons, plastic surgeons, geneticists, ophthalmologists, otolaryngologists, child neurologists, and psychologists may be necessary. Special comprehensive clinics, such as those for craniofacial or spina bifida, are established in some children's referral centers to facilitate care of patients, with multiple subspecialists forming a multidisciplinary team in the same clinical setting. In addition, speech and language, occupational, and physical therapists are often an integral part of the medical team. Initial and ongoing therapeutic services provided by each of these individuals must be monitored periodically to assess the progress and overall effectiveness of the treatment plan. Ideally, services should be coordinated so that children and parents miss a minimum number of school days and workdays (eg, Saturday and after-school appointments, visits to several practitioners on the same day). All information from diagnostic studies and initial evaluations should be shared among each of the health professionals. The AAP has produced a *Building Your Medical Home* toolkit (https://medicalhomes.aap.org), which can be very helpful to the primary care pediatrician.

The primary care physician also should offer counseling to parents on ethical issues pertaining to their child's condition. These issues include palliative care decisions, decision making in critical care situations, limiting nonbeneficial interventions at the end of life, and advance directives. Because of the pediatrician's relationship with the family, that physician may be in the best position to engage parents in conversations concerning these topics. Coordinated conferences with the primary care physician, specialists, social workers, and the family may be effective in counseling.

The family has a vital role in caring for the child with SHCN, and that care can frequently be stressful and emotionally draining. Family support and counseling should be readily available. The sociocultural context of the family and needs of any other children in the family should be considered when the care of the child with SHCN is addressed.

With improved medical care and services, 90% of children with SHCN reach adulthood. Transition into adult services can be challenging. Preparation for this transition should begin as early as 11 years of age to ensure success. The goal should be independence to the degree that is possible. The individual should be prepared for a work environment, if possible, and financial independence. The family and child should be evaluated to determine whether the child is capable of independent living or will need support in a group home or an institution or to remain with the family. If necessary, guardianship issues must be addressed. A successful transition to adult

health professionals must be ensured, and insurance coverage must be arranged. The Patient Protection and Affordable Care Act of 2010 has greatly improved insurance coverage for these patients, including extending the age of coverage for dependent children until age 26 years, preventing exclusion from coverage based on preexisting conditions, and prohibiting lifetime caps on medical expenses.

Psychological Concerns

Children with SHCN have more mental health issues than their peers. These conditions include behavioral problems, depression, anxiety, low self-esteem, peer relationship problems, school performance problems, and absenteeism. Children with SHCN that include a disability have even higher rates of psychological comorbidity. It is important that primary care physicians screen for these disorders and refer patients for counseling when appropriate.

Economic Concerns

The cost of care for children with SHCN is a significant financial burden for as many as 40% of these families in the United States. Families with an affected child are more likely to have a single income, have a single parent, live in poverty, and have poor-quality housing. Economic evaluation should be performed by caseworkers to determine the eligibility of children with SHCN for financial support through Supplemental Security Income and medical insurance under Medicaid. Caseworkers can help families apply for the appropriate assistance or to other programs, such as the Supplemental Nutrition Assistance Program and the Low Income Home Energy Assistance Program, which can help extend a family's resources.

It is apparent that children with SHCN from low-income families have reduced access to health, educational, and social services. Recent studies have been undertaken to determine the best strategy to improve access to services and availability of services for underserved communities. Early intervention services can reduce the economic burden of these patients and their families.

Specific Medical Conditions

Several medical conditions commonly occur in children with moderate to severe disabilities. While providing children with comprehensive well-child care, general pediatricians also can address and manage these conditions.

Problems with adequate nutrition, which usually result from insufficient caloric intake, manifest in the form of growth failure. Depending on the degree of disability and extent of oropharyngeal dysfunction, the placement of a nasogastric or gastrostomy tube may be necessary. Caloric needs may be 10% to 50% higher than that of children without SHCN.

Respiratory illness is not uncommon among children with SHCN. Close observation and conservative management of viral illnesses are often necessary. Aspiration pneumonia is likely to occur, especially in children with severe developmental delay resulting from poor handling of oral secretions or severe oral dyspraxia. To help minimize respiratory infections, these children always should be administered influenza vaccine during the winter months.

Maintaining good oral hygiene is another challenge, because some children with disabilities do not clear oral secretions well and retain food in their mouths, predisposing to cavity development. In addition, many children are treated with anticonvulsant agents and antibiotics that can cause gingival and enamel dysplasia. Abnormal oromotor coordination, tone, and posturing also contribute to the development of oropharyngeal deformities, such as high-arched palate and overcrowded teeth. As with other children, fluoride supplementation and consistent preventive dental care are recommended.

Bowel and bladder continence is important to attain for several reasons. It allows children to function in a socially acceptable fashion, provides independence, and prevents the development of complications such as recurrent urinary tract infections, diaper dermatitis, and decubitus pressure sores. Behavior modification techniques coupled with positive reinforcement are associated with the complete or partial success of bowel training.

Community Resources

Optimal care for children with SHCN depends on maximum use of community agencies and resources. An assessment of parental and patient needs should first be performed and prioritized. The appropriate resources should then be identified for individual children. Early intervention services should be used. Primary care physicians may need to help determine the appropriateness of specific services for patients and families. Emphasis should be placed on integrating each child into support services. Parent-to-parent support and sibling support groups can be quite helpful in relieving stress, helping parents understand the diagnosis, and avoiding feelings of isolation. Support groups for siblings as well as parents are available. Respite care to give parents a break from caregiving and in-home health service programs also should be investigated. In-home hospice care is available for children near the end of life; it can be an excellent support for the patient and family. Physicians should act as liaisons between all agencies. Case conferences are occasionally necessary to review the progress of individual children with each member of the health care team.

Education

By federal law, every child with a disability is entitled to an education. Every effort should be made to enroll children with disabilities in conventional schools and provide opportunities for socialization at an early age. Structured independence and mainstreaming children with disabilities in classes with children without disabilities can be quite productive for all the children involved regardless of disability status.

Mainstreaming may not be available in some areas, and the severity of some disabilities may preclude attendance at a regular school campus. Several other educational possibilities can be considered, and each case should be evaluated on an individual basis. Options include special education classes in designated schools (full- or part-time attendance), special education classes in regular schools (full- or part-time attendance), a mix of part-time special education classes and part-time regular classes, or homeschooling. The

decision can be facilitated through the development of an Individualized Education Program by a multidisciplinary team at the school. Parents and primary care physicians are encouraged to participate in this evaluation (see Chapter 36).

Prognosis

The prognosis for children with SHCN is dependent on the diagnosis, the severity and extent of any disability, medical and supportive intervention, and the child's environment. It may be impossible to establish a prognosis at the time of diagnosis. Children may adapt differently to the same diagnosis. It is important to establish realistic goals to determine the best intervention. With comprehensive care, many affected children can lead productive, independent lives, and maximal potential can be realized in all cases.

CASE RESOLUTION

Although the girl's medical condition of low lumbar spina bifida seems stable, the physician should inquire about any ongoing problems or concerns. A complete examination should be done. Routine screening laboratory tests and immunizations required for school entry should be performed. The family should be evaluated for financial stability and support services. The mother should be placed on folate supplementation for prevention of recurrence in future children. The patient should be referred to the local spina bifida clinic for comprehensive specialist care by orthopedists, urologists, and physical therapists. Integration into the regular classroom should be recommended. The school should be contacted to arrange for adaptive physical education and for intermittent catheterization by school nursing personnel. A follow-up visit is scheduled with the primary care physician in 2 months to review the child's integration into services.

CHAPTER 45

Injury Prevention

Sarah J. Atunah-Jay, MD, MPH, FAAP, and Iris Wagman Borowsky, MD, PhD, FAAP

CASE STUDY

A 16-year-old girl was brought to the emergency department after being rescued from her submerged vehicle. The girl was texting a friend while driving and crashed into a pond. After several weeks in the intensive care unit, she was transferred out for rehabilitative care from her injury.

Questions

1. How pervasive are childhood injuries?
2. What are different approaches to injury prevention? How could this particular injury have been prevented?
3. What is TIPP and how should it be used when counseling families?
4. What are some general guidelines for effective injury prevention counseling?
5. How does a child's age affect the advice offered to a family?

Traditionally, unintentional injuries have been called "accidents." The problem with this term is that it implies unpredictability, carrying with it connotations of chance, fate, and unexpectedness. The perception that injuries are chance occurrences that cannot be predicted or prevented has been a major barrier to progress in injury prevention and the study and control of injury as a scientific discipline. According to the modern view of injury, accidents must be anticipated to be prevented. Specialists in injury prevention have tried to replace the word *accident* with *injury* and have developed the idea of reducing injury risk. Thus, injuries are not random events at all; they occur in predictable patterns determined by identifiable risk factors. For example, if a 16-year-old is texting while driving, which has been shown to be a dangerous driving distraction, the resulting injury can hardly be called an accident. On the contrary, the injury is entirely predictable.

Epidemiology

Unintentional injuries are the leading cause of death among people aged 1 to 44 years in the United States. In 2016, unintentional injuries claimed the lives of more than 18,000 Americans 21 years and younger. Suffocation is the third leading cause of death among newborns and infants; drowning is the leading cause of death among 1- to 4-year-olds; and motor vehicle crashes are the leading cause of death among 5- to 21-year-olds. Fires and burns are another major cause of unintentional injury-related death in young people.

Intentional or violence-related injuries are also a major cause of mortality in young people. Suicide is the second highest cause of death among 10- to 21-year-olds. Homicides are the third highest cause of death among 15- to 21-year-olds and fourth highest cause of death among 1- to 14-year-olds. Most suicides and homicides are firearm related.

In addition to deaths, in 2016, nonfatal injuries led to almost 9 million hospital emergency department visits in people younger than 21 years in the United States. The most common causes of nonfatal injuries in children are falls, followed by injuries from being struck by or against something, overexertion, motor vehicle occupancy, cuttings/piercings, and bites/stings.

Several epidemiological factors are associated with higher rates of pediatric injuries, including sex, race, income status, and family stressors (eg, death in the family, new residence, birth of a sibling). There is a bimodal age distribution of injuries, with newborns/infants and adolescents at greatest risk. Males are more likely than females to die from injuries and slightly more likely to experience injuries. Females are more likely than males to experience sexual assault. American Indian/Alaska Native and black children have higher rates of total injury-related deaths than other racial and ethnic age-matched populations. Geography influences injury rates; drowning deaths tend to be higher in coastline states (ie, Alaska and California) or states with a higher number of swimming pools (eg, Texas), and injury-related deaths are higher in rural areas and may be related to decreased access to emergency medical care.

Strategies for Injury Prevention

Efforts to prevent injuries have shifted from changing the behavior of individuals to modifying the environments in which injuries occur. William Haddon, MD, a medical epidemiologist, devised 2 useful frameworks for developing injury prevention strategies: the Haddon matrix and a list of 10 countermeasures to prevent injuries or reduce the severity of their effects.

Haddon Matrix

This matrix relates 3 factors (host, vector, and environment) to the 3 phases of an injury-producing event (pre-event, event, and post-event). The 3 factors interact over time to produce injury. Table 45.1 shows

Table 45.1. The Haddon Matrix Applied to Motor Vehicle Crash Injuries

Phase	*Host (Human)*	*Vector (Vehicle)*	*Environment*
Precrash	Driver vision Driver impairment (eg, alcohol, drugs) Distracted driving (eg, telephone, text)	Brakes Tires Speed Crash avoidance equipment and technology	Speed limit Road curvature Road signs
Crash	Use of safety belts Use of age-appropriate car safety seats	Vehicle size Airbags	Median barriers Laws about use of car safety seats and safety belts
Postcrash	Age Physical condition	Fuel system integrity	EMS personnel training

Abbreviation: EMS, emergency medical services.

Adapted from the National Committee for Injury Prevention and Control. Injury prevention: meeting the challenge. *Am J Prev Med.* 1989;5(3 suppl):1–303.

a Haddon Matrix of motor vehicle crash injuries. The precrash phase describes elements that determine whether a crash will occur; the crash phase describes the variables that influence the nature and severity of the resultant injury; and the postcrash phase describes the factors that determine the degree to which the injury is limited and repaired after the crash occurs. By describing the "anatomy" of an injury, the Haddon Matrix illustrates the numerous characteristics that determine an injury and the many corresponding strategies for interfering with the production of an injury.

Haddon's list of 10 countermeasures to prevent injuries or reduce the severity of their effects are as follows:

1. Prevent creation of the hazard (eg, stop producing poisons, toys with small parts, and non-powder firearms; do not participate in dangerous sports; support community centers that engage children in safe after-school activities).
2. Reduce the amount of the hazard (eg, package drugs in nonlethal amounts; reduce speed limits).
3. Prevent the release of the hazard (eg, use child-resistant caps for medications, toilet locks, and safety latches on cabinets and drawers; pass and enforce distracted driving laws; implement restrictions on handgun purchases; counsel families who keep guns to store them unloaded in a locked case, with the ammunition locked separately).
4. Modify the rate or spatial distribution of release of the hazard (eg, require airbags in cars; use child safety seats and safety belts; make poisons taste bad).
5. Separate people from the hazard in space or time (eg, make sidewalks for pedestrians, bikeways for bicyclists, and recreation areas separated from vehicles).
6. Separate people from hazards with material barriers (eg, use bicycle helmets and protective equipment for athletes; install fences around swimming pools; build window guards).
7. Modify relevant basic qualities of the hazard (eg, place padded carpets under cribs; require guns to have safety locks; develop inter-vehicle communication systems).
8. Increase resistance to damage from the hazard (eg, train and condition athletes; make structures more earthquake-proof; use flame-retardant sleepwear).
9. Limit the damage that has already begun (eg, use fire extinguisher; begin cardiopulmonary resuscitation).
10. Stabilize, repair, and rehabilitate injured individuals (eg, develop pediatric trauma centers and physical rehabilitation programs; improve emergency medical services).

Haddon's work serves as a practical guide for thinking about ways to prevent injury. It emphasizes the importance of considering injuries as a result of a sequence of events, with many opportunities for prevention. The shift of emphasis away from changing human behavior to preventing injury is particularly appropriate for injuries in children because inhibiting children's curiosity is impractical as well as undesirable.

Passive and Active Interventions

Interventions to prevent injuries can also be categorized as passive or active. *Passive* or *automatic strategies* protect whenever they are needed, without the action of parents or children. An example is the automobile airbag that automatically inflates to cushion occupants during a crash. Other examples of automatic strategies are water heater temperatures set to 48.9°C (120°F) or lower, not having guns in the home, and the use of energy-absorbing surfaces under playground equipment. In contrast, *active interventions* require action to become effective, such as in the case of nonautomatic safety belts, which require individuals to "buckle up" every time they enter an automobile. Supervision of swimming children is another example of an active injury prevention strategy.

Some strategies are partially automatic, requiring some action by individuals. Smoke detectors can be very effective in preventing injury and death in house fires, but roughly one-third of smoke detectors do not have working batteries. Batteries should be changed once a year and ideally tested once a month. As might be expected, the greater the effort required for children to be protected, the smaller the chance that protection occurs. Therefore, whenever possible, passive measures are preferable because they are the most effective.

Several approaches have been used successfully to prevent childhood injuries, including engineering, education, legislation, and enforcement. An engineering intervention, the car safety seat, is extremely effective (Table 45.2). When used correctly, child safety seats in passenger cars reduce the risk of death by 71% for infants and 54% for toddlers aged 1 to 4 years. Booster seats reduce injury risk by 59% for children aged 4 to 7 years compared with safety belts alone. Unfortunately, studies indicate that between one-third and two-thirds of car safety seats are used incorrectly. To address this, newborn care units often have car safety seat education programs, and some require possession of an infant car safety seat prior to hospital discharge. Police departments and private motor companies hold free public events to teach and manually check appropriate

Table 45.2. Pediatric Car Safety Seat Guidelines[a]

Age Group	*Type of Car Safety Seat*	*General Guidelines*
Term newborns/ infants	Rear facing	Rear facing as long as possible, until they reach the highest weight or height allowed by their seat.
Toddlers/ preschoolers	Rear facing and forward facing	Rear facing as long as possible. All children who have outgrown their rear-facing seat should use a forward-facing seat with a harness until they reach the highest weight or height allowed by their seat.
School-age children	Belt-positioning booster seat	When weight exceeds limit for car safety seat. Use until adult safety belt fits correctly (usually at 4′9″ and between 8 and 12 years of age).
Older children	Safety belts	When old enough and large enough to use the vehicle safety belt alone.

[a] All children younger than 13 years should be restrained in the rear seats of vehicles.
Adapted from Durbin DR, Hoffman BD; American Academy of Pediatrics Council on Injury, Violence, and Poison Prevention. Child passenger safety. *Pediatrics.* 2018;142(5):e20182460.

car safety seat use. In addition to engineering and education, passage and strict enforcement of child restraint laws are essential to compliance. All 50 states and the District of Columbia have child restraint laws (www.iihs.org/topics/seat-belts#laws). Nevertheless, loopholes still exist, such as exemptions in some states for safety belt use if older children are riding in rear seats; for safety belt use in school buses, taxis, and police vehicles; and if all safety belts are already in use. Such exemptions reinforce parental misconceptions, particularly that the lap of an occupant (ie, the "child crusher" position) is a safe position.

Counseling by Pediatricians

Although the existence of significant gaps in parental knowledge about injury prevention has been clearly established, studies have shown that pediatricians spend surprisingly little time counseling parents about childhood safety. One survey found that only 42% of caregivers of children younger than 15 years who had a medical visit in the past year recalled receiving injury prevention information. Another survey found only 15% of patients presenting with an unintentional injury reported receiving injury prevention counseling. Reasons for limited discussion of safety issues may include lack of emphasis on preventive medical care in medical schools and pediatric training programs, inadequate time or payment, and lack of perceived self-efficacy or effectiveness. Research, however, has shown that injury prevention counseling in primary care settings is effective, resulting in increased knowledge and improved safety practices. Parents report that they would listen to physicians much more than any other group about child safety.

TIPP—The Injury Prevention Program was developed in 1983 by the American Academy of Pediatrics (AAP) to firmly establish injury prevention as a cost-effective standard of care for pediatricians. The AAP suggests that health professionals focus their safety counseling on a few topics targeted to individual risk factors (eg, age, sex, location, season of the year, socioeconomic status of family). Table 45.3 shows the age-specific counseling schedule of TIPP, which indicates the minimum topics to cover at each visit. Specific preventive measures should be reinforced at each visit. Areas of injury prevention guidance recommended for adolescents include traffic

Table 45.3. TIPP—The Injury Prevention Program Safety Counseling Schedule for Early and Middle Childhood

Visit	*Introduce*	*Reinforce*
Birth–6 months	Rear-facing car safety seat, fall risks, burn prevention, smoke alarm use, choking/ suffocation prevention	Safe sleep
6–12 months	Drowning prevention, poisoning risks, strangulation hazards	Safe sleep, rear-facing car safety seats, fall risks, burn prevention, smoke alarm use, choking/suffocation prevention
1–2 years	Firearm hazards	Poisoning risks, fall risks, burn prevention, smoke alarm use, drowning prevention, rear-facing car safety seats
2–4 years	Play equipment safety	Fall risks, firearm hazards, burn prevention, smoke alarm use, poisoning risks, car safety seats
5 years	Bike safety, street safety, water safety, fire safety	Firearm hazards, car safety seat or belt-positioning booster seat and safety belt use
6 years	Safe swimming	Fire safety, firearm hazards, bike safety, street safety, water safety, car safety seat or belt-positioning booster seat and safety belt use
8 years	Sports safety	Water safety, bike safety, firearm hazards
10 years	"Rules of the road" while biking	Firearm hazards, sports safety, water safety, safety belt use, bike safety

Adapted from the American Academy of Pediatrics Council on Injury, Violence, and Poison Prevention. *TIPP—The Injury Prevention Program: A Guide to Safety Counseling in Office Practice.* Itasca, IL: American Academy of Pediatrics; 2019

safety (eg, safety belts, alcohol use, motorcycle and bicycle helmets), water safety (eg, alcohol use, diving injuries), firearm safety, sports safety, and distracted driving.

Connected Kids: Safe, Strong, Secure is a violence prevention tool introduced by the AAP in 2006 to augment TIPP. Acknowledging that injury and violence prevention are intertwined, it uses an asset-based approach to engage parents in understanding and fostering healthy child development. An emphasis is put on support and open communication to promote emotional and physical safety.

Health professionals should involve parents and patients in educational efforts (eg, have a bicycle helmet in the office for children to try on). Safety counseling is most effective if limited to 2 or 3 topics per visit. Advice should be well defined and practical rather than general information (eg, write the Poison Help number on the phone; never leave children unattended in water). Advice should be tailored to each family after exploring individual situations through open-ended questions (eg, "Where does your baby spend awake time during the day?"; "What do you think is the biggest safety risk for your child?"). Health professionals should be aware of different levels of health literacy and confirm understanding rather than rushing through a prepared statement. Access to interventions should be considered, such as cost and accessibility of helmets and child safety seats. Whenever possible, pediatricians should coordinate their educational efforts with current community injury prevention efforts (eg, bicycle helmet campaigns, handgun regulation).

Recent Recommendations

The AAP has multiple safety recommendations. Following are newer and revised recommendations:

- Health equity is fundamental to child safety. Children should be protected from injury within their built environment and provided with access to quality, patient-centered, and culturally effective medical care (Reaffirmed 2013).
- All children should be restrained in a rear-facing–only or convertible car safety seat used rear facing as long as possible. Importantly, nearly all currently available convertible car safety seats have weight limits for rear-facing use that can accommodate children 35 to 40 lb (15.9–18.1 kg) (2018).
- Motor vehicle crashes are the most common cause of mortality and injury for adolescents and young adults in developed countries. Now present in all 50 states, graduated driver's license programs introduce driving in a staged manner of increasing risk and responsibility. The AAP recommends that pediatricians know their state laws addressing teenage drivers, encourage seat belt use, help parents identify acute or chronic medical or behavioral risk factors that might affect their teenager's driving ability, discourage distracted driving, encourage restrictions on nighttime driving and limits on number of passengers, and counsel teenagers about the dangers of driving while impaired (2018).
- Research suggests both benefits and risks of media use for the health of children and teenagers. Parents and pediatricians can work together to develop a Family Media Use Plan (www.healthychildren.org/MediaUsePlan) that considers children's developmental stages to individualize an appropriate balance for media time and consistent rules about media use (2016).
- Pedestrian injuries are a significant traffic-related cause of morbidity and mortality. Emphasis should be given to community- and school-based strategies to reduce exposure to high-speed and high-volume traffic, and to promote improvements in vehicle design, driver manuals, driver education, and data collection to reduce pediatric pedestrian injury (Reaffirmed 2019).
- The absence of guns from homes and communities is the most reliable and effective measure to prevent firearm-related injuries in children. The AAP supports a number of specific measures to reduce the destructive effects of guns, including the regulation of the manufacture, sale, purchase, ownership, and use of firearms; a ban on semiautomatic assault weapons; and the strongest possible regulations of handguns for civilian use (Reaffirmed 2016).
- Drowning is a leading cause of injury-related death in children. Pediatricians should provide specific targeted messages by age, sex, risk of drowning, alcohol or drug use, water competency, and geographical location. Children with special health care needs should have tailored anticipatory guidance related to water safety (2019).
- Injury is the leading cause of death in children 1 to 18 years of age in the United States. The unique needs of injured children must be integrated specifically into trauma systems and disaster planning at the local, state, regional, and national levels. Pediatric injury management should include an integrated public health approach from prevention through prehospital care, to emergency and acute hospital care, to rehabilitation and long-term follow-up, as indicated (2016).
- Children exposed to intimate partner violence are at an increased risk of being abused and neglected and are more likely to develop adverse health, behavioral, psychological, and social sequelae later in life. It is recommended that pediatricians receive training on the identification, assessment, and documentation of abuse; interventions to ensure patient safety; culture and values as factors that affect intimate partner violence; applicable legal responsibilities; and violence prevention (Reaffirmed 2019).
- The overall death rate attributable to sleep-related infant deaths remains high. Recommendations for a safe sleep environment include supine positioning, the use of a firm sleep surface, room sharing without bed sharing, and the avoidance of soft bedding and overheating (2016).
- Sport-related concussions are a major health concern in young athletes. Although all concussions cannot be prevented, reducing the risk through rule changes, educational programs, equipment design, and cervical strengthening programs may be of benefit. Health care professionals should have an understanding of their individual state's laws regarding return to play after a concussion (2018).

Additional policies and guidelines can be found at www.aappublications.org/search/%20subject_collection_code%3A100 using the key words "injury prevention."

Pediatricians as Advocates

As advocates for child safety, pediatricians can play a major role in injury prevention outside the clinical setting. Pediatricians have started community programs or provided support to ongoing programs. Safe Kids Worldwide (www.safekids.org) is an organization made up of safety experts, educators, corporations, foundations, governments, and volunteers whose mission is to prevent childhood injury through education and advocacy. Safe Kids and other issue-specific organizations, such as the Children's Defense Fund (www.childrensdefense.org) and Everytown for Gun Safety (https://everytown.org), can provide resources to support pediatricians in local or national projects and provide avenues for legislative participation. Through community pediatrics programs (www.aap.org/commpeds), the AAP provides grants to pediatricians and pediatric residents who want to create innovative community projects promoting child health.

Legislative advocacy is an exciting opportunity for health professionals to effect wide-reaching change. States have enacted laws covering many aspects of injury prevention, including car safety seats, poison centers, cribs, playgrounds, amusement parks, protective gear for sports, swimming pools, and school buses. Dramatic reductions in injuries often follow safety legislation. For example, infant walker-related injuries have decreased by 76% since the introduction of the ASTM International F977 Consumer Safety Performance Specification for Infant Walkers in 1997 and the introduction of stationary activity centers as alternatives to mobile infant walkers. Other examples of product-related legislation include federal crib standards of 1974 mandating close spacing of vertical slats to reduce the risk of entrapment, the Child Safety Protection Act of 1994 requiring toy safety labels on any balls with a diameter less than 1-¾ in (4.44 cm), window blinds manufactured with tassels instead of loops and children's clothing without drawstrings to prevent strangulation, and toy boxes manufactured with safer lids and air holes in case a child is trapped within. Similarly, in December 2010, the US Consumer Product Safety Commission voted to ban drop-side cribs, citing the recall of more than 9 million cribs over the previous 5 years and the entrapment and death of 30 babies over the previous 10 years. The ban went into effect in June 2011 and prohibits the sale of such cribs even at garage sales.

Pediatricians can heighten awareness about the magnitude of childhood injuries through calls or letters to legislators, testifying about the benefits of specific safety legislation, or partnering to introduce new legislation. Pediatrician legislative involvement is critical to ensuring evidence-guided local and national injury prevention.

CASE RESOLUTION

Your experience with this case prompts you to become more involved in advocacy about adolescent drivers and accident prevention. You have the opportunity to engage families in injury prevention as well as to influence the individuals who manufacture the products and pass the laws that affect children's risk of injury.

Some of the factors that influenced the injury and outcome include a significantly increased risk of fatal crash for adolescent drivers, evidence that graduated driver licensure laws and other restrictions on young drivers reduce deaths, passage and enforcement of laws pertaining to cell phone use in cars, vehicle design, road conditions, availability of emergency rescue services and access to specialized pediatric care, and pediatrician counseling to caregivers and adolescents advocating family driving rules.

CHAPTER 46

Fostering Self-esteem

Richard Goldstein, MD, FAAP

CASE STUDY

A 4-year-old girl is brought to the office for her annual physical examination. She has been healthy. The mother is concerned that her daughter is shy and does not seem eager to play with other children. She does not attend child care or group activities outside the home, and she spends most of her time with her mother, grandmother, and 7-year-old sister, with whom she gets along well. Both parents work outside the home.

The girl's medical history is unremarkable with the exception of an episode of bronchiolitis at 8 months of age. She has reached all her developmental milestones at appropriate ages, speaks clearly in sentences, can dress herself without supervision, and can balance on 1 foot with no difficulty.

Her physical examination is entirely normal. At times during the visit, her mother sharply tells her to "Sit up straight," "Stop fidgeting," and "Act your age." The mother rolls her eyes as she says, "She doesn't know how to act."

Questions

1. What is self-esteem?
2. How do parents or other caregivers affect the development of their child's self-esteem positively and negatively?
3. What role does discipline play in the development of self-esteem?
4. How does illness affect self-esteem?
5. What suggestions can primary care physicians give parents and other caregivers to help foster positive self-esteem in children?

A mother worries about her spouse's sarcasm with their son. A father worries that indiscriminate praise at school inflates his child's sense of her abilities while setting her up for "a rude awakening." As the pediatrician walks into an examination room, a parent whispers that he wants to discuss their child's obesity away from the child. An urgent care visit is scheduled to discuss the persistent bullying of a child in school. Embedded in these scenarios and countless others is a concern that a child's self-esteem is malleable and fragile and that its preservation is crucial to a child's success. What should a primary care pediatrician know about how a child's self-concept affects the child's thoughts, feelings, and behavior?

Basic Concepts

Parents often use the term "self-esteem" to describe their child's confidence, implying a sense of agency and feelings of self-worth. In fact, *self-esteem* is a social psychological construct; it is the product of how an individual understands the effects of that individual's actions (ie, agency) and how the individual believes those actions are seen by others (ie, self-worth). *Agency*, or *self-efficacy*, is a child's confidence in his, her, or their capacity to successfully complete tasks or accomplish goals. *Self-worth* is the assessment that what a child thinks, wants, and does is important. High self-esteem often is accompanied by a sense of self-respect, purpose, and self-awareness, whereas low self-esteem typically is associated with self-questioning, defensiveness, and disproportionate self-criticism, even when receiving positive feedback. Although it may be most apparent in moments of achievement, self-esteem is also demonstrated by confidence that difficulties, failures, and disappointments are tolerable and can be accommodated. Self-esteem is essential to a child's well-being and influences the development of relationships and identity during childhood and adulthood. It is grounded in the fact that success with other people is fundamental to a sense of who we are.

Whether a child's self-estimate is inflated, overly negative, or accurate is not of importance to the concept of self-esteem; no "objective yardstick" exists. In this regard, it is important to understand that a difference exists between high self-esteem and narcissism. A child can have a healthy self-regard without a sense of entitlement, grandiosity, or feelings of superior worth. This distinction is important when critically reading research finding correlations between bullies and high self-esteem, for example; studies also find high self-esteem in those who intervene on observing bullying behavior. Alternatively, a child's disfigurement or disability should not preclude that child from possessing feelings of positive self-esteem. Self-esteem is a phenomenologic construct, and its importance lies in how a child's self-concept shapes that child's actions.

Self-esteem requires the development of certain cognitive abilities, but it is also based on experiences with parents, peers, and other caregivers. Preschool-age children become much more independent and spend more time away from primary caregivers compared with younger children. This newly acquired independence, however, does not remove the need for attention, interest, and approval from their parents. Agency must be nurtured, and not simply controlled,

to support self-esteem. Opportunities to demonstrate the competence of children can be recognized in the autonomy that appropriate parenting supports and heard as a source of pride in parents taking note of it. Educating parents about what is developmentally correct can be important. Competent play among preschoolers, for example, may involve playing alongside other children and may not necessarily consist of cooperative play (eg, helping each other in addition to playing together).

The emergence of self-esteem can be framed in terms of Erik Erikson's conceptualization of a child's social development. In the "industry versus inferiority" stage, the task of a child is to demonstrate the child's efficacy and for those efforts to be acknowledged and appreciated. The joy of autonomy and initiative are suffused with a need to live up to expectations; for example, for a young daughter part of feeling that she is a big girl is feeling that she is a good girl. The first stirrings of conscience and confidence to manage measured responsibility occur in this stage. The complex interaction of temperament, developmental stage, family security, parental style of discipline, sibling and peer interactions, and school experiences coalesce in the experience of a uniquely competent child. For her caregivers, the desire to encourage a kind of fearlessness is balanced by the very real need to keep the child safe and appropriate. All these aspects of her life contribute to the development of her competence, autonomy, and relatedness and animate her self-esteem. The development of self-esteem can be seen when children at the age of 5 years begin to experiment with identity roles, when they demonstrate an awareness of social comparison at age 7 or 8 years in their peer play and activities, and most clearly when they develop a sense of global self-esteem at approximately 8 years of age. Research also concludes that a general decline in self-esteem occurs from childhood through adolescence. It has been suggested that social comparisons and increased awareness of the perspectives of others cause adjustments to a growing child's self-efficacy and self-worth. This is intensified during adolescence, when physical changes and increased academic and social complexity test children's sense of who they are.

Much of a child's self-concept is established and reinforced by those around them, especially primary caregivers. Although important activities occur when the child is alone and engaged in individual pursuits, much of a child's self-concept develops in a context of relatedness. This extends beyond the family during school years, when peers and teachers assume a more influential role in the continued development and reinforcement of self-esteem. The development of self-esteem is transactional, built by the responses children receive to their increasing initiative and abilities, resting on a foundation of security. A secure interpersonal environment is essential to exploration and correction. This transactional nature is at the core of self-esteem interventions and their enthusiasm for effects on individuals as well as society.

All parents hope that their children will develop a positive self-concept that will aid them throughout their lives. Unfortunately, discussions related to self-esteem usually are held as a result of a crisis or an observation by worried parents or teachers. Primary care physicians should bring the parent's or parents' focus to this important aspect of their child as a normal part of anticipatory guidance. Pediatricians and health professionals are uniquely positioned to offer specific recommendations for fostering self-esteem that may affect the lives of their patients. During health maintenance visits with the child, these health professionals should model respect for the child's self-concept and highlight the growing capabilities found in the child's interactions.

Research

Research on self-esteem examines *global self-esteem*, that is, a measure of the overall assessment of the self, and *domain-specific self-esteem*, that is, measures of self-assessment related to performance and attributes (eg, academic competence, physical appearance). The most widely used measure for self-esteem, the *Rosenberg Self-Esteem Scale*, assesses global self-esteem. One difficulty in the self-esteem literature is that interventions meant to address specific performance areas are sometimes assessed with global self-esteem measures and vice versa. It is no surprise that a child's general sense of self is insufficient to improve the child's performance on a spelling quiz.

Some proportion of self-esteem is biologically rooted. Twin studies indicate that approximately 40% of variability in self-esteem can be explained by genetic factors. However, self-esteem also is known to have cultural underpinnings that seem to especially resonate in contemporary American culture. Whether the prominence of self-esteem is somehow rooted in the US national identity is unknown, but it is clear that the importance of self-esteem is not universally shared in all populations. For example, it is hard to detect self-esteem as a motivating factor in more collectivist cultures, such as Japan. This stands in broad contrast to its importance in US classroom reform or claims by psychologists first introduced in the 1990s that "self-esteem has profound consequences for every aspect of our existence." The proper conceptualization and importance of self-esteem remains a matter of debate.

At first glance, it would appear that an association exists between level of self-esteem and important health outcomes. Credible research concludes that high self-esteem predicts decreased rates of depression and increased happiness. Adolescents with high self-esteem have better mental and physical health as well as higher graduation rates and are less likely to have a criminal record. Higher self-esteem predicts improved persistence when confronting failure. Lower levels of self-esteem are associated with increased rates of obesity, drug abuse, and tobacco use. It is uncertain, however, whether the demonstrated outcomes associated with levels of self-esteem are caused by those levels of self-esteem. For example, researchers are still trying to determine whether self-esteem results in higher performance or better performance results in higher self-esteem. Causation can also be considered in the context of known correlations between self-esteem and academic performance and motivation, task performance, aggression, sex and/or gender differences, ethnic differences, and health outcomes.

Whether interventions promoting enhanced self-esteem result in improved outcomes is debatable. Research seems to have tipped the scales toward benefit from such programs when the programs include 3 specific elements: attributional feedback (ie, helping children attribute outcomes to effort), goal feedback (ie, promoting realistic, attainable goals), and contingent praise (ie, praise based on effort and improvements in performance). This seems to underscore the central importance of examining domain-specific interventions and self-estimation.

Parental Guidance

Illness and Difficult Family and Social Challenges

Physical and psychiatric illnesses threaten children's sense of who they are, undermining their self-efficacy and self-worth. Children can be left uncertain of their standing, expecting failure or feeling that they are inferior. Opportunities may exist for trusted physicians to help affected children and their families find realistic, achievable goals that affirm the children's sense of agency. It is often beneficial to help a child and family shift the narrative away from preexisting ideals and toward what is possible and of value.

A child's self-esteem can be particularly vulnerable in certain social and familial situations. A child may respond to negative experiences in school or at home with feelings of shame and worthlessness. Marital conflict, divorce, or the abuse of a parent may negatively influence the self-esteem of children who may feel complicit in or responsible for the problem. In such circumstances, parents are often concerned about the effect on the child, which provides an opportunity to work together to minimize negative effects. Honest, open communication between the physician and the parent or parents reinforces the need for sensitive support of the child and helps the parent or parents set priorities or rehearse how they will talk with the child about a given social or familial situation. (For in-depth discussion of divorce in particular, see Chapter 149.)

The issue of self-esteem is important in the context of managing "new morbidities." The diagnoses of obesity, attention-deficit/hyperactivity disorder, and learning disabilities can have in common the taint of personal judgment and the threat of undermining self-worth. Frank language that is sensitive to a child's self-esteem has a role in the disclosure of diagnosis, in addressing the reactions of both parent and child, in determining a realistic treatment plan, in acknowledging the frustrations and shame that come with slow progress, and in the framing of ultimate outcomes. Parents and patients will benefit from careful modeling by the pediatrician of how to represent and talk about the problem.

In the clinical setting, it can be challenging to provide practical advice that reflects research in this area. One helpful model for understanding self-esteem is the *self-determination theory*, in which a child's general self-concept is understood as an organization of complex, hierarchically interrelated components. Self-esteem is the evaluative aspect of self-concept and is linked to intrinsic motivation. Research has demonstrated that optimal challenges, effectance-promoting feedback, and freedom from demeaning critique; parenting that promotes autonomy rather than control; and a secure interpersonal environment of relatedness are all essential contributors to intrinsic motivation and, by extension, self-esteem.

Optimal Challenges

Successful parenting creates opportunities for children to safely extend their boundaries while ensuring their feeling of personal control. An overly critical or controlling style of parenting constrains the emergence of a child's young sense of competence and, by extension, affects the child's self-esteem. Being handed a scribble drawing by a preschooler and told what it represents is emblematic. An appreciative, interested, positive response to the disordered marks is sustaining, whereas disinterest and immediate correction or criticism is undermining. Inconsistent or harsh parenting and authoritarian as opposed to authoritative parenting styles detrimentally affect levels of self-esteem.

It may be important to discuss the difference between encouragement and pressure with parents, and many parents may benefit from an introduction to the concept of "positive communication." To support positive self-esteem, children need encouragement at all levels of their development (Box 46.1). This is communicated verbally and nonverbally and should be distinguished from overt pressure. For example, a first grader learning to spell should be praised for early, if flawed, application of phonemes, such as spelling "winter" as "wntur," and may not need correction at that point. Generally, children should be given room to experiment and develop at their own rate and should not be coaxed into activities before they are ready or judged too harshly for earnest, early attempts.

When pressure occurs, it may be the result of parents having unrealistic expectations of how a child learns and develops or an improper sense that lack of success is caused by laziness or a character flaw. Inadvertent pressure can be detrimental and can cause tremendous frustration when, for example, a parent tries to lead a toddler into toilet training when the child has shown few signs of readiness. Pressuring young children to give up pacifiers or another security object without giving thought to the child's readiness may also be quite anxiety provoking to them.

Box 46.1. Encouraging Self-esteem

Don'ts

- Have negative expectations.
- Focus on mistakes.
- Expect perfection.
- Overly protect children.

Dos

- Show confidence in children's abilities.
- Build on children's strengths.
- Value children as they are.
- Stimulate independence.

Children may not know what is best for their ultimate development, but well-intentioned pressure can be harmful as children grow older. Forcing children to participate in rigid, structured play and, sometimes, classes or lessons does not foster individual creativity or independence. The acquisition of technical skill is only part of learning, and the absence of intrinsic motivation can lead the child to feel that the effort is meaningless or inauthentic. Children ought to, but should not merely, do what parents have arranged. Encouragement to explore and occasionally take risks should build on their "islands of competence" or areas of strength. Mistakes should be put into the context of a sincere effort and understood in terms of what can be learned rather than as a humiliation. Pressuring children to do things "right" or "perfectly" discourages normal, healthy, risk-taking effort and can hinder future participation in activities unless they are certain they can succeed.

A variation on this theme is *overprotection*, in which the parent controls the child's environment to reduce any risk of failure or discomfort to the child. This generally comes at the cost of sacrificing the experience of novel achievement and developing the competence to work through frustrations and disappointments. Indiscriminate, unanchored praise is a corollary to this. Parents should be cautioned against always speaking in the superlative to their child and avoiding acknowledgment of any shortcomings. Children are adept at seeing the world as it is. A failure to see themselves reflected realistically by parents or caregivers may feed a sort of insecurity in which despite the glowing language of parents, the children feel uncertain of their actual worth. It robs children of opportunities to make accommodations. Both overprotection and indiscriminate, unanchored praise have a negative effect on self-esteem.

Effectance-Promoting Feedback and Freedom From Demeaning Critique

Specific means of communication that support self-esteem include active listening, use of positive language, discarding "labels," use of encouragement rather than pressure, and use of the "I" method of communication (Box 46.2). The pediatrician can coach parents that a child's behavior should not be expected to follow a rigid code of conduct at all times, but rather that the goal is a "good enough" environment in which well-intended parents make a consistent effort to be mindful of how they interact with their children. A useful way to set the correct tone with parents and caregivers is with the application of strength-based counseling, in which advice grows out of a focus on what parents are doing right.

Box 46.2. Communication That Builds Self-esteem

- Active listening
- Use of positive language
- Discarding "labels"
- Use of encouragement
- Use of the "I" method of communication

The purpose of active listening is to hear the child's message and understand its meaning. The success of active listening rests on a centered approach to important parenting moments; parents should strive to be attentive and present at these moments. They should stop what they are doing and look directly at their children. They should be aware of nonverbal cues, such as body posture and facial expression. If children are having trouble understanding their feelings, the parent should repeat what they hear them saying, for example, "It sounds like...."

A nonjudgmental response that is validating and nondismissive should be the goal of communication between primary caregivers and children. The basic message should be stated simply, clearly, and at a level that respects the maturity of the child. Words should be easily understood and spoken in a moderate tone, especially in cases in which discipline is necessary. Facial expression and body language should also be consistent with the message parents or caregivers are trying to convey.

Many parenting courses teach primary caregivers to use the "I" method of communication, which requires that parents explain their feelings to children rather than blame them for their actions. This approach is believed to be less threatening and demeaning for children, especially in situations requiring discipline. The "I" method has 4 recommended steps: statement of behavior or situation to be addressed (eg, "When you..."); statement in specific terms of how one feels about the effect of the situation on oneself (eg, "I feel..."); statement of reason (eg, "Because..."); and statement of expectations (eg, "I would like...," "I want..."). Using this approach, a parent might state, "When you speak so unkindly, I feel upset because I would never speak with you in that way. It makes you seem like the kind of person that you are not. I would like you to speak with me in the way we all try to speak with you, no matter how angry you feel."

Parents should be encouraged to reflect on the complex relationship between discipline and self-esteem, and they should be questioned about their impressions of their child's independence and competence. Promoting the growth of healthy autonomy should be a goal for all parents. As children grow, so too does their ability to act responsibly and maintain greater self-control. This central insight is an important means of helping parents conceptualize discipline as more than simply punitive.

The poorer outcomes associated with authoritarian parenting underscore the importance of positive language, even when disciplining children (see Chapter 50). For instance, when children are playing kickball in the house, it is understandable that a parent might yell, "Don't play ball in the house!" or "Haven't I told you before? No ball playing inside!" Although emotionally honest parenting in a loving context is the best parenting, parents should be mindful of when they are speaking in a reprimanding and negative fashion or transmitting their frustration. Parents or other adults should attempt to tell children clearly what they can do, what the limits are, and the reason for these rules. For example, a calm, more positive response might be, "You have to stop playing ball right now. If you kick the ball inside, you may break a window or hurt yourself or someone

else. You may kick the ball outside in the backyard." Communicating in a clear manner changes the tone of the interaction from a reprimand for being bad to one in which rules are clarified to a child who wants to do the right thing.

Parents should praise their children for successes and achievements. Failures should be put into context whenever possible, although the acknowledgment of mistakes can be important. A forgotten jacket or a careless job with homework can be frustrating, but neither is worthy of a demeaning critique. Negative labels have no helpful role. If children hear themselves referred to pejoratively by their primary caregivers, not only is an undesirable behavior modeled, but they will feel undermined and wonder about the truth of such statements, no matter how innocuous they may initially seem to parents.

Promoting Autonomy

Children do best when they are provided with clear, consistent guidelines for their behavior while simultaneously being encouraged to do well, pursue their interests, and increase their abilities. They are more likely to achieve autonomy when they see this behavior modeled in the adults around them. Parents and other caregivers should remember that certain methods of discipline, particularly if harsh or shame provoking, can be detrimental to a child's self-esteem. Several different approaches to discipline have been adapted by various ethnic, cultural, religious, and socioeconomic groups. It is important to explore strategies with parents and caregivers; these methods are discussed in more detail in Chapter 50.

Talents and abilities should be recognized and highlighted. Children should know that their parents have confidence in their abilities and that any display of effort is appreciated. Even small successes should be noted and not overshadowed by either the large successes or the failures. Children thrive on the joy and pride they see in the eyes of their parents. Lack of encouragement can limit their optimism for continued success.

No parent wants his, her, or their child to feel badly about themselves. Indeed, from the perspective of most parents, self-esteem in itself is an important goal. Children with high self-esteem are happier, less likely to be depressed, and better able to persist in the face of challenges and failure. But high self-esteem is not achieved by withholding all criticism and praising without merit. In many ways, the importance of self-esteem lies in its role in the discussion of criticism and praise in careful parenting. Children need to feel good and confident about themselves while also perceiving themselves accurately and with self-awareness. There may be broad agreement about the goals, but neither is there a sole means of parenting nor a single prescription for how to talk with children. Pediatricians have a special role in bringing together all these elements as they advocate for the children under their care and the people those children are becoming.

CASE RESOLUTION

The health maintenance visit provides an opportunity for promoting parental support of the child's self-esteem. The pediatrician can interview the shy child and demonstrate the use of sincere general compliments to coax the child's engagement. The interviewer might invite her to speak about herself (eg, "What are your favorite things?" "What is your favorite color?"), while using humor and enthusiasm to engage her in sharing some details. This models interactions, which allows the child to demonstrate her autonomy, with the hope that this approach will be repeated by the parent at home. The health professional can reassure the girl and her mother that the child's overall health and development are normal. Additionally, after expressing appreciation for the careful, protective experience the parent has managed for the child, the physician should attempt to normalize the child's behavior for the parent. Although it may be important to directly discuss shyness in a developmental context, whether the girl is shy is not certain, and the parent's sense of deficiencies should be challenged by a view of developing competencies. Concrete suggestions should be offered for positive communication, such as minimizing "don't" and "no" phrases and being cognizant of how the parent speaks about the daughter. The parent should be encouraged to think about the child's temperament when considering involvement in multiple school activities but be reminded that the parent has not yet seen the child in an independent setting, where she may negotiate quite well and show sociability not yet evident at home.

CHAPTER 47

Sibling Rivalry

Carol D. Berkowitz, MD, FAAP

CASE STUDY

An 8-year-old boy is brought to the office for an annual checkup. During the course of the evaluation, his mother reports that her son and his 6-year-old sister are always fighting. She says her son hits his sister and pulls her hair, and nothing she does prevents them from fighting. The boy is a B student and has no behavior problems in school. The medical history and physical examination are completely normal.

Questions

1. What is sibling rivalry?
2. What is the physician's role in counseling a family about sibling rivalry?
3. What is the role of anticipatory guidance in preparing older children for the birth of a new sister or brother?
4. How does birth order and an individual's sex affect sibling rivalry?
5. What are some of the unique considerations related to sibling rivalry between stepsiblings?
6. What are some practical suggestions to share with parents about sibling rivalry?

Sibling relationships are important in helping children shape peer and, later, adult interactions. Moderate levels of sibling rivalry are a healthy indication that each child is assertive enough to express his or her needs or wants. Siblings educate and socialize together and mediate parental demands. Siblings often spend more time interacting with each other than with either parent. The sibling relationship is characterized by continuity and permanence, but the relationship is not without turmoil.

Sibling rivalry refers to the competitiveness between siblings based on the need for parental love and esteem. The rivalry is often characterized by jealousy, teasing, and bickering. The term was introduced in 1941 by David Levy, who described it as "a common feature of family life." Alfred Adler, the noted psychologist, described siblings as "striving for significance" within the family and noted that birth order had a strong influence on development. Historical examples of sibling rivalry include relationships between the biblical figures Cain and Abel, Joseph and his brothers, Jacob and Esau, and Leah and Rachel. Sibling rivalry is also noteworthy in pairs of celebrities, such as actresses Joan Fontaine (Academy Award winner for *Suspicion*) and her older sister, Olivia de Havilland (Academy Award winner for *To Each His Own* and *The Heiress*). Even after more than 40 years, the turbulence of their relationship has remained legendary, was termed one of the most dysfunctional sibling relationships in Hollywood, and may have had its roots in their simultaneous nomination for an Academy Award in 1942. By 1975, the sisters were no longer in communication with each other. Other siblings whose performances have often been compared include football players Peyton and Eli Manning, tennis stars Venus and Serena Williams, and musicians Liam and Noel Gallagher of Oasis and Ray and Dave Davies of the Kinks. Many Shakespearean plays have battling siblings. Television has included the issue of sibling rivalry in sitcoms, sometimes trivializing the challenges for parents. However, some shows portray unrealistic compatibility between children. Shows such as *Good Luck Charlie* and *Jessie* have shown large families in which conflicts are easily and humorously resolved. This may perpetuate unrealistic expectations in families. The 2019 comedy *Fighting With My Family* relates the true story of a former wrestler and the deterioration and subsequent competition that develops between a sister and brother and their careers as wrestlers.

Sibling rivalry is a universal phenomenon occurring even in the animal kingdom. For instance, the firstborn eaglet pushes the other eaglets out of the nest as soon as they are hatched as a way of ensuring an adequate food supply. Studies in animals show variation depending on brood or litter dominance and sex dominance (male or female) within the species. Aggressive interactions are more likely when there are multiple offspring in a single brood. Among wolves, however, older siblings help to feed and guard younger ones. In humans, the fear of displacement, dethronement, and loss of love occurs with the birth of a new brother or sister, leading to sibling rivalry. Older children fear they are not good enough and that their parents need to replace them with a new offspring. Such feelings lead to a fear of abandonment. Jealousy also plays a role, and older children may be angry with younger siblings for displacing them within the family.

Sibling rivalry frequently has a negative effect on parents because it is hard for them to see 1 of their children hurt, even if it is by a sister or a brother. The challenge for parents is to know when, and when not, to intervene and what strategies to use to minimize conflicts.

Physicians can help by offering anticipatory guidance to all parents and specific recommendations to parents who are experiencing such individual problems.

Sibling abuse is a relatively recent concept that recognizes the occurrence of physical, emotional, or sexual abuse of 1 sibling by another. The aggression may range from very mild to severe. Parents may not recognize the intensity of the aggression and may attribute negative interactions to sibling rivalry. Physicians should be knowledgeable about sibling abuse and be able to help parents to differentiate between rivalry and abuse.

Epidemiology

Sibling rivalry is a universal phenomenon, and a number of factors influence its development. Time interval between children affects the degree of rivalry, as does the age of the older children. Toddlers who are entering the "terrible 2s" may have a particularly hard time mastering independence and tolerating the presence of their younger sibling. Close spacing results in more problems, particularly when children are fewer than 2 years apart. In such situations, older children still have dependency needs, often feel less secure, and experience a need for maternal attention. They stay closer to mothers, are less playful, and are tenser. Closely spaced children engage in less spontaneous play, seem angrier, and issue sterner commands to their playmates. Sex of a new sibling also influences the relationship. There tends to be greater rivalry between same-sex siblings. Additionally, a child's temperament affects sibling relationships. The 3 components of temperament include emotional intensity, activity level, and sociability. It is also important to remember that children are egocentric, which, according to Erich Fromm, lasts through 8 years of age. This contributes to a child's willingness to share (including toys and parental attention) and to act unselfishly.

Position in the family also influences sibling rivalry. Middle children experience what is referred to as middle-child syndrome; they lack the prestige of older children and the privileges of younger ones. These children are often the least secure and strive hardest to gain affection. Special difficulties may develop if middle children are the same sex as older ones. Middle children grow up to be flexible, adaptable, and good negotiators. In myths and folklore, youngest children are "favorites." They are often the ones defended by parents when there are bouts of fighting.

Twins rarely present a problem of sibling rivalry; instead, they have a problem maintaining their individuality. However, sets of twins create problems for older siblings because the older siblings are not as unique as the pair of twins.

Stepsiblings also present a unique problem in sibling rivalry. Children of divorce frequently feel abandoned by 1 parent and in competition for the time and love of the custodial parent (see Chapter 149). Competition with stepsiblings is especially difficult if the stepsiblings are in the same home.

There are also unique considerations when 1 child has a chronic or potentially terminal illness or long-term disability. Similarly, being the sibling of a gifted child (see Chapter 35) places unique challenges on sibling relationships. The unique strengths of each child need to be acknowledged.

Issues of sibling conflict change over time. Toddlers are protective of their toys and belongings and are particularly upset when a younger sibling touches their possessions. Sharing is a challenging theme of the toddler years. During their school-age years children are concerned about equity and fairness. They may be upset by what they construe as preferential treatment (eg, when a 1-year-old sibling is not expected to put his or her toys away). Sibling competitiveness is said to peak between the ages of 10 and 15 years. Adolescents, with their additional responsibilities, including minding younger siblings, may resent the siblings for imposing on their time. Sibling rivalry can persist into adulthood, and one-third of adults describe their relationship with a sibling as distant or rivalrous. After age 60 years, 80% of siblings report being close.

Significant sibling abuse is said to affect 3 in 100 children. Less violent abuse is reported to occur in as many as 35 per 100 children. These figures are reported to cross all socioeconomic levels.

Clinical Presentation

Parental concerns related to sibling rivalry consist of fighting between siblings, including physical violence and verbal abuse, bickering, and regression to immature behavioral patterns. Although such immature behavior occurs most often following the birth of a new baby, it may also be apparent if 1 sibling is receiving more attention, such as during an illness or after a major accomplishment. Regressive behavior includes bed-wetting, drinking from a bottle, and wanting to be carried to bed. Substitution behavior, such as nail-biting in place of biting the new sibling, may occur after the birth of a new baby.

Before the birth of a new baby, parents may report that their children exhibit temper tantrums, irritability, and solemnness. They may mimic the pregnancy by eating a lot and putting a pillow under their clothes. In addition, children may have psychosomatic symptoms such as stomachaches or headaches. Risk factors for maladjustment following the addition of a sibling include family discord, physical or emotional exhaustion in parents, and housing insecurity. Conversely, a good marital relationship and family support facilitates the adjustment to new siblings.

Differential Diagnosis

Dilemmas concerning the correct diagnosis of sibling rivalry most often relate to the appearance of behavioral changes, such as regressive or aggressive patterns after the birth of a new sibling. For example, a child who was previously toilet trained may become incontinent of urine. Although urinary tract infection may be considered in the diagnosis, a careful history concerning the birth of the sibling reveals the correct etiology.

The other issue to consider is whether the sibling rivalry has moved into the arena of sibling abuse. Risk factors for sibling abuse include the absence of parents from the home, domestic or community violence, and children having inappropriate family roles (eg, having to care for younger siblings).

Evaluation

The evaluation of children with suspected sibling rivalry involves a history of the problem and parental strategies for addressing the difficulties. The parent should be particularly queried about 1-to-1 opportunities between parents and individual children. Physical examination and laboratory assessment are noncontributory.

If there is concern for sibling abuse, appropriate additional questions include the following: Is one child always avoiding another sibling? Has there been a significant change in a child's behavior? Does one sibling always seem to be the aggressor and the other the target?

Management

The focus of management is to allow parents to recognize the normalcy of sibling rivalry while helping them define the behaviors that are acceptable or unacceptable within the family context and to recognize when the rivalry has progressed to sibling abuse. Children fight more often in families when parents condone fighting and aggression between siblings as normal behavior. Likewise, children of parents who are angry may interact with their siblings through anger. Parents should be counseled about this. Parents may not appreciate their child's fear of loss of parental love as the basis of sibling conflicts. They should be reminded that many children think, "If I am so good, why do I have to be replaced?" Parents should be prompted to empathize by imagining how they would feel if their spouse brought home another mate, even if they were reassured about being loved. Physicians can also help parents address sibling rivalry by having them consider their treatment of children in terms of uniqueness versus uniformity and quality versus inequality. In general, parents should be advised to set the ground rules for acceptable behavior. Such rules include no hitting, punching, hairpulling, name-calling, cursing, or door slamming. There may be a neutral area in the home that can be set aside for arbitration should disagreements arise. Moving to a neutral area also allows for some time to cool off. Parents should be reminded that children who are hungry, tired, or bored are more easily frustrated and may start fights more readily.

Birth of New Siblings

Parents may notice behavioral changes in their children before the birth of a new sibling. These changes depend on the age of the children and presence of other siblings. Children should be told about the upcoming birth. The timing depends on the children's age; younger children do not need much lead time. Some studies have evaluated the inclusion of older children in the birthing process. The results of these studies vary, but they suggest that children younger than 4 years need their mother for emotional support and are concerned about her physical exertion during the birthing process. Some older children may also want to distance themselves from the actual events.

Physicians should suggest that older children be involved in planning for the arrival of the new baby as a means of minimizing their feelings of exclusion. For example, they can help purchase clothes or prepare the baby's room. Physicians should also suggest that parents purchase a gift for older children that represents a present from the new baby, such as T-shirts that announce the older sibling's new status, such as "big sister" or "big brother." In addition, older siblings may be given a doll to serve as a baby they can care for. Parents should point out the advantages of being older with comments such as, "You can stay up later," or "You can walk and play with all these toys." Frequently, the birth of a new baby is met with regressive behavior in older siblings. Regressive behavior should be addressed with tolerance and a realization that symptoms resolve with time.

Once the birth mother goes to the hospital, she should be advised to maintain contact with older children by telephoning or video chatting. Video chatting will also allow the older siblings to see the new addition to their family. Many hospitals now allow for visitation by siblings. Currently, hospital stays are so brief (often just 24 hours) that this period of separation is much shorter than it was previously. Household changes that may be necessitated by the birth of the new baby, such as room changes, the substitution of a bed for a crib, and entrance into nursery school, should be made before the arrival of the new baby.

Rivalry Between Older Children

Physicians need to consider individual parenting techniques when counseling parents of older children. Parents who compare 1 child with the other may foster contentious behavior, and those who strive to treat all children equally may inadvertently perpetuate rivalry. Children need to feel that they are unique rather than ordinary. For example, parents who buy both children the same presents may think they are preventing rivalry from developing, but they are actually depriving each child of a sense of uniqueness. The harder parents try to be uniform, the more vigilantly children may look for inequality. Each child needs a parent's undivided attention and time alone together. Siblings also need time apart from each other, and they should be encouraged to hold separate playdates and individual activities. Not all children in a family need piano lessons and soccer practice. Individuality and uniqueness are important. The more agreeable a parent-child relationship is, the more agreeable a sibling-sibling relationship is because each child has good self-esteem. Practitioners should recommend uniqueness and quality in each parent-child relationship.

Parents sometimes have to contend with sibling rivalry between older children. Physicians should reassure parents that these older children should be allowed to vent their negative feelings toward each other. For example, if a girl refers to her brother by saying, "I hate him," the parents should respond by validating these emotions and saying something like, "It sounds as if he's done something to really annoy you." Parents should also be advised not to take sides. They should examine how they usually respond to squabbling between siblings. Is one child's name always called first during a fight? Do they perpetuate sibling rivalry by using certain nicknames (eg, "turkey brain") or other derogatory terms? Parents should assume that both parties are at least partially guilty and should not allow themselves to be drawn into the fight as referees. Parents can respond to a request for arbitration with a statement such as, "I wasn't here when things started, so I don't know who is right or wrong." The parents should also advise siblings that they do not have to be friends with

one another, but they should not hurt each other's feelings. Positive, authoritative parenting should be encouraged (see Chapter 50).

Anticipatory guidance helps parents anticipate conflictual situations, such as who sits where during long car rides and who holds the remote control. Family meetings can be held to determine the ground rules that may avoid such battles. If conflicts arise, children should be allowed to work out a solution by themselves, with the stipulation that the parents will solve the problem if the children do not reach an agreement. If fights between siblings have recurrent themes (eg, which television shows to watch [who controls the remote] or video games to play), parents can devise a weekly schedule. Failure to abide by the schedule means both children forfeit the activity. If borrowing is the source of disputes, children who borrow from their siblings should leave collateral, which gets given back when the borrowed item is returned. Box 47.1 lists suggestions for parents who are seeking advice about fighting between children.

Siblings of Children With Special Health Care Needs

Nearly 1 in 5 children in the United States is a child with special health care needs (see Chapter 44). Caring for such children places increased demands on parents and their resources, and there is less parental attention or time available for unaffected siblings. Integrating the unaffected sibling into the families' care plan and activities can be empowering for children and positively influence their self-esteem. As with all children, time alone between unaffected children and parents should be strongly encouraged. Support groups for siblings of children with special health care needs have been demonstrated to help youngsters cope and deal with their often-conflicted feelings of anger at the special attention their brother or sister receives and their guilt about being healthy.

Box 47.1. Coping With Rivalry Between Siblings: Physicians' Advice to Parents

Dos

- Allow children to vent negative feelings.
- Encourage children to develop solutions.
- Anticipate problem situations.
- Foster individuality in each child.
- Spend time with children individually.
- Compliment children when they are playing together.
- Tell children about the conflicts you had with your siblings when you were children.
- Define acceptable and unacceptable behavior.

Don'ts

- Take sides.
- Serve as a referee.
- Foster rivalry.
- Use derogatory names.
- Permit physical or verbal abuse between siblings.

Sibling Abuse

Addressing sibling rivalry can reduce the risk of the rivalry progressing to abuse. As noted previously, setting ground rules, spending time with individual children, and modelling conflict-solving skills and nonviolent behavior are positive preventive measures.

If violence does occur between siblings, parents should separate the children immediately and clearly state that such behavior is unacceptable. Children should be given a cooling off period, and then parents should convene a family meeting. Parents should encourage children to discuss their feelings and devise solutions if similar situations arise in the future. If violent behavior continues, the family should be advised to seek professional family and mental health services.

Prognosis

Although sibling rivalry may last for years, most siblings become good friends as adults. Occasionally, mental health services are needed, especially if the sibling conflict has led to marital discord, there is concern about physical or severe emotional harm, or there is evidence of another psychiatric disorder, such as depression. Learning how to negotiate with one's siblings enables children to develop skills to collaborate with peers and colleagues as adolescents and adults.

CASE RESOLUTION

The mother should be advised not to serve as a referee. She should learn how to validate each child's feelings about the other. The physician can help her by talking to her son about his feelings. The mother should be advised to have a discussion with her children during which each child has the opportunity to define areas of conflict and the means to resolve them. The mother has the right and responsibility to prohibit physical fighting and encourage verbal dialogue.

CHAPTER 48

Toilet Training

Jung Sook (Stella) Hwang, DO, FAAP, and Lynne M. Smith, MD, FAAP

CASE STUDY

A 2-year-old boy is brought to the office for a well-child visit. His mother, who is about to begin toilet training her son, asks your advice. The mother says that by the time her daughter was 2 years old she was already toilet trained, and she wants to know if training her son will be any different. The boy was the product of a full-term pregnancy and a normal delivery. He has been in good health, and his immunizations are current. He is developmentally normal, uses some 2-word phrases, and has been walking since the age of 13 months. His physical examination is normal.

Questions

1. When should the physician begin discussing toilet training with parents?
2. What factors help determine a child's readiness to begin toilet training?
3. Is toilet training in boys different from toilet training in girls?
4. What are some of the methods used to toilet train children?

The age at which toilet training is carried out is culturally determined. Some cultures train children at a very early age. For example, among the Digo, an East African tribe, some children between 2 and 3 months of age are conditioned to urinate or defecate when placed in certain positions. In the United States, the cultural emphasis is on the learning aspects of toilet training rather than the conditioning aspects. Training based on the learning aspects focuses on the cognitive development of children and children's readiness to learn the complexity of the task.

Toilet training is potentially a rewarding and frustrating experience for children and parents alike. Parents may have unrealistic expectations of their child's capability or may be quite intolerant of normal accidents that occur in the training process. It is important for the physician to introduce the topic of toilet training early on to prevent these unrealistic expectations. Refusal by a child to toilet train or accidents related to toilet training are often cited as a precipitating event for child physical abuse. It is recommended that the physician introduce to parents the issue of toilet training and provide anticipatory guidance by the time a child is 18 to 24 months of age to help parents develop reasonable expectations.

Epidemiology

The age at which children are toilet trained varies depending on social considerations and pressures. Before the 1920s, the approach to toilet training in the United States was permissive. After this attitude changed, the training methods became more rigorous, requiring that children be trained at an earlier age. In 1947, only 5% of children in the United States were not trained by 33 months of age, but by 1975 this figure had increased to 42%. Currently, approximately 25% of typically developing US children are daytime toilet trained at 24 months of age and 98% by 36 months of age.

The renewed interest in earlier toilet training in the United States has been attributed to 3 societal factors: the lower cost and increased options for child care and schooling associated with children after they are toilet trained, concerns about contagious illnesses (eg, hepatitis and infectious diarrhea in child care facilities in which diapers are changed), and the adverse environmental effects of nonbiodegradable disposable diapers.

Generally, girls are trained a bit earlier than boys, but only by a matter of a few months. Additionally, younger siblings often require less time to achieve daytime continence than firstborn children. Most children (80%) are trained simultaneously for bladder and bowel control. Approximately 12% are trained first for bowel control, with approximately 8% trained first for bladder control. Girls achieve nighttime continence at a younger age than boys.

Pathophysiology

Toilet training involves the ability to inhibit a normal reflex release action and then relax the inhibition of the involved muscles. For the process to be successful, a certain degree of neurologic and biological development is essential. Although a recent literature review found no consensus on which or how many readiness signs are ideal to start toilet training, several factors affect a child's toilet training readiness. Myelination of the pyramidal tracts and conditioned reflex sphincter control are necessary. Voluntary control is evidenced by myelination of the pyramidal tracts by age 12 to 18 months. Conditioned reflex sphincter control occurs by 9 months of age, and voluntary cooperation occurs between 12 and 15 months of age. In assessing the neurologic development of children, walking is viewed as 1 of the milestones that indicate motor readiness for toilet training. Appropriate motor skills, including getting to the bathroom, being able to remove clothing,

and sitting on the toilet, are also key skills required for successful toilet training.

Toilet training depends on physiologic and psychological readiness. Cognitive development is assessed by a child's ability to follow certain instructions and understand what the potty is used for. Two years of age has been suggested as the appropriate age to initiate toilet training in most children given that the developmental and physiologic skills necessary for successful toilet training begin maturing at this time. Toilet training usually takes 2 weeks to 2 months to master. Achieving nighttime continence is often separate from daytime continence. Although opinions about nighttime wetting are culturally dependent, it is considered normal in the United States up to 6 years of age.

A child's temperament can also affect the success of toilet training. Children who struggle with inflexibility, are less persistent, or have a more negative mood often experience delays in toilet training. Unlike physiologic or psychological readiness, temperament is not likely to change after a 2-month delay in training; understanding a child's temperament can better assist parents in supporting their child through the process of toilet training. In addition to the child's temperament, the child's emotional readiness is influenced by parental attitudes and parent-child interactions.

Differential Diagnosis

The differential diagnosis of toilet training difficulties focuses on factors that contribute to a delay in acquisition of skills. The physician should look for associated symptoms, such as dysuria, a weak urinary stream, constantly wet underwear, or fecal soiling when assessing a child who continues to manifest signs of urinary or stool incontinence. Additionally, it is important to determine if children are essentially toilet trained but are having intermittent accidents.

Dysfunctional voiding involves an abnormal voiding pattern stemming from a problem with the bladder filling or emptying. Such voiding is characterized by urine leakage, an increase in urgency, and an increase in frequency, and it often results in frequent urinary tract infections (UTIs). The most common cause of isolated daytime wetting in previously trained children is UTI (see Chapter 112). Although UTI is not associated with age at the onset of toilet training, earlier toilet training is associated with later onset of UTIs. No association exists between toilet training methods and dysfunctional voiding. Chemical urethritis may also be associated with urinary incontinence. Stress incontinence, which has also been called "giggle incontinence," may result in wetting. *Urgency incontinence* occurs when children delay going to the bathroom and then are unable to hold urine any longer. Some children have ectopic ureters, which can empty into the lower portion of the bladder, vagina, or urethra and cause a constant dribble of urine. Labial fusion with vaginal reflux of urine may also be associated with daytime wetting. Urine pools behind the fused labia or labia that do not separate sufficiently to allow natural egress during voiding, and when the child stands up the urine exits. The child with a neurogenic bladder may also have symptoms of daytime enuresis.

Stool-related accidents may be associated with chronic constipation and overflow incontinence or with congenital megacolon (ie, Hirschsprung disease; see Chapter 56). Stool toileting refusal occurs when a child is trained to urinate in the toilet but refuses to defecate in the toilet for at least 1 month. Although many parents perceive stool toileting refusal as insignificant, it is often associated with developing encopresis, constipation, painful bowel movements, and delayed completion of toilet training. If a child has persistent constipation, the child may develop megacolon and may not be able to sense a full rectum, thereby causing overflow of loose stools. A complete history and physical examination are required to differentiate functional constipation from organic causes. The physician should recognize and address functional constipation early to avoid acquired megacolon, because it takes 3 to 12 months to treat megacolon caused by chronic constipation. Children who prefer to stand in a corner to defecate should be commended for recognizing their physiologic urge. However, parents should be aware that children who hide while passing stool in their diaper are more likely to exhibit stool toileting refusal and be constipated. Successful management of constipation may decrease the incidence of toileting refusal.

Evaluation

History

Typically developing toddlers should be assessed for their physiologic and psychological readiness to initiate toilet training, as well as for any underlying medical conditions that may affect their ability to learn toileting skills at the customary age. The physician should provide anticipatory guidance to parents about toileting readiness. Affirmative answers should be obtained to the following 3 questions:

1. Does the child exhibit bladder control as evidenced by periods of dryness that last up to 2 hours and facial expressions that show the child's physiologic response to the elimination process?
2. Does the child have the motor skills necessary to get around? This essentially involves the child's ability to walk and remove their clothing.
3. Does the child have the cognitive ability to understand the task at hand?

Cognitive ability can be assessed by giving a child 10 one-step tasks to determine whether the child can complete at least 8 of the 10 tasks (Box 48.1). The ability to carry out these tasks does not ensure a willingness to be toilet trained, however. When language readiness is apparent (ie, use of 2-word phrases and 2-step commands), training can commence. In addition to language readiness, understanding of the cause and effect of toileting, desiring independence, and having sufficient motor skills and body awareness are helpful for successful training.

Stress in the home may negatively affect a toddler's ability to master the task of toilet training. The physician might counsel a family to delay toilet training if the family has moved recently, the birth of a new baby is expected, or a major family crisis has occurred, such as a death or serious illness.

The child who has had difficulties with toilet training must undergo a similar assessment.

Box 48.1. Requests or Imperatives Used to Help Assess Toilet Training Readiness

- Bring me the ball.
- Go to the door.
- Sit on the chair.
- Pick up the doll.
- Open the door.
- Give the pen to your mom.
- Put the ball on the table.
- Put the doll on the floor.
- Take off your shoes.
- Open the book.

Physical Examination

A physical examination should be performed to rule out underlying problems, such as spina bifida occulta, which may be associated with a neurogenic bladder. A neurologic examination may reveal nerve damage impeding muscles from relaxing or tightening at the right time. A careful examination of the genitalia is important in the child with urinary incontinence to determine if conditions such as labial fusion, meatal stenosis, or posterior urethral valves are evident. In the child with a problem related to passage of stool, the physician should check for an abdomen with feces-filled intestines, which is a sign of obstipation. Additionally, a rectal examination should be considered to determine the presence of hard or impacted stools or any other abnormalities in the anal area.

Laboratory Tests

Although a laboratory assessment is not indicated in the normal toddler who is being toilet trained, diagnostic studies may be appropriate in the child who is having problems with training. In the older child, urinalysis may show evidence of a UTI.

Management

The physician should help parents understand the appropriate approach to the toilet training process. Unfortunately, most parents do not obtain the necessary advice from physicians. In 1 report, no parents attending a clinic and only 7% of parents in a private practice received advice about toilet training from their physician. Therefore, it is important for the physician to initiate the discussion early enough to prevent the development of any problems.

Two main contrasting styles of toilet training exist. The first method, which is endorsed by the American Academy of Pediatrics (AAP), is a child-oriented approach that stresses the child's physiologic and psychological readiness to toilet train. The 3 versions of this approach are the Brazelton method, the AAP guidelines, and the Dr. Spock method, all of which use the same components with only minor variations. All involve gradual training and emphasize the use of rewards rather than punishments.

When toilet training the typically developing child, a parent should be advised to take the approach outlined in Box 48.2.

Additional suggestions involve allowing children to have their undergarments off and keeping the potty chair near them during play.

Children who use the potty successfully should be rewarded. Rewards can be in the form of verbal comments such as "Mommy is so proud of you," hand clapping, or the use of star charts that can be redeemed for rewards. Children can be consulted about what rewards they like. The AAP recommends using praise rather than treats for reinforcement. Punishment should not be used, particularly physical punishment. One report indicates that 15% of parents of clinic patients believe that spanking their children for accidents is acceptable. Parental disapproval of accidents can be articulated; however, parents should understand that accidents may continue to occur for months. *Regression*, that is, the state of being no longer willing or able to execute toilet training skills, may also occur with stressors, such as a recent move, a new sibling, or divorce. Consistent parental reminders and a consistent schedule can assist with eliminating regression. It is important to normalize regression and encourage parents to focus on regression as a temporary step on the way to being successfully toilet trained.

The second method, described by Azrin and Foxx, is parent-oriented and uses intense operant conditioning methods and a potty doll to assist with learning. The 6 components of the method include increasing the amount of fluids consumed; regularly scheduled times for toileting, starting with 15-minute intervals; positive reinforcement for asking about, approaching, or sitting on the potty chair; lowering/raising pants and successful urination or defecation in the potty chair; time-out from positive reinforcement/cleanliness training following accidents; and teaching the child to differentiate between wet and dry pants, checking for dry pants every 5 minutes. Although this method has been effective in training children, including those individuals with intellectual disabilities, it is not recommended for training typically developing children. A child with autism spectrum disorder who does not understand the social reward system recommended by the AAP may benefit from the intense conditioning methods described by Azrin and Foxx.

Two additional conditioning methods are available that are less commonly used in North America. The first is assisted newborn toilet training, which begins when the newborn is 2 to 3 weeks of age. The baby is placed over a toilet after feeding or if showing signs of elimination and is rewarded with food or affection for voiding or passing stool. The second method focuses on elimination communication and begins at birth. The parent learns baby's body language, noises, and elimination patterns. The parent also makes noises, such as the sound of running water, to associate with voiding while the newborn is placed in positions to facilitate elimination. Interest in these conditioning methods has increased in the past few years.

A child may use training pants, which are thickened underwear, or disposable diaper-like underwear, rather than diapers. Standard

Box 48.2. Toilet Training Approach for the Typically Developing Child

1. Teach children the appropriate vocabulary related to the toilet training process. This could include words such as "pee," "poop," "urine," "stool," "dry," "wet," "clean," "messy," and "potty."
2. Tell children what the purpose of the potty is. Placing the contents of a soiled diaper into the toilet can educate them on the purpose of the potty. Generally, a child potty chair should be purchased. The potty chair has several advantages over the toilet. Parents can encourage children to decorate the potty and put their names on it. The potty can be kept in a place where children spend much of their time, not necessarily in the bathroom. Children can sit on the potty and have their feet on the floor, which is more physiologically sound and gives them a greater sense of security. Parents should suggest that children stand fully clothed in the bathroom as an initial step in encouraging their use of a potty. Children should be allowed to sit on the potty with their clothes on for approximately 1 week before the process of toilet training begins. Next, children should sit on the potty without their undergarments, but no attempt should be made to catch stool or urine. Boys should learn to urinate in the seated position, because they may otherwise resist sitting for defecation.

   When away from home, the potty chair should be packed to maintain the established routine. It is important that all individuals caring for the child (eg, grandparents, babysitters) understand the parent's or parents' plans for toilet training.

   Toilet adapter rings can be used if the family is resistant to using a potty chair or if the transition from a potty chair to the toilet is likely to be stressful, as is true for many children with autism spectrum disorder. Adapter rings fit directly onto the toilet and do not require emptying, as do separate potty chairs. They require that the toddler climb up on the toilet, and they need to be removed for others to use the toilet. A step stool should be used to aid in climbing onto the toilet and to provide more leverage while defecating.
3. Encourage cleanliness and dryness by changing children frequently. Parents should ask their children whether they need to be changed using the appropriate vocabulary. This phase is important to continue as the toilet training process proceeds. Some parents mistakenly do not change their soiled children as a means of punishing them for having accidents. This gives children a confusing message about the need for cleanliness.
4. Explain to children the connection between dry pants and going to the potty. Children should understand that dry pants feel good and that they can keep their pants dry by going to the potty.
5. Help children understand the physiologic signals for using the toilet. Parents can facilitate this by observing children's behavior around the time of elimination and making comments such as, "When you jump up and down like that, Mommy knows you have to go to the bathroom."
6. Children must have the physiologic ability to postpone the "urge to go." This usually occurs when children are capable of delaying voiding for at least 2 hours. Parents then can initiate toilet training by taking children to the bathroom at 2-hour intervals. Additionally, children should sit on the toilet immediately after naps and 20 minutes after meals. Children should not be left on the toilet for more than 5 minutes and should be permitted to get up if they want. While sitting on the potty, they can be entertained with reading a story or playing games. It is helpful to have designated toys or books enjoyed only when the child is sitting on the potty. Parents are encouraged to rotate the toys so toilet training continues to be interesting to the child.

underwear is promoted as advantageous because it feels different from diapers and encourages the use of the potty. Using a bigger size or snipping the waistband facilitates children's ability to remove their underpants and can be recommended.

Some children seem fearful of certain aspects of the toilet training process, including fear of falling into the toilet, which can be circumvented with the use of a potty or toilet adapter rings, and fear of the noise of the flush. Allowing a child to flush the toilet without using it may dispel the fear. Toilet phobias can cause children to hold their urine until the last moment, resulting in wetting, or cause children to hurry and not fully empty their bladder, resulting in possible infections. Some children become fascinated with flushing or unrolling toilet paper, and parents should discourage children from wasting water or paper.

Modeling is 1 of the major components of toilet training children. Children should be allowed to enter the bathroom with parents and even sit on the potty chair as a parent sits on the toilet. Some children who are quite strong-willed and independent, coupled with perfectionist parents, may have problems with toilet training.

Special considerations must be made for children attending child care. Children should have open bathroom privileges; that is, they should be permitted to leave the room to go to the bathroom without raising their hands or receiving other reminders. Child care offers the advantage of peer modeling and peer pressure during the toilet training process. Potty chairs should not be used in child care settings because of the risk of infectious diseases.

Children with special needs generally encounter more obstacles when mastering toileting. Communication delays, less developed motor skills, sensitivity to stimulation, and preference for routine are just a few of the additional challenges that make it difficult to ascertain whether the child is ready to toilet train. Although incontinence was once thought to be inevitable for children with special needs, it is important for parents to understand that continence can be achieved but that expectations need to modified (ie, it may take until age 5 years to achieve, and standard toilet training methods rarely are successful).

Medications have a limited role in toilet training. Although some physicians recommend the use of drugs to increase bladder capacity, such drugs should not be used because they do not assist children with the toilet training process. However, children who are constipated may require stool softeners, such as mineral oil, polyethylene glycol solution, or magnesium citrate, or the addition of fiber bulk to their diet as well as increased fluid consumption to facilitate the passing of stool. The child who seems to have particularly challenging

toilet training problems should be seen by the physician on a weekly or biweekly basis until the child exhibits improvement.

Parents can also be referred to the many books on toilet training, particularly if problems arise. Many books are written for children to help them understand their body and the elimination process. Videos are also available to help children with toilet training. A child may benefit from the opportunity to practice with dolls designed to wet or poop after being fed.

Prevention

If a child demonstrates resistance to toilet training, the process should be delayed for 1 to 2 months. The child who learns how to withhold needs additional time to learn how to relax the sphincter when sitting on a potty. It is important for parents to avoid an aggressiveness/resistance struggle, because this may become the source of future bowel problems, including constipation. The child who is regular, particularly the individual who has a bowel movement at the same time every day, is more easily toilet trained. Creating a regularly scheduled toilet sitting session can assist with reducing the incidence of or stopping withholding.

Prognosis

All typically developing children are eventually toilet trained. The age at which this occurs varies and is significant only if it restricts a child from participating in school.

CASE RESOLUTION

The mother in the case history should be advised that this is a good time to initiate the toilet training process. She should be told that boys, as a group, are successfully toilet trained at a later age than girls. Her son can be assessed to determine whether he can follow at least 8 of 10 instructions (Box 48.1). If the boy can do so, the mother should be given the stepwise approach to initiating the toilet training process. The mother should be informed it may take months to years to achieve nighttime continence after daytime continence is achieved.

CHAPTER 49

Crying and Colic

Geeta Grover, MD, FAAP

CASE STUDY

The parents of a 2-week-old neonate bring their son to the emergency department because he has been crying persistently for the past 4 hours. He has no history of fever, vomiting, diarrhea, upper respiratory tract infection, or change in feeding. The newborn is breastfed.

On physical examination, the neonate appears well developed and well nourished. His weight is 3.37 kg (7.4 lb), which is 0.20 kg (0.4 lb) more than when he was born. Although he is fussy and crying, he is afebrile with normal vital signs. The remainder of the physical examination is within normal limits.

Questions

1. What is the normal crying pattern in newborns and young infants?
2. What is colic?
3. What conditions are associated with prolonged crying in newborns and young infants?
4. What are key factors in the history of crying newborns and infants?
5. What tests or studies, if any, are indicated in crying newborns and infants?
6. What are a few of the management strategies that can be used by parents to soothe their crying or colicky newborns and infants?

Crying is an important method of communication between babies and caregivers; it is nonspecific, however, and many stimuli (eg, hunger, fatigue, pain) can provoke the same response. Parents report that they can discriminate among various types of cries in their babies. Crying can be divided into 3 categories: normal or physiologic crying, excessive crying secondary to distress (eg, hunger) or disease, and excessive crying without an apparent cause (eg, colic).

The difference between normal and excessive crying may be more qualitative than quantitative. Some investigators have used the mnemonic "PURPLE" to characterize crying during early infancy focusing on the qualities that make the crying particularly frustrating to caregivers: P, peak pattern (increases weekly until 2 months of age); U, unexpected bouts of crying; R, resistance to soothing measures; P, pain-like facial grimacing; L, long periods of crying; and E, evening clustering. Deciding whether crying is excessive varies based on parental expectations and thresholds. Expressed parental concern about extreme crying or fussiness requires attention. If parents complain that newborns and infants cry inconsolably or continuously as well as excessively, the crying may have an underlying organic etiology. Crying with no organic etiology or definable cause is often attributed to colic.

Colic is a poorly understood, benign, self-limited condition in which healthy infants experience paroxysms of inconsolable crying. It manifests as unexplained crying in newborns and infants that usually occurs in the late afternoon or evening. During an episode of colic, babies cry and may draw the knees up to the chest or rigidly stiffen the legs, flex the elbows, clench the fists, and turn red (Figure 49.1). Although neonates and infants may appear to be miserable during an episode of colic, they are otherwise healthy, eat well, and demonstrate good weight gain.

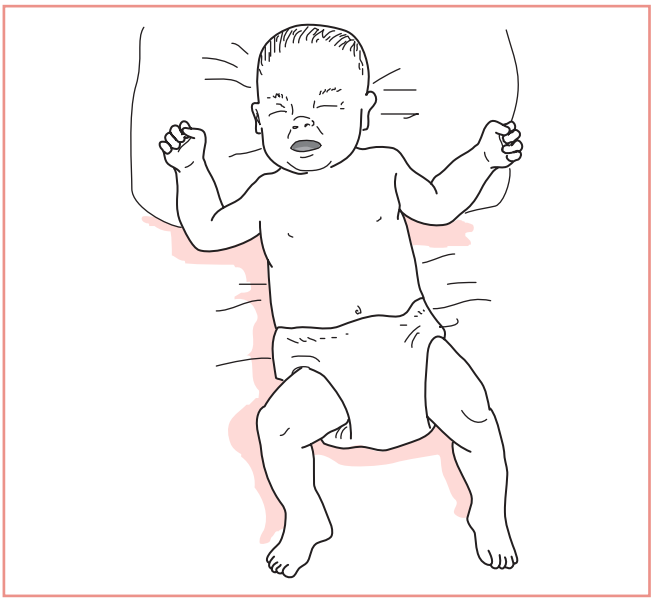

Figure 49.1. Illustration of a baby exhibiting characteristic physical signs of colic, such as crying, flexed elbows, and clenched fists.

Epidemiology

Qualitatively, *excessive crying* is any amount of crying that concerns or worries parents. Quantitatively, definitions of excessive crying have been based on the results of Brazelton's study of normal newborns

and infants. Excessive crying begins at 2 weeks of age (median daily crying time, approximately 2 hours per day), peaks at 6 weeks of age (median daily crying time, approximately 3 hours per day), and decreases to less than 1 hour per day by 12 weeks of age. More crying occurs during the evening hours, especially between ages 3 and 6 weeks.

Although many neonates and infants exhibit a relatively similar pattern of fussiness that peaks at approximately 6 weeks of age, those with colic tend to be inconsolable for longer periods and cry with greater intensity. Colic affects 10% to 20% of newborns and infants younger than 3 months. Colic affects both males and females equally and has no correlation with gestational age (eg, full-term vs preterm), type of feeding (eg, breast vs bottle), socioeconomic status, or season. Postpartum depression and abusive head trauma have been associated with colic and the stressfulness of infant crying. Colic usually begins at 2 to 3 weeks of age, peaks at 6 to 8 weeks of age, and resolves by 3 to 4 months of age. In general, symptoms of colic last for more than 3 hours per day, for more than 3 days per week, and for more than 3 weeks' duration (ie, *rule of 3s*).

Clinical Presentation

Colicky babies are otherwise healthy newborns and infants younger than 3 months who cry or fuss inconsolably for extended periods, usually during the afternoon or evening. Typically, the crying resolves within a few hours.

Pathophysiology

Crying is a complex vocalization that changes during the first year after birth as babies develop. In the first few weeks after birth, crying is a signal that newborns are experiencing a disturbance in homeostatic regulation (eg, hunger, discomfort). As babies mature and begin to differentiate internal from external stimuli, crying may also be an indication of too little or too much environmental stimulation. During the second half of the first year, as infants mature neurologically and gain voluntary control over vocalizations, crying can be an expression of different affects (eg, frustration, fear).

Various explanations for the etiology of colic have been proposed, but the cause remains unknown. Some authorities believe that colic may not be a pathologic entity but instead may be simply an extreme variant of normal crying. Proposed causes of colic include cow's milk protein or lactose intolerance, abnormal intestinal peristalsis, alterations in fecal microflora, gastrointestinal immaturity resulting in incomplete absorption of carbohydrates and resultant excessive gas production, increased serotonin secretion, poor feeding technique, and maternal smoking or nicotine replacement therapy. Recent studies have demonstrated increased levels of fecal calprotectin, a marker of colonic inflammation, in infants with colic. Others have proposed that colic is caused by problems in the interaction between babies and their environment, specifically their parents. This interactional theory requires not only excessive crying on the part of the newborn or infant but also an inability of the parents to soothe the crying baby. More than 1 of these factors may contribute to the pathogenesis of colic.

Differential Diagnosis

An acute episode of excessive crying may be secondary to disease (eg, fever, otitis media). An organic etiology should be suspected in newborns and infants who present with inconsolable crying of acute onset. Box 49.1 lists the most common causes of acute, unexplained, excessive crying in newborns and infants. Some conditions

Box 49.1. Common Causes of Acute, Unexplained, Excessive Crying in Newborns and Infants

Idiopathic[a]
- Colic[a]

Infectious
- Otitis media
- Urinary tract infection
- Stomatitis
- Meningitis

Gastrointestinal[a]
- Constipation
- Anal fissure
- Gaseous distention
- Peristalsis problems
- Reflux
- Pyloric stenosis
- Intussusception

Trauma
- Corneal abrasion
- Foreign body in the eye
- Hair tourniquet syndrome

Behavioral[a]
- Overstimulation
- Persistent night awakening

Drug Reactions
- Immunization reactions (previously common with diphtheria-tetanus-pertussis vaccine)
- Neonatal drug withdrawal (eg, narcotics)

Child Abuse
- Long bone fracture
- Retinal hemorrhage
- Intracranial hemorrhage

Hematologic[a]
- Sickle cell crisis

Genitourinary
- Incarcerated hernia
- Testicular torsion

Cardiovascular
- Arrhythmia (eg, supraventricular tachycardia)
- Congestive heart failure
- Anomalous left coronary artery[a]

[a] May present as acute or recurrent episodes of excessive crying.

occur in a more chronic or recurrent pattern, particularly if the condition is not treated.

The differential diagnosis of newborns and infants who experience recurrent episodes of excessive crying or recurrent night awakening associated with crying is focused more on behavior and temperament. Colic, neonatal abstinence syndrome, or difficult temperament (eg, extreme fussiness) may cause recurrent crying. Recurrent night awakening and difficult temperament are discussed in Chapters 30 and 51, respectively.

Evaluation

A thorough patient history and physical examination usually provide clues to the diagnosis in instances of acute onset of crying.

History

The focus of the history should be on determining the presence of any associated symptoms. Additionally, circumstances surrounding the crying (eg, occurrence during day or night) should be ascertained (Box 49.2).

Physical Examination

A thorough physical examination is required for accurate diagnosis. Red flags in the evaluation of crying infants include fever, lethargy, and abdominal tenderness or tenseness. The following aspects of the examination warrant particular attention:

1. Careful inspection of the skin after all clothing has been removed to look for any suspicious bruises or marks
2. Palpation of all long bones to detect occult fractures
3. Examination of all digits and the penis to check for hair tourniquets (ie, single strands of hair wrapped around digits or the penis)
4. Examination of the retina for retinal hemorrhages, which may be indicative of prior head injury
5. Eversion of the eyelids to check for ocular foreign bodies
6. Fluorescein staining of the cornea to look for corneal abrasion.

Laboratory Tests

With the exception of urinalysis, most screening laboratory tests likely are not useful unless indicated by the patient history and physical examination. Afebrile infants with urinary tract infection may present with crying. Even when the initial history and physical examination are nondiagnostic, a serious underlying condition (eg, intracranial hemorrhage, drug ingestion) should be suspected in babies who persist in crying inconsolably. Such newborns and infants may warrant an extended period of observation or a more extensive workup that includes laboratory assessment.

Imaging Studies

Radiographic studies may be necessary in some situations (eg, long bone radiographs for newborns and infants with long bone tenderness on palpation, cases of suspected child abuse). Computed tomography of the head should be performed on infants with retinal hemorrhage.

Management

Management of excessive crying is determined based on identification of the cause. Underlying organic conditions (eg, urinary tract infection, fractures) should be managed. The cornerstone of management of colic is parental reassurance and support, practical suggestions of feeding and handling techniques (eg, cuddling, holding), and education about the benign, self-limited nature of colic.

If symptoms persist and parents desire additional management, further treatment is individualized based on patient history, physical examination, and family characteristics. Common management techniques are listed in Box 49.3. First-line interventions that may be considered include changes in feeding techniques and/or soothing techniques, both of which address some of the potential etiologies of colic, including swallowed air and overstimulation. Currently, data on probiotic supplementation, dietary changes, various medications, and complementary and alternative medical therapies are insufficient for routine recommendation; however, such options may be considered on an individual basis after a discussion of the potential risks and benefits. Changes in sensory input (eg, soothing sounds or motions) may resolve crying and soothe colicky babies. Soothing techniques include using a pacifier, swaddling, shushing, swinging, rocking, rubbing the abdomen, holding the infant or placing the infant in a front carrier, providing white noise, and giving a warm

Box 49.2. What to Ask

The Newborn or Infant With Crying or Colic

- Is this the first time the newborn/infant has cried inconsolably, or does this happen on a recurring basis?
- Has the newborn/infant had a fever?
- Does the newborn/infant have any cold symptoms, vomiting, or diarrhea?
- Is the newborn/infant having any difficulty feeding? Is the newborn/infant formula-fed or breastfed?
- Has the newborn/infant had a recent fall or accident?
- What do you do when your newborn/infant cries?

Box 49.3. Management of Colic

- Parental reassurance
- Parental education
- Alteration in techniques of newborn/infant feeding and handling
  - Increased carrying
  - Responding quickly to crying
- Alteration of sensory input to the newborn/infant
- Prevention of swallowed air from passing through the pylorus
- Probiotics
- Dietary modifications
- Medication
- Complementary and alternative medicine therapies (after discussion of potential risks and benefits)

bath. Parents should be encouraged to experiment with various techniques, because the success of any given method may vary from 1 episode of colic to the next. Changes in feeding techniques to minimize the passage of swallowed air through the pylorus also can be useful. Such techniques include feeding in an upright position and limiting the period of sucking at the breast or bottle to approximately 10 minutes, after which time greater amounts of air are swallowed relative to the amount of milk or formula ingested. Some newborns and infants eat very fast and swallow a lot of air. Burping these babies every 5 to 10 minutes during feeds may help alleviate discomfort caused by excessive air swallowing (ie, aerophagia). Decreasing the size of the opening of a nipple for a bottle-fed baby may reduce the amount of air swallowing.

Data from several recent clinical trials indicate that in breastfed infants, use of the probiotic *Lactobacillus reuteri* DSM 17938 may decrease the duration of crying. A similar decrease in crying time has not been demonstrated in formula-fed infants given *L reuteri*.

Data on dietary changes, such as the use of hypoallergenic diets by breastfeeding mothers, are inconclusive but suggest that such changes may have some therapeutic benefits. Similarly, the use of partially, extensively, or completely hydrolyzed infant formulas also seems to have beneficial effects on the symptoms of colic. The switch to soy-based formulas is generally not recommended because soy can be an allergen. Generally, these dietary modifications should be reserved for newborns and infants with additional symptoms of allergy (eg, wheezing, rash) or intolerance (eg, vomiting, diarrhea, hematochezia, weight loss).

Various medications, including anticholinergic agents, motility-enhancing agents, proton-pump inhibitors, barbiturates, laxatives, and antiflatulence agents, have limited success and are best avoided. Currently, antiflatulence agents (eg, simethicone) are prescribed most commonly. Despite lack of scientific evidence to support their efficacy, anecdotal reports from parents indicate that they are effective.

Complementary and alternative medical therapies may be considered. Limited amounts (eg, 1–2 oz per day) of herbal remedies (eg, chamomile tea) can be administered if parents report satisfaction and no evidence exists of adverse effects. Evidence is insufficient to support the recommendation of physical therapies such as chiropractic or osteopathic manipulation, infant massage, or acupuncture. However, they may be considered on an individual basis after a discussion of the potential risks and benefits with the parents. Finally, physicians should encourage parents to respond to their baby's cries quickly and carry the baby as much as possible (eg, at least 3–4 hours per day). Parents should be advised that it is not possible to "spoil" babies younger than 4 months and that the baby's behavior may improve with increased parental responsiveness.

Prognosis

The physician should understand and should reassure the parent or parents that the natural history of persistent crying during infancy is one of resolution over time. Mothers of colicky newborns and infants have an increased likelihood of stopping breastfeeding early and also are at increased risk for postpartum depression. Excessively fussy babies are at increased risk for child abuse.

CASE RESOLUTION

The newborn is experiencing an acute episode of unexplained crying. Despite a normal physical examination, he was observed for 1 hour in the emergency department because his crying persisted. A septic workup was done, which resulted in the diagnosis of a urinary tract infection.

CHAPTER 50

Discipline

Carol D. Berkowitz, MD, FAAP

CASE STUDY

A 3-year-old boy is being threatened with expulsion from preschool because he is biting the other children. His mother states that he is very active and aggressive toward other children. In addition, his language development is delayed. She is at her wits' end about what to do. The birth history is normal, and the mother denies the use of drugs or cigarettes, but she drank socially before she realized she was pregnant. The medical and family histories are noncontributory, and the physical examination is normal.

Questions

1. What is the definition of discipline?
2. What are the 3 key components of discipline?
3. What is meant by parental monitoring?
4. What are 4 different parenting styles?
5. What strategies can parents use to discipline children?
6. What are the guidelines for using time-out?
7. What is the relationship between corporal punishment and child abuse?

Discipline can be defined as an educational process in which children learn how to behave in a socially acceptable manner. The word is derived from *disciplinare,* meaning to teach or instruct. It involves a complex set of interactions of attitudes, models, instructions, rewards, and punishments. Discipline is not synonymous with *punishment,* which denotes a negative consequence to one's actions. The goal of effective discipline is to help children gain self-control and respect for others and to learn behavior that is appropriate for given situations. It also serves to ensure a child's safety in the environment. *Proactive discipline* is action taken by parents to encourage good behavior, and *reactive discipline* is parental action following misbehavior. To be effective, child discipline must have 3 components: a learning environment with a positive, supportive parent-child relationship; a refined strategy for teaching and reinforcing desired behaviors; and a defined strategy for decreasing or extinguishing undesired behaviors. Children thrive in a supportive environment in which they are praised for socially appropriate behavior and are able to participate in the responsibilities and activities of the household. Appropriate discipline teaches a child empathy and to consider how other children feel when they are hit or teased. Parents, however, may be more focused on eliminating unwanted behaviors and may bring these specific concerns to their child's pediatrician.

Parental monitoring relates to the oversight of children's activities at home, in school, and in the community. The extent and form of parental monitoring varies with the age of the child. Parental monitoring occurs when parents ask their children, "With whom are you going to be? Where are you going? What will you be doing?" Parental oversight involves children's access to and use of the internet and social media (see Chapter 7). Inadequate parental monitoring has long-term sequelae, including an increased incidence of risk-related behaviors. Parental monitoring must be coupled with parental discipline to promote desirable behaviors and eliminate undesirable ones.

Anticipatory Guidance: Talking With Parents About Discipline

Practitioners can assist parents by giving them guidance about appropriate childhood discipline related to routine and problem development and to counsel about the scope of monitoring. The age and temperament of the child are important factors to consider. In addition, pediatricians can educate parents about corporal punishment, especially as the major method of discipline. Pediatricians also have a role in advising against corporal punishment in schools. While most states have banned corporal punishment in the school setting, 19 states, mostly in the south, still permit it.

Parenting Styles

Diana Baumrind is credited with delineating a classification of parenting styles, which are known as Baumrind's parenting typology and consist of 4 distinct categories. *Authoritarian* parenting focuses on specific rules and the belief that the rules should be followed without exception. Children are not encouraged to participate in decision-making or problem-solving. Children are punished for their mistakes and, as a consequence, self-esteem may be negatively affected.

Authoritative parenting, however, encourages participation of children in decision-making and focuses on positive discipline strategies and reinforcing desired behaviors. Rules and consequences do exist, but children play a participatory role. Children's feelings are considered, children learn empathy, and high self-esteem is fostered.

Permissive parenting is also referred to as indulgent or lenient parenting. Rules are rarely enforced, although children may be

threatened, such as, "If you do that again, you will be grounded. I really mean it this time!" Children may feel anxious because they are uncertain about the boundaries that might separate them from harmful decisions they make on their own.

Uninvolved parenting occurs when parents may be more involved in their own lives and have less interest in or time with their children. They are unaware of their children's progress in school, their children's interests, or their children's friends.

These categories suggest mutually exclusive parenting styles, but many parents use all styles for truly effective parenting. There are times when parents may have to say, "Because I said so" (authoritarian), and other times when they say, "Go ahead; it's fine with me if you want to try that" (permissive).

Regardless of parenting style, it is important to encourage parents to establish a positive interactive environment with verbal communication, monitoring children's behavior and commending desirable behavior, ignoring trivial problems, and consistently applying predetermined consequences for misbehavior. Psychologist Marshall B. Rosenberg promotes the concept of *compassionate communication,* using the analogy of the language of the giraffe, which is a language of requests, versus the language of the jackal, one of demands. Identifying feelings is integral to the language of giraffes. Rules should be simple, clear, and established ahead of time.

Frequently, physicians fail to inquire about children's behavior. Unless parents bring up the topic, discipline is not routinely discussed during the physician visit. On average, physicians spend only 90 seconds per visit on anticipatory guidance and counseling. However, a survey of mothers in a physician waiting room showed that up to 90% were concerned about 1 aspect of behavior. Sixty percent of mothers surveyed found physician advice quite helpful. The American Academy of Pediatrics recommends anticipatory guidance about discipline at each health supervision visit between 9 months and 5 years, and studies report that physicians counsel parents about discipline about 40% of the time. Such counseling is especially important to help parents understand the value of appropriate discipline in shaping their children's self-esteem. Information about discipline in the media may be confusing and contradictory and often supports the unfounded approaches of nonprofessionals. Starting when a child is 5 years old, physician-parent discussions should include the notion of monitoring.

Early in the physician-parent relationship, physicians may express their interest in behavioral problems by saying, "I am interested not only in your child's physical well-being but also in his [or her or their] growth and development and how he [or she or they] gets along with friends and family." They may then question parents about how children spend their days. During subsequent visits, pediatricians may say, "Parents of children of [child's name]'s age frequently worry about discipline. I wonder if you have any concerns." In making these inquiries, the physician may establish what factors, such as religious or ethnic beliefs, or family influences are shaping parents' decisions about discipline. Certain tools exist that can assist the primary care physician with counseling parents. One such model, Play Nicely, involves a multimedia educational program in English and Spanish that presents videos of hypothetical scenarios and has parents select from a list of options how they would manage the behavior. The program helps augment parents' repertoire of responses to their child's behaviors.

Corporal Punishment

The relationship among harsh punishment, use of corporal punishment, and child abuse has been addressed in a number of studies. The American Academy of Pediatrics has published extensively on the issue of corporal punishment and highlighted how approval of corporal punishment as an acceptable means of disciplining children has significantly decreased in recent years. It is of interest that the UN Convention on the Rights of the Child (1989) endorses banning corporal punishment and promoting positive discipline. Slapping, smacking, spanking, kicking, shaking, and throwing are all enumerated, as are other punitive measures. Data support physical discipline as being associated with subsequent aggressive behavior on the part of toddlers. There are also data linking corporal punishment with adverse childhood experiences (see Chapter 142). Scolding (yelling) is sometimes equated with harsh verbal abuse, especially if it is pervasive and may escalate to physical punishment. Receiving harsh verbal abuse before 13 years of age has been linked to adolescent behavioral and mental health issues.

Common Problem Behaviors

Common behavioral problems can be placed in 5 major categories.

1. **Problems of daily routine.** Such problems include the refusal of children to go about their daily activities, such as eating, going to bed, awakening at a certain time, and toilet training.
2. **Aggressive-resistant behavior.** Such behavior is characterized by negativism and includes temper tantrums and aggressive responses to siblings and peers. Some undesirable behavior can place children or those around them in danger or at risk for injury.
3. **Overdependent or withdrawal behavior.** This behavior is typical of children who are very attached to their parents These children find separation difficult, especially when beginning preschool.
4. **Overactivity or excessive restlessness.**
5. **Undesirable habits,** which include thumb-sucking, nail-biting, throat clearing, and playing with genitals (see Chapter 54).

Some of the listed behaviors are age appropriate, and physicians can help parents by counseling them about stage-related behavior, such as oppositional behavior in a 2-year-old and independence-dependence conflicts in a 3- to 5-year-old. Parents may be more tolerant of a particular behavior if they understand what is typical at a given age. Just because something is typical, however, does not mean that it should be tolerated. Physicians can suggest to the parents means of dealing with age-appropriate behavior (eg, placing breakable objects out of reach of toddlers).

Some behavioral problems reflect differences in childhood temperaments. Temperament is the biological predisposition to a style of behavior. William B. Carey, MD, has compiled a series of

temperament scales to assess children and adolescents of different ages. For example, some children are shy and have a hard time adjusting to new situations. If parents anticipate such problems, they are often less angry when difficulties arise. Parental expectations can vary with a child's sex. Boys may be permitted to act a certain way ("He's all boy!") that would be disapproved of in girls. Physicians can discuss such expectations at health supervision visits.

Physicians can also be particularly helpful in detecting and advising parents about disparities in the achievement of different developmental skills. Some children acquire motor skills before verbal skills, yet parents expect their children to be equally versatile in speech and movement.

Psychophysiology

All behaviors are modified by the responses and reactions of other individuals. The basic premise of discipline is to discourage unwanted behavior and to encourage desired behavior. This is accomplished by using techniques that are based on conditioning modalities.

Several factors contribute to an increased incidence of behavioral problems in children. Ten percent to 15% of all preschool-age children are raised in challenging or disrupted family situations. Homes may be affected by divorce, death, separation, violence, parental substance use, mental illness, or extreme poverty (see Chapter 141). Parental inexperience may also be a factor. In addition, families may have fewer social contacts than they once did because of greater mobility within society. As a result, families face greater social isolation and less availability of extended family.

Differential Diagnosis

In addition to providing anticipatory guidance about discipline, consider whether a specific behavior represents typical childhood behavior or an abnormality in behavior that warrants more specific intervention. Between 8% and 18% of behavioral disturbances may deserve physician intervention. More intensive management may be necessary for problems related to aggressive-resistant behavior and hyperactivity. Overactive behavior, which may exist as part of attention-deficit/hyperactivity disorder (ADHD), may be a sign of a significant underlying problem that warrants 1-to-1 intervention or the use of neuropharmacological agents (see Chapter 133).

Occasionally, children will be seen and noted to have bruises that were sustained during physical punishment. Although physical punishment is not illegal, the presence of significant bruises or injuries may warrant a report to child protective services.

Evaluation

History

The key component in the evaluation process is the assessment of the means parents use to discipline children (Box 50.1). To obtain this information, physicians may simply ask parents, "How do you get your child to mind you?" This question is designed to lead to a discussion of how parents interact with their children. A follow-up question could be, "What do you do if your child doesn't mind you?" This may help initiate a discussion related to parenting style and whether physical punishment is used to achieve adherence to parental rules. If parents have specific concerns, such as oppositional behavior, they should be questioned about the strategies they have used in their effort to discipline their children. It may also be useful to ask parents how they were disciplined as children to better understand their personal experience.

Box 50.1. What to Ask

Discipline

- What does the child do that the parents wish the child would not do?
- What do the parents do to stop unwanted behavior?
- Does the child usually obey the parents?
- What does the parent do if the child does not mind the parent?
- When and where does most of the unwanted behavior occur? Does it occur mainly if a child is tired?
- Which parent is responsible for disciplining the child?

Physical Examination

Children's behavior should be assessed during the office visit. A general physical examination is useful to check for any signs of physical abuse as well as to evaluate children's well-being. A developmental assessment is also helpful because it may delineate disparities in the achievement of certain skills. Some overly active children may warrant a more extensive psycho-developmental assessment to look for findings consistent with ADHD. Behavioral checklists may be used to evaluate children's temperament.

Laboratory Tests

No specific laboratory or imaging studies are indicated for children with discipline problems. Diagnostic studies are indicated if child abuse is suspected (see Chapter 144).

Management

Physicians should assist parents in establishing appropriate guidelines for disciplining their children and reinforce the role of parents as the source of authority (Box 50.2). It is important for parents to realize that total freedom, which may be seen in families with permissive parenting, may result in poorly controlled anxiety. Children mimic behavior, and parents should act as role models. If parents have temper tantrums when they are frustrated, their children may act in a similar manner. Consistency is also important. A system with a limited number of enforced rules is better than one with many different rules. In families in which both parents are working, especially if they have overlapping time schedules, consistency is sometimes difficult to attain, particularly if children are supervised by non-parental caregivers. Likewise, if parents are divorced and children are moving between 2 different households, rules may vary depending on which parent is caring for the child (see Chapter 149).

Box 50.2. Advice for Parents About Discipline

- Set rules.
- Set limits.
- Define consequences.
- Be consistent.
- Ignore trivial problems.
- Compliment desirable behavior.
- Take time out when angry.

Physicians should emphasize to parents that it is best to avoid power struggles. Children engaged in a struggle can often win because in some situations they have final control (eg, refusing to eat). Children should always be given the opportunity to graciously back out of a situation and save face. It is easier to avoid situations that lead to head-on confrontations than to gracefully emerge from them once the confrontation has occurred. Physicians can commend parents on appropriate handling of difficult situations, validate parental ability to handle their children appropriately, and guide parents on alternative strategies if there is a need to do so.

Physicians should remind parents that forestalling undesirable behaviors is easier than treating behavioral disorders once they arise. Reasoning is a useful modality, but it is unrealistic to expect infants and toddlers to have the cognitive skills to understand adult reasoning or to consistently respond to verbal commands or reprimands. Discipline should not only discourage bad behavior but also reinforce good behavior.

Following are 5 examples of reactive discipline: redirection, spanking, scolding, ignoring, and time-out and removal of privileges.

Redirection

Redirection is a simple and effective method in which the parent removes the problem and distracts the child with an alternative. This technique is frequently used to remove some object (eg, a valued knickknack) from the hands of an infant, replacing it with a toy. Parental patience, ingenuity, and enthusiasm facilitate this approach. This approach is also important in teaching children what is acceptable behavior. For instance, one cannot draw on the wall, but one can draw on a piece of paper. Children also respond to making tedious routines into a game. For example, children can be challenged to see who can get their clothes on faster or who can brush their teeth first. Parental creativity and energy often avert confrontations.

Spanking

Spanking involves inflicting physical pain, which can be successful in bringing about the immediate cessation or a decrease in problem behavior. Spanking is highly prevalent as a form of discipline, with between 70% and 94% of parents reporting using the practice. However, only 6% of pediatricians have a positive attitude toward spanking. Spanking is used more often for younger children and for boys and correlates with parental attributes such as age, education, socioeconomic status, and religious orientation. Spanking is often employed when other methods of discipline have failed to abort the unwanted behavior. Spanking tends to clear the air and get the punishment over with rather than producing a lingering guilt. To be truly effective, however, physical punishment must immediately follow the act. The "wait until Daddy comes home" approach is less effective because of the lack of temporal association. In addition, spanking tends to become situation-specific so that children associate a particular action with being spanked. This learning does not generalize to other situations. Spanking can teach children to be afraid of adults rather than to respect them.

Spanking, as well as other forms of physical punishment, can damage the parent-child relationship and have a long-term effect on a child's self-esteem. Parents may feel remorseful after spanking a child, and some acknowledge that they spank out of anger and frustration and question the efficacy of this modality. Most pediatricians discourage spanking as a means of disciplining children. Differentiation of physical punishment from child abuse can be difficult. In general, physical punishment using objects (eg, belts) and spanking on parts of the body other than the buttocks or thighs is unacceptable. Punishing a child by making them engage in physical exercise (eg, 200 jumping jacks) is also inappropriate. Spanking may be a precursor of later physical violence and subsequent abuse. Again, parents act as role models. Children should never be allowed to hit their parents. This makes children feel extremely insecure.

Devices that are marketed for child discipline and inflict physical pain on a child, such as a sudden sting (modified stun gun), are obviously never appropriate.

Scolding

Scolding involves the excess use of reasoning and explanations and is used by most parents as part of the discipline process. In families in which communication or interaction is minimal, scolding or verbal reprimands may result in an initial increase in inappropriate behavior because this is the only way children receive any attention. Verbal reprimands are more effective if used infrequently. Verbal reprimands should not be used during time-outs because they reinforce undesirable behavior.

Scolding, because of its negative focus, can be damaging to children's self-esteem. Scolding may be equated with yelling, verbal abuse, and harsh parenting practices. Scolding would be categorized by Rosenberg as "jackal language."

Ignoring

Ignoring represents the opposite of explaining and reasoning. This form of discipline is difficult to use successfully because parents must totally ignore children's behavior. If even the least flicker of recognition occurs, activity increases. A brief initial increase in unwanted behavior, a so-called response burst, may occur with ignoring. This disciplinary method works better in younger children.

Time-out and Removal of Privileges

Time-out, the form of discipline most often recommended, refers to time away from positive reinforcement. In sports, teams call a time-out to rethink what they are doing and to replan their strategies. Children are placed in a neutral or boring environment whenever they engage in inappropriate behavior. The time-out technique can be used to discourage undesired habits as well as inappropriate behavior. For example, parents may say, "You can suck your thumb, but you may only do it in such and such a room." This type of discipline is better than ignoring, especially if "ignored" children are receiving attention from siblings and peers. Children should understand the rules ahead of time and why the behavior is unacceptable. Once this is accomplished, time-out may occur without any warning.

A timer should be used, and children should stay in the time-out area for 1 minute per 1 year of age. An appropriate area must be selected. This area should be fairly boring, so children's rooms with their toys and electronic devices may not be appropriate. A laundry room, a corner, or a specific chair may be better. If children act unacceptably during the time-out, the timer should be reset. If children have to go to the bathroom during the time-out, they are allowed 1 trip. After they return from the bathroom, the timer is reset.

The use of the time-out method is not always easy. If the inappropriate behavior occurs in the morning when children are getting ready for school, time-out just encourages children's delaying tactics. "Beat the buzzer" is a better idea that may be used in such situations. With "beat the buzzer," the timer is set. For example, if children are dressed before the timer goes off, they may be rewarded for the behavior by being allowed to go to bed half an hour later, but if the buzzer "beats" them, they have to go to bed half an hour earlier.

Inappropriate behavior away from home presents an even greater challenge. These situations can be dealt with in numerous ways, particularly if the behavior problem involves temper tantrums. When children are crying or screaming uncontrollably, it is best to remove them from the embarrassment of the situation. This "manual guidance" often occurs in a supermarket, where children select something that parents do not wish to buy. Parents can often circumvent this problem by walking into the supermarket and saying, "If you are good during the whole trip, then I will get you something at the checkout counter." If children still have temper tantrums, they should be removed from the area and brought to a neutral place, such as the automobile or a restroom, and allowed to finish their crying and screaming. Inappropriate behavior can also be managed by "marking" time-out. This consists of putting a mark with a colored water-soluble marker on the child's wrist every time he or she engages in an inappropriate behavior. When the child returns home, the marks are totaled, and the time-out method is used. Once again, separating the undesirable behavior from the disciplinary consequence may limit the effectiveness of marking time-out.

Removal of privileges is a strategy applied with older children. Classically, this involves grounding a child, prohibiting television or video games, limiting the use of cell phones or other electronic devices, or loss of driving privileges. The privilege must be something of value to the child for this method to be effective.

Parents who report inappropriate behavior should be asked to keep a record of children's behavior for 1 to 2 weeks. This helps determine the nature of the behavior (eg, whether it is age-appropriate) and what is motivating it. Parents should be encouraged to talk to their children in a reasonable manner and to verbalize what they think children are feeling. They might say something like this: "It's terrible to be 3 years old and get so upset. You feel that you can't always get things you want. Once you grow up, you will be in charge. I am really sorry it is so hard for you right now." Physicians should tell parents that it is important to set limits for children and to avoid threatening, judging, and constantly criticizing children. Frequent threats, such as, "If you don't stop hitting your sister, you'll get a time-out," that are not carried out undermine the entire discipline process. To help foster compassionate communication, parents should ask themselves, "If someone said this to me, how would I feel?" Many parents have themselves been disciplined only with spanking and physical punishment and know no other means, and the advice that physicians offer is valuable.

There are models that can help parent improve their parenting skills. Triple P is an evidence-based proven parenting program, as are HealthySteps (www.HealthySteps.org) and Help Me Grow (https://helpmegrownational.org). Pediatricians are encouraged to be familiar with these resources and be able to share them with families.

Prognosis

Children raised in a supportive environment that teaches respect for others and self-control grow up as caring adults. Children who have been exposed to excessive physical punishment show aggressive behavior later. The physician is in an excellent position to influence parenting practices and child well-being.

CASE RESOLUTION

Further history should be elicited about the mother's disciplining techniques. It is also significant that the child's speech is delayed. The boy's ability to articulate his feelings may be limited, and a formal speech and hearing assessment is warranted. The preschool should be advised that the evaluation is underway. A report from the preschool concerning the boy's behavior is requested.

CHAPTER 51

Temper Tantrums

Geeta Grover, MD, FAAP, and Peter Jinwu Chung, MD, FAAP

CASE STUDY

During a routine office visit, the parents of a 3-year-old boy express concern about his recent behavior. They report that whenever he is asked to do something he does not want to do, he throws a "fit." He cries fiercely, falls to the floor, bangs his hands on the floor, and kicks his feet until his parents give in. He often displays such behavior at bedtime or mealtime if he is asked to turn off the television or eat foods that he does not want. He has 2 to 3 such episodes per week. The parents state that their home life has not changed, and the boy's teacher reports that he displays no such behaviors at preschool.

Questions

1. At what age are temper tantrums common in children?
2. What aspects of child development contribute to temper tantrums?
3. How do parents' reactions encourage or discourage temper tantrums?
4. What appropriate management strategies may help control problematic tantrums?
5. What factors or aspects of problematic tantrums may indicate underlying pathology?
6. What referrals, if any, are appropriate for the management of temper tantrums?

Temper tantrums are common, normal, age-related behaviors in young children. To a certain extent, oppositional behaviors such as negativism, defiance, and tantrums are part of the normal progression toward self-reliance and independence. Toddlers need to assert their freedom and explore their environment, which often puts them at odds with the limitations imposed by society and well-meaning parents. Young children cannot appreciate that rules and limitations have been established in the interest of their own safety and well-being. They see only that their own desires have been thwarted, and they may react to this disappointment with intense emotions. Children are not simply upset because they cannot have their way. They are angry and frustrated, and they lose control over their emotions. During tantrums, children cry and scream uncontrollably. They may fall to the floor, bang their heads, kick their feet, pound their hands, and thrash about wildly. Some children may throw things, try to hit one another, or destroy property.

Such intense displays of anger may be a terrifying experience for children and parents. Some children use tantrums to gain attention, whereas others use them to achieve something or avoid doing something. Recurrent temper tantrums may strain relationships among parents, children, and other family members.

Epidemiology

Temper tantrums are noted most often in children who are 2 to 3 years of age, but they may occur any time between the ages of 1 and 5 years. Parental surveys reveal that approximately 20% of 2-year-olds, 18% of 3-year-olds, and 10% of 4-year-olds have at least 1 tantrum per day. Most children can express their feelings verbally by 3 to 4 years of age, at which point temper tantrums begin to taper off. Children who cannot express their feelings well with words, such as children with developmental delays, especially those with speech and language delays or with an autism spectrum disorder (ASD), are more likely to continue to have tantrums. Boys and girls are affected equally. Although temper tantrums are unusual in school-age children, they often reappear in the form of verbal tantrums during adolescence, when autonomy and independence once again become developmental issues.

Pathophysiology

Temperament, or adaptability and emotional style, affects the ease with which children adjust to environmental inputs and their reactions to these inputs. Temperament is the "how" of behavior, as opposed to the "why." It is innate rather than learned. Although inherent from birth, temperament may be modified in the early years by children's experiences and interactions. Stella Chess, MD, and Alexander Thomas, MD, identified 9 major temperamental traits based on their study of children's behavioral characteristics during the 1950s: activity level, rhythmicity (regularity), approach or withdrawal, adaptability, intensity, mood, persistence and attention span, distractibility, and sensory threshold. Three common patterns of temperament based on whether a child shows a greater or lesser degree of each of these traits are *easy* (high rhythmicity and adaptability with a positive mood), *slow to warm up* or *shy* (slow adaptability and tendency to withdraw initially in new situations), and *difficult* or *challenging* (low rhythmicity and adaptability, resulting in negative and intense reactions to the environment).

Appreciation of children's temperament allows parents to anticipate and understand their children's reactions, thereby affording them the opportunity to rethink how the parents interpret and respond to their children's behaviors. Ultimately, this knowledge

allows parents to guide children in ways that respect their individual differences. Temperament does not excuse children's unacceptable behaviors, but it does provide some insight into the origins of problematic behaviors, such as tantrums. For example, allowing extra time in the morning for the high–activity-level child with high distractibility and low attention span to get ready for school may avoid the daily negative interactions between parent and child. A discussion of temperament is not complete without noting that ultimately it is the "goodness of fit" between parental and child temperaments that is the key issue. What may appear to be a behavioral problem may in fact be a mismatch between parental and child temperaments (eg, a high-energy and high-intensity child may be quite challenging for the slow to warm up or shy parent). It is important to help parents appreciate that such mismatches in temperamental traits between themselves and their children do not necessarily represent problems in their children's character.

Understanding the child's level of maturity and the developmental tasks normally associated with the toddler and preschool years, which is when temper tantrums most often occur, facilitates further understanding of tantrum behavior. Young children who are exploring the world and developing a sense of autonomy think primarily in egocentric terms. They view reality from their own perspective and are unable to appreciate the perspective of other individuals. Only as they mature and enter school do they learn to recognize the position of others and begin to develop a sense of morality—of right and wrong. Toddlers may become frustrated or angry because of their lack of control over the world, their inability to communicate, or limitations of their cognitive and motor abilities, which do not allow them to accomplish desired tasks. Unlike adults, who can verbalize frustrations or simply walk away from unpleasant situations, young children have neither the sophisticated ability to articulate their feelings nor the freedom to walk away. Therefore, they may react to disappointments with temper tantrums. With cognitive and emotional maturation, children should gradually learn to exhibit more emotional control and/or use language to express themselves. If caregivers consistently reinforce tantrum behavior, however, such as by "giving in," this maturation process may be delayed.

Temper tantrums may be classified as normal or problematic based on their cause, frequency, and characteristics. *Normal tantrums* can simply be demands for attention or signs of frustration, anger, or protest. In the interval between tantrums, the child's disposition and mood are normal. The well-behaved 3-year-old boy who has an occasional tantrum after the birth of a sibling, the girl age 2 years 6 months who throws a tantrum to express frustration because no one understands what she is trying to say, and the 2-year-old boy who cries uncontrollably because he cannot complete the puzzle he started or run fast enough to keep up with his 4-year-old brother are all examples of normal tantrums. A typical reason for an avoidance-type tantrum is not wanting to go to bed at bedtime. All types of tantrum are more common when children are tired, ill, or hungry, because their ability to cope with disappointment and frustration is limited under these circumstances.

Frequent tantrums (>5 per day) and tantrums that result in destruction of property or physical harm to the child or others are signs of *problematic tantrums* (Box 51.1). These tantrums may result from factors that are beyond the child's control, such as parental problems, school difficulties, or health-related conditions (Box 51.2). For example, the child with unrecognized hearing loss may be performing poorly at school and resort to tantrum behavior in frustration. Marital discord or domestic violence may create anxiety for a child, which may manifest as frequent or destructive tantrums. Additionally, problematic temper tantrums may be a symptom of an underlying psychiatric or neurodevelopmental condition.

Differential Diagnosis

Temper tantrums are readily recognizable because of their classic pattern in which a child becomes frustrated, reacts physically, and cries or screams.

Box 51.1. Features of Problematic Tantrums

- Tantrums that persist or get worse beyond 4–5 years of age
- Frequent tantrums (>5 per day)
- Tantrums lasting more than 15 minutes
- Persistent negative mood or behavior in intervals between tantrums
- Recurrent tantrums at school
- Destruction of property during tantrums
- Harm to self or others during tantrums
- Other behavioral problems (eg, sleep disorders, aggressive behaviors, enuresis)

Box 51.2. Underlying Causes of Problematic Tantrums

Parent-related Factors

- Marital discord
- Abusive behavior toward children
- Domestic violence
- Substance abuse
- Depression
- Inappropriate parental expectations

Child-related Factors

- Developmental or learning disabilities
  - Hearing loss
  - Speech and language delays
  - Autism spectrum disorder
- Mood disorders (eg, depression, disruptive mood dysregulation disorder)
- Disruptive behavior disorders (eg, attention-deficit/hyperactivity disorder)
- Trauma-related impairment (eg, posttraumatic stress disorder)
- Temperament (eg, high persistence and intensity of response and slow adaptability)
- Illness
  - Unrecognized illness (eg, otitis media, sinusitis)
  - Chronic or recurrent illness

Evaluation

History

Obtaining a thorough history is essential (Box 51.3). Frequency of temper tantrums, circumstances that provoke them, a description of actual tantrums, and parental reaction must be ascertained. In some instances, this reaction may provide insight into why tantrums recur. Parental expectations should be assessed as well. Expectations that are inappropriate for children's age and developmental maturity may create unnecessary tensions between parents and children and result in tantrum behavior. Factors associated with problematic tantrums should also be assessed (Box 51.2).

It is important to remember that physicians usually see children whose tantrums are frequent, severe, or cannot be controlled by parents. First, the pediatrician must determine whether any underlying pathology may be contributing to the behavior and, if so, what parental or child factors may be provoking it. Second, the pediatrician must differentiate between normal and problematic tantrums (Box 51.1). Identification and remediation of the cause of problematic tantrums are the first steps toward cure.

Problematic temper tantrums can be a presenting symptom of an underlying neurodevelopmental or psychiatric condition, especially if the tantrums persist or worsen after 4 to 5 years of age despite the development of typical expressive language skills. Conditions associated with problematic temper tantrums include ASD, attention-deficit/hyperactivity disorder (ADHD), internalizing disorders, exposure to trauma, disruptive mood dysregulation disorder, and disruptive behaviors.

The child with ASD may have problematic temper tantrums related to the core deficits of the disorder, such as rigidity, difficulty with change, and perseverative interests (eg, a child who lines up toys may get upset if the arrangement is disrupted). In such situations, careful history about the "trigger" for the tantrum as well as an investigation into the child's developmental history (especially language and social skills) is warranted. For a more complete discussion of ASD, refer to Chapter 132.

Children with ADHD may react impulsively and lack the executive function skills necessary to regulate their emotional responses, which can precipitate problematic tantrums. Parent and teacher feedback should be solicited about behaviors of inattention and hyperactivity. For a more complete discussion of ADHD, refer to Chapter 133.

The child with an internalizing disorder, such as anxiety or depression, may exhibit generalized irritability or overreactivity with frequent temper tantrums. In the child with depression irritability, rather than sadness, may be the presenting mood symptom. Adolescent depression is discussed in Chapter 66.

The child with exposure to trauma can present with behavioral regression (eg, recurrence of temper tantrums) or changes in mood. If the severity or frequency of temper tantrums has recently increased, the pediatrician may screen for trauma by asking a simple question, such as "Since your last visit, has anything really scary or upsetting happened to your family or your child?" Cases of suspected traumatic exposure are best referred to a mental health professional for evaluation and treatment. Adverse childhood experiences and trauma-informed care are discussed in Chapter 142.

For the child with severe temper outbursts, the health professional should ask about characteristics suggestive of disruptive mood dysregulation disorder (Box 51.4). Referral to a subspecialist for further evaluation and treatment may be indicated. For more details about diagnostic criteria, see *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition.

Disruptive behaviors, such as oppositional defiant disorder and conduct disorder, may present with severe temper tantrums in young childhood. High intensity of defiance, aggression to people and/or animals, self-harm, destruction of property, and difficulty recovering from tantrums occur more commonly in disruptive behavior disorders and warrant referral to a subspecialist.

Physical Examination

A thorough physical examination is appropriate, as is a developmental assessment to determine if the child exhibits findings such as speech delay or behavioral signs consistent with ASD or ADHD. Typically, the physical examination is normal.

Box 51.3. What to Ask

Temper Tantrums

- How often does the child have temper tantrums?
- What circumstances provoke the tantrums?
- How does the child behave during the tantrums? What does the child do?
- How does the child behave in the interval between tantrums?
- How do the parents react to the child during the tantrums? What do they do or say?
- Are parental expectations consistent with the child's developmental stage?
- Have there been any changes at home or school (eg, birth of a sibling, new school)?
- Is the child having any other behavioral or development-related problems (eg, enuresis, sleep difficulties)?
- Are there any other signs or symptoms of an underlying psychiatric or neurodevelopmental condition?

Box 51.4. Characteristics of Disruptive Mood Dysregulation Disorder

Temper Outbursts

- Are verbally and/or behaviorally disproportionate to the situation
- Are developmentally inappropriate
- Occur ≥3 times per week
- Occur in a child who is irritable or angry between tantrums
- Last for a defined time period
- Are not related to other mental health issues such as depression, medication, medical, or neurological conditions

Derived from *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition.

Laboratory Tests

No laboratory tests are indicated in the assessment of the child with temper tantrums. Routine tests that are age-appropriate and suggested as part of health maintenance are appropriate.

Management

Health maintenance visits are an ideal time to provide anticipatory guidance on tantrums and discuss strategies to prevent or minimize this behavior. Parents typically report that their children become defiant and difficult to manage during the "terrible twos." At the 12- and 15-month visits, the physician should alert parents that this period is approaching and remind them that it is a normal part of development. Preventive strategies should be discussed, such as childproofing the home to minimize unnecessary conflicts. Additionally, parents can give young children frequent opportunities to make choices, such as which color shirt to wear or which of 2 foods to have for lunch. These opportunities allow children to exercise independence and autonomy in a positive rather than a negative manner. The physician can provide reassurance that this unpleasant stage will pass; children eventually become more cooperative and agreeable. Punishment is not the solution to temper tantrums (see Chapter 50).

A parent may inadvertently reinforce negative behaviors by primarily giving attention to the child during the moments the child is misbehaving. Setting aside special time between parent and child on a regular basis gives children a close connection with parents without having to misbehave. Similarly, *time-in* is a strategy in which the parent, upon noticing that the child's behavior is beginning to escalate, spends 5 to 10 minutes soothing and comforting the child in an effort to mitigate the emerging negative behavior.

Parents should be advised that helping children learn self-control and how to manage anger are keys to managing temper tantrums. To expect that a child will never become angry is unrealistic. Instead, children should be taught how to vent their anger and frustration in an acceptable manner, such as articulating their feelings or hitting a designated punching bag or pillow. As children mature, their ability to verbalize their feelings increases, but even young children can say, "Me angry." Physicians should emphasize that it is important for parents to remain calm during children's temper tantrums. Shouting and spanking indicate to children that parents are also out of control. Children feel more secure if the adults around them are calm and in control.

Different types of temper tantrum may require specific treatment and management strategies. A parent can prime a child by outlining expectations before common triggers occur, such as explaining before going to into a store that they are not going to buy a toy. Parents should be supportive of a child who is having a tantrum resulting from frustration or fatigue by letting the child know that the parent understands. The child's energy should be redirected into activities the child can do well. Parents should be encouraged to praise positive behavior, for example, completing tasks properly or managing anger in an acceptable fashion. They should ignore some tantrums, such as those for the purpose of attention seeking or wanting something. The child with no audience has no need to perform. Time-outs may also be used in such situations (see Chapter 50). Parents should not give in to children's wishes, because doing so may reinforce tantrum behavior. Physical movement of children to where they belong may be necessary if they are refusing to do something (eg, bed for the child who is refusing to go to sleep at bedtime) or in danger of hurting themselves. Holding children who are raging may give them a sense of security and help calm them. If temper tantrums occur outside the home, it may be necessary to accompany children to a quiet, private place, such as an automobile, until they calm down. Distracting children by suggesting another activity or pointing out something of interest in the environment may also interrupt the unwanted behavior. Corporal punishment is associated with increased aggressive behavior and loses potency with repeated administration. The American Academy of Pediatrics strongly discourages striking a child, including spanking.

If parents continue to struggle with their child's temper tantrums, referral to a parenting program should be considered (Table 51.1). Several parenting programs have demonstrated efficacy in decreasing disruptive behaviors and temper tantrums and may be available at community centers, parent support centers, and mental health facilities.

Table 51.1. Programs for Parents of Children With Temper Tantrums

Name of Program	*Child Eligibility*	*Comments*
The Incredible Years (www.incredibleyears.com)	Different groups for infant, toddler, preschool, and school age (up to 12 years)	Parenting classes provided in small group setting Course duration is 12–20 weeks Includes children's group for older children Programs also available for teacher training
Triple P—Positive Parenting Program (www.triplep.net)	Birth–16 years of age Multiple delivery methods to match specific needs Separate modules available for children with disabilities, medical concerns, and divorce	Range of services, including public seminars, telephone consultation, targeted counseling, small group learning sessions, online instruction, and 1-to-1 consultation
Parent-Child Interactive Therapy International (www.pcit.org)	Treatment modality for children with attention-deficit/hyperactivity disorder, oppositional defiant disorder, and conduct disorder	Averages 14 sessions lasting 1–2 hours each

CASE RESOLUTION

The child seems to be having normal, age-appropriate tantrums. The boy's tantrums occur when he is asked to do something that he does not want to do. In these situations, the parents should try to ignore the tantrums as much as possible and not give in to the child's wishes.

CHAPTER 52

Breath-Holding Spells

Geeta Grover, MD, FAAP, and Peter Jinwu Chung, MD, FAAP

CASE STUDY

A 15-month-old girl is brought to the office because of parental concern about seizures. In the past month she has passed out momentarily 3 times. Each episode seems to be precipitated by anger or frustration on her part. Typically, she cries, holds her breath, turns blue, and passes out. Each time she awakens within a few seconds and seems fine. The medical history and family history are unremarkable, and the physical examination is entirely within normal limits.

Questions

1. What are breath-holding spells?
2. What is the differential diagnosis of breath-holding spell?
3. What, if any, laboratory studies are indicated in the evaluation of breath-holding spells?
4. What measures can be taken to prevent breath-holding spells? Are anticonvulsant agents necessary?
5. What are the effects of breath-holding spells on family functioning?
6. What, if any, are the long-term sequelae of breath-holding spells?

Breath-holding spells (BHSs) are a benign, recurring condition of childhood in which anger or pain produces crying that culminates in noiseless expiration and apnea. The frequency of BHSs, which are involuntary phenomena, is variable and ranges from several episodes a day to only several episodes per year. Although the spells are innocuous, they usually provoke fear and anxiety among parents and caregivers because children often turn blue and become limp. The diagnosis usually can be made on the basis of a characteristic history and description of the episode; however, the possibility of seizures should be considered.

Epidemiology

Breath-holding spells occur in approximately 5% of all children between ages 6 months and 6 years, but they are most common in children between 12 and 18 months of age. Most children with BHS will have experienced their first episode by 18 months of age and nearly all will have done so by 2 years. Although BHSs have been described in children younger than 6 months, occurrence in such young infants is uncommon. Boys and girls are affected equally. Approximately 25% of patients have a positive family history for BHSs.

Clinical Presentation

The typical clinical sequence of the major types of BHSs is described in the Pathophysiology section of this chapter and in Box 52.1. After a spell, the child may experience a short period of drowsiness.

Pathophysiology

Breath-holding spells may be classified as 1 of the nonepileptic paroxysmal disorders of childhood. These recurrent conditions, which have a sudden onset and no epileptiform focus, resolve spontaneously. Other disorders in this heterogeneous group include syncope, migraine, cyclic vomiting, benign paroxysmal vertigo, paroxysmal torticollis, sleep disorders (eg, narcolepsy, night terrors, somnambulism), and shudder attacks.

The 2 major types of BHS are cyanotic and pallid. Approximately 60% of children with BHS have cyanotic spells, 20% have pallid spells, and 20% have both types. Most commonly, affected children experience several spells per week. Approximately 15% of children with BHSs have complicated features. Complicated BHSs are defined as a typical BHS followed by seizure-like activity or rigid posturing of the body. Unlike the postictal period of epileptic seizures, prolonged periods of lethargy or drowsiness following spells are uncommon.

Pallid spells are similar to cyanotic BHSs with some exceptions. Pallid episodes are more commonly provoked by minor injury, pain, or fear rather than frustration or anger; the initial cry is minimal prior to apnea and loss of consciousness; and children become pale rather than cyanotic. In pallid BHSs, children often lose consciousness or tone after only a single gasp or cry, whereas in the cyanotic form, the period of apnea prior to loss of consciousness is much longer.

Etiology

Although the spells are triggered by identifiable stimuli, they are involuntary phenomena. It is believed that loss of consciousness in the cyanotic and pallid forms is caused by cerebral anoxia. The mechanisms of the 2 types of BHS are different. The processes involved in cyanotic BHS are not clear. Proposed mechanisms include centrally mediated inhibition of respiratory effort and altered lung mechanics, which may inappropriately stimulate pulmonary reflexes, resulting

Box 52.1. Diagnosis of Breath-Holding Spells

- Identifiable precipitating event or emotion
- Brief duration
- Color change, if present, prior to loss of consciousness and rhythmic jerking of extremities
- Rapid restoration of full activity
- Normal neurologic examination

in apnea and hypoxia. In the pallid form, the pale coloration and loss of tone are thought to result from vagally mediated severe bradycardia or asystole. Pallid spells have been spontaneously induced in the electroencephalogram (EEG) laboratory using ocular compression to trigger the oculocardiac reflex. Vagally mediated bradycardia or asystole lasting more than 2 seconds has been produced by this maneuver.

An association between iron deficiency anemia and BHSs has been recognized for many years but is poorly understood. It may be related to the importance of iron in the function of various enzymes and neurotransmitters in the central nervous system or because children with anemia have decreased cerebral oxygenation, making them more susceptible to BHSs.

Although children with BHSs have not been shown to have higher rates of psychiatric conditions compared with their otherwise healthy peers, they are more likely to exhibit difficult temperamental traits, including increased intensity of reactions and general states of anger, annoyance, and/or irritability. Mothers of children with BHSs have been shown to have higher rates of anxiety, depression, stress, and family functioning problems than mothers of children without BHSs. Breath-holding spells are also associated with stressful life events during pregnancy, although the mechanism and directionality of this association is not known.

Differential Diagnosis

The differential diagnosis primarily includes seizures and syncope secondary to cardiac arrhythmia or a vasovagal episode. Although vasovagal syncope, like BHS, may be provoked by fear or pain, it is uncommon in children younger than 12 years. Three factors may help differentiate BHSs from true epileptic seizure activity. First, spells usually are provoked by some upsetting event or emotion, unlike seizures, which generally lack a recognizable precipitating event. Second, episodes are brief in duration and are followed by rapid restoration of full activity. Third, color change precedes loss of consciousness and rhythmic jerking of the extremities, whereas in the typical epileptic seizure, convulsive activity and loss of muscular tone usually precede change in color. Box 52.2 shows the differential diagnosis of BHSs.

Evaluation

History

History alone may be diagnostic (Box 52.3). A family history of BHSs should be obtained. It is essential to record a detailed history of the suspected breath-holding episode. The sequence in which the events occurred may help differentiate BHSs from epileptic seizures.

Box 52.2. Differential Diagnosis of Breath-Holding Spells

Central Nervous System
- Seizures (ie, epilepsy)
- Occult or overt brain stem lesions (causing dysfunction within the pontomedullary area)
- Benign paroxysmal vertigo

Cardiovascular
- Cardiac arrhythmia (eg, long QT syndrome)
- Syncope (orthostatic or vasovagal)

Miscellaneous
- Gastroesophageal reflux/Sandifer syndrome
- Cataplexy (ie, transient loss of muscle tone associated with narcolepsy); rare before adolescence)
- Central or obstructive apnea
- Factitious disorder imposed on another (ie, Munchausen syndrome by proxy)

Box 52.3. What to Ask

Breath-Holding Spells
- What happened before the episode?
- Was the child crying?
- What was the child's color before and during the episode?
- Was the child lethargic after the episode?
- Does the family have a history of breath-holding spells?

Physical Examination

The child should undergo a complete physical examination, including a thorough neurologic evaluation. Focal neurologic signs or evidence of structural lesions, such as meningomyelocele or hydrocephalus, may be suggestive of a diagnosis other than BHSs.

Laboratory Tests

If the history is consistent with BHSs and the physical examination is normal, laboratory evaluation is usually unnecessary. Because of the association of BHSs with iron deficiency anemia in some children, it is appropriate to determine a hemoglobin level. An EEG may be obtained if the physician is concerned about the possibility of epileptic seizures. The interictal EEG is normal in the child with BHSs, whereas it is often abnormal in the child with epilepsy. In both forms of BHS, during attacks the EEG shows generalized slowing followed by flattening; this pattern is characteristic of cerebral anoxia. It is unusual to capture a BHS during the EEG, however. Simultaneous EEG and video recordings can be quite useful in helping to distinguish BHSs from seizures, especially in the child with

frequent episodes. An electrocardiogram may be obtained if there is any question about cardiac arrhythmia (eg, long QT syndrome).

Management

Management of BHSs includes parental support and reassurance. Breath-holding spells may be extremely frightening for parents to witness, especially if the episodes are routinely associated with loss of consciousness or seizure-like activity. Parents should be told of the involuntary nature of the attacks and cautioned against reinforcing the spells by giving in to the child's wishes. They should be advised to avoid unnecessary confrontations with the child. It is impossible to ensure that the child will never be frustrated or injured, however. Instead, parents should be encouraged to address the episodes in a matter-of-fact manner and continue using age-appropriate discipline. They should be reassured that the long-term prognosis is excellent. Research has demonstrated that psychoeducation about the disorder can reduce the level of anxiety, depression, and stress experienced by the caregivers; therefore, the physician may wish to consider screening caregivers for mental health concerns and referring them to the appropriate supportive services.

For a subset of children with iron-deficiency anemia and BHSs, iron therapy may be effective in the management of cyanotic and pallid BHSs. More recent research has demonstrated that iron supplementation, even in the absence of iron deficiency/insufficiency, may be effective in reducing the frequency of BHSs.

Referral to a neurologist, cardiologist, or psychiatrist may be considered for the child with frequent episodes or for complex cases. Pharmacologic therapy usually is not necessary, but atropine sulfate may be considered in the treatment of children with frequent pallid BHSs because of the anticholinergic action of atropine. Anticonvulsant agents are not effective. Successful cardiac pacemaker implantation has been performed for complex cases of pallid BHSs with severe and frequent spells associated with seizures, life-threatening bradycardia, or asystole. Case reports have noted the successful management of pallid BHSs with fluoxetine or a combination of glycopyrrolate and theophylline in small cohorts of patients. Finally, several blinded, randomized controlled trials performed outside the United States have demonstrated efficacy of piracetam in the management of BHSs, although this medication is not approved for any use by the US Food and Drug Administration.

Prognosis

Breath-holding spells resolve spontaneously in most children by 5 to 6 years of age. Approximately 50% of cases resolve by 4 years of age, and 90% resolve by 6 years of age. Neither pallid nor cyanotic BHSs are associated with an increased risk for developing epilepsy, although children with pallid BHSs do have an increased incidence of developing syncopal attacks in adulthood.

CASE RESOLUTION

The child has a history and physical examination suggestive of BHSs. The girl's episodes are consistent with cyanotic BHS. The episodes are preceded by an identifiable emotion, brief in duration, and followed by a rapid recovery of normal consciousness and activity. Assessment of the hemoglobin level revealed mild iron deficiency anemia. The child received iron therapy, and the parents were reassured about the benign nature of BHSs.

CHAPTER 53

Fears, Phobias, and Anxiety

Carol D. Berkowitz, MD, FAAP

CASE STUDY

A 5-year-old girl is brought into the office by her mother, who complains that her daughter has been afraid to sleep alone since the occurrence of an earthquake. The house did not sustain any significant damage, but the entire family was awakened. The mother says that the girl has become more timid. As nighttime approaches, she becomes particularly fearful. She will not stay in her bed, and she is comforted only by sleeping with her parents. In addition, the girl has begun bed-wetting since the earthquake, and the mother wonders whether she should put her daughter in diapers. The physical examination, including vital signs, is normal, except for the observation that the child is very clingy and whiny.

Questions

1. What are normal childhood fears and when do these fears commonly occur?
2. What strategies are used to deal with these fears?
3. What are phobias? What are social phobias?
4. What is school phobia, and how is it best handled?
5. What are common anxiety disorders in children and adolescents?
6. How can families deal with childhood disturbances that emerge after natural and artificial disasters?

Fears are normal feelings that cause emotional, behavioral, and physiological changes that are essential for survival. Fears are associated with psychological discomforts, such as a negative, unpleasant feeling. Children may develop fears in response to actual events (eg, earthquakes) or as a result of the temporal association of 2 events (eg, seeing a scary movie on a rainy day and then becoming afraid of rain). Some fears seem to be innate, and others seem to be developmental. Children fear different things at different ages. For example, school phobia is sometimes particularly problematic in young, school-age children. Worry is the cognitive manifestation of fear and anxiety.

Phobias are overwhelming, intense, highly specific, and often irrational fears. The *Diagnostic and Statistical Manual of Mental Disorders,* 5th Edition, defines a *phobia* as excessive anxiety accompanied by worry occurring more often than not, for at least 6 months and associated with 1 or more of the following: restlessness, easy fatigability, difficulty concentrating, irritability, tense muscles, and disturbed sleep. Childhood phobias can be divided into 5 categories: animals (eg, spiders, snakes, dogs), natural environment (eg, heights), medical related (eg, doctors, dentists, injections), situations (eg, flying), and other (eg, loud noises, rain, thunder). Specific phobias are often managed by avoidance and may not present to the physician for treatment. Social phobias (also called social anxiety disorders) are specific to social situations that arouse intense concerns about humiliation or embarrassment. Fear of speaking in public may represent a social phobia. Selective mutism involves children who are able to speak but are unable to do so in certain settings, such as school. This probably represents 1 form of a social phobia. When these fears are combined with avoidance behavior, they may be incapacitating. *Anxiety* refers to fear without a definable source. It is characterized by a physiological response and may be perceived as a vague feeling of uneasiness, apprehension, and foreboding of impending doom. A child may experience an anxiety problem where there is significant but not severe distress and an anxiety disorder when the distress is excessive or functioning is impaired. Fifteen percent to 20% of youths have anxiety disorders, the most prevalent psychiatric condition in children and adolescents. Girls are twice as likely to develop anxiety disorders as boys. There is often a positive family history of anxiety disorders, which is felt to be related to a genetic predisposition and environmental factors. Children with autism spectrum disorder have an increased incidence of anxiety and anxiety-related disorders (see Chapter 132).

Different strategies are useful for dealing with different fears. It is important for parents not to trivialize these fears or reinforce them but to empower children to deal with them.

It is also important to realize that parents sometimes foster fears by using threats with children, such as, "The doctor will give you a shot unless you eat your spinach," or "The boogeyman will get you." By fostering fears, the parents are also fostering dependency. Parents lack the imagination that children have and find it difficult to understand the degree of fear that children experience.

The opportunities for primary care physicians to counsel families about childhood fears has increased over the past decades related to a number of catastrophic events, such as the terrorist attacks of September 11, 2001 (9/11), hurricanes Katrina and Sandy, the earthquake in Haiti, the tsunami in Sri Lanka, and tornados in the midwestern United States. Acts of violence, such as multiple mass shootings, often at schools (eg, Columbine, Sandy Hook, Virginia

Tech, Marjory Stoneman Douglas High School), also create fear and anxiety in children and adolescents who witness these events on television and through messages posted on social media. It is important to recognize the pervasiveness of mental health sequelae following disasters and the factors that influence the prevalence of these disturbances. One percent of children in New York, NY, lost a relative on 9/11. There is a greater risk of mental health sequelae if there are poor social supports or a prior history of psychopathology or if the child is fearful or shy by nature. Natural disasters have a lesser effect than intentional ones. While many of the recent disasters have been acute and unexpected, there are children who are continuously exposed to what has been called "process trauma" in the form of war, detention of children and families seeking political asylum in the United States, and child abuse.

Epidemiology

Fears follow a developmental pattern (Box 53.1). Neonates are believed to have no fear, although young infants whose faces are covered with a blanket struggle to toss off the blanket. Infants who are 6 months of age exhibit what is known as *stranger anxiety* in response to unfamiliar persons, places, or objects. To combat this anxiety, infants seek refuge with a parent. Stranger anxiety becomes equated with separation anxiety and reaches a peak at 2 years of age. Children between 6 months and 2 years of age are also frightened by loud noises and falling or quickly moving objects.

Children between the ages of 2 and 5 years are in what is termed the *age of anxiety*. They fear many things, including animals, abandonment, loud noises, and darkness. Children in this age group are particularly fearful of physicians, hospitals, and getting hurt. Young children are afraid of those who are physically disabled, who represent bodily injury, and monsters and scary movies. They sometimes displace their anger onto monsters and witches and attribute to these imaginary characters the bad feelings they are experiencing. Children in this age group have strong imaginations, which makes it difficult for them to differentiate fantasy from reality.

Children between 6 years of age and adolescence tend to have more abstract thoughts, and their fears are less relevant to physical immediacy. These children are afraid of the death of their parents or the burning of their home. They also fear war, growing up (expressed as "How will I know what to do?"), going into the next grade, being alone or kidnapped, and the divorce of their parents. Children in this age group are often reluctant to bother their parents with their fears, and they can easily misinterpret parental concerns when they overhear parental conversations. *Separation anxiety*, which may manifest as school phobia and may be referred to as separation anxiety disorder, may occur in school-age children. The prevalence is estimated at 3.2% to 4.1%, although up to 50% of third graders report separation anxiety symptoms. *Separation anxiety disorder* is defined as developmentally inappropriate, excessive anxiety precipitated by actual or anticipated separation from home or family. Affected children develop physical complaints (eg, stomachaches) on school days. The parent-child relationship may be disturbed or made insecure (eg, marital discord, maternal illness), and the child is fearful of leaving the parent alone. Childhood school phobia and parental history of panic attacks and agoraphobia may be associated.

Fears during adolescence relate to social functioning, such as public speaking or talking to members of the opposite sex. Older children are also concerned about school failure and physical injury. They have many of the same fears expressed by school-age children, although phobias are uncommon. Social phobia is a distinct entity and is different from shyness, as reported in a recent study of adolescents. Social phobia is a potentially impairing psychiatric disorder. Overall, phobias occur in less than 1.7% of the general population but are reported in 13% of children with other emotional or behavioral problems.

Anxiety disorders are rare in childhood but more common during adolescence. They may include panic attacks, which involve the sudden onset of intense fear or discomfort associated with physiological symptoms such as palpitations and shortness of breath. Fear about a panic attack may lead to agoraphobia (ie, the avoidance of going away from home). Posttraumatic stress disorder (PTSD) involves a set of symptoms that recurs after a person has experienced a traumatic event. Symptoms include intense fear, helplessness, or a sense of horror. The person reexperiences the trauma, avoids circumstances that are reminiscent of the trauma, and is in a state of hyperarousal. It is estimated that 5% of men and 10% of women have a lifetime prevalence of PTSD.

Box 53.1. Common Fears During Childhood

- Neonates: no fears
- 6 months–2 years: separation anxiety, loud noises, quickly moving objects, the dark
- 2–5 years (ie, age of anxiety): animals, abandonment, loud noises, darkness, physicians, hospitals, getting hurt, monsters, witches, ghosts, storms
- 6 years–adolescence: death (parental death), parental divorce, natural and artificial disasters, growing up, school performance (going into the next grade), war
- Adolescence: social situations, school performance, health, public speaking

Pathophysiology

Fear has its basis in a series of psychophysiological reactions, which are mediated through a series of neurotransmitters. The reaction is often referred to as the fright/flight response and is critical for survival. The response is regulated through the limbic system. Elevated levels of certain transmitters, such as γ-aminobutyric acid and norepinephrine, are associated with feelings of anxiety. Excess serotonin has also been related to anxiety disorders.

Studies on the neurobiology of pediatric anxiety disorders demonstrate dysfunction in the amygdala prefrontal-based circuits. The amygdala is responsible for the initiation of the central fear response and is noted to be "overactivated" in magnetic resonance imaging of

individuals with anxiety disorders. The prefrontal area helps regulate amygdala activity. Other areas of the brain have also been implicated in anxiety disorders in youth.

Differential Diagnosis

The challenge for physicians is to assess the etiology of the fear and to differentiate normal fears from those that may be signs of unusual stresses or signs of psychopathology. Appropriate fears represent a real reaction to a real danger. As a rule, children are more resilient than adults and recover more rapidly from traumatic events. However, children are prone to inappropriate fears, which may develop for a number of reasons.

Inappropriate fears may occur because of operant conditioning, in which a conditioned stimulus becomes associated with another object. Fear of the other object becomes reinforced through this association. Inappropriate fears may also develop in a child whose parent has the fear (modeling) or through witnessing a fearful event in the media (informational). True phobias represent neuroses and may occur in more than 1 family member.

School phobia, also called school refusal, may occur under 3 distinct conditions. Not uncommonly, young children who are entering school for the first time are frightened. This fear is a normal component of separation anxiety, which usually resolves within a few days of starting school. This is also referred to as adaptive anxiety. In contrast, older children may experience school phobia because they are truly afraid of a school situation. They may fear a teacher, violence, or a bully. To avoid the problem, children may actually request to change classrooms or schools. It is important to talk with children to find out what is behind their fear of school.

Some children who seem fearful of school, however, are actually concerned about parental separation (ie, separation anxiety). Frequently, these children enjoy school and miss it when they are absent. Absences occur when children's feelings of separation from parents are so intense that they do not allow them to function well in school settings. Children are worried that something bad will happen to them or to their parents when they are apart. This separation anxiety disorder may result from parental illness or parents' fostering dependency in children. Children then see parents as vulnerable and are uncomfortable about leaving them alone. To qualify as an anxiety disorder, the symptoms must last at least 4 weeks.

School phobia is the third leading cause of school absenteeism after transient illness and truancy. Fifty percent of children with school phobia have other problems, including depression (28%), tantrums (18%), sleep disturbances (17%), obsessive-compulsive behavior (11%), other fears (10%), enuresis (3%), and learning disabilities (3%). Overall, school phobia has a good prognosis, although adolescents do not do as well as younger children, and individuals with a higher IQ have a poorer outcome. Twenty percent of parents of children with school phobia have a diagnosable psychiatric disorder. Issues of parent-child dependency are often a concern.

Another type of childhood fear concerns physicians and hospitals. Children have many concerns about what happens to them at the doctor's office. They are particularly fearful of needles. To children, needles represent possible mutilation. When asked to represent needles in drawings, children often portray needles as larger than themselves and very pointed. They comment that needles are sharp (eg, "Needles can make you pop, just like a balloon"; "Needles can also take out all your blood until you die"). In addition, children are preoccupied with what happens to their blood. One youngster commented, "They check out your blood to see if it's good or bad, and if your blood is bad, then it means that you need to have more tests." Another youngster thought that physicians were doing a "blood taste" rather than a blood test.

Hospitalization raises other issues concerning parental separation as well as painful procedures. As children adjust to hospitalization, they progress through 3 stages: protest, during which they complain about the hospital and cry; despair, during which they have given up hope that their parents will return; and detachment, during which they seem to be adjusting but actually have distanced themselves from their parents. Unrestricted visitation by family members and involvement of child life specialists mitigates much of the distress.

Evaluation

Physicians should explore the area of childhood fears and phobias at routine health supervision visits, even if parents do not have specific concerns. Sometimes parents are embarrassed by children's fears (eg, the fear of an older child to sleep without a night-light; the fear of dogs, which may preclude the child from visiting certain friends). Parents may not report children's fears unless these fears seem to be unusually intense. Practitioners may ask children, "What is the scariest thing you can think of?" If children are having difficulty providing details, physicians may ask them to name things that other children fear or to complete the sentence, "I feel afraid when...." Alternatively, practitioners may suggest things that other children may fear: "Do the kids you know seem to be worried about kidnapping?"

Several instruments have been used to assess the level of anxiety in children. These include the *Multidimensional Anxiety Scale for Children,* 2nd Edition; *Spence Children's Anxiety Scale*; and Screen for Child Anxiety Related Disorders. The latter instrument is in the public domain and readily available. It includes statements for children (eg, "I get scared if I sleep away from the house") that are then scored "Not True or Hardly Ever True" (0), "Somewhat True or Sometimes True" (1), and "Very True or Often True" (2). There is a separate page for parents that includes similar statements framed as, "My child gets...", rephrasing the statement that their child rated. Scores are added up and the total score, plus the items that scored high, help distinguish the nature of the anxiety; a score of greater than 25 indicates an anxiety disorder, with subcategories including panic disorder or significant symptoms, generalized anxiety disorder, separation anxiety disorder, social anxiety disorder, and significant school avoidance. Another instrument is a book called, *What to Do When You Worry Too Much: A Kid's Guide to Overcoming Anxiety.* This book suggests a number of strategies (eg, setting up a worrying time, not worrying if it's not the designated time) in addition

to discussing the origin of different worries (eg, "How do worries get started?").

History

The evaluation of children with specific fears demands a careful history that provides information about situations in which children are fearful (Box 53.2). Physicians should consider fears within a developmental context because many childhood fears are normal and experienced by all children. It is also important to look at changes in the family situation. Children sometimes develop what seem to be fears but in fact are behaviors designed to manipulate other family members. For instance, young children who sense marital discord may insist on sleeping with their parents as a way of ensuring that the parents are together rather than separate.

Physical Examination

A routine examination is warranted, but findings are usually normal. Such an evaluation, however, is particularly important if presenting complaints include symptoms such as abdominal pain, headache, or palpitations.

Laboratory Tests

As a rule, laboratory tests are not required unless the symptoms suggest an organic etiology, such as hyperthyroidism, as the cause of palpitations.

Management

Management of the fear or phobia is determined by the degree to which children are incapacitated. As a general rule, children should be empowered to conquer their fears. Children's books that address the issues of certain fears can help achieve this empowerment; for example, *The Berenstain Bears in the Dark* discusses specific worries such as fear of lightning and thunder. These books often explain the basis of such natural phenomena in easy-to-understand terms. Books also normalize particular fears and show how 1 character is fearful. Parents can recreate some of the sounds that children fear. For example, children who are afraid of the noise the wind makes are shown a teakettle from which hot steam blows through the whistle, creating the same noise as the wind. For fears about nuclear war, empowering children to become active, such as joining a nuclear protest group, may be useful.

Box 53.2. What to Ask

Fears and Phobias

- What fear does the child have? Exactly what does the child fear?
- Under what circumstances was the fear originally expressed? Did any changes in the child's life occur around the time that the fear appeared?
- Under what conditions is the fear currently expressed?
- How long has the child had the fear?
- How does the fear affect the daily living of the child and family?
- What has the family done to help the child deal with the fear?

Parents may feel helpless because they do not know how to deal with children's fears. Physicians should give them the necessary information. Children's fears should not be trivialized. Even if the fears are unfounded, they should be validated. When discussing fears with children, parents should always provide physical comfort and help children develop a sense of safety and security. In general, children should be questioned about whether they are fearful about a situation. The following 2 examples illustrate the proper handling of fears in children:

If children are visiting the dentist for the first time, it is appropriate for parents to ask, "Are you afraid?" If children reply, "Yes, a little bit," parents can say, "Almost everybody is afraid. Tell me what it is you're afraid of. Fear is a normal emotion, and I'm glad you told me about it."

Parents of children who express fear of imaginary characters can reassure children that they do not exist. In addition, parents can tell children what the parents would do if such characters did exist. For instance, the father of a little girl who was afraid of witches told her, "There are no such things as witches. But if there were, and they came into your room, I would punch them in the nose and punch them in the stomach and beat them up, and then there would be no more witches to hurt you." For those who would opt for a less violent approach, the parent could state: "I would tell any witch who came into your room, 'STOP! Go away. No witches allowed in here.' And the witch would run away, and I would slam the door!" By doing this, parents establish the reality of the situation and then also create a plan to deal with the problem should it actually happen.

Parents can also help to limit or reduce children's fears by minimizing their exposure to fear-provoking situations such as television shows or scary movies. These programs can be particularly frightening for some children, who should not watch them without adult supervision. Minimizing exposure to television is particularly important following a disastrous event. The recurrent images of planes flying into buildings on 9/11 were interpreted by children as repeated different attacks. Watching the nightly news can be anxiety provoking not only for children but for their parents. Even if a family chooses not to watch the evening news, "breaking news" including graphic images often appears on cell phones and other electronic devices automatically, intruding during the school day.

When dealing with children who have school phobia because of problems in school, it is important to determine if a change in school would be appropriate to facilitate their school attendance. This may be particularly appropriate in children whose schools are plagued with violence.

Cognitive-behavioral therapy (CBT) is reported to have the highest rate of success for dealing with anxiety-related conditions. Cognitive-behavioral therapy includes psycho-education, somatic management (eg, relaxation techniques), cognitive restructuring (ie, modifying negative thoughts), and exposure methods, including desensitization. The goal of the therapist is to teach the child alternative ways of viewing the feared object and of coping with the fear itself. Social Effectiveness Therapy for Children and Adolescents is geared to specifically address social phobia (social anxiety disorder).

Studies have demonstrated it is more effective than placebo and superior to fluoxetine on certain measures of social functioning. Mindfulness-based psychotherapies have also been incorporated into the management of anxiety disorders. The focus is on the development of mindfulness skills to help mitigate the symptoms associated with anxiety.

Medications such as antidepressants, anxiolytics, sedatives, and beta blockers have an unsubstantiated role in managing phobic disorders in children but may be indicated in other conditions, such as anxiety disorders.

When school phobia is linked to separation anxiety, a program of *desensitization or habituation (graded exposure)* is recommended. Desensitization may involve the participation of parents in the classroom for a time. When children acclimate and can tolerate some separation, mothers move to another area in the school, such as the principal's office. Next they go outside the school grounds. As children reestablish a sense of well-being in spite of the separation, the mothers gradually move farther and farther away. This solution is somewhat problematic for mothers who work outside the home. There is some research to suggest that children adjust more readily if they resume school immediately without the gradual withdrawal of their parent. Children with significant school phobia may need the assistance of child psychologists or psychiatrists.

Phobias may be treated using the concept of *flooding*, which consists of rapid, prolonged exposure to the feared item. For example, a child who is afraid of dogs is exposed to a friendly, docile, small dog while in the company of the child's parents. Alternatively, systematic desensitization, during which children are exposed to the feared objects over a series of weeks, coupled with relaxation techniques, is also used. Phobias usually require the help of mental health specialists. Selective serotonin reuptake inhibitors (see Chapter 134) have been found to be beneficial in the management of certain anxiety disorders in children and adolescents. They are noted to be effective for panic disorders, social phobia, generalized anxiety disorder, obsessive-compulsive disorder, and PTSD. Benzodiazepines are safe and generally used on a short-term basis. Sedation is a frequent side effect, and there is the potential for misuse, tolerance, and drug dependence. Propranolol lessens the peripheral autonomic nervous system symptoms of social phobias and may be used for specific instances. Combined therapy involving CBT and medication is beneficial in some patients.

Children who must undergo hospitalization benefit from a prehospital visit, when possible. This visit familiarizes the child with the facilities and explains proposed procedures. Many hospitals have child life specialists who ease the adjustment of children as well as their parents to the hospital stay.

Prognosis

Most childhood fears resolve with time, nurturing, and reassurance. Most fears last only several weeks, and then new fears may develop. As a rule, specific fears should not last longer than 2 years, and the younger the child, the shorter the duration of the fear.

Prognosis is good for children with true phobias, with 100% resolution of monosymptomatic phobias. More significant anxiety disorders may persist into adulthood, at which time similar management involving CBT and medications may be indicated. Persistent anxiety disorders are associated with increased morbidity, including an increased risk for self-injurious behavior and suicide. Early recognition and appropriate management can significantly affect the prognosis of this common pediatric disorder.

CASE RESOLUTION

The girl's fear of sleeping in her bed was triggered by a significant environmental event. Although earthquakes are uncontrollable, the girl can be empowered to cope with manageable aspects of an earthquake as much as possible. She should be assured that in the same situation, many adults probably would also fear sleeping alone. The parents should stock a box with shoes, a flashlight, a radio, and water and place the box under the child's bed. In addition, they may have their daughter get into her bed and then shake it, simulating the jiggling that she would experience during an earthquake. The girl should also practice getting out of bed and standing in the doorway. To combat the child's fear of separation during times of natural disaster, the parents should reassure their daughter that they will all be together.

CHAPTER 54

Thumb-sucking and Other Habits

Carol D. Berkowitz, MD, FAAP

CASE STUDY

A 5-year-old boy is brought to the office because of thumb-sucking. His mother claims that she has tried nearly everything, including tying his hands at night and using aversive treatments on his thumbs, but nothing has worked. She reports that her son has been teased at school and has few friends. He is in good general health, and his immunizations are up-to-date.

His growth parameters are at the 50th percentile. Except for a callus on the right thumb, the physical examination is normal.

Questions

1. What are common habits in children?
2. What is the significance of transitional objects?
3. What are the consequences of common habits in children?
4. What are strategies used to break children of habits?
5. How are benign habits differentiated from self-injurious behaviors?

Habits are defined as somewhat complicated, repetitive behaviors that become automatized, fixed, and carried out easily and effortlessly. They are different from *tics,* which are rapid, repetitive muscle twitches involving the head, face, or shoulders. Tics are also referred to as habit spasms (see Chapter 130). Children have many habits that are characteristically discouraged, such as thumb-sucking, nail-biting, skin picking, nose picking, hairpulling (trichotillomania), rocking, biting other children, and teeth grinding (bruxism). Some habits, such as pica (the ingestion of nonfood substances), are potentially harmful. Children engage in most of these habits because of their soothing potential. In recent years, cutting, a form of self-injury in adolescents, has received attention. While not a habit in a traditional sense, cutting is described by teenagers as a way of dealing with stress and alleviating anxiety. One-third of children use transitional objects for comfort. Blankets or favorite toys are traditional transitional objects that represent an age-appropriate coping strategy. Most transitional objects are stroked, and the stroking often occurs in association with thumb-sucking. Transitional objects sometimes present a problem because children experience distress if these objects are lost or misplaced or need cleaning.

Epidemiology

Thumb-sucking probably represents the most common habit of children and is also reported in other primates, including chimpanzees. Up to 90% of children engage in this habit at some point. Prenatal ultrasonography has demonstrated in utero thumb-sucking in some fetuses. The median age for the onset of hand sucking is 54 minutes after birth, and 90% of newborns show hand-sucking behavior by the age of 2 hours. Forty percent of children between the ages of 1 and 3 years, 33% of children between the ages of 3 and 5 years, and 25% of children at the age of 5 years still suck their thumbs. Some children suck fingers rather than thumbs. Other oral behavior may involve lip sucking, lip biting, and toe sucking. Lip sucking and biting begin at about 5 to 6 months of age and occur in about 90% of infants. It is unusual for these actions to persist as habits. Toe sucking is noted in infants who are 6 to 7 months of age and is reported in 80% of typically developing infants.

Trichotillomania is a disorder once believed to be uncommon but now thought to affect 8 million Americans (about 5 in 1,000). The term, first coined in 1889 by French dermatologist Hallopeau, is derived from the Greek *thrix* (hair), *tillein* (pull), and *mania* (madness). The condition is an impulse control disorder in which alopecia develops from compulsive hairpulling. Hairpulling may involve hair from the head, eyebrows, eyelashes, or pubic area. Trichotillomania is reported from infancy into adulthood. In young children, boys and girls are equally affected, but in older children and adolescents, females outnumber males. In preschool-age children, trichotillomania is viewed as benign, similar to thumb-sucking. When the condition appears in older children (most common age of onset is between 9 and 13 years) the condition is more likely to persist into adulthood. The disorder is not associated with comorbid psychopathology, but there may be some association with mood disorders or attention-deficit/hyperactivity disorder. There is a condition in infants, called "baby trich," in which infants pull their mother's

hair when they are being held or nursed. This is considered typical exploratory behavior.

Rhythmic movement habits are stereotypical, repetitive behaviors that usually occur in infants younger than 1 year. Based on parental reporting, rhythmic movements are noted in up to 15% to 20% of the population. Rhythmic movements include rocking (about 19% of infants), when infants rock back and forth; jouncing (5%–10%), when they move in an up-and-down manner on their hands and knees so that the whole crib rocks; head rolling (8%); and head banging (5%). Rhythmic movements are seen more commonly in boys; the male to female ratio is 3:1. These habits usually occur with a frequency of 60 to 80 movements per minute, often when infants are tired, and last for less than 15 minutes before they fall asleep. In a recent study that used home videosomnography to assess the occurrence of sleep-related rhythmic movements in more than 700 infants and toddlers, the prevalence was significantly less, at only 2.87%.

Rhythmic movements have sometimes been referred to as *sleep tics*. These tics are reported in 20% of children, most often between the ages of 6 and 10 years. As a rule, tics are 3 times more common in boys than girls. They tend to be noted with increased frequency in children who are shy or overly self-conscious or have obsessive-compulsive tendencies. Tics usually occur when children are under stress.

Biting, an aggressive habit noted in toddlers, may be related to teething. It occurs more often in children with delayed language development.

Nail-biting (onychophagia) is deemed to be a sign of internal tension and affects 10% to 40% of children. Nail-biting begins between the ages of 3 and 6 years, and the peak age is 13 years. One-third of adolescents bite their nails, but 50% of these adolescents break the habit by the time they reach adulthood. When nail-biting persists into adulthood, it may be considered an oral compulsive disorder and classified under obsessive-compulsive and other disorders in the *Diagnostic and Statistical Manual of Mental Disorders,* 5th Edition (*DSM-5*). The family history for nail-biting is often positive. Identical twins are concordant for the condition in 66% of cases. In contrast, the incidence in dizygotic twins is 34%.

Nose picking, noted in children and adults, is reported in more than 90% of individuals. In general, adults and older children limit nose picking to when they are unobserved, but younger children will pick their noses in public. There are no sex-based differences in the prevalence of nose picking. Nosebleeds are the most common complication of nose picking (see Chapter 90).

Pica is defined as the ingestion of nonfood, nonnutritive products. The peak prevalence of pica is between the ages of 1 and 3 years. The prevalence is increased in children of lower socioeconomic status, and the behavior occurs in 10% of children who present with lead poisoning. To meet the *DSM-5* criteria, pica must persist for longer than 1 month at an age when eating such objects is developmentally inappropriate and not part of a culturally sanctioned practice. The word *pica* is derived from the Latin word for the magpie (picave), a bird attributed with eating anything. Patients with pica may prefer specific substances to ingest, such as ice (pagophagia), soil (geophagy), or stones (lithophagia).

Teeth grinding (bruxism) is reported in 5% to 15% of children and frequently occurs during sleep. Boys are more commonly affected than girls, and the disorder seems to regress later in life. It is reported with increased incidence among children with developmental delays, including those with autism spectrum disorder. The cause is unknown, although it may be associated with malocclusion in some children. There is some evidence that sleep bruxism in childhood is associated with an increased incidence of exposure to secondhand smoke. The disorder may contribute to temporomandibular joint dysfunction and pain.

Self-injury has been reported in up to 20% of adults with intellectual disabilities. Autism spectrum disorder and the absence of speech are the highest associated risk factors. Nail-biting, head banging, and self-biting are frequently described associated behaviors. Severe self-injury related to biting is seen in Lesch-Nyhan syndrome.

Clinical Presentation

Children with common habits, such as thumb-sucking or rhythmic movements, may be brought to the physician with these particular complaints because the parent wants advice about stopping the behavior. Other children may present with consequences of habits, such as alopecia (trichotillomania), paronychia (nail-biting), or lead intoxication (pica). Whitlow (infection of the tip of the finger; also called felon) and, rarely, osteomyelitis of the distal phalanx have also been reported with nail-biting. Osteomyelitis should be considered in a nail-biting child who presents with an abscess of the finger. Hairpulling can be associated with hair ingestion, also referred to as trichophagia. Trichobezoars that can complicate trichotillomania associated with trichophagia may present with gastric outlet or bowel obstruction. Symptoms then include abdominal pain, anorexia, early satiety, nausea, vomiting, halitosis, and weight loss (Box 54.1).

Pathophysiology

Children engage in habits to reduce stress and provide comfort. Thumb-sucking is related to nonnutritive sucking. Although the initial purpose of sucking is nutritional, the pleasure associated with sucking reinforces the behavior. Infants who are served from a

Box 54.1. Diagnosis of Habits in Pediatric Patients

Childhood Habits

- History of a habit
- Callus on thumb or fingers
- Short, chewed nails
- Alopecia
- Lead intoxication
- Iron deficiency anemia
- Tooth surface loss
- Masticatory muscle hypertrophy

cup from birth develop no interest in sucking. Humans and other primates spend more time in nonnutritive than in nutritive sucking. Monkeys use a 5-point hold, with 2 hands, 2 feet, and mouth (holding on to their mother's nipple) for attachment. Universal thumb-sucking is noted even in orphan monkeys, and sucking is thought to be an important aspect of environmental adaptation. Nonnutritive sucking occurs even in the absence of fatigue, hunger, or discomfort and has a purpose in itself—to provide comfort and be self-soothing. The maximum intensity of sucking occurs at 7 months of age. For older children (≥3 years), sucking is also a way of coping with boredom.

In bottle-fed infants, thumb-sucking seems to commence when feeding stops. Some infants, described as "type A," seem to be satisfied only when their thumb is in their mouth. As infants spend more time engaged in motor activity, they spend less time thumb-sucking. Placid infants who cry less also do less sucking. Some studies have shown that thumb-sucking is less common in breastfed infants and that thumb-suckers as a group feed less frequently (every 4 hours rather than 3 and for 10 minutes rather than 20).

Nail-biting is related to thumb-sucking, a form of oral gratification, and children may progress from thumb-sucking to nail-biting. The pattern of nail-biting usually involves placement of the hand in the vicinity of the mouth, tapping of the fingers along the teeth, quick spasmodic bites with the fingers around the central incisors, and the removal and inspection of the hands. Other oral habits, such as pencil gnawing, gum chewing, lip biting, and nail picking, are related activities, as is nose picking. The cause of teeth grinding is unclear but may be related to malocclusion.

Rhythmic movements are kinesthetically pleasing and soothing and a means of autostimulation. The etiology of hairpulling is less apparent. The *DSM-5* defines trichotillomania as chronic hairpulling often associated with hair ingestion. In recent years, investigators have linked trichotillomania to disorders of serotonin reuptake and placed it in the category of obsessive-compulsive behavior. Some individuals who engage in trichotillomania have abnormal findings on head positron emission tomography. Although the etiology of trichotillomania is unclear, affected children share certain features, which have been characterized as fiddling SHEEP (sensation, hands, emotion, environment, perfectionism). The overriding factor is a need for tactile stimulation. Pica, which is also considered abnormal, may be associated with intellectual disability, environmental deprivation, or inadequate nutrition, particularly iron deficiency. It may also have a cultural basis. Geophagy (ie, ingesting earth substances such as clay) was related to the ingestion of kaolin, found in clay, in individuals of west African origin. Such clay had antidiarrheal properties and helped treat dysentery and other intestinal conditions. This practice persisted in Georgia, which, following the slave trade, had a large population of descendants from west Africa. Adolescents with pica may experience stress relief when they ingest certain nonfood products.

Differential Diagnosis

The differential diagnosis of most habits is not difficult. Tics or habit spasms should be differentiated from *Tourette syndrome*, which is a neurologic disorder, reported in 1 in 3,000 children, characterized by severe, frequent, and multiple tics (see Chapter 130). These tics are also often vocal and consist of sounds such as hissing, barking, grunting, or coprolalia (repeating profanities). Some rhythmic habits may be mistaken for seizures but can be easily distinguished because of the stereotypical, repetitive nature of the behavior.

Trichotillomania usually has a classic physical appearance that has been referred to as *tonsure* (*Friar Tuck*) pattern baldness, with baldness around the vertex of the head. Unilateral temporal baldness is also a consequence of trichotillomania. The differential diagnosis of trichotillomania includes alopecia areata, tinea capitis, syphilitic alopecia, and androgenic alopecia (see Chapter 136). Broken hairs of variable length usually characterize alopecia secondary to trichotillomania. Other disorders in the differential diagnosis include traction alopecia, related to tight braids or hair brushing; atopic eczema; seborrheic dermatitis; hypothyroidism; systemic lupus erythematosus; and dermatomyositis. When trichotillomania is associated with a trichobezoar and signs of gastric outlet obstruction, the differential diagnosis includes neuroblastoma, lymphoma, and gastric carcinoma.

Cutting is not a benign habit, but it can provide stress relief, a feature of many benign childhood habits. It is usually associated with a wide range of mental and behavioral health issues, including depression; anxiety; eating disorders, especially bulimia nervosa; a history of prior sexual abuse; and obsessive-compulsive symptoms. The mechanism by which cutting alleviates stress and anxiety has not been elucidated, but the role of endogenous endorphins has been suggested. Cutting is felt not to represent suicidal behavior, but some studies differentiate the site of cutting as predictive of suicidality: Wrist cutters, as opposed to arm cutters, have a higher rate of suicidal ideation and attempts. All cutters are at greater risk for suicide than the general population. Management generally involves referral to a mental health specialist and the use of psychotherapy. Other forms of self-injury are reported with increased frequency among children with developmental disabilities, including autism spectrum disorder (see Chapter 132).

Evaluation

History

Children who present with thumb-sucking, nail-biting, and teeth grinding usually do not require an assessment other than a routine health supervision history and physical examination. The history should determine the specific circumstances when the habit is manifest. Is the habit more likely to emerge when the child is tired or stressed? Habits must also be evaluated in the context of the child's developmental level and home situation. Understanding the effect of the habit on the child and family is important. Children who present with movements that resemble tics should be carefully questioned about the frequency and duration of the tics, the effect of the tics on their behavior, and whether coughing is associated with the tics (sign of Tourette syndrome).

The occurrence of obsessive-compulsive mannerisms should also be noted (Box 54.2).

Physical Examination

A routine physical examination should be performed. The physical examination may reveal the sequelae of the habit, such as thumb calluses, candidal infection of the nails, or evidence of malocclusion with an overbite (Figure 54.1). Children with suspected trichotillomania should undergo a thorough assessment of their scalp in an effort to differentiate other causes of alopecia (see Chapter 136). A careful neurologic examination should be performed in children with tics, and referral to a child neurologist may be indicated in children with suspected neurologic disorders.

Laboratory Studies

Routine laboratory studies are not needed in children diagnosed with common habit disorders. Studies are indicated if the children have experienced complications from the habit. For instance, if osteomyelitis is suspected in a nail-biting child, magnetic resonance imaging would be the study of choice.

Children with trichotillomania should be evaluated for the disorders listed previously. An easy evaluation process for trichotillomania involves shaving the hair in the middle of the area of baldness. The growth of these small hairs is uniform because children are unable to pull them out. Head shaving may not be acceptable, however, to the parent or child. Disorders such as syphilis and collagen vascular diseases can be ruled out using appropriate laboratory studies. Fungal infections can be differentiated by the use of appropriate cultures. A Wood light examination may reveal fluorescence noted with certain fungal infections.

Children who present with pica should be evaluated for the presence of iron deficiency anemia and lead poisoning. If the history involves geophagy, testing stool or blood for parasites may be warranted, especially if a complete blood cell count reveals eosinophilia.

Box 54.2. What to Ask

Childhood Habits

- What about your child's habit concerns you?
- Is your child experiencing any adverse consequences (eg, being teased at school) as a result of the habit?
- What have you done to discourage your child from engaging in the habit?
- Does the habit interfere with your child's routine activities?
- Can you identify stressors in your child's life?
- Is your child comforted by the habit?

Figure 54.1. Anterior open bite associated with thumb-sucking.

Management

In general, parents should be queried about what they have done to decrease their child's engagement in the habit. The management of childhood habits should be tailored to the specific habit and the associated symptoms. For older children, self-monitoring and relaxation training may be helpful as alternative means of coping with stress. The issue of thumb-sucking versus the use of pacifiers can be addressed by anticipatory guidance. Pacifiers, which were previously discouraged, are now believed to have some advantages over thumb-sucking. A report from the American Academy of Pediatrics noted a decrease in the incidence of sudden infant death syndrome in infants who used a pacifier. With pacifiers, the risk of dental disturbances is lower because the pacifiers are softer and are accompanied by a plastic shield that puts counter pressure on the teeth. Pacifiers are also detachable and cleanable.

Pacifiers can be lost, however. Parents should be advised not to attach a pacifier to the child's shirt with a string because of risk of strangulation. For children who are pacifier dependent and unable to go back to sleep if they lose their pacifier at night, multiple pacifiers can be placed in the crib to make finding one easier. For infants who desire pacifiers because they complete their feeding in less than 20 minutes, a nipple with a smaller hole can be used or the cap can be screwed on the bottle more tightly to prolong the time spent in nutritive sucking. Dental problems may develop when pacifiers are used upside down, all day long, or after the eruption of permanent dentition.

It is suggested that parents do not try to stop thumb-sucking behavior until children have reached the age of 4 years. Dental problems in late thumb-suckers include anterior open bite, increased horizontal overlap (protruding upper incisors), intruded and flared upper incisors, lingually flipped lower incisors, and warped alveolar ridge. When thumb-sucking persists to school age, tongue thrust is noted, as are articulation problems, specifically with consonants *s, t, d, n, z, l,* and *r.* The physician should reassure parents that children who stop sucking their thumbs prior to the eruption of the secondary dentition are not at risk for poor dentition.

Numerous devices have been proposed to help with the cessation of thumb-sucking, but reported success has been variable. The use of arm restraints, particularly at night, is not recommended and may result in rumination. Bitter paints seek to reduce thumb-sucking by subjecting children to a bitter, aversive taste. This medication consists of 49% toluene, 19% isopropyl alcohol, 18% butyl acetate,

11% ethyl cellulose, and 0.3% denatonium benzoate. A 3/4-oz bottle is toxic if ingested in its entirety. Application of aversive tasting chemicals are used less frequently. Nocturnal application is needed if children suck their thumbs during the night. The principle of retraining, in which thumb-sucking becomes a duty and children are required to suck all 10 fingers one at a time, has also been recommended. Some recommend that elastic bandages be put on the hand of nocturnal thumb-suckers. Problems associated with thumb-sucking include sore thumbs, calluses, and candidal infections. Dentists may fashion a reminder appliance, called a palatal crib or rake, making it difficult for children to suck their thumbs. Such devices are usually applied for a minimum of 3 months. A fixed appliance is preferable to a removable one, and treatment should be initiated in spring or summer when children are engaged in numerous physical activities. A number of dental devices are available commercially and online including TGuard and Hand Stopper or Thumb Sucking Handaid. They may consist of a plastic covering for the thumb and hand. This covering eliminates the pleasurable sensation created by the interaction of thumb, saliva, and mouth. Encouragement works better than nagging, as a rule, and a reward system is particularly useful in children who are 5 to 6 years of age. Parents may be referred to books such as *Thumbs Up, Brown Bear* and encouraged to talk to their children about how good it feels not to suck their thumbs. A star chart and diary are also useful. Sometimes, telling children something like, "Mommy would be so proud of you if you didn't suck your thumb now that you're such a big girl or a big boy," is effective. In addition, the pressure to stop thumb-sucking becomes greater during the school years. Children who suck their thumbs are regarded by their peers in first grade as less intelligent, less happy, less likable, and less desirable as friends. A Cochrane review showed that orthodontic appliances and psychological intervention, both positive and negative, were successful in stopping thumb-sucking both short- and long-term.

In children who suck their thumbs and twirl their hair at the same time, the hair twirling stops once the thumb-sucking ends. The phenomenon is referred to as *habit covariance*. Hairpulling in young children often seems to resolve spontaneously but is more problematic in adolescents and adults. Management of trichotillomania usually involves non-pharmacological treatments. In children, behavior modification, including putting socks on the hands and the use of time-out for hairpulling, in addition to extra attention for not pulling the hair, is recommended. Substituting behavior is also encouraged. For instance, children should be advised to sit on their hands, wear gloves, pull rubber bands, or squeeze a ball whenever they have an urge to pull their hair. In older individuals, hairpulling may be related to obsessive-compulsive disorders. A form of cognitive-behavioral therapy referred to as habit reversal therapy is said to have significant empirical support. This therapy involves an understanding of the hairpulling by the patient and then a combination of awareness training, self-monitoring, stimulus control, and competing response procedures. Habit reversal therapy is more appropriate for older children and adolescents. Trichotillomania may lead to the presence of trichobezoars (hair balls) from swallowed hair. Sometimes, hair balls can extend through the gastric outlet into the small intestine, a phenomenon referred to as Rapunzel syndrome. Gastric hair balls can be dissolved enzymatically or with the installation of a cola soda through a nasogastric tube. If such maneuvers fail, they are removed endoscopically or through surgery. Pharmacological therapy for trichotillomania is not routinely recommended for the management of affected children. In adults, selective serotonin reuptake inhibitors, clomipramine, bupropion, and risperidone have been used. There are currently several mobile apps that can be used to monitor behavior and assist with treatment strategies. Children whose symptoms have not improved with behavioral interventions should be referred to a mental health professional for additional management.

Nail-biting also often responds to behavior modification. As is sometimes used to stop thumb-sucking, denatonium benzoate, a bitter chemical compound, can be applied to nails, although results are variable. Olive oil may be put on the nails to make them soft so there are fewer jagged edges to bite. Habit reversal therapy is another recommended modality to reduce biting. The promise of a professional manicure may be an incentive for young girls to let their nails grow. Recently, smart watches, as well as other devices worn on the wrist, have been used to track hand movements and alert the individual to the biting. In the children's book, *The Berenstain Bears and the Bad Habit,* collecting pennies is suggested as a habit substitution for nail-biting.

Rhythmic habits are less easy to modify. For the most part, reassurance is all that is needed. The use of metronome-like devices has had no demonstrable effect. Children older than 3 years who disturb the family's sleep with their rhythmic habits may be given mild sedatives, such as diphenhydramine or hydroxyzine. Medications to reduce head banging include transdermal clonidine and thioridazine (eg, Mellaril). Other maneuvers involve placing the crib or bed on carpeting or bolting the crib to the wall to decrease the amount of noise from movement.

Children who engage in biting behavior should be managed with behavior modification, including praising of good behavior and time-out for inappropriate behavior. Aversive conditioning involves the placement of some unpalatable food, such as a lemon or onion on a necklace, and having the child bite on that object rather than biting another child. Biting behavior is reported to be extinguished with this technique. Another option is the placement of a whistle. The child blows the whistle rather than biting the other child.

Nose picking is a common habit in children and adults. One suggestion to extinguish or minimize this habit involves letting children look in a mirror and pick their nose or videotaping the child while nose picking. Their reaction is that nose picking looks "gross" and the habit may decrease in frequency. Keeping the nasal mucosa moist through the application of lubricant such as petroleum jelly will reduce the presence of dried material in the nose, which often provides the impetus to pick.

Iron deficiency related to pica requires iron supplementation. Lead intoxication should be managed with chelation and environmental manipulation. One strategy suggested to reduce pica is to create a "pica box." The individual puts substitute substances, such

as popcorn or chewing gum, in the box, and the substitute material is used to satisfy the urge to ingest the desired product.

Prognosis

Most habits are not harmful to children's health. The major problem is social acceptability. Parents should be encouraged to stop a habit before it becomes ingrained. This can often be done by praising good behavior and encouraging activities during which the unwanted behavior does not appear. Habits that do not respond to parental influence often resolve spontaneously under peer pressure.

CASE RESOLUTION

It is important for the physician and the mother to empower the boy to stop thumb-sucking before he finds himself ridiculed by his classmates. He might be allowed to suck his thumb at certain times and in certain places (eg, "You can suck in your room after school for 15 minutes"). Books geared at children and parents to help stop thumb-sucking are recommended, and the boy is rewarded for times when he is not sucking his thumb.

CHAPTER 55

Enuresis

Carol D. Berkowitz, MD, FAAP

CASE STUDY

A 9-year-old boy who is in good general health is evaluated for a history of bed-wetting. He is the product of a normal pregnancy and delivery, and he achieved his developmental milestones at the appropriate time. The boy was toilet trained by the age of 3 years, but he has never been dry at night for more than several days at a time. Bed-wetting occurs at least 3 to 4 times a week even if he is fluid restricted after 6:00 pm. The boy never wets himself during the day, has normal stools, and is an average student. His father had enuresis that resolved by the time he was 12 years old.

The boy's physical examination is entirely normal.

Questions

1. What conditions account for the symptoms of enuresis?
2. What is the appropriate evaluation of children with enuresis?
3. What is the relationship between enuresis and emotional stresses or psychosocial disorders?
4. What management plans are available for enuresis?
5. How do physicians decide which management technique is appropriate for which patients?

Enuresis is defined as involuntary or intentional urination in children whose age and development suggest achievement of bladder control. Voiding into the bed or clothing occurs repeatedly (at least twice a week for at least 3 consecutive months). On average, urinary continence is reached earlier in girls than in boys, and the diagnosis of enuresis is reserved for girls older than 5 years and boys older than 6 years. The term *diurnal enuresis,* wetting that occurs during the day, has been replaced by *daytime incontinence.* The International Children's Continence Society promotes a standardization for enuresis-related terminology. It prefers the use of the term *incontinence* to denote uncontrollable leakage of urine, intermittent or continuous, that occurs after continence should have been achieved. *Nocturnal* or *sleep enuresis* refers to involuntary urination or incontinence that occurs during the night. The term *primary nocturnal enuresis* is used when children have never achieved sustained dryness, and *secondary enuresis* is used when urinary incontinence recurs after 3 to 6 months of dryness. Monosymptomatic nocturnal enuresis means that nighttime wetting is the only symptom. Children who experience urgency, frequency, dribbling, or other symptoms have *polysymptomatic enuresis.* Such symptoms may be related to inappropriate muscle contraction, are often associated with constipation, and are termed *dysfunctional elimination syndrome* or *bowel/bladder dysfunction.*

Physicians can be particularly helpful by routinely questioning parents about bed-wetting during health supervision visits. Many families are otherwise reluctant to bring up this embarrassing concern because enuresis is viewed as socially unacceptable. It poses particular difficulties if children are invited to sleep away from home, such as at a slumber party. In addition, enuresis may be associated with other behavioral or developmental problems, such as attention-deficit/hyperactivity disorder (ADHD), anxiety, and depression, that warrant inquiring about.

Epidemiology

Enuresis affects 5 to 7 million individuals in the United States. It is 1 of the most common conditions of childhood, affecting 10% to 20% of first-grade boys and 8% to 17% of first-grade girls. By age 10 years, 5% to 10% of boys still are enuretic (1% of US Army recruits are enuretic). Seventy-four percent of affected children have nocturnal enuresis, 10% daytime incontinence, and 16% both. Primary enuresis affects the majority (75%–80%) of children with enuresis, and 80% to 85% of these children have monosymptomatic nocturnal enuresis. Although the overall prevalence of secondary enuresis is lower (20%–25%), it increases with age; secondary enuresis makes up 50% of cases of enuresis in children 12 years of age.

Several epidemiological factors have been associated with enuresis, including low socioeconomic status, large family size, single-parent family, low birth weight, short height at 11 to 15 years of age, immature behavior, relatively low IQ, poor speech and coordination, and encopresis (fecal incontinence; 5%–15% of cases). Enuresis has been associated with obstructive sleep apnea, in which an increased level of atrial natriuretic factor has been reported. Atrial natriuretic factor inhibits the renin-angiotensin-aldosterone pathway, causing diuresis. Correcting obstructive sleep apnea with tonsillectomy or adenoidectomy can lead to the elimination of enuresis. Enuresis has a familial basis, with 44% being enuretic if 1 parent was enuretic and as many as 77% of children being enuretic if both parents were similarly affected. Concordance for enuresis is reported in up to 68% of monozygotic twins and between 36% and 48% of dizygotic twins.

Clinical Presentation

A history of enuresis may be obtained as a presenting symptom or elicited by physicians during a health supervision visit. Medical conditions such as encopresis, obstructive sleep apnea (nighttime snoring), or ADHD may be associated with enuresis (Box 55.1). Children with ADHD have a 30% greater risk of being enuretic compared with their peers who do not have ADHD. The physical examination is usually normal.

Pathophysiology

Delayed control of micturition has several possible causes (Box 55.2).

- Faulty toilet training may perpetuate diurnal and nocturnal enuresis but is not expected to selectively perpetuate the latter. Parental expectations are believed to play a role in the toilet-training experience. Parents who allow children to sleep in overnight diapers or pull-ups may delay the achievement of nighttime dryness, but it is unlikely that the use of diapers or pull-ups causes nocturnal enuresis. Poor toilet habits, particularly infrequent voiding or constipation, may be associated with urinary tract infections (UTIs) and account for secondary enuresis.
- Maturational delay. The development of the inhibitory reflex of voiding may be delayed in some children, which may contribute to enuresis until the age of 5 years. This is similar to the range in which children achieve other developmental milestones. It is unlikely that maturational delay persists as a cause of enuresis beyond this age. Experts believe that maturational delay is not a reasonable explanation if children can achieve dryness in the daytime but not at night.
- Small bladder capacity. Evidence suggests that some children with enuresis have smaller than normal bladder capacities. Bladder capacity in ounces is estimated as the age in years plus 2. For example, 5-year-olds have a bladder capacity of 7 oz (210 mL). Adult bladder capacity is 12 to 16 oz (360–480 mL). Small bladder capacity is associated with diurnal frequency or incontinence.
- Sleep disorder/impaired arousal. The relationship between enuresis and sleep has been the focus of numerous studies, some with conflicting results. It has been suggested that children with enuresis are in "deep sleep" and do not sense a full bladder. This is often the parent's perception of their child's sleep pattern. However, studies have shown that enuresis occurs during all stages of sleep, particularly in the first one-third of sleep and in transition from non-rapid eye movement (non-REM) stage 4 to rapid eye movement (REM) sleep. During this period, body tone, respiratory rate, and heart rate increase, and erection and micturition occur. Studies suggest that the arousal center in the brain fails to respond (ie, the child does not awake) to full bladder sensation. Children with enuresis do not seem to sleep more deeply than other children. However, children with enuresis may have diminished arousal during sleep. In one study, 40% of children with enuresis, compared with only 8.5% of children without enuresis, did not awaken to an 80-dB noise. Other studies highlight the association of nocturnal enuresis with fragmented sleep, a lower proportion of motionless sleep, and more nighttime awakenings.

  Recent studies suggest a correlation between nocturnal enuresis and periodic limb movement disorder. This disorder consists of involuntary movement of the lower extremities (ie, knee, hip, or ankle) during non-REM sleep. Periodic limb movement disorder is related to dopamine-depletion, leading to the disinhibition of spinal-cord motor and sensory reflexes. Dopamine deficit may affect the micturition center in the brain, leading to increased bladder contractions; hence, the association with enuresis.
- Allergens. No evidence confirms the notion that exposure to certain foods (eg, food additives, sugar) contributes to enuresis. However, some parents believe that bed-wetting is decreased if certain foods, such as sodas and sweets, are eliminated from the diet. The ingestion of caffeine-containing beverages may exacerbate nocturnal enuresis through the diuretic effect of caffeine.
- Nocturnal polyuria/relative vasopressin deficiency. Research has shown that although children who do not have enuresis exhibit a diurnal variation in arginine vasopressin (AVP) secretion, this rhythm is disturbed in some children with enuresis, resulting in

Box 55.1. Diagnosis of Enuresis in Pediatric Patients

Enuresis

- Bed-wetting
- Wet underwear
- Old enough to be toilet trained
- Bowel and bladder dysfunction
- Precipitating problem, such as diabetes or urinary tract infection
- Encopresis
- Attention-deficit/hyperactivity disorder
- Family history of enuresis

Box 55.2. Causes of Enuresis

Primary Enuresis

- Faulty toilet training
- Maturational delay
- Small bladder capacity
- Sleep disorder/impaired arousal
- Allergens
- Nocturnal polyuria/relative vasopressin deficiency
- Dysfunctional bladder contraction

Secondary Enuresis

- Urinary tract infection
- Diabetes mellitus
- Diabetes insipidus
- Nocturnal seizures
- Genitourinary anomalies
- Sickle cell anemia
- Medication use
- Emotional stress

nocturnal polyuria. In addition to regulating urine formation, AVP also regulates circadian rhythm. Dysregulation of AVP can, therefore, be associated with nocturnal polyuria as well as disturbed sleep.

- Dysfunctional bladder contraction. In cases of daytime incontinence, contractile disturbances of the bladder affect normal voiding. Children with an "uninhibited bladder" have not learned to inhibit bladder contraction. They may assume a certain posture, called Vincent curtsy, in an effort to prevent micturition. Some children exhibit uncoordinated, incomplete voiding and the urine exits the urethra in a staccato stream. Trabeculations or bladder wall thickening may be noted on imaging studies.

  Daytime incontinence can be related to problems with bladder filling and storage or to bladder emptying. Each of these functions is under different neurologic control, with filling and storage under the sympathetic nervous system and bladder emptying related to the action of acetylcholine and the parasympathetic system. Effective voiding requires the coordinated effort of these 2 phases. Management of daytime incontinence is dependent on which phase is malfunctioning.

Differential Diagnosis

The differential diagnoses for both primary and secondary nocturnal enuresis are noted in Box 55.1. A specific organic problem is rarely the cause of primary nocturnal enuresis, although abnormal AVP regulation may affect some children. However, secondary enuresis may result from an organic problem, such as UTI, diabetes mellitus, diabetes insipidus, nocturnal seizures, genitourinary anomalies (eg, ectopic ureter), sickle cell anemia, medication use (eg, diuretics, theophylline, lithium), or emotional stress. When primary enuresis is diurnal and nocturnal, some of these conditions should be considered. Additional diagnoses include neurogenic bladder, which may occur in association with cerebral palsy; sacral agenesis; and myelomeningocele. Some children experience urinary frequency, a benign self-limited condition characterized by the sudden need to urinate very frequently, often 25 to 30 times a day. The condition occurs most often in children between 3 and 8 years of age, is self-limited, and is felt to be stress related. A urinary diary, noting time and amount of voiding, is sometimes helpful in diagnosing the condition.

Evaluation

History

A thorough history should be obtained when evaluating children with enuresis (Box 55.3). It may be helpful for the child or family to keep a diary recording the episodes of nocturnal enuresis over several weeks to a month. It may be useful to note the time the child ate dinner, what was eaten, and the time the child went to bed to help determine if there is any discernible pattern or contributing environmental factors.

Physical Examination

A general physical examination should be performed, with particular attention to certain areas. The pattern of growth should be plotted. Blood pressure should be obtained. The abdomen should be assessed for evidence of organomegaly, bladder size, and fecal impaction. An anal examination should be performed to evaluate rectal tone.

If possible, physicians should watch children void. Practitioners should determine whether children can start and stop micturition and whether the stream is forceful. Dribbling in girls may indicate an ectopic ureter. A more sophisticated approach involves the uroflow test, in which the patient voids into an apparatus that electrically senses the rate of flow. A graph is generated that notes the flow rate and quantity. This study is most useful in children with diurnal incontinence. The appearance of the genitalia should be assessed. A rash in the genital area may be secondary to wetness from urinary incontinence. The skin may be macerated, erythematous, or hyperpigmented secondary to persistent moisture and irritation.

Labial fusion in girls may trap urine, allow reflux into the vagina, and lead to dribbling. Meatal stenosis, epispadias, hypospadias, or cryptorchidism may be present in boys. Any of these conditions is suggestive of a possible underlying genitourinary anomaly.

Neuromuscular integrity of the lower extremities should be evaluated. This may provide a clue to a disorder such as spina bifida occulta. The presence of some anomaly in the sacral area, such as a sacral dimple or a tuft of hair, may also be a sign of this condition.

Box 55.3. What to Ask

Enuresis

- Is the enuresis primary or secondary?
- Is the enuresis diurnal, nocturnal, or both?
- How old was the child when toilet training occurred?
- How old was the child when daytime and nighttime dryness was achieved?
- How often does the child urinate and defecate during the average day?
- Is the child's urinary stream forceful or dribbling?
- Does the child dribble before or after voiding?
- Does the child experience symptoms such as polydipsia, polyuria, dysuria, urgency, frequency, or problems with passing stool?
- Who changes the bed and who washes the bedclothes after bedwetting occurs?
- Does the child wear diapers or pull-ups or use incontinence pads overnight?
- Does the child seem to delay using the toilet?
- Does the child assume any unusual or distinct postures to avoid being incontinent?
- What is the attitude of the family toward the child with enuresis? Are family members accepting or ashamed?
- Has the family tried any treatments yet?
- Is there a family history of enuresis?
- Does the child have other symptoms, such as encopresis, attention-deficit/hyperactivity disorder, or obstructive sleep apnea?

Laboratory Tests

Usually the diagnosis of nocturnal enuresis is determined by the history. Only a minimal laboratory evaluation is indicated in most children with primary enuresis. Urinalysis, including specific gravity, is usually indicated. A complete blood cell count, serum electrolytes, and blood urea nitrogen should also be considered. Studies such as urine culture and blood glucose are more often indicated in cases of secondary enuresis.

Some studies suggest that AVP levels be assessed, although this is challenging because of the instability of the molecule and the short half-life (20 minutes). In addition, more than 90% of AVP is bound to platelets. There is a biomarker for AVP, which is a precursor peptide, copeptin. Copeptin has been used to differentiate central diabetes insipidus from nephrogenic diabetes insipidus and, in a single study to date, helped differentiate those with severe bedwetting from those with milder enuresis. The role in the routine evaluation of children with nocturnal enuresis is yet to be defined.

Imaging Studies

In cases in which urinalysis is abnormal, the culture is positive, or genitourinary anomalies are apparent on physical examination, renal ultrasonography and voiding cystourethrography may be warranted. Vertebral radiography or magnetic resonance imaging is appropriate in the diagnosis of spina bifida. Magnetic resonance urography is helpful in girls suspected of having an ectopic ureter. Electroencephalography is indicated if nocturnal epilepsy is suspected. Urodynamic studies to evaluate bladder contractility are controversial but are recommended by some urologists in children who do not respond to traditional therapy or are suspected of having spina bifida occulta not revealed on other studies.

Management

Primary Enuresis

Family counseling about enuresis should be part of all management plans. Issues related to psychosocial stress should be explored, particularly in cases of secondary enuresis. Families should be advised that the wetting is not intentional and that punishing children for accidents is inappropriate. However, children should be given the opportunity to help by removing soiled bedding or helping with the laundry. Limiting fluids and caffeinated beverages in the evening and having children void before bedtime are recommended steps. Children should be rewarded for dry nights. Star charts, in which a sticker or gold star is applied to a calendar for each dry night, have traditionally been used. Star charts and rewards are part of motivational therapy, which is a recommended first-line intervention for younger children (5- to 7-year-olds) who do not wet the bed every night. Success, as defined by a 2-week period of dry nights, occurs in 25%, and improvement is reported in more than 70%. The exclusive use of these charts without other interventions, however, has limited success and suggests that the enuresis may have a volitional component. Star charts should be used in conjunction with other management strategies.

Two treatment modalities are acceptable for managing enuresis. Most studies do not support the use of fluid restriction as a reliable isolated means of controlling enuresis. Some children benefit from sequential or combination therapy.

Conditioning therapy involves the use of an alarm that is triggered when children void during the night. Children are awakened by the sounding of the alarm, and further urination is inhibited. Eventually, bladder distention is associated with inhibition of the urge to urinate. When conditioning therapy is used for 4 to 6 months, it is associated with a success rate of 70%. If the alarm is used for 4 more weeks with sustained dryness, relapses are uncommon.

Because patient cooperation is needed with the alarm system, its use is reserved for children age 7 years and older. There are multiple different types of alarm systems, including wireless alarms, wearable alarms, and pad-type alarms. For example, 1 system involves a transistor device that contains a small sensor in the underwear and an alarm on the wrist or collar. Some of these alarms are watches that resemble devices for measuring steps or heart rate. Most systems now use vibrations so other family members are not disturbed by loud alarms.

Overall, conditioning devices have a cure rate of 70% to 85% and a relapse rate of 10% to 15%. They incur a one-time cost of $50 to $75, although some of the newer systems may cost up to $200. Conditioning devices may be covered by insurance companies if the alarm is prescribed by a physician as a medical device. Approximately 30% of families discontinue use of the alarm before the recommended period for various reasons. Conditioning without the use of auxiliary alarms may also be undertaken. One proposed method involves instituting a self-awakening program. Older school-age children practice lying in bed during the daytime and simulating the experience of awaking, sensing a full bladder, and going to the toilet. Another dry-bed training program involves parents awaking their children first hourly and then at longer intervals over the period of about 1 week. Children eventually learn to self-awake. A 92% success rate with a relapse rate of 20% is reported with this program.

Transcutaneous electrical neural stimulation therapy, which has been used successfully in patients with hyperactive bladder and polysymptomatic enuresis, has been tried in patients with monosymptomatic enuresis with some success, but the results are preliminary.

Pharmacological agents include tricyclic antidepressants and desmopressin. Generally, medications produce a more rapid response but have a higher rate of relapse. Tricyclic antidepressants, especially imipramine, have been successfully used to treat nocturnal enuresis, although the mechanism of action is uncertain. The antidepressant action of the drug, its effect on sleep and arousal, and its anticholinergic properties may all play a role. There is also some evidence that imipramine increases concentrations of antidiuretic hormone. Imipramine may also act partially by reducing clearance of solutes and partially by increasing urea and water

reabsorption from the kidneys. The bladder capacity of individuals with enuresis treated with imipramine may be increased by 34%, which indicates that the anticholinergic effects of the drug may be the most significant.

Imipramine should not be prescribed for children younger than 6 or 7 years because of potential adverse effects. The recommended dosage is 0.9 to 1.5 mg/kg/day. In general, children younger than 8 years are given 25 mg 1 to 2 hours before bedtime, and older children are given 50 to 75 mg. Beneficial results usually occur within the first few weeks of therapy. Medication is usually continued for 3 to 6 months to prevent relapses, which are reported in up to 75% of cases. The drug should be tapered by reducing the dose or using an alternate-night regimen. Side effects are rare and include insomnia, nightmares, and personality changes. Acute overdoses are potentially fatal secondary to cardiac complications. The initial cure rate is 10% to 60% with a relapse rate of 90%. The monthly cost of imipramine is about $25 to $30. Because of the potential cardiotoxicity, reboxetine, a newer antidepressant, has been used with equal benefit, although the cost may be higher.

Desmopressin, an analog of vasopressin, the antidiuretic hormone, is another pharmacological agent used for enuresis. Desmopressin most likely works by decreasing nocturnal urine production. Most patients who respond to desmopressin have a large bladder capacity, large overnight urine volume, and low urine osmolarity overnight. These patients respond rapidly to desmopressin and become dry within 1 to 2 weeks of the initiation of therapy. The medication is taken orally as a 0.2-mg tablet 1 hour before bedtime. The dose may be increased by 1 tablet at weekly intervals (maximum dose: 0.6 mg). Desmopressin in nasal spray is no longer recommended for the treatment of enuresis because of the risk of severe hyponatremia, seizures, and even death. Hyponatremia has also been reported with oral desmopressin in the setting of high fluid intake sometimes associated with habit polydipsia. Fluid restriction is recommended from 1 hour before until 8 hours after desmopressin administration. While some physicians recommend a 6-month course of the medication, others suggest a shorter trial period. If patients achieve a 2-week period of dryness, the dose can be tapered at 2-week intervals. The cure rate is 40% to 50% with a relapse rate of 90% off medication. There is a biomarker, aquaporin 2, that can assess for clinical effectiveness. The cost of desmopressin is less than when initially recommended, ranging from $30 to $50 a month, although some insurers may require prior authorization for its use.

Some children do not respond to desmopressin. They tend to have small bladder capacity, low overnight urine volume, and high urine solute load. These patients frequently have comorbidities that require management. In other nonresponders, excessive prostaglandin production has been noted, and some of these patients will respond to nonsteroidal anti-inflammatory drugs.

Oxybutynin is an antispasmodic, anticholinergic agent used in the management of daytime incontinence or polysymptomatic nocturnal enuresis. The dosage is 5 mg at bedtime for children 6 to 12 years of age and 10 mg at bedtime for children older than 12 years. The response rate is 33%, and the major side effects include drowsiness, flushing, dry mouth, constipation, and hyperthermia. Hyoscyamine sulfate and flavoxate hydrochloride are 2 other medications used for daytime incontinence.

Treatment of enuresis in children with small bladder capacities includes bladder retention training. Such children are fluid loaded and asked to delay voiding for 5 to 10 minutes. This strategy is generally reserved for children with daytime incontinence.

Associated symptoms, particularly constipation and encopresis, should be adequately addressed.

Secondary Enuresis

The management of secondary enuresis should focus on the treatment of the causal disorder, such as a UTI or diabetes mellitus.

Prognosis

The prognosis for children with enuresis is good. The spontaneous cure rate is 15% per year overall, although those with severe bed-wetting (ie, 5 wet nights per week) have only a 50% chance of achieving spontaneous remission before adulthood. Medical management results in a reduction in symptoms in more than 70% of affected children.

CASE RESOLUTION

The boy has primary nocturnal enuresis. The history of childhood enuresis in the father is significant. Two management options, behavior modification and treatment with desmopressin or imipramine, can be discussed with the family. The child's symptoms will probably spontaneously improve over time.

CHAPTER 56

Encopresis

Carol D. Berkowitz, MD, FAAP

CASE STUDY

A 7-year-old boy is seen with a report of soiling his underpants. His mother states that he has never been completely toilet trained and that stool-related accidents occur at least 2 to 3 times a week, mainly during the day. The boy rarely has a spontaneous bowel movement without assistance. He sits on the toilet for just a few minutes and passes small, pellet-like stools. His mother has not previously sought medical care for this problem.

The boy is quite fidgety during the physical examination. His vital signs are normal, and his height and weight are at the 25th percentile. His abdomen is soft but distended, with palpable loops of stool-filled bowel. A small amount of stool is present around the anus and in the boy's underpants. Digital examination of the rectum reveals hard stool. The rectal tone is normal, as is the rest of the physical examination.

Questions

1. What is the definition of encopresis?
2. What is the difference between retentive and nonretentive encopresis?
3. What are some physiologic conditions that contribute to encopresis?
4. What conditions may be mistaken for encopresis?

Encopresis is the voluntary or involuntary repeated passage of stool into inappropriate places (eg, clothing) in children who, based on their age, should be toilet trained (usually at least 4 years of age, the age at which 95% of children have achieved stool continence) and who exhibit a normal developmental level and who have no primary organic pathology. One such encopretic event occurs each month for at least 3 months. The term encopresis, which was coined in 1926 by Weissenberg and originally was used for children with psychogenic soiling, is similar to *enuresis* (ie, urinary incontinence). Unlike enuresis, however, encopresis rarely occurs at night. Currently, "encopresis" is used in a broader sense to refer to all types of fecal incontinence. "Functional fecal incontinence" is the currently preferred term as recommended by the Multinational Working Teams to Develop Diagnostic Criteria for Functional Gastrointestinal Disorders.

Retentive encopresis, also referred to as *functional fecal retention with encopresis* or *retentive fecal incontinence*, occurs in the setting of functional constipation (ie, obstipation), in which chronic rectal distention results in the seepage of liquid stool around hard, retained feces. Sometimes this is called "overflow," "fecal soiling," or "pseudoincontinence," because the individual has the potential for bowel control. Onset of symptoms is usually approximately 4 years of age. Between 80% and 95% of cases of fecal incontinence are retentive. *Nonretentive fecal incontinence* is characterized by the passage of soft stool without colonic distention or retention of stool. Fecal incontinence in the absence of constipation is reported in up to 20% of children with encopresis. There are 2 categories of children with nonretentive fecal incontinence: those who can control defecation but who pass stool in inappropriate places and those who have true failure to achieve bowel control. *Primary encopresis* occurs when a child has never been completely toilet trained. *Secondary encopresis* occurs in a child who has had a period of complete continence of stool. Most children with encopresis have the secondary form.

Epidemiology

Encopresis is reported in approximately 1.5% of school-age children, and boys are affected 2 to 6 times more often than girls. This sex ratio reverses in the elderly, in which the prevalence of fecal incontinence is twice as high in females as in males. An association between encopresis, enuresis, attention-deficit/hyperactivity disorder, and autism spectrum disorder is sometimes present. Approximately 15% of children with enuresis also have encopresis. Family history for encopresis may also be positive; 16% of affected children have 1 affected parent (usually the father). An association between encopresis and child sexual abuse has been reported in a small number of children. No reported relationship exists between socioeconomic status, parental age, child's birth order, or family size.

Clinical Presentation

Children with encopresis have a history of staining of the underpants, which may be hidden in drawers or under beds by embarrassed children. Occasionally, parents are unaware of the problem. Stool incontinence occurs more frequently at home than in school. Some children have a history of constipation. Other children may be initially misdiagnosed as having diarrhea and are inappropriately placed on antidiarrheal medications, which exacerbate their problem. Parents may complain that their child exudes a fecal odor, but children are unaware they are malodorous (Box 56.1).

Approximately one-half of children with encopresis report abdominal pain, which may be vague and nonspecific or severe and crampy. Approximately 30% to 35% experience urinary incontinence or have a history of urinary tract infections (UTIs).

Pathophysiology

The 3 identified milestones at which a child may be at risk for the development of functional constipation are the introduction of dietary solids into an infant's diet, toilet training, and the start of school. Other factors that may precipitate secondary encopresis include change in schedule (eg, overnight school trips with use of communal bathrooms) and parental separation. Constipation, if associated with painful defecation, may contribute to the manifestation of retentive fecal incontinence. With time, the colon distends and liquid feces seeps around impacted stool (Figure 56.1). In 30% to 50% of children anal spasm (ie, anismus) occurs, and contraction rather than relaxation occurs during evacuation of feces. In another 40% of children, rectal hyposensitivity is apparent, resulting in unawareness of the presence of stool. Some children have an evacuation release disorder in which the presence of stool does not result in relaxation and stool evacuation. In such cases, the rectum is chronically distended by stool, water is absorbed, and stool becomes harder and drier. The distended rectum cannot sense the presence of the stool. When evacuation is attempted, the process is painful, resulting in further retention (see Chapter 124).

Encopresis has been associated with a short attention span and a high level of motor activity. Affected children are unable to sit on a toilet for more than a few minutes and do not adequately attend to the task of stool evacuation. As a result, they get off the toilet after the incomplete evacuation of only small amounts of stool. In some toddlers, constipation is related to the struggle of toilet training and an unwillingness to sit on the toilet (see Chapter 48).

Box 56.1. Diagnosis of Encopresis

- Incontinence of stool
- Urinary incontinence
- Constipation
- Hyperactivity
- Distended abdomen
- Stool-filled loops of bowel
- Lax rectal tone
- Soiled clothing or bedding
- Fecal odor

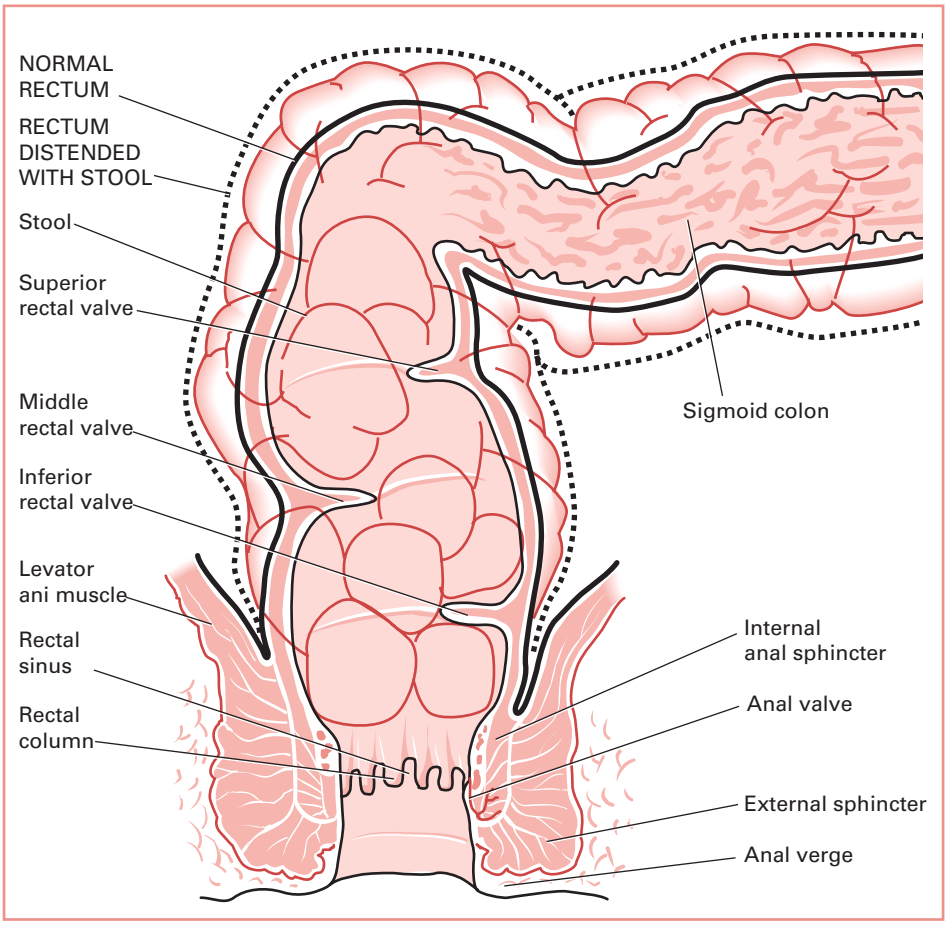

Figure 56.1. Diagram of the rectum, anal canal, and sigmoid colon distended with stool.

The etiology of nonretentive encopresis is unclear; however, 40% of children with nonretentive encopresis have never been adequately toilet trained. Comorbid psychiatric disorders as well as a history of sexual abuse have also been reported. Some children who have been chronically sexually abused have lax anal tone, which may contribute to fecal incontinence. A small proportion of children with nonretentive encopresis have a history of prior surgery in the rectosigmoid colon for the management of conditions such as congenital megacolon (ie, Hirschsprung disease) and imperforate anus. The child with acute proctitis secondary to cow milk protein allergy or inflammatory bowel disease may experience fecal incontinence; in this setting often the stool is also blood-tinged.

Differential Diagnosis

The differential diagnosis of encopresis focuses on organic conditions associated with chronic constipation. Organic conditions, which account for 5% to 10% of fecal incontinence, include congenital megacolon (ie, Hirschsprung disease), disorders of intestinal motility (eg, pseudo-obstruction), disorders of anal tone and anal anatomy (eg, imperforate anus with fistula), disorders of the lumbosacral spine (eg, meningomyelocele), previous surgeries (eg, repair of imperforate anus) and neurologic disorders (eg, intellectual and developmental disabilities, hypotonia). Neurofibromatosis, lead poisoning, and hypothyroidism are also associated with constipation. Congenital anorectal anomalies, which occur in 1 in 5,000 live births, are rare.

Most of these conditions can be ruled out on the basis of a careful history and physical examination. In some cases, specific testing, such as anal manometry or rectal biopsy, may be necessary to exclude a particular disorder.

Box 56.2. What to Ask

Encopresis

- At what age was the child toilet trained?
- Does the child have spontaneous bowel movements (without enemas or suppositories)? If so, how frequently?
- Does the child have large, dry, hard stools that clog the toilet?
- Does the child pass blood with the stool?
- Did the child pass meconium within the first 24 hours after birth?
- Has the child had any surgery in the anogenital area, spine, or bowel?
- Is the child taking any medication that can promote constipation, such as aspirin, iron, methylphenidate hydrochloride, imipramine, calcium channel blocking agent, or an anticholinergic agent?
- Does the child seem to resist the urge to defecate (eg, squeezes legs together and rocks back and forth)?
- Does the child have a history of enuresis or attention-deficit/hyperactivity disorder?
- What is the pattern of encopresis (ie, is the encopresis primary or secondary)?
- When and where does the child soil (eg, nocturnal, at home)?
- Have changes or stresses occurred in the home or family?
- What happens to the child's stained underwear?
- What has the family done to manage the problem?
- What is the child's diet? How much milk does the child drink? Does the child eat fruits and vegetables?

Evaluation

History

The physician should determine the age of onset of fecal incontinence as well as the age of initiation of toilet training. Generally, affected children are 4 years of age or older. A detailed history of the stool pattern should be obtained as well as a dietary history (Box 56.2). The frequency, consistency, and quantity of stools should also be noted. Additionally, the presence of nocturnal episodes of fecal incontinence should be determined. In cases of secondary encopresis, the duration of prior fecal continence and the occurrence of any events (eg, birth of a sibling, start of school) that may have precipitated the episodes of encopresis should be noted. Some children experience the onset of encopresis when they start school. Because of "toilet phobia," they are unwilling to use the public toilet in the school setting. It is important to note that not all children who experience constipation develop encopresis.

Physical Examination

A comprehensive physical examination is necessary, paying particular attention to the abdomen to check for the presence of distended, stool-filled loops of bowel. Fifty percent of children with retentive encopresis have a palpable fecal mass. The rectal area should be assessed for rectal tone, anal wink, and the presence of hard stool (which may be noted in up to 90% of children with encopresis). To elicit an anal wink, the skin adjacent to the anus should be stroked using a cotton swab. Some children with retentive encopresis may forcibly tighten their anal sphincter and their buttocks in response to a digital examination or because they are frequently contracting their external anal sphincter to prevent the seepage of liquid stool.

The child with a patulous anus may have a neurologic disorder and should undergo a thorough neurologic examination. Rectal prolapse, if present, may be indicative of chronic constipation or another condition (eg, cystic fibrosis). Perianal fissures may reflect passage of large, hard stools. Hemorrhoids are unusual in children and can be indicative of chronic constipation. Location of the anus should also be noted; anterior displacement may be suggestive of an incomplete type of imperforate anus.

Dysmorphic features should be noted; these may be suggestive of a syndrome of which constipation is a feature. Abnormalities around the anus, such as fistulas, should also be noted. Fistulas are found in Crohn disease. The underpants should be evaluated for the presence of stool, mucus, or pus. A sensory and motor examination of the lower extremities helps determine if any signs of spinal cord dysfunction are evident. An evaluation of the skin over the spinal area may reveal abnormalities, such as sacral dimples or tufts of hair.

The child who does not exhibit abdominal distention may have soft stool on rectal examination, which is indicative of nonretentive encopresis. Patulous anal tone is suspicious for spinal cord abnormalities or prior child sexual abuse.

Laboratory Tests

Most children with encopresis require few laboratory studies. Studies are selected with a focus on eliminating organic causes of encopresis, such as congenital megacolon (Hirschsprung disease) or spinal cord anomalies. Urinalysis and urine culture are recommended in children with fecal impactions to exclude UTI. Encopresis is reported to be an independent risk factor for UTI. Thyroid function studies, a lead level, celiac serology, and electrolytes, including serum calcium, have been suggested, particularly in children with refractory constipation. Anorectal manometry, which may be used to measure the pressure generated by the anal sphincter, may also reveal abnormalities of anal tone or evidence of aganglionosis. Manometry may also detect dyssynergic defecation characterized by failure of the muscle of the pelvis floor to relax during defecation. The Child Behavior Checklist is useful to determine if certain behavior problems exist. Such problems may potentiate the encopresis or result from it.

Imaging Studies

In most children with encopresis, imaging studies are not necessary. Abdominal radiographs obtained from children with retentive encopresis may reveal a distended, stool-filled bowel. In children with suspected nonretentive encopresis, abdominal radiographs can confirm the absence of constipation. A contrast enema with barium or a hydrosoluble substance is useful if congenital megacolon (Hirschsprung disease) or an anorectal malformation is suspected. Strictures, which may occur after necrotizing enterocolitis, are also detected on such radiographs. Electromyography to determine whether the innervation of the external anal sphincter is intact is recommended for the child with encopresis who does not respond to routine treatment.

Management

The management of encopresis is focused on patient and parent education and counseling with the goal of eventual complete rectal evacuation of stool. Typically, it takes 2 to 6 months to regain muscle tone of the anal canal. The child with anorectal malformations or prior gastrointestinal tract surgery may require additional surgical procedures to help them achieve fecal continence.

Rectal evacuation inevitably requires pharmacologic management to ensure an adequate cleaning out of retained stools. The decision about which laxatives to use depends on the severity of constipation. Polyethylene glycol 3350 has a very high success rate in the management of constipation and encopresis and in recent years has become the mainstay of therapy. The medication comes as a powder; generally, 17 g (0.6 oz) is added to juice or water. The medication may be given twice a day if there is no initial response. Other modalities include a high-fiber diet and stool-bulking agents or oral laxatives, such as senna derivatives, bisacodyl, or lactulose syrup, which may be used in association with stool softeners or lubricants (eg, mineral oil). Use of mineral oil has decreased. The amount of mineral oil may be titrated up to ensure success. Some physicians recommend that mineral oil be given until it oozes from the rectum, after which the amount may be titrated back to a lower level. Magnesium sulfate is also recommended to relieve constipation. Magnesium citrate can be used but should be administered cautiously and with the admonition to drink plenty of fluids to prevent dehydration. If the degree of retention is more severe, suppositories or enemas may be necessary. Occasionally, manual disimpaction is required. Alternative methods to manual disimpaction include 2 to 3 sodium phosphate enemas over 1 to 2 days or 226.8 g (8 oz) of mineral oil a day for 4 days. Pulsed irrigation–enhanced evacuation involves the insertion of a rectal tube and the installation of pulses of warm irrigating solution, simultaneously draining rectal contents. If these modalities are unsuccessful, it may be necessary to admit the child to the hospital for oral administration or nasogastric lavage using polyethylene glycol-electrolyte solution at 30 to 40 mL/kg/hour until successful evacuation has occurred. This procedure requires insertion of a nasogastric tube and 6 to 8 hours of treatment. After the fecal accumulation has been relieved, every effort should be made to keep the child regular. This can be accomplished with the combined use of toilet retraining, stool softeners or laxatives, and enemas or suppositories. Prokinetic agents, such as metoclopramide hydrochloride, may also be used.

Dietary manipulation is important to ensure sustained regular passage of stool. Parents should be advised that children require a high-fiber diet with fruit juices (eg, pear, peach) and decreased milk consumption (<16 oz/day). It has been suggested that a "team and coach" approach is the most successful route and that bowel training be likened to fitness training.

The toilet retraining process, or "enhanced toilet training," requires that the child sit on the toilet at least 2 or 3 times a day, usually after meals, for approximately 10 minutes or until the child has had a bowel movement. Some physicians recommend the use of an egg timer to ensure that the child spends the appropriate amount of time on the toilet. Some children are more receptive to time on a toilet if they have access to video games or shows during their time on the toilet. Children should be requested to maintain a diary of their evacuation, which may take the form of a star chart. Stars or other rewards are given for successful bowel movements in the toilet.

If a child skips a day between bowel movements, a suppository may be used (eg, glycerin, bisacodyl). If after administration of the suppository the child still has not had a bowel movement, an enema may be appropriate. This sequence should be maintained until the child is having bowel movements in the toilet and is not soiling for at least 1 month. Generally, it is necessary to use stool softeners for at least 3 to 6 months. It may be necessary to modify the regimen, particularly in younger children.

Behavior modification and biofeedback, such as using external anal sphincter electromyography, are 2 other modalities that can be used to help manage encopresis. Consultation with a specialist, such as a pediatric gastroenterologist, may be required.

Thirty percent of children with encopresis may need psychologic consultation. Psychologic intervention in the form of interactive parent-child family guidance has been successful when standard gastroenterologic intervention has failed. The child with evidence of child sexual abuse or nonretentive encopresis should be referred to a psychologist early in the course of therapy. The underlying psychosocial problems of the child with nonretentive encopresis must be adequately addressed before the condition can improve.

Prognosis

The prognosis for the child with retentive encopresis is reportedly good with appropriate intervention. In 1 study, children who were able to defecate a rectal balloon filled with 100 mL of water within 5 minutes were twice as likely as those who could not do so to recover from constipation and encopresis. It is estimated that approximately 30% to 50% of affected children experience long-lasting remission after 1 year, and up to 75% of affected children are in remission by 5 years.

The prognosis for the child with nonretentive encopresis is less predictable and is highly dependent on the underlying psychopathology.

CASE RESOLUTION

The boy exhibits typical manifestations of retentive encopresis. His condition should be managed with the use of laxatives, stool softeners, and toilet retraining with a star chart. The possible diagnosis of attention-deficit/hyperactivity disorder should be addressed separately but may be contributing to his inability to attend to the task of toileting.

PART 4

Adolescent Health

CHAPTER 57

Culturally Competent Care for Diverse Populations: Sexual Orientation and Gender Expression

Ilana Sherer, MD, FAAP; Brittany Allen, MD, FAAP; Joseph H. Waters, MD; and Lynn Hunt, MD, FAAP

CASE STUDY

The mother of an 11-year-old boy makes an appointment with you to discuss her son's "behavior problems." He is the youngest of 4 children and is doing well in fifth grade, but she is concerned that her son does not like typical "male" activities. He dropped out of Little League, will not join other sports teams, and prefers riding his bike by himself. Additionally, he still likes dressing up in costumes and prefers playing with girls rather than boys. His mother finally mentions that she is worried that her son will be gay and is wondering what she can do to help him develop "normally."

Questions

1. What is meant by gender expression, sexual orientation, and gender identity?
2. What is the role of the pediatrician in counseling parents and patients about gender expression, sexual orientation, and gender identity?
3. What are some of the consequences of discrimination against sexual orientation and gender identity minority populations?
4. How can the physician help families support their children who are lesbian, gay, bisexual, transgender, or queer/questioning (LGBTQ+)?

Introduction

Lesbian, gay, bisexual, transgender, or queer/questioning (LGBTQ+) individuals are members of nearly all communities. All pediatricians will have the privilege of caring for an individual from this population at some point in their career. Youth who are LGBTQ+ are a diverse and resilient population who, when supported, grow into healthy, well-adjusted adults. The stigma associated with being LGBTQ+ can result in a host of adverse health outcomes, however. The American Academy of Pediatrics position statement on caring for LGBTQ+ youth clearly states that there is nothing inherently high risk or abnormal about these youth, but that stigma often causes psychological distress, with a resultant increase in risk behaviors.

Stigma may also be encountered in health care settings. Many LGBTQ+ youth have had negative health care experiences and often do not "come out" to the health professionals they consult. As a result, pediatricians caring for these youth may not be aware of their patients' identity. Children and adolescents of all variations of gender identity and sexual orientation will come under the care of a pediatrician during childhood and adolescence, and it is known that adult outcomes are dependent on the level of nonjudgmental support received.

Language concerning sexual orientation and gender identity is important and constantly changing. In this chapter, the most commonly used acronym, LGBTQ+, is used to refer generally to people with diverse bodies, sexual orientations, and gender identities. Longer or different acronyms are used as well, such as LGBTQIAAP+ (lesbian, gay, bisexual, transgender, queer/questioning, intersex, asexual, ally, and pansexual; see Table 57.1 for definitions), with the goal of being more inclusive and acknowledging that certain groups have not been well represented by some labels or acronyms. The plus symbol at the end of LGBTQ+ is used to indicate that this population includes but is not limited to people who identify as lesbian, gay, bisexual, transgender, and queer/questioning, and that a list of letters can never be fully inclusive.

Table 57.1. Glossary of Terms Concerning Sex, Gender Identity, and Sexual Orientation[a,b]

Term	*Definition*
Affirmed gender	An individual's true gender identity.
Agender	A person who does not identify as having a particular gender.
Ally	An individual who supports and stands up for the rights of LGBTQ+ persons and communities.
Asexual	The sexual orientation of individuals who feel little or no attraction to others. Having an asexual orientation is different from choosing to abstain from sex.
Bisexual	The sexual orientation of individuals who develop both same-sex and opposite-sex romantic, physical, and emotional attractions.
Cisgender	A person who identifies as and expresses a gender that is consistent with the culturally defined norms of the sex they were assigned at birth. Used as an adjective.
FTM; affirmed male; trans male/man; transmasculine	Terms used to describe individuals who were assigned female sex at birth but whose gender identity and/or expression is asserted to be more masculine.
Gay	An individual whose romantic, physical, and emotional attractions (ie, sexual orientation) are to persons of the same sex. Often it refers to men, but it may be used to describe a person of any sex with a same-sex orientation. Used as an adjective.
Gender diverse/gender expansive	Umbrella terms used to describe people with gender behaviors, appearances, or identities that are incongruent with those that are culturally normative for their birth sex. Gender-diverse individuals may refer to themselves by many different terms, such as transgender, nonbinary, genderqueer, gender fluid, gender creative, gender independent, or noncisgender. *Gender diverse* is used to acknowledge and include the vast diversity of gender identities that exists. It replaces the formerly used term, "gender nonconforming," which has a negative and exclusionary connotation. Children who do not yet have language to describe themselves as transgender may be referred to by others by one of these terms.
Gender dysphoria	A clinical symptom characterized by a sense of alienation to some or all of the physical characteristics or social roles of one's assigned gender. Gender dysphoria is also the psychiatric diagnosis in the *DSM-5* that focuses on the distress stemming from the incongruence between one's expressed or experienced (ie, affirmed) gender and the gender assigned at birth. Previous versions of the *DSM* included Gender Identity Disorder, which is no longer appropriate to use but may be found in older research.
Gender expression	The diverse means of communicating one's gender to others, such as through behavior and mannerisms, clothing, hair, voice/speech, and roles/activities. Such expression may be the result of conscious or unconscious decisions and may or may not align with social expectations for gender identity or sex assigned at birth.
Gender identity	The internal sense of one's own gender, which may be female, male, a combination of both, somewhere in between, or neither. Gender identity may or may not align with the social expectations for the sex an individual was assigned at birth and results from a multifaceted interaction of biologic traits, environmental factors, self-understanding, and cultural expectations. Gender identity is distinct from sexual orientation.
Genderqueer/nonbinary	Terms to describe or name the identity of an individual whose gender identity is beyond or outside the gender binary categories of man/male and woman/female.
Homosexual	An outdated term that refers to same-sex sexual orientation. This term is often considered abrasive and offensive. Currently preferred terms may include gay, lesbian, or queer, depending on the individual.
Intersex/differences of sex development	An umbrella term used to describe the variety of conditions in which an individual's physical sex characteristics (ie, external genitalia, internal anatomy, chromosomes, or hormone levels) are considered atypical based on categories of male and female. These conditions may be apparent at birth or may be diagnosed later. For some affected individuals, intersex may also be an identity.
Lesbian	A woman whose romantic, physical, and emotional attraction (ie, sexual orientation) is to other women. May be used as an adjective or a noun.
LGBTQ+	Lesbian, gay, bisexual, transgender, or queer/questioning.
MTF; affirmed female; trans female/woman; transfeminine	Terms used to describe individuals who were assigned male sex at birth but whose gender identity and/or expression is asserted to be more feminine.

Table 57.1. Glossary of Terms Concerning Sex, Gender Identity, and Sexual Orientation[a,b] (*continued*)

Term	*Definition*
Pansexual	An individual whose romantic, physical, and emotional attraction (ie, sexual orientation) may be to individuals of any sex or gender identity. Sometimes shortened to "pan."
Queer	Umbrella term used by some individuals to describe having a sexual orientation or gender identity that is beyond or outside societal norms and expectations. Although "queer" was historically a pejorative term for LGBTQ+ people, some LGBTQ+ individuals have reclaimed this term to describe their identities; however, it is not embraced by all members of the LGBTQ+ community.
Sex	An assignment that is made at birth, usually male or female, typically based on external genital anatomy but sometimes on the basis of internal gonads, chromosomes, or hormone levels.
Sexual orientation	A term used to describe an individual's inherent emotional, romantic, or sexual feelings toward other persons in relation to the sex or sexes to which they are attracted. Examples of sexual orientations include but are not limited to gay, lesbian, bisexual, pansexual, asexual, heterosexual/straight, and queer.
Transgender	An adjective used for an individual who identifies and expresses a gender that differs from the sex assigned at birth or, more generally, who experiences or expresses gender differently from what people expect. Gender identity is different from sexual orientation. Transgender individuals can be any sexual orientation, including but not limited to gay, straight, lesbian, or bisexual. The term "transgender" also encompasses many other labels individuals may use to refer to themselves.

Abbreviations: *DSM-5*, *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition; FTM, female to male; MTF, male to female.

[a] This list is not comprehensive. It is important to recognize that language used to describe identities changes over time. PFLAG maintains a "National Glossary of Terms" at https://www.pflag.org/glossary.

[b] Some definitions adapted from PFLAG. National glossary of terms. PFLAG.org website. https://www.pflag.org/glossary. Accessed July 23, 2019 as well as from Rafferty J; American Academy of Pediatrics Committee on Psychosocial Aspects of Child and Family Health; Committee on Adolescence; Section on Lesbian, Gay, Bisexual, and Transgender Health and Wellness. Ensuring comprehensive care and support for transgender and gender-diverse children and adolescents. *Pediatrics*. 2018;142(4):e20182162.

With proper knowledge, skills, and understanding, every pediatrician can be equipped to help all LGBTQ+ youth grow and thrive (Box 57.1).

Incidence

It is challenging to get an accurate estimate of the number of LGBTQ+ youth in the United States. Large-scale surveys indicate that approximately 5% of the adult population identifies as LGBTQ+ or reports being in or having been in a same-sex relationship. Younger adults are more likely to identify as LGBTQ+; thus, it is likely that these percentages will continue to increase over time. The prevalence of sexual minority persons is consistent across all ethnic and socioeconomic groups. Although less research is available specifically about gender identity, studies show that 0.17% to 2.7% of youth identify as transgender or gender diverse in surveys of middle school, high school, and college students in the United States.

Gender Identity and Sexual Orientation

Gender identity, gender expression, and sexual orientation are 3 separate concepts that are often confused and sometimes inaccurately interchanged (see Table 57.1). *Gender identity* refers to an individual's internal sense of self as male, female, some combination of both, an identity in between, or neither, whereas *gender expression* is the way in which individuals present their gender to people around them through outward markers, such as clothing, hair, and mannerisms. It is important to understand and distinguish between gender identity and gender expression. Although gender expression can vary based on cultural expectations and may be influenced by parental and peer support or rejection, gender identity is intrinsic to the self and cannot be changed by external influences.

For most people, gender identity coincides with cultural norms associated with their biologic or natal sex; the word used to describe this alignment is *cisgender*. For some individuals, gender identity is incongruent with cultural norms associated with their biologic sex; the word used to describe this alignment is *transgender*. Gender identity often develops before puberty, as young as 2 to 3 years of age. Many children display variations in gender expression and are gender expansive or gender variant throughout early childhood and into adolescence. Some of these children eventually identify as transgender and some as cisgender. Additionally, some may identify as *nonbinary*, *genderqueer*, *gender-creative*, or *agender*, meaning that their gender identity is something outside the binary of male or female.

In contrast, *sexual orientation* refers to an individual's attraction to others and usually develops in late childhood and adolescence. Traditionally, individuals who experience same-sex attraction have been called *gay* or *lesbian*, those who experience opposite-sex

Box 57.1. Best Practices for Creating an LGBTQ+-Friendly Office

Before the Visit

- Decorate the office with affirming rainbow stickers and posters.
- Brochures, books, and website images should represent the full spectrum of gender expressions and family structures.
- Intake forms should include space for different family structures and gender identities. The forms should include questions about preferred name and gender marker. Examples of such questions can be found here: www.ama-assn.org/delivering-care/creating-lgbtq-friendly-practice.
- Electronic medical records should represent the patient's preferred name and pronoun.
- All office staff should be trained to use open-ended language when discussing family structure and preferred name and/or pronoun.
- Bathrooms should be gender neutral or single stall, and signage should indicate this.

During the Visit

- Provide the same level of care that you would for any patient. Use the American Academy of Pediatrics or the Society for Adolescent Health and Medicine guidelines.
- Use the appropriate pronoun and/or name.
- Discuss confidentiality. Concerns about possible disclosure often are mentioned by LGBTQ+ youth as a reason to avoid seeking health care.
- Use open-ended language during the interview. See Box 57.2 for examples of language to use to ask about sexual orientation and gender identity.
- When asking questions about identity or behavior, explain to the youth the medical reasoning behind the question. Avoid asking invasive questions only to satisfy curiosity. The physician should avoid asking the youth to be the physician's educator about issues of sexuality and gender.
- As for all youth, it is important to know about recommendations for screening based on sexual risk behaviors and to avoid making assumptions about risk based on sexual orientation or gender identity.
- Genital examinations can be particularly traumatic for gender diverse patients. Explain the medical rationale behind the examination and allow the youth as much control over the process as possible.
- LGBTQ+ status is only 1 of the patient's many identities and may not be the main reason for the patient's visit. It is important to conduct routine health maintenance and devote attention to other identities important to the individual patient, such as race, religion, and chronic illness.

After the Visit

- The physician must be the patient's advocate and help families and communities support the child. The physician can provide parents with the information offered in Box 57.3.
- If referrals are necessary, the primary care physician should call ahead to ensure that the specialist or therapist is aware and supportive of the needs of LGBTQ+ youth and families.
- The physician should advocate for LGBTQ+ youth within the school district to encourage implementation of support systems, such as peer organizations and anti-bullying policies.

Abbreviation: LGBTQ+, lesbian, gay, bisexual, transgender, or queer/questioning.

attraction have been called *heterosexual* or *straight*, and those who experience attraction to both sexes have been called *bisexual*. Like all people, those who are transgender can be attracted to a person of any sex or gender, and they may identify as straight, bisexual, gay or lesbian, or something else. It is also important to note that language around sexual attraction shifts with every new generation, and currently it is common to hear youth use new terms and language to more fully describe the complexities of their sex and gender as well as to whom they are attracted.

Intersex Conditions

Intersex conditions are important to consider in discussions of sexual orientation and gender identity, but these states and identities should not be conflated. Individuals with intersex conditions, or differences of sexual development, have bodies that differ from typical male or typical female medically defined sex designations. External genitalia, internal anatomy, chromosomes, or hormone levels are atypical based on categories of male and female. These conditions may be apparent at birth or may be diagnosed later. Historically, and sometimes even currently, those in the medical profession have tried to "correct" these bodies to align individuals' genital appearance with typical male or female definitions. These procedures have at times resulted in harm, such as removal of tissue important for sexual sensation, fertility, and hormone production, or performing a surgical sex assignment that does not align with that person's identity as the individual ages. Many members of the intersex community feel that such irreversible elective procedures performed on young children are harmful and unnecessary and put children and adults at risk; instead, individuals with this view would prefer that these intersex children be left intact and celebrated as existing on the continuum of normal of healthy bodies. Additionally, individuals with certain intersex conditions have increased rates of identity as a member of a sexual or gender minority population compared with the general population. Although the medical needs of intersex individuals are different from those of sexual and gender minority groups, advocacy for people with intersex conditions shares common themes, values, and goals with broader advocacy for the LGBTQ+ community.

Health Consequences of Discrimination

Despite an increase in public dialogue and recent changes in some discriminatory laws, LGBTQ+ youth continue to experience stigmatization and its consequences. Often, LGBTQ+ youth are the objects of bullying, isolation, and family rejection. Individuals at particular risk are those whose gender expression or identity differs from societal expectations; this is especially true for transgender women (ie, assigned male sex at birth but with self-identified female or feminine gender identity) and people of color. National surveys of LGBTQ+ youth show that verbal, electronic, and physical harassment in schools are commonplace and are associated with school avoidance and other far-reaching consequences. Additionally, persons of sexual and gender minority groups are targeted in approximately 20% of violent hate

crimes in the United States. The result of these high rates of victimization is that the lives of many LGBTQ+ youth have been touched by violence or the threat of violence. This trauma is compounded for LGBTQ+ youth who are part of other vulnerable groups, such as people with disabilities, people of color, and immigrants.

Most LGBTQ+ youth are resilient and develop into healthy adults; however, compared with their cisgender heterosexual peers, as a group they are at increased risk for adverse health outcomes, such as suicide attempts, substance use, and risky sexual behavior. It is important for health professionals to understand the key mediators of these adverse health outcomes. Youth who have been victimized or who perceive discrimination are more vulnerable to engaging in high-risk behaviors.

Family support is particularly important for persons who are LGBTQ+. One study showed that LGBTQ+ young adults who experienced higher levels of family rejection during adolescence were 8 times more likely to report suicide attempts, 6 times more likely to report significant depression, and 3 times more likely to use illegal drugs or engage in unprotected sexual intercourse compared with those who did not experience family rejection. Conversely, families that are highly supportive are more likely to have children who are resilient and well adjusted. Family acceptance during adolescence is associated with better general health, self-esteem, and social support in LGBTQ+ young adults.

Youth who are LGBTQ+ are also significantly overrepresented among homeless youth. Studies estimate that up to 40% of homeless youth identify as a person of a sexual or gender minority population. Youth often become homeless resulting from family conflict about their sexual orientation or gender expression. Sexual and gender minority youth are more likely to suffer negative outcomes associated with living on the streets. Physical assault, sexual victimization, substance abuse, and high-risk sexual behavior are all more common for LGBTQ+ homeless youth than for heterosexual cisgender homeless youth.

Transition and Transgender Youth

Transgender youth may choose to undergo a transition in which their gender expression shifts from 1 gender to another. Transition may be different for every individual and can take months or years. It may involve *social transition*, which involves changing one's name, pronoun, and gender expression to align with the gender identity; *medical transition*, which can involve hormones or surgeries to physically change the body; and *legal transition*, which involves changing name and sex marker on documents, such as birth certificates and passports. Decisions around transition are often informed by personal choice, finances, and medical barriers. It is important to note that there is no such thing as a "complete transition," and neither surgery nor medical intervention is necessary to legitimize a person's identity as transgender or fully male or female.

"Reparative" or Conversion Therapy

Care for LGBTQ+ youth involves affirmation and support for their identities. Historically, some religiously and politically motivated groups have used outdated and discredited medical theories to justify trying to "cure" the natural sexual orientation or gender identity of those who are LGBTQ+. Because of the harm caused by this ineffective approach, reparative/conversion therapy is now banned in an increasing number of states and municipalities and is opposed by most professional organizations, including the American Academy of Pediatrics. Although such "therapies" are still practiced within some communities, pediatricians should actively discourage families from pursuing them.

Children With LGBTQ+ Parents

As many as 6 million American children and adults have a lesbian, gay, bisexual, or transgender parent, and combined data suggest that almost 2 million children younger than 18 years in the United States are being raised by at least 1 gay or lesbian parent. Children join families with same-sex parents in a variety of ways, including adoption, assisted reproductive technologies, or from previous heterosexual contact as stepfamilies or blended families. Like all families, families led by LGBTQ+ parents are diverse. These families are more likely to be composed of racial minorities, include adopted children, include children with disabilities, and have lower household incomes than families of opposite-sex couples. Multiple longitudinal and cross-sectional studies indicate that children with same-sex parents do well in domains of social, academic, and total competence. Many studies have shown that children in families headed by same-sex parents in 2-parent households have outcomes similar to children with heterosexual parents.

Important Role of Pediatricians

Pediatric health professionals have a unique opportunity to model acceptance of each patient, provide appropriate risk-reduction counseling, and encourage family support. LGBTQ+ adolescents want the same attributes in their health professionals that other groups of teenagers value, including confidentiality, honesty, respect, competence, and a nonjudgmental approach to history taking and guidance. To maintain a supportive role, the physician must take care to avoid making assumptions. The physician should not assume genital anatomy, the gender of partners, or family constellation. Neutral language should be used until the physician has completed important components of the history (Box 57.2).

It is also critical never to assume information about a person's sexual practices based on that individual's stated gender identity or sexual orientation, because people's identities do not always align with their behavior. In 1 survey, more than twice as many youth reported same-sex sexual experiences as those who eventually identified as gay. These data reinforce the important distinction between sexual orientation and sexual behavior. A wide range of sexual behavior exists in teenagers, and sexual identity formation is a dynamic developmental process. Teenagers who eventually identify as gay may have had heterosexual sexual contact, and those who identify as straight may have had a same-sex experience. For this reason, the pediatrician should be prepared to ask questions about sexual behaviors as well as identity when evaluating the LGBTQ+ pediatric patient.

Equally important is to ask for and use the individual's preferred name and pronoun. Pronouns can be "he," "she," the singular "they," or other nonbinary pronouns. It is most appropriate to refer to people by their gender identity and not by their assigned sex. For example, someone assigned male at birth who identifies as female is called a transgender woman or simply a woman, and she/her pronouns are used. The term transgender is used as an adjective. It is not a noun, as in "transgenders," nor a verb, as in "transgendered." If pronouns or preferred name are not clear, it is acceptable to ask the individual. Health professionals can also show support by avoiding unnecessarily invasive questions about genital status.

Many physicians report that they feel unprepared to care for LGBTQ+ individuals. Part of this process involves learning how to ask and how to respond when a youth answers in the affirmative.

Box 57.2. What to Ask

Gender

- What is your gender? What pronouns do you use?
- Do you consider yourself male, female, both, or neither?
- Some people feel as though there is a mismatch between their sex assigned at birth and the gender they feel themselves to be. Does that resonate with you?

Sexuality

- To whom are you attracted?
- Do you have a partner or partners?
- What is the sex of your partner(s)?
- Are you intimate with your partner?
- What parts of your body do you use for intimacy?

Box 57.3. Supportive Behaviors That Help Families Promote the Well-Being of Their Lesbian, Gay, Bisexual, or Transgender Child

- Talk with your child about his, her, or their lesbian, gay, bisexual, transgender, or queer/questioning (LGBTQ+) identity.
- Express affection when your child tells you or when you learn that your child is LGBTQ+.
- Support your child's LGBTQ+ identity even though you may feel uncomfortable.
- Advocate for your child anywhere he, she, or they is mistreated because of an LGBTQ+ identity.
- Insist that all family members respect your LGBTQ+ child.
- Bring your child to LGBTQ+ organizations or events.
- Connect your child with an LGBTQ+ adult role model to show your child positive options for the future.
- If you are part of a faith community, work to make it supportive of LGBTQ+ members or find a supportive faith community that welcomes your family and LGBTQ+ child.
- Welcome your child's LGBTQ+ friends and partner to your home as well as family events and activities.
- Support your child's gender expression.
- Believe your child can have a happy future as an LGBTQ+ adult.

Adapted with permission from Ryan C. *Supportive Families, Healthy Children: Helping Families with Lesbian, Gay, Bisexual & Transgender Children*. San Francisco, CA: Marian Wright Edelman Institute, San Francisco State University; 2009.

CASE RESOLUTION

The child is displaying behaviors that do not meet his mothers's expectations for male gender expression. The pediatrician should let the mother know that gender expression, sexual orientation, and gender identity are separate and distinct and that a broad range of normal exists for each of these. Neither sexual orientation nor gender identity can be predicted from the behaviors described.

Many adolescents go through a period of questioning their sexuality. The child's mother should be informed that no matter her child's sexual orientation or gender identity, a major risk factor for engaging in unsafe behaviors in adolescence is parental rejection. Attempts to change a person's sexual orientation do not work and are in fact dangerous; they are associated with significant depression and thoughts of suicide. For this child to develop normally, he needs supportive adults in his life—ideally, his parents—who accept and love him.

Particularly because of this child's social withdrawal, it is important to determine if he has been a victim of bullying at school or on sports teams, or if he is experiencing depression. An appointment for the child should be scheduled, and some time should be spent during the visit without his parents present. This will provide an opportunity to evaluate the child's strengths and note if he is displaying any signs of anxiety or depression. The sample questions about gender identity and sexual orientation found in Box 57.2 should be adapted to the developmental stage of the child. The child should be assured that his responses to these questions will be kept confidential. The pediatrician could also facilitate a discussion between the patient and his parents while modeling support and acceptance. An ongoing dialogue with the mother will also help the pediatrician determine if or when referrals to support and educational groups, such as PFLAG (formerly parents, families and friends of lesbians and gays), are appropriate.

Online Resources

Health professionals recognize that patients often come to them having already searched online for the answers to their questions. What follows is a list of reliable organizations to recommend or refer to for more information and support.

For LGBTQ+ Youth

GLSEN (formerly the Gay, Lesbian & Straight Education Network)
www.glsen.org
GLSEN strives to ensure that each member of every school community is valued and respected regardless of sexual orientation or gender identity or expression.

It Gets Better Project
www.itgetsbetter.org
The website offers hundreds of videos of encouragement, and young people who are LGBTQ+ can see the ways in which love and happiness can be a reality in their future. Straight allies can visit the website and support their friends and family members.

National Runaway Safeline
www.1800runaway.org
1-800-RUNAWAY is a confidential and anonymous crisis hotline for runaway and homeless youth available 24 hours a day, 365 days a year.

The Trevor Project
www.thetrevorproject.org
The Trevor Project is a national organization focused on crisis and suicide prevention efforts among LGBTQ+ youth. Trained counselors are ready 24/7 at 1-866-488-7386.

For LGBTQ+ Parents and Their Children

COLAGE: People with a Lesbian, Gay, Bisexual, Transgender or Queer Parent
www.colage.org
COLAGE is a national movement of children, youth, and adults with 1 or more LGBTQ+ parents. COLAGE connects people with LGBTQ+ parents into a peer support network and offers organized events for families as well as youth leadership development opportunities.

Fenway Institute. *Pathways to Parenthood for LGBT People*
www.lgbthealtheducation.org/wp-content/uploads/Pathways-to-Parenthood-for-LGBT-People.pdf
This publication is a readily available resource for information and guidance for potential or current parents as well as health professionals about the various pathways to parenthood for LGBTQ+ people and some of the unique issues faced by LGBTQ+ parents.

For Parents and Others

Family Acceptance Project
familyproject.sfsu.edu
A research-based, culturally grounded approach to help ethnically, socially, and religiously diverse families decrease rejection and increase support for their LGBTQ+ children. The website offers printable handouts in multiple languages.

Gender Spectrum
www.genderspectrum.org
Gender Spectrum provides education, training, and support to help create a gender-sensitive and inclusive environment for all children and teenagers. It provides resources to help families, educators, professionals, and organizations understand and address the concepts of gender identity and expression.

PFLAG (formerly Parents, Families and Friends of Lesbians and Gays)
https://pflag.org
PFLAG promotes the health and well-being of LGBTQ+ persons, their families, and friends through support, education, and advocacy.

For Professionals

American Academy of Pediatrics Section on Lesbian, Gay, Bisexual, and Transgender Health and Wellness
www.aap.org/en-us/about-the-aap/Sections/Section-on-LGBT-Health-and-Wellness/Pages/SOLGBTHW.aspx
The mission of this American Academy of Pediatrics section is to support the health and wellness of LGBT children and their parents/guardians, families, and health providers; children with variations in gender presentation; as well as LGBTQ+ pediatricians and trainees.

Centers for Disease Control and Prevention Lesbian, Gay, Bisexual and Transgender Health Website
www.cdc.gov/lgbthealth/index.htm
The perspectives and needs of LGBT people should be routinely considered in public health efforts to improve the overall health of every person and eliminate health disparities.

Fenway Institute
https://fenwayhealth.org/the-fenway-institute
The Fenway Institute is dedicated to advancing the skills, attitudes, and knowledge of clinicians and other health professionals by providing professional development, educational materials, and resources on LGBTQ+ health topics. The website offers several online educational modules for physicians.

GLMA: Health Professionals Advancing LGBTQ Equality (formerly Gay and Lesbian Medical Association)
www.glma.org
The mission of GLMA is to ensure equality in health care for LGBTQ+ individuals and health professionals. The GLMA website features an online provider directory and educational materials.

Society for Adolescent Health and Medicine
www.adolescenthealth.org/Resources/Clinical-Care-Resources/Sexual-Reproductive-Health.aspx
This website offers a variety of information of sexual and reproductive health information for adolescents categorized by target population, including providers, parents, and teenagers.

CHAPTER 58

Reproductive Health

Monica Sifuentes, MD

CASE STUDY

An 18-year-old female college student in good health comes in for a routine health maintenance visit during her spring break. She is unaccompanied by her parents and has no complaints, stating that she just needs a checkup. She enjoys college, passed all her fall and winter classes, and has some new friends. She denies tobacco use but says many of her friends smoke e-cigarettes. She occasionally drinks alcohol and has tried marijuana once. Although she is not currently sexually active, she is interested in discussing contraceptive options. Her last menstrual period, which occurred 2 weeks previously, was normal. She is taking no medications. Her physical examination is entirely normal.

Questions

1. What issues are important to discuss with adolescents at reproductive health maintenance visits?
2. What are the indications for a complete pelvic examination?
3. When is a Papanicolaou test indicated as a part of the reproductive health visit?
4. What methods of contraception are most successful in adolescent patients? What factors about each method should be considered?
5. What are the legal issues involved in prescribing contraception to minors in the absence of parental consent?

Adolescent visits to primary care physicians are relatively infrequent by the time teenagers reach puberty. At most, the healthy adolescent patient is seen once or twice during high school for preparticipation sports or camp physicals. If an adolescent is not involved in athletics or if activities in which the adolescent is involved do not require periodic assessments, such a teenager will rarely visit a health professional while in high school except for an acute illness. Therefore, it is extremely important to use any interaction with an adolescent as a unique opportunity to provide anticipatory guidance and health education, particularly reproductive health education. This chapter is largely devoted to a discussion of the reproductive health of adolescent females. However, the Evaluation section is divided into 2 sections, 1 for females and 1 for males. The reader is referred to Chapter 60 for more information on sexually transmitted infections.

Reproductive health is multidimensional and includes sexuality-related services, screening for communicable infections, anticipatory guidance, and counseling. Such services should be included as a part of the routine health maintenance examination for male and female adolescents for several reasons. The high incidence of sexually transmitted infections (STIs) in this age group, the risk of acquiring HIV, and the reality of an unplanned pregnancy make reproductive health issues increasingly important for teenagers and young adults. Additionally, adolescents rarely schedule appointments with primary care physicians prior to the initiation of coitus. Experimentation with drugs and alcohol at this time in their lives also contributes to early, unplanned sexual experiences (Box 58.1).

Aside from issues of sexual activity, the adolescent also may have questions about the progression through puberty. Normal variants in body habitus or certain physical characteristics can be a source of unnecessary anxiety for the uninformed teenager. Health education to alleviate these fears is ideal. The adolescent who is seen for a health maintenance examination should be allotted extra time so that topics such as puberty, abstinence, gender identity, sexual behaviors and activity, STIs, and contraception can be discussed. Additionally, during more acute, problem-oriented visits, the adolescent should be encouraged to voice any other concerns he or she may have. Depending on the nature of these issues, follow-up appointments can be scheduled.

Normal Secondary Sexual Development

Puberty begins during early adolescence with the development of secondary sexual characteristics. Because of the tremendous variation in the age, duration between pubertal stages, and somatic growth of adolescents, a sexual maturity rating (SMR [ie, Tanner stage]) is used to describe breast and pubic hair development in females and genital development and pubic hair growth in males (Figures 58.1, 58.2, and 58.3). The average age of menarche in the United States is 12.5 years, which for most females occurs during SMR 3 and 4. In contrast, spermarche occurs early in pubertal development in boys, at approximately 13 years of age, with little to no pubic hair development. Full fertility is generally achieved by age 15 years, or mid-adolescence, in most boys and girls.

Box 58.1. Reproductive Health: Sexual Activity

Statistics on sexual activity among adolescents in the United States have changed over the last decade. Previously, it was reported that 1 in 4 females and 1 in 3 males had had sexual intercourse by 15 years of age. Currently, only 13% of teenagers have ever had vaginal intercourse by age 15, according to the Guttmacher Institute. Currently, most adolescents are waiting to initiate sexual activity; by their 19th birthday, 7 in 10 teenagers of either sex have had sexual intercourse. Contraceptive use at first premarital sexual encounter has increased to nearly 80% in adolescent females and 87% in adolescent males; however, unintended pregnancy and sexually transmitted infections (STIs) continue to be a major public health concern for this age group. Although the pregnancy rate among teenagers has dropped steadily over the past 10 years, each year nearly 850,000 adolescent females younger than 20 years become pregnant. Most of these pregnancies are unintended and occur premaritally, especially among certain racial and ethnic minority groups. The outcome of these pregnancies in 15- to 19-year-olds varies. An estimated 50% to 60% of these pregnancies result in live births, 30% end in abortion, and 10% to 15% are miscarried or stillborn.

Unprotected sexual activity among adolescents has several adverse health consequences, the most obvious being teenage pregnancy. Of the adolescents who continue their pregnancies, preterm birth (<37 weeks' gestational age) and low birth weight (<2,500 g [5.5 lb]) are 2 of the most frequently reported neonatal complications. Long-term maternal psychosocial sequelae of adolescent pregnancy include undereducation/school failure, limited vocational training and skills, economic dependency on public assistance, subsequent births, social isolation, depression, and high rates of separation and divorce among teenage couples.

In addition to unintended pregnancy, the risk of contracting an STI, such as chlamydia, human papillomavirus, herpes, and HIV, is increased. In cases of pelvic inflammatory disease from gonorrhea or chlamydia, future problems with fertility and an increased risk of ectopic pregnancy can occur. Human papillomavirus, which is associated with the development of genital warts, cervical dysplasia, and cancer, accounts for approximately one-half of STIs diagnosed in adolescents and young adults. The prevalence rates of other STIs, such as chlamydia and gonorrhea, are still highest among 15- to 19-year-old females compared with older age groups in the United States. More alarming, however, is the relationship between AIDS in young adults aged 20 to 29 years and probable exposure to HIV during adolescence.

Many factors have been associated with the initiation of early coitus in adolescents. They include male sex; race/ethnicity; poverty; a large, single-parent family; previous teenage pregnancy in the household, whether of the mother or a sibling; poor academic achievement; discrepancy between the onset of physical puberty and cognitive development; peer group encouragement; and problem behaviors, such as drug use. Additionally, religious affiliation and cultural norms likely influence this decision. The role of hormonal changes during puberty and their influence on behavior remains unknown.

The adolescent with an intellectual disability that may or may not be associated with chronic illness requires special consideration in terms of reproductive health. With recent advances in medical therapy for conditions such as diabetes mellitus and sickle cell disease, many of these adolescents experience normal pubertal development and fertility. Like their healthy peers, some begin engaging in sexual intercourse at an early age. Unintended pregnancy and childbirth can exacerbate some chronic illnesses and can increase health risks significantly for both the adolescent and developing fetus. The genetic implications and specific patterns of inheritance of certain medical conditions must also be considered. Thus, attention to sexual issues is essential for the adolescent or young adult with chronic medical illness and/or intellectual disability.

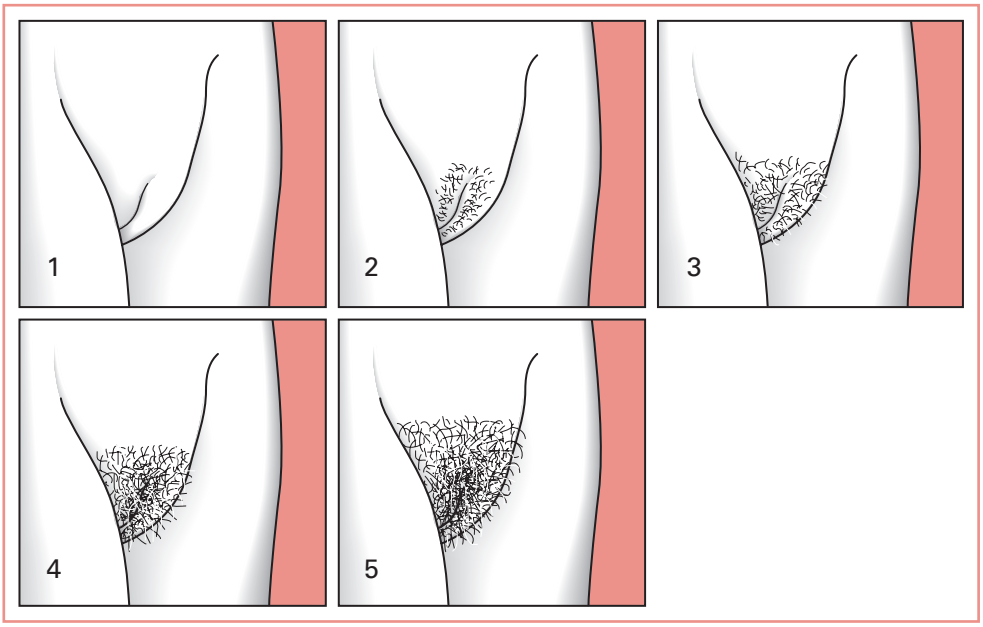

Figure 58.1. Female pubic hair development. Sexual maturity rating 1: prepubertal, no pubic hair. Sexual maturity rating 2: straight hair is extending along the labia and between ratings 2 and 3, begins on the symphysis pubis. Sexual maturity rating 3: pubic hair is increased in quantity; is darker, coarser, and curlier; and is present in the typical female triangle. Sexual maturity rating 4: pubic hair is more dense, curled, and adult in distribution but is less abundant. Sexual maturity rating 5: abundant, adult-type pattern; hair may extend on the medial aspect of the thighs.

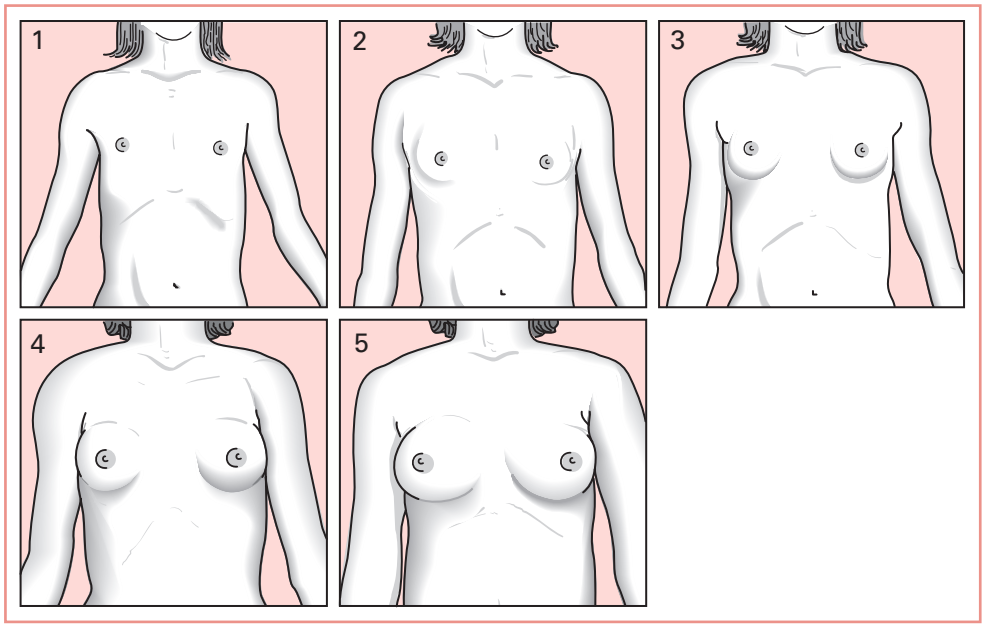

Figure 58.2. Female breast development. Sexual maturity rating 1: prepubertal, elevations of papilla only. Sexual maturity rating 2: breast buds appear, areola is slightly widened and projects as small mound. Sexual maturity rating 3: enlargement of the entire breast with no protrusion of the papilla or of the nipple. Sexual maturity rating 4: enlargement of the breast and projection of areola and papilla as a secondary mound. Sexual maturity rating 5: adult configuration of the breast with protrusion of the nipple, areola no longer projects separately from remainder of breast.

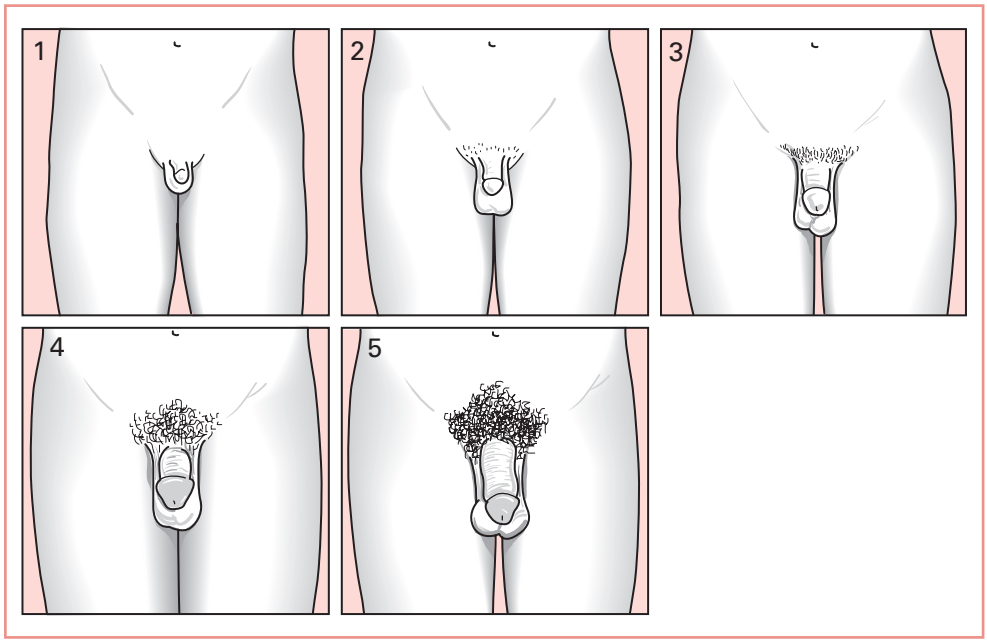

Figure 58.3. Male genital and pubic hair development. Sexual maturity rating 1: prepubertal, no pubic hair, genitalia unchanged from early childhood. Sexual maturity rating 2: light, downy hair develops laterally and later becomes dark; penis and testes may be slightly larger; scrotum becomes more textured. Sexual maturity rating 3: pubic hair is extended across pubis; testes and scrotum are further enlarged; penis is larger, especially in length. Sexual maturity rating 4: more abundant pubic hair with curling, genitalia resemble those of an adult, glans has become darker. Sexual maturity rating 5: adult quantity and pattern of pubic hair, with hair present along the inner borders of the thighs. The testes and scrotum are adult in size.

Evaluation

History

The history obtained at a reproductive health visit should include 2 parts: the medical history, which in females focuses primarily on the gynecologic history, and the psychosocial interview. Regardless of the type of visit scheduled, the physician should take a few moments at the beginning of the interview to address routine health maintenance issues with the adolescent (Box 58.2). For the female patient, the primary care physician should ask whether she has ever undergone a genital or pelvic examination. Additionally, current methods of contraceptive use, if any, should be reviewed (Box 58.3). If the adolescent female has just started taking oral contraceptives, compliance, common side effects, and a review of the more emergent complications of birth control pills is warranted, especially at an initial visit. The acronym ACHES (abdominal pain, chest pain, headaches, eye problems, severe leg pain) is useful to remember life-threatening reactions that can be associated with hormonal contraceptive use (Box 58.4), although these reactions are uncommon in otherwise healthy adolescent girls. If the adolescent is using another form of contraception, adherence to and satisfaction with the particular method should be reviewed along with the respective common side effects. The physician should specifically inquire if the adolescent desires to continue the same method of birth control or is interested in another method.

The remainder of the psychosocial history, otherwise known as the HEADSS assessment (home, employment and education, activities, drugs, sexuality, suicide/depression), should be completed regardless whether the adolescent is currently sexually active (see Chapter 4). Risk factors for an unplanned pregnancy or unintentional exposures to STIs should be kept in mind when formulating a health care plan with the teenager.

Box 58.2. What to Ask

Reproductive Health

For Males and Females

- How is the adolescent feeling overall?
- Has the adolescent had any recent illnesses or conditions that the health professional should know about?
- When was the last physical examination performed? Did it include a genital or pelvic examination?
- Is the adolescent sexually active?
  - If so, are their sexual relationships with males, females, or both?
  - When was the last episode of vaginal or anal intercourse?
  - Was the last episode of sexual intercourse protected or unprotected?
  - Does the adolescent have oral sex?
  - How old was the adolescent when he or she they began having sexual relationships? Was it consensual? Coerced? Forced?
  - How many sexual partners does the patient have currently? How many sexual partners has the patient had in his or her lifetime?
- Is there any history of or ongoing physical or sexual abuse?
- Has the adolescent or any of the adolescent's partners ever been treated for a sexually transmitted infection or tested for HIV?

For Females Only

- What was the age at menarche?
- What was the date of the last menstrual period and the duration and amount of flow?
  - Are any symptoms, such as cramping, bloating, or vomiting, associated with menses?
  - Are any of these symptoms incapacitating? Do they cause the adolescent to miss school or work?
  - Does the mother or do any siblings have similar problems? If so, how do they manage them, if at all?

Box 58.3. What to Ask

Contraceptive Use

- Does the adolescent use condoms never, sometimes, or always?
- Is any other method of birth control also used?
- Is the adolescent female currently using oral contraceptives?
  - If so, what particular type is she taking, and how long has she been using this method of contraception?
  - How often does she miss taking the pill? What does she do when she fails to take the pill?
  - Does she experience common minor side effects, such as breakthrough bleeding, headache, or nausea?
- Is the adolescent female using a long-acting progestin, such as Depo-Provera? If so, has she experienced irregular bleeding, weight gain, hair loss, headache, or acne?
- Is there another method of contraception that the adolescent has used or might be interested in discussing or starting, such as long-acting reversible contraception?
- What does the adolescent know about emergency contraception?

Box 58.4. Danger Signs Associated With Oral Contraceptive Use

A	Abdominal pain (severe)
C	Chest pain (severe) with shortness of breath
H	Headaches
E	Eye problems (visual loss or blur)
S	Severe leg pain (calf and/or thigh)

Physical Examination

A complete physical examination should be performed on all adolescents, with particular attention paid to SMR, blood pressure, and growth chart. A chaperone should be present during the physical examination, particularly during the breast and genital examination, even if the patient and examiner are the same sex.

Males

The genitalia should be examined closely for penile and testicular size, distribution of pubic hair, and presence of any ulcerative,

vesicular, or wart-like lesions. Any urethral erythema or discharge should be noted. Testicular masses require further evaluation. Ideally, the physician should use this opportunity to teach the male adolescent how to perform a testicular self-examination.

Females

Before performing the physical examination, the physician should determine whether a full-speculum examination is indicated (Box 58.5). This decision should be based on the details of the individual case and not solely on the basis of sexual activity. With the advent of noninvasive screening methods for STIs, a routine pelvic examination often is unnecessary and not required before initiating contraception. Most experts now recommend the use of urine or vaginal-based nucleic acid amplification tests (NAATs) to screen for gonorrhea or chlamydia in lieu of endocervical swabs. If a speculum examination is indicated, however, proper preparation of the adolescent is imperative. This should include an explanation of the procedure and the physical sensations felt while the speculum is being inserted and the endocervical specimen is being obtained. In addition to a chaperone, the choice of who should be present during the examination (eg, parent or friend who may have accompanied the patient) and a discussion of the desired positioning (ie, supine or semi-sitting) are also important points to review with the patient. Additionally, the speculum, specimen swabs, and other equipment should be shown to the adolescent before she is draped. The goal is to minimize the adolescent's fears, anxieties, misconceptions, and discomfort about the examination.

A breast examination should be performed on female adolescents, and any breast tenderness, nodularity, or masses should be noted. This portion of the examination can be used to educate the patient about the purpose and importance of breast self-examinations and to document breast SMR.

The external genitalia should be examined in all adolescent females at least once during puberty regardless whether they are sexually active. The SMR and any congenital anomalies, such as asymmetric enlargement of the labia minora or an imperforate hymen, should be identified. In the sexually active adolescent, the external genitalia should be carefully examined for warts, ulcers, and vesicular lesions. Any urethral erythema, edema, or discharge that may indicate an otherwise asymptomatic chlamydial infection should be noted. If a pelvic examination is indicated, a vaginal discharge may be appreciated before inserting the speculum; ideally, however, the cervix should be examined for cervical ectopy, friability, and any lesions or discharge from the os. The vaginal mucosa should also be inspected as the speculum is withdrawn.

During the bimanual examination, the cervix should be palpated for any cervical motion tenderness. Uterine size and position should be appreciated, and adnexal tenderness or masses should be noted. Because normal ovaries are approximately the size of almonds, many physicians do not palpate them. A rectovaginal examination is necessary to rule out fistulas, especially in the postpartum adolescent. If the physician is unable to perform a vaginal bimanual examination, a rectoabdominal examination can be done to assess uterine size and position and the presence of adnexal masses.

Box 58.5. Indications for a Complete Pelvic Examination

- Pregnancy
- Request by the adolescent
- Unexplained lower abdominal pain
- Persistent abnormal vaginal discharge
- Unexplained vaginal bleeding
- Dysmenorrhea that is unresponsive to nonsteroidal anti-inflammatory drugs
- Suspected or reported sexual assault
- Perform a Papanicolaou test

Laboratory Tests

Because most *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infections in adolescents are asymptomatic, screening for these organisms via noninvasive urine-based or vaginal NAATs is recommended annually in all sexually active adolescents and more frequently in those who have a history of unprotected intercourse or a new sexual partner. If the adolescent has a vaginal discharge or cervical friability noted on speculum examination, the specimen should be obtained directly from the endocervix. A saline and potassium hydroxide wet mount should also be collected from the symptomatic patient. A Papanicolaou (Pap) smear should be performed in sexually active females who are 21 years or older. Although the Pap smear may detect *Trichomonas vaginalis* or the cytologic changes associated with human papillomavirus infection, routine screening in asymptomatic adolescents is not recommended. A NAAT (eg, polymerase chain reaction) for human herpesvirus should be performed if painful vesicles are noted on examination. As clinically indicated, a fresh vesicle can also be unroofed and a specimen sent for herpesvirus cell culture or NAAT.

Other laboratory tests include a rapid plasma reagin test for syphilis and an HIV screening test in the adolescent identified as high risk or at least annually. Baseline complete blood cell count, liver function tests, cholesterol, and hemoglobin A_{1C} may be indicated as part of the health maintenance visit but are not required before starting contraception. A pregnancy test is warranted in the sexually active female if the physician chooses to begin oral contraceptives or another method of hormonal contraception mid-cycle ("quick start" method) or if menses are late.

Management

Reproductive Health Education

All management plans during reproductive health visits should include a frank discussion of puberty, gender identity, sexual orientation, sexual behavior, and STIs regardless of current or prospective sexual activity. The adolescent also should be counseled about abstinence as an acceptable choice. Ideally, preventive health care measures, such as breast and testicular self-examinations, have been

reviewed during the physical examination. It is hoped that by encouraging adolescents' familiarity with these self-examinations, they will continue to perform them throughout their adult lives. The use of posters, plastic models, and electronic or written materials to reinforce the discussion is strongly encouraged. The goal of reproductive health education is to assist adolescents in identifying and communicating their thoughts and feelings about sexual abstinence as well as sexual activity and to aid in the prevention of unintended pregnancy, young parenthood, and STIs. Prevention programs offered by schools must be supplemented by open parental communication in the home about sexuality, although this varies considerably by family.

Legal Issues

The issue of confidentiality is important to consider when providing reproductive health care for the adolescent. Parental involvement should be strongly encouraged; however, health professionals are not required to disclose any confidential information to parents or guardians except in cases of suicidal ideation, harmful intent to others, and sexual or physical abuse. In most states, contraceptive services can be provided to adolescents age 12 years and older without specific knowledge or consent of a parent or guardian. In the United States, the complex issue of parental consent and pregnancy termination varies from state to state and should be reviewed by the individual health professional based on the state in which that individual practices medicine. All 50 states and the District of Columbia explicitly allow minors to consent for their own health services for STIs and do not require parental consent for STI care. Providing confidential care for adolescents enrolled in private health insurance plans, however, remains a difficult issue because many states mandate that health plans provide a written statement to the beneficiary about the services covered and received, including clinical services provided confidentially to teenagers.

Pap Smear

The recommendation of the American College of Obstetricians and Gynecologists is that cervical cancer screening should begin at 21 years of age. After the initiation of screening, a Pap smear for average-risk women age 21 through 29 years should be performed every 3 years. The rationale for not screening teenagers for cervical cancer is that there is little risk in not treating abnormal cervical cytology in adolescents because in this age group 90% to 95% of low-grade lesions, as well as many high-grade lesions, regress to normal spontaneously. Premature screening can result in an overdiagnosis of cervical dysplasia and an overtreatment of lesions with potentially harmful procedures, such as excision or ablation of the cervix. Because the incidence of cervical cancer is quite low among adolescents, the benefits of the Pap test are offset by the potential harm of unnecessary procedures and treatments in this young age group.

Contraceptive Methods

The appropriate method of contraception should be individualized according to the needs and acceptability for each adolescent. The risks, benefits, and limitations of the various contraceptive modalities should be discussed to maximize effectiveness, minimize discontinuation, and avoid contraceptive failures.

Barrier methods include male and female condoms, which have a typical pregnancy failure rate of 15% when used alone but provide protection against many STIs. Nonlatex male condoms are available for individuals with latex allergies; however, these condoms have an increased risk of slippage and breakage. Vaginal spermicides, such as nonoxynol-9, are available in a variety of forms (ie, foams, gels, films, suppositories) and should be used in conjunction with a barrier method because general concerns exist that these products in high doses can increase the risk of genital ulceration and irritation, thereby facilitating STI acquisition.

Hormonal contraceptive methods include combination oral contraceptives (COCs), the transdermal patch, the intravaginal ring, injectable long-acting progestin agents, and long-acting reversible contraceptives, such as the subdermal implantable rod and intrauterine devices (IUDs). Although previously not recommended but now offered for nulliparous teenagers, the levonorgestrel IUD is a highly effective and cost-efficient reversible contraceptive method that requires little compliance, making it especially useful for adolescents. Previous reports about increased rates of pelvic inflammatory disease in teenagers with IUDs are unsubstantiated. The withdrawal method, or coitus interruptus, and natural family planning are ineffective methods for adolescents for protection against pregnancy.

Hormonal Contraception

Combination oral contraceptives are an effective means of birth control for adolescents, with most pills containing 30 to 35 mcg ("low dose") to 20 mcg ("very low dose") of ethinyl estradiol (ie, a synthetic estrogen) and a progestin. Monophasic pills contain a fixed dose of estrogen and progestin throughout the 21-day pill cycle. Biphasic preparations contain a lower dose of the progestin component during the first 10 days of the cycle but are rarely used in teenagers. In triphasic pills, the doses of estrogen and progestin, or the progestin component alone, are varied 3 times throughout the cycle. This contraceptive was created to decrease the overall progestin-related side effects, such as hypertension, acne, and lipid abnormalities, but has not been shown to have any great advantage over a monophasic pill. Most recently, very low-dose monophasic estrogen (20 mcg) pills have been developed to minimize estrogen-related side effects and decrease discontinuation rates. However, 20-mcg estrogen pills may be associated with a higher rate of intermenstrual bleeding and less bone mass acquisition than 30- to 35-mcg pills, especially in young patients. Because of this, monophasic pills with 30 to 35 mcg of ethinyl estradiol are considered the first-line therapy for most teenagers who wish to use COC. Specific instances may exist, however, in which the lower efficacy of these pills must be taken into account and the ethinyl estradiol dose increased to 50 mcg, such as in patients concurrently receiving medications that increase the metabolism of synthetic steroids (eg, certain anticonvulsant agents).

Another COC regimen is 3-month continuous hormonal therapy followed by 1 week of withdrawal bleeding for young women

who prefer to menstruate only 4 times a year, that is, an extended-cycle pill. To reduce the frequency of breakthrough bleeding often experienced by users of the extended-cycle pill, another product is now available that replaces the placebo pills with 7 days of low-dose estrogen.

Progestin-only pills, referred to as minipills, also are available and are particularly useful in postpartum and lactating teenage mothers and for women with contraindications or an intolerance to estrogen. Because ovulation is not consistently inhibited by progestin-only pills, however, they must be taken at the same time every day, because the effect of cervical mucus thickening diminishes in 22 hours.

Clear medical benefits associated with COC use include prevention of pregnancy, protection against ovarian and endometrial cancers, decreased risk of functional ovarian cysts and benign breast conditions, improvement of acne, and decreased menstrual blood loss and menstrual symptoms, such as dysmenorrhea. The most common side effects of COCs include breakthrough bleeding, nausea, and breast tenderness, which generally resolve after 3 cycles. Although potential risks of COC include venous thromboembolic events, hypertension, and changes in the lipid profile, actual risks are minimal in most healthy adolescents without a personal or family history of thromboembolic events compared with the morbidity and mortality associated with teenage pregnancy and childbirth.

Other combined hormonal contraceptive methods for the adolescent include the vaginal ring (eg, NuvaRing, Annovera) and the transdermal patch (eg, Ortho Evra, Xulane). Approved in 2001, the vaginal contraceptive ring is a soft, flexible device that contains estrogen and progestin, which is released directly through the vaginal wall into the bloodstream. The ring is inserted into the vagina for 3 weeks, then removed for 1 week to allow for a withdrawal bleed. The ring can also be removed intermittently for up to 3 hours and remain effective. Systemic side effects are similar to other low-dose combined hormonal methods (eg, headache, breast tenderness, nausea, breakthrough bleeding and/or spotting); specific local effects include vaginal discharge and discomfort secondary to local irritation. Sensation of a foreign body and expulsion of the ring during coitus may also occur. The teenager must be comfortable with insertion and removal of the device for successful use of this method.

The transdermal adhesive patch is a thin, beige, 3-layered plastic patch that contains estrogen and progestin and is applied weekly to specific areas of the body (ie, lower abdomen, upper torso, upper arm, or buttocks) to complete the application of 1 patch per week for a total of 3 weeks, followed by 1 week patch-free during which menses occurs. Although these patches are well tolerated, high complete or partial detachment rates in teenagers have been documented. Additionally, an adolescent may have concerns about the visibility of the patch. Side effects are similar to those of other combined hormonal methods of contraception. Local effects include skin irritation, redness, and rash at the site of application. Reduced effectiveness has been reported in women weighing more than 198 lb (>90 kg). Additionally, concerns have been cited by the US Food and Drug Administration (FDA) about the risk of venous thromboembolic events associated with the patch, although conflicting data have been reported. The reader is referred to the article by Trenor et al in Selected References for a comprehensive review of this topic.

The long-acting injectable progestin depot medroxyprogesterone acetate (DMPA) (eg, Depo-Provera) is given intramuscularly every 3 months (12–14 weeks) to inhibit ovulation, thicken cervical mucus, and induce an atrophic endometrium; a subcutaneous formulation is also available. The most common side effect is irregular menstrual bleeding, especially in the first few months, and eventual amenorrhea with prolonged use. Weight gain remains a significant issue for some patients, particularly in the adolescent with overweight or obesity in whom exaggerated increases in weight occur. Breast tenderness and mood disturbances occur less frequently than weight gain. In 2004, the FDA issued a black box warning for DMPA about possible irreversible bone loss in women with long-term use of DMPA and a potential reduction in overall bone mineral density in teenagers that may contribute to the development of osteoporosis later in life. The FDA therefore recommends that DMPA should not be used in adolescents for longer than 2 years; however, many experts believe that the risk for pregnancy using an inferior method of birth control far outweighs the risk for the development of osteoporosis in a healthy teenager. Ongoing studies suggest that although an adolescent may not increase her bone mineral density while receiving DMPA and does experience bone loss, the effects appear to be temporary and reversible with the discontinuation of DMPA. The adolescent desiring this method of contraception should be made aware of the black box warning and receive adequate calcium and vitamin D and recommend supplementation if the diet appears suboptimal.

A subdermal implant (eg, Implanon, Nexplanon) is available for young women who desire a long-acting reversible method of contraception and has gained popularity as a good option for most adolescents because it requires no compliance after insertion. It is designed to deliver a low, steady dose of continuous progestin for 3 years via a single plastic polymer rod placed below the skin. Formal instruction for insertion and removal is required for the health professional interested in providing this form of contraception. The subdermal implant is highly effective; however, as with other long-acting progestin-only contraceptives, it is associated with bleeding irregularities, especially during the first year of use, which may contribute to its early discontinuation.

Other long-acting reversible contraceptives include levonorgestrel-releasing intrauterine systems (eg, Mirena, Skyla) and the copper IUD (ParaGard). Although previously not recommended for nulliparous women, including teenagers, Mirena was approved by the FDA in 2009 for treatment of severe menorrhagia and dysmenorrhea and is effective for up to 5 years. The Skyla IUD releases a lower dose of levonorgestrel and is approved for 3 years. An increased risk of pelvic inflammatory disease was previously thought to be associated with IUDs in teenagers, but this belief is no longer supported by

the literature. Side effects of intrauterine systems include headache, acne, and breast tenderness as well as irregular menstrual bleeding, particularly during the first 3 to 6 months of use. Additionally, 50% of women develop amenorrhea after 1 year of intrauterine system use. The copper IUD is approved for 10 years of effective long-term contraception and can be used for emergency contraception (EC) as well.

Emergency Postcoital Contraception

Emergency contraception (ie, the "morning-after pill") is an effective means of preventing unintended pregnancy in adolescents by providing high-dose progestin up to 5 days after unprotected intercourse. It requires, however, that the health professional educate teenagers about its availability and usage and that teenagers feel comfortable contacting their physician, if necessary, within 72 to 120 hours of unprotected or inadequately protected intercourse. Although EC is not meant to be used repeatedly as the sole method of contraception, it is useful for the unplanned sexual encounter, which is often the case with adolescents, or after a failed contraceptive method (eg, condom breakage) or sexual assault. Although different EC regimens exist, the most frequently used EC contains a total dose of 1.5 mg of levonorgestrel in a 1- or 2-dose regimen (eg, Plan B One-Step, Next Choice One Dose, My Way). Emergency contraception acts primarily by delaying or inhibiting ovulation. Levonorgestrel-based EC does not interrupt or disrupt an already established pregnancy and is not an abortifacient. Because levonorgestrel EC is not teratogenic, a pregnancy test is not required before its use.

The original EC regimen is a combination of high-dose estrogen and progestin, known as the Yuzpe method; however, nausea and vomiting occurs in approximately 25% to 30% of patients. To reduce these side effects, 2-pill formulations of progestin-only EC (eg, Plan B, Next Choice) are available, consisting of 2 doses of 0.75 mg of levonorgestrel taken 12 hours apart within 3 days of unprotected intercourse. Based on data reported by the World Health Organization, however, this regimen has been modified to take both pills at once up to 5 days after unprotected or inadequately protected intercourse. As a result, Plan B One-Step and its generic forms are now available as a single-pill regimen of 1.5 mg of levonorgestrel, which may improve adherence.

In the United States, progestin-only EC is now available over-the-counter without age restrictions and can be purchased from a pharmacy without the need to show identification. Some state laws also allow pharmacists to provide EC pills directly to individuals of all ages without requiring a doctor's prescription. Emergency contraception is most effective when used within the first 24 hours after unprotected coitus. Although side effects are less common than with the Yuzpe method, the side effects of single-dose progestin-only EC include nausea, vomiting, breast tenderness, and irregular bleeding patterns (eg, spotting); shortened interval to menses; and lighter or heavier menses. Because EC is safe and highly effective in preventing pregnancy, the physician should provide the sexually active teenager with information about the different types of EC, where and how to obtain it, and a prescription (for insured patients, if necessary) at the annual preventive health care visit.

Another type of EC, ulipristal acetate (eg, Ella), is a progestin receptor agonist/antagonist with a mechanism of action similar to levonorgestrel EC; it primarily works by delaying or inhibiting ovulation. Important differences, however, must be considered between ulipristal acetate and progestin-only EC. First and foremost, ulipristal acetate is more effective than progestin-only pills, particularly on the fifth day after sex. It also is more effective closer to the time of ovulation, when women are at greatest risk of pregnancy. Recent data also suggest that ulipristal acetate may be more effective for women with overweight or obesity (body mass index ≥26 or weight >74.8 kg [>165 lb]). Finally, ulipristal acetate is available only with a prescription, regardless of age. Pregnancy must be excluded before prescribing ulipristal because of the risk of fetal loss if used inadvertently in the first trimester of pregnancy. Patients also must be counseled to seek immediate medical attention if they become pregnant or experience severe lower abdominal pain within 6 weeks after its use, because ectopic pregnancy can occur. Common side effects of ulipristal acetate include headache, nausea, and abdominal pain.

Regardless of the type of EC used, the patient should be scheduled for a follow-up office or clinic appointment 2 to 3 weeks after using EC so that a repeat pregnancy test can be performed, treatment failures can be identified early, STI screening can occur, and consistent contraceptive options can be discussed.

Nonhormonal Contraception

Numerous studies and clinical experience have shown that nonhormonal methods are less effective in adolescents than in adults. Latex condoms in conjunction with a spermicide have become a crucial method of contraception since the emergence of AIDS, however. Although they help prevent transmission of some STIs, such as gonorrhea, chlamydia, trichomoniasis, and HIV, condoms do not protect against human papillomavirus and human herpesvirus infection overall because the genital area is not completely covered. Thus, the physician should take time during the office visit to explain these details and demonstrate proper use of condoms. Risks of condom use are minimal, except for allergic reactions to the spermicide, latex, or lubricants. The female condom is not widely used by adolescents but may be helpful in situations in which a male partner refuses to wear a condom. The inner ring may be inserted into the vagina up to 8 hours before intercourse, and neither a prescription nor physician visit is necessary to obtain a female condom. Some teenagers, however, may be uncomfortable with its insertion and the fact that the outer ring remains on the vulva during vaginal intercourse. Similar issues are encountered when considering the diaphragm as a contraceptive method for teenagers; therefore, it is not recommended as a first-line contraceptive method for most adolescents.

Sexually Transmitted Infections

All STIs should be managed according to the most recent guidelines published by the Centers for Disease Control and Prevention based on current epidemiology. See Chapter 60 for detailed discussion of the diagnosis and treatment of STIs in adolescents.

CASE RESOLUTION

A more detailed history should be obtained about the adolescent's menstrual history and daily activities (eg, With whom does she spend most of her time? What does she like to do in her spare time?). Additionally, the indications for a pelvic examination should be reviewed because most teenagers are not familiar with the new recommendations to delay the Pap smear until 21 years of age. Because the patient does not meet the new criteria for a Pap smear, the pelvic examination can be deferred. A discussion should follow about barrier and hormonal methods of contraception and their role in the prevention of pregnancy and STIs. Particular attention should be paid to the use of long-acting reversible contraceptives. Emergency contraception should also be reviewed with the patient. Written information as well as useful website addresses should be given to the adolescent for future reference. A follow-up visit should be scheduled for sometime in the next few months, especially if the patient decides to begin contraception.

CHAPTER 59

Vaginitis

Monica Sifuentes, MD

CASE STUDY

An 11-year-old girl is brought to your office with vaginal itching for 1 week and a yellow discharge on her underwear for the past 4 days. The girl reports no associated abdominal pain, vomiting, or diarrhea. She has no urinary problems and denies any history of sexual abuse. Although she occasionally bathes with bubble bath, she most often takes showers. Except for the vaginal complaint, she is healthy, and she takes no medications.

The physical examination is notable for a soft, nontender abdomen with no organomegaly. Bowel sounds are audible in all quadrants. The genitalia are sexual maturity rating (ie, Tanner stage) 2. The labia majora and minora and the clitoris all appear normal, and the hymen is annular in shape with a smooth rim. A scant amount of yellow discharge, along with minimal perihymenal erythema, is noted at the vaginal introitus. The anal examination is normal, with an intact anal wink.

Questions

1. What are the most common causes of vaginal discharge in prepubescent girls? In pubescent girls?
2. What basic history-related information must be obtained from all females whose chief complaint is vaginal discharge?
3. What specific methods are used to perform a gynecologic examination in prepubescent girls? In pubescent girls?
4. What is the appropriate laboratory evaluation for prepubescent girls who complain of vaginal discharge? For pubescent girls? How does this evaluation differ for pubescent girls who are sexually active?
5. What are the various treatment options for girls with vaginitis?

Vaginal discharge is not an uncommon occurrence in prepubescent and pubescent girls. Primary care physicians are largely responsible for differentiating between a physiologic discharge, or leukorrhea, and a pathologic discharge, which occurs, for example, with a bacterial or yeast infection. In cases of an abnormal discharge, the possibility of sexual abuse must be considered and investigated appropriately (see Chapter 145). Primary care physicians should become familiar with the various causes of vaginal discharge in prepubescent and pubescent girls. More importantly, they should be comfortable performing age-appropriate gynecologic examinations in these patients so that the appropriate treatment can be initiated.

Vulvovaginitis, a term that often is used interchangeably with vaginitis or vulvitis, signifies inflammation of the perineal area, often accompanied by vaginal discharge. The discharge may be bloody, malodorous, or purulent, depending on the etiology (Table 59.1).

Epidemiology

Vulvovaginitis is a common gynecologic complaint in prepubescent girls. Most cases of vulvovaginitis in this age group result from nonspecific inflammation; vaginal cultures show normal flora in 33% to 85% of such cases. The incidence of more specific bacterial causes, such as group A β-hemolytic streptococcus, has been reported in approximately 10% to 20% of patients. Its occurrence seems to be seasonal, however, and confirming the diagnosis depends on the use of proper culturing techniques using the appropriate media. Other bacterial causes include respiratory pathogens, such as *Haemophilus influenzae, Neisseria meningitidis,* and *Streptococcus pneumoniae,* and enteric organisms, such as *Escherichia coli, Shigella*, and *Yersinia enterocolitica.* A positive culture for sexually transmitted pathogens such as *Chlamydia trachomatis* or *Neisseria gonorrhoeae* is found in approximately 5% of children who are evaluated for child sexual abuse. Higher figures have been reported from select centers and when data from adolescent victims are included. These organisms are not considered part of the normal flora in prepubescent girls. Vaginal and rectal infections with *C trachomatis* can be acquired perinatally but usually are not considered perinatally acquired after 2 to 3 years of age.

Parasitic infections may also cause vaginal symptoms. Twenty percent of females with a rectal infestation of *Enterobius vermicularis,* the organism known as pinworm, have vulvovaginitis. Affected patients often complain of anal pruritus in addition to the vaginal discharge. Mycotic infections with organisms such as *Candida albicans* also can cause symptoms in prepubescent girls, although many of these girls have a previous history of recent oral antibiotic use, diabetes mellitus, immunosuppression, or other risk factors.

Clinical Presentation

Prepubescent and pubescent girls with vulvovaginitis most commonly present with a vaginal discharge, which may be white, purulent (ie, yellow or green), or serosanguineous. Consistency of the discharge can range from smooth and thin to thick and cottage

Table 59.1. Characteristics and Specific Causes of Vaginal Discharge

Color	*Consistency*	*Amount*	*Cause*
Clear/white	Thin	Variable	Physiologic leukorrhea; bacterial vaginosis
White	Cottage cheese–like	Moderate	*Candida*
White/yellow	Variable	Variable	Chemical irritation, pinworms, *Chlamydia trachomatis*, bacterial vaginosis
Yellow/green	Thick	Moderate–profuse	*Neisseria gonorrhoeae,* foreign body, *Trichomonas vaginalis,* group A β-hemolytic streptococci
Bloody	Variable	Variable	*Shigella,* group A β-hemolytic streptococci, foreign body

cheese-like. The discharge may also be malodorous. In addition, girls may complain of associated pruritus, erythema, urinary problems such as dysuria and increased frequency, and abdominal pain (Box 59.1). Sexually active pubescent girls with vaginitis from a sexually transmitted infection (STI) (eg, gonorrhea) generally have a more profuse, purulent discharge.

Pathophysiology

Prepubescent girls are at risk for developing vulvovaginitis for anatomic and physiologic reasons. Unlike pubertal girls and young adult women, prepubescent girls have no pubic hair and a smaller labial fat pad to protect the vaginal introitus. The labia minora are small and tend to open when girls are in a squatting position, thereby exposing the vaginal introitus. The relative proximity of the anus to the vagina in young girls also contributes to vaginal contamination with enteric organisms. More importantly, poor hygienic practices (ie, wiping back to front after urination or defecation) can further compound the problem.

In addition, the normal physiology of the vaginal epithelium in prepubescent girls predisposes to vaginitis and vulvar inflammation. The unestrogenized vaginal epithelium is relatively thin, immature, and easily traumatized. Additionally, unlike the acidic environment of the vagina in adult females, in prepubescent girls the pH of the vagina is neutral to alkaline, which allows overgrowth of pathogenic fecal and oropharyngeal bacteria. Local antibody production also may be lacking in the vagina of prepubescent girls. Vulvar skin is also easily irritated by harsh soaps, medications, chemicals such as bubble baths, and tight-fitting clothing or synthetic underwear. Girls who are overweight may be particularly susceptible to perineal irritation and subsequent inflammation of the area.

Box 59.1. Diagnosis of Vaginitis in Prepubescent and Pubescent Girls

- Nonphysiologic vaginal discharge
- Profuse, malodorous, or purulent vaginal discharge
- Perineal erythema
- Vaginal pruritus or irritation
- Dysuria

Differential Diagnosis

A vaginal discharge is normal at 2 distinct times in prepubescent girls: shortly after birth, secondary to the effects of maternal estrogen, and approximately 6 months to 1 year before the onset of menarche (physiologic leukorrhea), which occurs, in most girls, by sexual maturity rating (SMR) (ie, Tanner stage) 4. Other causes of vaginal discharge in prepubescent and pubescent girls are presented in Box 59.2.

Evaluation

Prepubescent Girls

History

A complete history should be obtained in all girls with a vaginal discharge (Box 59.3). Practitioners should inquire about the appearance of the discharge, its duration, and the relative amount. A profuse, purulent discharge is probably more consistent with 1 specific etiology (eg, *N gonorrhoeae*) than is a scant, thin discharge, which is suggestive of a nonspecific etiology. The existence of urinary problems also should be determined. Pooling of urine in the vagina secondary to labial fusion can result in vulvovaginitis in addition to a urinary tract infection. Changes in bowel or bladder habits and sudden changes in behavior, such as nightmares or inappropriate stranger anxiety, also should be noted. Such changes in behavior warrant a further inquiry into the possibility of sexual abuse, regardless of the practitioner's index of suspicion. Depending on the information disclosed and the age of the patient, a decision might be made to interview the child and parents or guardians independently. Other points to discuss include the type of detergents or soaps used for laundry as well as for bathing, because these may be irritating. Any recent illnesses also should be documented as a possible source of autoinoculation or, if oral antibiotics were prescribed, as a reason for the alteration of the normal vaginal flora. Additionally, patients' hygienic practices should be reviewed. Adolescent patients should always be interviewed alone (see Chapter 4). In particular, a confidential reproductive history must be obtained, keeping in mind that puberty and sexual activity alter normal vaginal flora.

Physical Examination

Although the genital examination is the priority, a complete physical examination should be performed. Doing so not only allows physicians to identify other abnormal physical findings, but also alleviates some

Box 59.2. Causes of Vaginal Discharge in Prepubescent and Pubescent Girls

Prepubescent Girls

- Estrogen withdrawal (neonates)
- Nonspecific vulvovaginitis
- Chemical irritation secondary to soaps and detergents
- Mechanical irritation from nylon panties or tight-fitting clothes
- Foreign body in vagina
- Poor hygiene
- Pinworms (*Enterobius vermicularis*)
- Yeast infection (eg, *Candida*)
- Bacterial infection (eg, group A β-hemolytic streptococcus, *Staphylococcus* species, nonencapsulated *Haemophilus influenzae, Escherichia coli, Shigella* species, *Salmonella* species, *Yersinia*)
- Sexually transmitted infection (eg, gonococcal infection, chlamydial infection, trichomoniasis, human herpesvirus, human papillomavirus)
- Congenital abnormality (eg, ectopic ureter [local inflammation])
- Acquired abnormality (eg, labial fusion [pooling of urine in vagina])
- Urethral prolapse
- Systemic illness (eg, scarlet fever, measles, varicella, Kawasaki disease, Crohn disease)
- Vulvar skin disease: lichen sclerosis, contact dermatitis, psoriasis, zinc deficiency

Pubescent Girls

- Physiologic leukorrhea
- Foreign body in vagina (eg, retained tampon or condom)
- Yeast infection (eg, *Candida)*
- Bacterial infection (eg, group A β-hemolytic streptococcus, *Staphylococcus aureus*)
- Sexually transmitted infection (eg, gonococcal infection, chlamydial infection, trichomoniasis, bacterial vaginosis)
- Chemical irritation (eg, douches, spermicides, latex [condoms])
- Local trauma (eg, penile or labial piercings)

Box 59.3. What to Ask

Vaginitis

Prepubescent Girl

- What is the color of the discharge?
- What is the consistency of the discharge?
- How profuse is the discharge?
- Is the discharge malodorous?
- How long has the discharge been present?
- How often does the discharge occur (ie, is it found on the panties daily)?
- Are there any associated problems (eg, dysuria, abdominal pain, enuresis, anal pruritus)?
- What types of laundry soap or detergent are used?
- Does the child take bubble baths?
- Has the child had any recent illnesses or treatment with oral antibiotics?
- Does the child clean herself after using the toilet, or does she require help?
- In what direction does she tend to wipe after a bowel movement?
- Is there a concern for, or history of, child sexual abuse?
- Has there been any recent behavioral changes (eg, nightmares, crying, recurrent abdominal pain)?
- What has the family done to manage the discharge?

Pubescent Girl (all of the above questions plus the following)

- What is the reproductive history (menstrual and sexual)?
- Does the adolescent douche or use scented panty liners?
- Does the adolescent use or share sex toys?
- Is there a history of sexual assault or abuse?
- If appropriate, is the adolescent using any form of barrier or hormonal contraception? When was the last episode of unprotected intercourse?
- How many sexual partners has the patient had?
- Does the patient or partner have any history of a previous sexually transmitted infection, including hepatitis B or C?

of the anxiety often associated with a genital examination. Because most vaginal discharges in prepubescent girls result from nonspecific vulvovaginitis, visualization of the cervix with a speculum is not indicated. Regardless of the sex of the examiner, a chaperone is required during the genital examination, particularly in postpubertal patients.

The overall demeanor of the young patient at the onset of the genital examination should be noted. Overly compliant, apathetic behavior in children may be a cause for concern for sexual abuse, especially in the context of a chronic or recurrent purulent vaginal discharge.

On physical examination, the patient's SMR must be noted and recorded. In addition, the external genitalia should be examined closely for the presence of any lesions or evidence of erythema. Chronic changes in labial skin, such as those associated with constant scratching, also should be documented.

Girls should be placed in the modified lithotomy or batrachian (ie, frog-leg) position, and the labia majora should be gently spread apart to visualize the hymen. The knee-chest position also can be used, depending on the comfort level of the practitioner and the patient. If the labia cannot be spread apart, the girl may have labial fusion or adhesions. Perihymenal and periurethral erythema should be noted, in addition to any evidence of edema, trauma, or abnormal masses such as urethral prolapse. Hymenal size and appearance should be carefully evaluated for any evidence of suspected sexual abuse (see Chapter 145). The appearance, consistency, and amount of the vaginal discharge, including the presence or absence of an odor, also should be documented. These findings may vary depending on the characteristics and cause of the discharge. Finally, the anus should be inspected for tone and any evidence of trauma or abnormal lesions such as genital warts. An anal wink is normally elicited. Although not usually indicated, a rectal examination should be performed to attempt to palpate a foreign body or mass in patients with chronic or bloody vaginal discharge. If the examiner cannot adequately visualize the perineum, vulva, and vaginal introitus using the batrachian or knee-chest position and the patient has persistent or significant symptoms, an examination under anesthesia may be warranted.

Laboratory Tests

Laboratory studies are often unnecessary in prepubescent girls with a nonspecific, non-bloody vaginal discharge, diffuse vulvar erythema, and no suspicion or history of sexual abuse. A vaginal culture for isolation of group A β-hemolytic streptococcus is indicated in girls with an abrupt onset of a serosanguineous discharge and a history of a systemic illness. The cellophane tape test may be helpful in diagnosing a pinworm infection in prepubescent girls with associated vulvar or anal pruritus. A potassium hydroxide (KOH) wet mount reveals pseudohyphae if a monilial infection is present; however, this diagnosis is often made clinically.

If the discharge is purulent, persistent, or malodorous or if sexual abuse is suspected, vaginal cultures must be obtained for *N gonorrhoeae* and *C trachomatis.* For suspected cases of sexual abuse or assault, culture remains the standard because of the risk of a false-positive result with nonamplified probe tests (eg, direct immunofluorescent smears, enzyme immunoassays) and nucleic acid amplification tests (NAATs). With genital and anal specimens, false-positive results can occur because of cross-reaction with fecal flora. In certain cases, a normal saline wet mount to check for mobile trichomonads may be indicated.

Pubescent Girls

History

In adolescent or pubescent girls with vaginal discharge, physicians should inquire about a history of sexual activity or assault in addition to other information that relates to their condition (see Box 59.3). Questions concerning the possible acquisition of an STI also must be asked in a nonjudgmental, confidential manner.

Physical Examination

Pubescent girls with an uncomplicated history who have never been sexually active should be examined in a similar fashion as the prepubescent female. The external genitalia should be examined to evaluate the SMR of the patient and the presence of any lesions or anatomic abnormalities, although SMR assignment may be challenging in the adolescent who has shaved her pubic hair. Perihymenal or periurethral erythema and hymenal size and appearance should be noted. In the absence of a mucopurulent or bloody discharge, a speculum examination is generally not warranted, particularly in the virginal adolescent.

In addition to an overall physical examination, a complete external genital and speculum examination is indicated in symptomatic, sexually active girls (ie, history of lower abdominal pain, severe dysmenorrhea, vaginal discharge). The purpose of the speculum examination is to visualize the cervix, properly obtain vaginal and cervical specimens, and examine the vagina for lesions (eg, condylomata acuminata). A bimanual examination also should be performed to check for cervical motion tenderness as well as adnexal masses or uterine tenderness, which are associated with pelvic inflammatory disease.

Laboratory Tests

For pubescent girls who are not sexually active, the laboratory evaluation should be similar to that described for prepubescent girls. Sexually active adolescents, however, warrant a more thorough evaluation to establish the etiology of their symptoms and investigate for cervicitis. Generally, if a speculum examination is being performed in these adolescents, a single-swab endocervical sample should be obtained and sent for gonorrhea and chlamydia via NAATs (eg, ligase chain reaction, polymerase chain reaction). Urine or a vaginal swab also should be sent for *N gonorrhoeae* and *C trachomatis* in those adolescents who refuse a pelvic examination or for screening purposes in the asymptomatic sexually active patient. Recommendations have changed for teenagers concerning the age at which cervical cancer screening (ie, Papanicolaou test) is indicated (see Chapter 58 for details). A culture or polymerase chain reaction test for herpes simplex is indicated only if the history of exposure is positive and ulcerative or vesicular lesions are present.

Other causes of vaginal symptoms can be determined by the pH and microscopic analysis of a fresh sample of the vaginal discharge. A normal saline wet mount should be made using a sterile, saline-moistened swab, especially if a nonspecific discharge is present or bacterial vaginosis (BV) is a concern. In addition, motile or static trichomonads may be seen on a wet mount as well as white blood cells, although a diagnosis of trichomonas should be made using NAAT on a vaginal, endocervical, or urine specimen. A 10% KOH mount is appropriate in cases of suspected candidiasis. Mixing 10% KOH with the discharge may also produce a "fishy" odor (ie, positive "whiff test"), which is consistent with BV and sometimes a trichomonad infection. Additionally, a vaginal pH greater than 4.5 is common with BV or trichomoniasis, although it is not specific. Commercial kits to evaluate for BV, trichomoniasis, and candida via nucleic acid probes are available for the office setting in which pH paper, KOH, and microscopic analysis of vaginal fluids is not possible. A Gram stain of any purulent material may result in an early diagnosis of gonococcal cervicitis. Serologies for syphilis also should be obtained in adolescents with suspected (ie, symptomatic) or proven STIs. In addition, these patients should be offered annual testing for HIV and syphilis.

Management

The goal of management of a nonspecific vaginal discharge is relief of the uncomfortable symptoms associated with this type of inflammation. Prepubescent girls should be instructed to discontinue use of all chemical irritants, including bubble baths and harsh soaps, in the genital area. The physician should recommend once or twice daily warm water sitz baths for approximately 1 week or until symptoms have improved. A small amount of vitamin A and D ointment or similar emollient can be used to protect the vulvar skin and promote healing. In addition, girls should be instructed in proper hygiene (eg, wiping front to back after a bowel movement, appropriate hand washing). The use of cotton or cotton-crotch underwear

and loose-fitting skirts or pants should be encouraged. Occasionally, a persistent, nonspecific vaginal discharge of more than 2 to 3 weeks' duration may benefit from a 10-day course of oral antibiotics such as amoxicillin, amoxicillin-clavulanate, or clindamycin. Girls with obesity and poor hygiene are especially prone to recurrences of vulvovaginitis.

Anticandidal medications, such as clotrimazole or miconazole cream, may be prescribed if a monilial infection is present. Empiric treatment with either of these medications may be warranted in children or adolescents with a previous history of oral antibiotic usage, diabetes mellitus, or other chronic conditions that may alter the normal vaginal flora.

Pinworms are treated with 2 oral doses of albendazole 400 mg, or pyrantel pamoate 11 mg/kg per dose (maximum dose, 1 g), with the second dose given 2 weeks after the first. Most authorities recommend repeat treatment after 2 weeks to kill worms that may have hatched after the first dose. All household contacts and caregivers of the infected person also should be treated with medication and instructed on good hand hygiene to prevent reinfection. Bedding and clothing should be laundered in hot water and dried in a dryer.

If a retained foreign body is suspected in a prepubescent girl, an examination under general anesthesia may be necessary. Alternatively, in a cooperative child practitioners can attempt vaginal irrigation by placing a small feeding tube at the hymenal opening and injecting warm saline. Toilet paper is the most commonly retrieved material in prepubescent girls.

Pubescent girls who are not sexually active should be treated in a similar fashion as prepubertal girls. If the discharge is consistent with a diagnosis of physiologic leukorrhea, practitioners should reassure patients and educate them about other issues related to puberty (eg, menarche, body odor). Sexually active adolescents with positive vaginal cultures, NAATs, or highly suspicious vaginal discharges should receive treatment depending on the suspected or causal organism (see Chapter 60 for details concerning treatment). Table 59.2 briefly outlines current treatment recommendations.

Any disclosure of molestation or assault by prepubescent or pubescent girls must be reported to the appropriate authorities. In addition, abnormal physical findings and positive cultures for STIs in prepubescent and pubescent girls who have never been sexually active must be reported to law enforcement and investigated.

Prognosis

In most prepubescent girls, vaginitis resolves spontaneously or after appropriate treatment with no permanent sequelae. In contrast, pubescent girls treated for vulvovaginitis or uncomplicated cervicitis from an STI continue to be at future risk for the development of pelvic inflammatory disease, HIV, and pregnancy because of their high-risk behavior, inconsistent use of barrier contraception (eg, condoms), and recurrent exposure to STIs.

Table 59.2. Treatment Recommendations for Adolescents With Infectious Vaginal Discharge

Organism	*Treatment*[a]
Neisseria gonorrhoeae	Ceftriaxone 250 mg intramuscularly once, *PLUS* azithromycin 1 g orally in a single dose
Chlamydia trachomatis[b]	Azithromycin 1 g orally once, or doxycycline orally 100 mg twice per day for 1 week
Trichomonas vaginalis	Metronidazole 2 g orally once, or tinidazole 2 g orally once
Bacterial vaginosis	Metronidazole 500 mg orally twice per day for 7 days; or metronidazole gel 0.75%, 1 applicatorful intravaginally once per day for 5 days; or clindamycin cream 2%, 1 applicatorful intravaginally at bedtime for 7 days[c]
Candida albicans	Over-the-counter intravaginal agents: 1% clotrimazole cream 5 g intravaginally for 7–14 days; 2% clotrimazole cream 5 g intravaginally for 3 days; 2% miconazole cream 5 g intravaginally for 7 days Prescription intravaginal agents: 4% miconazole cream 5 g intravaginally for 3 days; 0.4% terconazole cream 5 g intravaginally for 7 days; 0.8% terconazole cream 5 g intravaginally for 3 days; fluconazole 150 mg orally once

[b] May be associated with vaginal discharge, because it causes cervicitis.

[c] Oil-based product; thus, condom efficacy may be decreased during treatment.

CASE RESOLUTION

The girl and her parents should be assured that the discharge is consistent with a nonspecific inflammatory process. She should be instructed to take sitz baths for 1 week, discontinue bubble baths and the use of soap in the genital area, and wear loose-fitting clothes and cotton underwear. The girl should be reexamined in 1 to 2 weeks for resolution of her symptoms. No laboratory studies or medications are warranted at this time.

CHAPTER 60

Sexually Transmitted Infections

Monica Sifuentes, MD

CASE STUDY

A 17-year-old boy presents with a small red lesion on the tip of his penis. He noticed an area of erythema a few weeks previously, but it resolved spontaneously. He reports no fever, myalgia, headache, dysuria, or urethral discharge. He is sexually active and only occasionally uses a condom. He did not use a condom during his last sexual encounter 2 weeks previously, however, because his partner uses oral contraception. The adolescent has never been treated for any sexually transmitted infection and is otherwise healthy. His partners are exclusively female.

On examination, he is a sexual maturity rating (ie, Tanner stage) 4 circumcised male with a 2- to 3-mm vesicle on the glans penis. Minimal erythema is present at the base of the lesion, and no urethral discharge is evident. The testicles are descended bilaterally, and no masses are palpable. Bilateral shotty, nontender, inguinal adenopathy is evident.

Questions

1. What conditions are associated with vesicles in the genital area?
2. What risk factors are associated with the acquisition of sexually transmitted infections during adolescence?
3. What screening tests should be performed in the patient with suspected sexually transmitted infection?
4. What recommendations about partners of the patient with sexually transmitted infection should be given?
5. What issues of confidentiality are important to address with the adolescent who seeks treatment for a sexually transmitted infection?

Many teenagers in the United States have their first sexual experience before they graduate from high school. In the 2017 national Youth Risk Behavior Surveillance System conducted by the Centers for Disease Control and Prevention (CDC), 40% of all students in high school reported having had sexual intercourse, with 3.4% of students nationwide reporting sexual intercourse for the first time before age 13 years. More important, nearly 12% of boys and 8% of girls in grades 9 to 12 reported having had 4 or more sexual partners during their life. The consequences of sexual activity in adolescents include increased rates of bacterial and viral sexually transmitted infections (STIs), unintended pregnancy, and the possible acquisition of long-term infections (eg, HIV) in the 15- to 24-year age group. Early detection and effective management of these infections, particularly HIV, can greatly enhance the teenager's current health and overall lifespan and reduce the risk of transmitting HIV to others. Because of the complex nature of these consequences, the physician must be skilled in and comfortable obtaining a complete sexual history in the adolescent patient and in diagnosing and managing common STIs and must refer individuals with more complicated infections to the appropriate subspecialists.

Increasing levels of risk-taking behaviors and sexual activity in adolescence directly affect STI trends in that patient population. Other influential factors include multiple sex partners, whether sequential or concurrent; inconsistent and incorrect use of condoms; unprotected sex; experimentation with drugs, including alcohol, which results in poor judgment concerning sexual activity; mental health issues; poor adherence to antibiotic regimens; and biologic factors, such as young age at onset of menarche and the presence of cervical ectopy in adolescent females. The feeling of invulnerability and the desire for autonomy that occur commonly during adolescence make most sexual encounters spontaneous rather than premeditated. As a result, preventive measures are forgotten, ignored, or overlooked by individuals of this age group, and the short- and long-term consequences of their actions are seldom considered. Other factors that influence STI trends are related to societal norms. Traditionally, unlike in other industrialized countries, educational materials and STI services have not been readily available to adolescents in some areas of the United States. Many teenagers also have difficulty accessing comprehensive health care in their communities and are concerned about confidentiality when obtaining medical services for sensitive issues. Additionally, the depiction of casual sexual relationships in the media, music videos, and motion pictures may contribute to the glamorization of sex. Advances in technology via unlimited internet access also give teenagers the opportunity to communicate with peers who were previously unreachable and to access health information that is unfiltered and may be misleading.

Epidemiology

The overall prevalence of STIs in adolescents is difficult to estimate because not all STIs are reportable, many infections are asymptomatic, and collected data may not include specific subsets of the population. It has been estimated, however, that more than 50% of all new STIs diagnosed annually in the United States occur among teenagers and young adults aged 15 to 24 years. After human papillomavirus (HPV), *Chlamydia trachomatis* is the second most common STI in the United States. *Chlamydia trachomatis* remains the most common cause of cervicitis and urethritis in adolescents, with age-specific rates highest among girls and young women 15 to 24 years of age and young men 20 to 24 years of age. Additionally, studies have shown that certain adolescent subpopulations are at increased risk for chlamydial infection, such as homeless and incarcerated youth, socioeconomically disadvantaged youth, ethnic minority youth, teenagers attending family planning clinics, and pregnant adolescents. Complications of unmanaged chlamydial cervicitis occur in 10% to 15% of cases and include pelvic inflammatory disease (PID), ectopic pregnancy, chronic pelvic pain, and infertility. Epididymitis, a result of urethral infection, occurs in 1% to 3% of infected males. Other conditions that may occur in males engaging in receptive intercourse include proctitis, proctocolitis, and reactive arthritis (formerly known as Reiter syndrome).

In 2017, the CDC reported gonorrhea rates to be highest among adolescents and young adults compared with the general population, particularly among teenage girls and young women. The highest rates of gonorrhea reportedly occur in adolescent females, young men in their early 20s, young ethnic minority adults living in the inner city, incarcerated youth, men who have sex with men, and commercial sex workers. Injection drug use, exposure to commercial sex workers, and numerous sexual contacts also contribute to the risk of infection. The prevalence of gonorrhea in 15- to 19-year-old girls and young women was 557 per 100,000 population. Boys and young men 15 to 19 years of age had the second highest rates of gonorrhea (323 per 100,000) compared with men age 20 to 24 years, who had even higher rates of gonorrhea (705 per 100,000). Of the more than 1 million cases of PID reported annually in the United States, approximately 20% occur in sexually active adolescents. The risk of developing PID is increased several fold in this age group compared with adult women for several reasons: failure to use condoms consistently, multiple new partners within the previous 12 months, and a history of other STIs. Additionally, according to the National Survey of Family Growth conducted by the CDC, girls who initiated vaginal intercourse at younger than 15 years had the highest prevalence of PID. Complications of PID, such as tubo-ovarian abscess (TOA) formation, are more likely to occur in adolescents as a result of late presentation, delayed diagnosis, difficulty accessing health care, and nonadherence with prescribed treatment regimens.

Although the rate of primary and secondary syphilis declined from 1990 to 2000, the number of cases has since been increasing at epidemic proportions, primarily among young men of color who have sex with men. During 2005, the incidence of syphilis was highest among women in the 20- to 24-year-old age group and among men in their mid-30s. In 2017, however, young men age 20 to 24 years had the highest rates of syphilis. Studies have shown that people with syphilis, as well as other STIs that cause genital ulcers, also are at increased risk for HIV acquisition.

Human papillomavirus is the most common STI in the United States, with the highest infection rates among adolescents and young adults. Recent studies report a prevalence in sexually active adolescents ranging from 30% to 60%, with one-half of new infections occurring in individuals 15 to 24 years of age. The prevalence of HPV in adolescents varies widely for 2 reasons: infection with HPV is often latent and generally regresses spontaneously, particularly in young adolescents, and HPV is not a reportable condition. Behavioral and biological risk factors for HPV infection have been identified and include early age of sexual initiation, unprotected intercourse with multiple sexual partners, the partner's number of sexual partners, a lack of consistent condom use, and a history of another STI, such as genital herpes, which may facilitate HPV acquisition by compromising mucosal integrity. Cigarette use also increases the risk of infection and HPV-related disease, as does an altered immune system.

Infection with herpes simplex virus (HSV-1 and HSV-2) is underestimated and is the most common cause of genital ulcerative disease in the United States. Most primary episodes in adolescent females and young men who have sex with men are caused by HSV-1 and recurrent infections by HSV-2.

As of 2016, 21% of all new HIV diagnoses in the United States were among youth. According to the CDC, most of those new diagnoses occurred among young gay and bisexual men, particularly young black/African American and Hispanic/Latino gay and bisexual men. Because the time from acute HIV infection to immunosuppression is, on average, 10 years for untreated adolescents, estimates of asymptomatic or early HIV infection often are based on reported cases of AIDS in young adults in their third decade. Most of these individuals are infected through sexual contact or injection drug use. Teenage subpopulations who are at particularly high risk for acquiring HIV are youth who have male-to-male sexual contact; are transgender; are experiencing homelessness or who have run away; are users of injection drugs; are incarcerated; are in the foster care system; or have been sexually or physically abused. Of note, research has shown that young gay men who have sex with older partners are at increased risk for HIV infection because the older partner is more likely to have had more sexual partners and therefore has an increased likelihood of being infected with HIV.

Clinical Presentation

The adolescent with an STI may consult his, her, or their physician with specific complaints related to the genitourinary system, such as painful urination or vaginal discharge. The adolescent also may report more generalized complaints, such as fever, rash, and malaise, especially in cases of primary HSV-1 and HSV-2 infection or during the viremic phase of HIV acquisition (Box 60.1). Additionally, some teenagers use a vague complaint as an opportunity to visit their primary care physician with the hope that the physician will inquire

Box 60.1. Diagnosis of Sexually Transmitted Infection

Males

- Dysuria
- Urethral discharge or pain
- Testicular pain
- Presence of any lesions in the genital area, such as ulcers, vesicles, or warts
- Nonspecific rash
- Sexual partner who has a sexually transmitted infection

Females

- Dysuria
- Abnormal vaginal discharge
- Intermenstrual or irregular vaginal bleeding
- Dysmenorrhea
- Dyspareunia
- Postcoital bleeding
- Lower abdominal pain
- Nonspecific rash
- Systemic symptoms, such as fever, nausea, vomiting, or malaise
- Presence of any lesions in the genital area, such as ulcers, vesicles, or warts
- Sexual partner who has a sexually transmitted infection

about sexual behaviors. The likelihood that the adolescent will disclose his, her, or their true concern about an undiagnosed infection is greatly increased if the physician appears genuinely interested and nonjudgmental.

Pathophysiology

Several biologic factors contribute to the increased prevalence of STIs in adolescents, particularly in females. At the onset of puberty, the columnar epithelial cells in the vagina transform to squamous epithelium, while columnar cells at the cervix persist (Figure 60.1). With increasing age, the squamocolumnar junction recedes into the endocervix. In adolescent females, however, this junction, referred to as cervical ectopy, often is located at the vaginal portion of the cervix and is relatively exposed, which places these individuals at particular risk for gonococcal and chlamydial infections. The infectious organisms preferentially attach to cervical columnar cells and infect them. The use of oral contraceptives prolongs this immature histologic state.

The cytologic changes observed in cervical cells of adolescents with HPV infection are also believed to be age-related. The immature cervical metaplastic or columnar cells seem to be more vulnerable to infection and neoplastic changes. Additionally, exposure to other cofactors (eg, tobacco use, multiple episodes of new HPV infection) is likely to promote the development of squamous intraepithelial neoplasia and cervical carcinoma. Not all young women exposed to

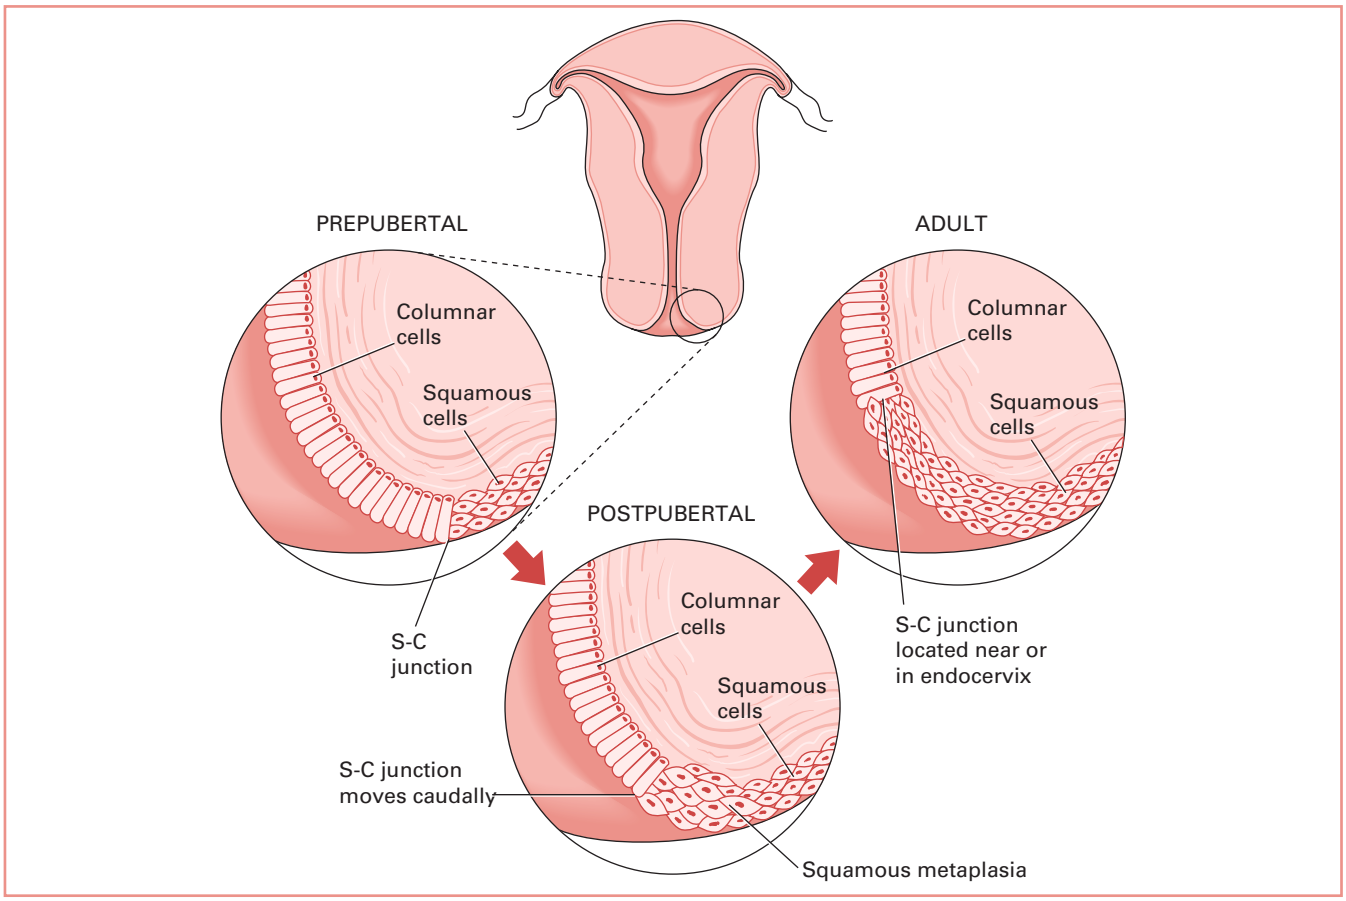

Figure 60.1. Development of the cervical squamocolumnar (S-C) junction, from puberty to adulthood.

HPV develop lesions or progress to squamous intraepithelial neoplasia, however, and most do not remain positive for HPV throughout their lifetime.

The presence of genital ulcers has been shown to facilitate the transmission and acquisition of HIV. Such ulcers provide a point of entry past denuded epithelium. Additionally, it is hypothesized that many activated lymphocytes and macrophages are located at the base of the ulcer and are therefore susceptible to infection by HIV.

Pelvic inflammatory disease usually manifests from an ascending mixed polymicrobial infection, often related to an untreated STI of the cervix and vagina. The infection spreads contiguously upward to the upper genital tract, resulting in inflammation involving the endometrium, fallopian tubes, and/or ovaries. The most common causal organisms, which account for more than one-half of the cases of PID in most series, are *C trachomatis* and *Neisseria gonorrhoeae.* Other organisms include *Escherichia coli,* other enteric flora, and microbes implicated in bacterial vaginosis, such as *Mycoplasma hominis*, *Mycoplasma genitalium*, *Ureaplasma urealyticum*, *Bacteroides* species, and anaerobic cocci. Viruses such as HIV and HSV-1 and HSV-2 can facilitate the process of this ascending infection by disrupting normal immunologic barriers to infection, such as altering the vaginal pH and flora and the cervical mucus barrier.

Differential Diagnosis

Most patients with STIs present with 1 of 5 clinical syndromes: urethritis/cervicitis, epididymitis, PID, genital ulcer disease, or genital warts, all of which are easily diagnosed with the appropriate diagnostic studies (Box 60.2). Other conditions that mimic STIs must be considered, however, particularly in certain cases in which the adolescent denies sexual activity or in which the disorder does not respond to routine medical management. These disorders include mucocutaneous ulcers associated with systemic lupus erythematosus and Behçet syndrome. Often, systemic disorders such as these can be ruled out based on the history, although a minimal workup may be necessary. Benign oral lesions, such as aphthous ulcers, also can be confused with herpetic ulcers. When evaluating an adolescent female with acute lower abdominal pain, it is necessary to rule out surgical conditions such as appendicitis, ovarian torsion, and ectopic pregnancy. In the sexually active male with testicular pain, testicular torsion must be cautiously considered and thoroughly evaluated before a diagnosis of acute epididymitis is made.

Box 60.2. Differential Diagnosis of Sexually Transmitted Infection by Clinical Syndrome

Urethritis
- *Neisseria gonorrhoeae*
- Nongonococcal disease
  - *Chlamydia trachomatis*
  - *Ureaplasma urealyticum*
  - *Trichomonas vaginalis*
  - *Mycoplasma genitalium*
  - Herpes simplex (HSV-1 and HSV-2) virus
  - *Yeasts*

Cervicitis
- *C trachomatis*
- *N gonorrhoeae*
- *T vaginalis*
- *M genitalium*
- HSV (primarily HSV-2)

Pelvic Inflammatory Disease
- *N gonorrhoeae*
- *C trachomatis*
- Anaerobes
- Gram-negative rods
- Streptococci
- *Mycoplasma hominis*
- *M genitalium*
- *U urealyticum*

Vaginitis
- *T vaginalis*
- *Candida albicans* and other yeast
- *Gardnerella vaginalis*

Genital Ulcers
- *Treponema pallidum* (syphilis)
- HSV-1 and HSV-2
- *Haemophilus ducreyi* (chancroid)
- *C trachomatis* (lymphogranuloma venereum)
- Epstein-Barr virus (infectious mononucleosis)

Genital Warts
- *T pallidum* (condyloma latum)
- Human papillomavirus (condyloma acuminata)

Proctitis
- *N gonorrhoeae*
- *C trachomatis*
- *T pallidum*
- HSV-1 and HSV-2
- Particular to youth who engage in same-sex sexual activity (in addition to the above)
- Hepatitis A and B virus
- *Shigella*
- *Campylobacter*
- *Giardia lamblia*
- *Entamoeba histolytica*

Pharyngitis
- *N gonorrhoeae*
- HSV-1 and HSV-2

Evaluation

In all sexually active adolescents, a complete medical and psychosocial history, including a sexual history, should be obtained confidentially (Box 60.3). The risk assessment for an STI, particularly HIV, should be based on a review of actual sexual behaviors rather than on an adolescent's stated sexual orientation at the time of the visit. A detailed gynecologic history also should be reviewed with females, including any recent changes in menstrual bleeding and dyspareunia. The remainder of the history should focus on the patient's specific complaint and any associated symptoms. A complete physical examination, including a thorough genital examination, should be performed. Although diagnostic tests are determined based on findings from the history and physical examination, it is important to remember that many adolescent patients are asymptomatic, and screening for common STIs, such as chlamydia and gonorrhea, should be performed at least annually on all sexually active teenagers through noninvasive urine or vaginal nucleic acid amplification testing (NAAT). Adolescents at increased risk for STI (eg, a history of STIs, multiple partners, young men who have sex with men) should be screened every 6 months or more frequently depending on their risk factors or current symptomatology.

Urethritis and Epididymitis

History

Because infectious urethritis is more common in young men than in older men, all sexually active adolescent males should be asked about the presence of dysuria, urethral discharge, and urethral erythema or pruritus. In females, symptoms such as dysuria and increased urination may have a more gradual onset and are reported more frequently than other symptoms, such as meatal edema, erythema, or urethral discharge, which are rarely noticed in girls. General urinary symptoms, such as acute urinary frequency and urgency, are uncommon with urethritis, especially in males. More often, urethritis is asymptomatic, and the diagnosis is made by routine annual screening in sexually active adolescents or through known contact with a partner with an STI (eg, *C trachomatis, N gonorrhoeae*).

To diagnose acute epididymitis, the sexually active male should be asked about testicular pain and swelling. Symptoms associated with urethritis also may be present or may have preceded the scrotal symptoms.

Box 60.3. What to Ask

Sexually Transmitted Infections

- Are you currently in a relationship?
- Are you sexually active? Do you have or have you had oral, vaginal, and/or anal intercourse?
- At what age did you begin to have sex?
- Do you have sex with men, women, or both?
- How many partners have you had? When was your last contact?
- Have you ever been forced to have sex, had sex while under the influence of alcohol or drugs, or exchanged sex for food, shelter, money, or drugs?
- Do you or your partner(s) use contraception? What type?
- Do you or your partner(s) use drugs or alcohol?
- Have you or any of your sexual contacts ever been diagnosed with a sexually transmitted infection? Did you and they undergo treatment?
- Do you have abdominal pain, dysuria, increased urinary frequency, or hesitancy?
- Have you noticed any ulcers, blisters, warts, or other bumps in the genital area? Are the lesions painful?
- Have you had any recent systemic symptoms, such as fever, chills, body aches, sore throat, or rashes?
- For females: Do you have a vaginal discharge or itching? Is sex uncomfortable or painful? Do you have bleeding between periods or after intercourse?
- For males: Do you have a discharge from your penis? Any testicular pain or swelling? Any associated burning or itching?

Physical Examination

The genital examination in both males and females must be performed in the presence of a chaperone, regardless of the sex of the health professional.

In males, the presence of a urethral discharge and its consistency (ie, mucopurulent or purulent) should be noted. Any other urethral or genital lesions also should be assessed. The epididymis, spermatic cord, and testes should be palpated carefully for tenderness and swelling.

In symptomatic females, a full pelvic examination should be performed after careful examination of the external genitalia for any ulcerative or wart-like lesions. The urethra should be inspected for edema, erythema, or any evidence of a discharge prior to insertion of the speculum. Urethritis is most often caused by *C trachomatis,* but HSV-1 and HSV-2 and trichomoniasis can also cause urethritis. The presence or absence of a vaginal or endocervical discharge also should be noted during the pelvic examination; however, its absence does not rule out the possibility of an STI.

Laboratory Tests

Screening tests using urine or vaginal samples are considered standard of care for detecting gonorrhea and chlamydia, especially in the asymptomatic sexually active adolescent. These nonculture tests rely on amplification of DNA (ie, polymerase chain reaction [PCR], ligase chain reaction) and are highly sensitive and convenient for screening teenagers because the test can be performed on a routine patient-obtained urine or a physician- or patient-obtained vaginal specimen. A disadvantage is that these tests may have an increased potential for false-positive results, making a definitive diagnosis questionable in a judicial setting (eg, child sexual abuse). In the adolescent population, however, NAATs definitely are more acceptable than tests requiring a direct urethral swab specimen and should be used to confirm chlamydial or gonococcal urethritis for screening or diagnostic purposes. In cases of persistent symptoms or recurrent urethritis, particularly in males, infection with *M genitalium* should be considered. Testing for this organism is not currently available in most laboratories, however.

Color duplex Doppler ultrasonography may be necessary to differentiate between epididymitis and testicular torsion in the adolescent male. Whether the diagnosis of testicular torsion is questionable or confirmed, an immediate urologic consultation is necessary.

Cervicitis

History

Cervicitis in females is parallel to urethritis in males. Because cervicitis is a local infection, systemic symptoms may not occur, which makes asymptomatic infections, especially with *C trachomatis,* quite common. A variety of important points related to the patient history and associated complaints should be addressed with all sexually active female teenagers to rule out other etiologies, however. The physician should ask questions such as, "Do you have a vaginal discharge?"; "What color is the discharge?"; "Is there any odor?"; "Are you experiencing any urinary frequency, urgency, or dysuria?"; and "Have you had any nonmenstrual vaginal bleeding or spotting, including postcoital bleeding or dyspareunia?" A known exposure to other STIs must be ascertained as well, which can be discerned with questions such as, "Is your current partner symptomatic or receiving antibiotic treatment?"; and "Do you or your current or any past partner have a history of an STI?"

More generalized symptoms, such as moderate lower abdominal pain (acute or chronic) associated with nausea, vomiting, and fever, may be indicative of a complication of untreated or undetected cervicitis, such as PID. Additional symptoms associated with disseminated gonococcal infection, such as fever, arthritis, and rash, should be investigated as well as the involvement of other areas of the body (eg, sore throat).

Physical Examination

After completing the full physical examination, with particular attention paid to the patient's skin, pharynx, hands, fingers, and joints, the physician should focus on the genitourinary examination. In the presence of a chaperone, the sexual maturity rating should be noted first, and the external genitalia should be examined for the presence of any lesions or inflammation of the perineum. Any urethral erythema or discharge also should be noted. The presence of a vaginal discharge can be assessed more completely when performing the speculum examination, which should be considered in all sexually active adolescent females with vaginal or persistent lower urinary tract complaints.

During the speculum examination, the vaginal mucosa should be inspected, the presence of a vaginal discharge identified, and the appearance of the cervical os documented. The physician should determine whether a purulent or mucopurulent exudate is coming from the endocervix and look for any evidence of cervical friability or sustained endocervical bleeding as a swab is gently passed through the cervical os to perform the NAAT. A cotton swab of the vaginal discharge should be collected for a microscopic evaluation of wet preparations (wet mount), if necessary. Cervical inflammation must be differentiated from normal adolescent cervical ectopy. A presumptive diagnosis of mucopurulent cervicitis is made in the setting of copious discharge from the cervical os, cervical erosion, or friability. A bimanual examination also must be performed to evaluate for cervical motion tenderness (CMT), adnexal masses or fullness, and uterine tenderness.

Laboratory Tests

According to the CDC, NAATs for *N gonorrhoeae* and *C trachomatis* are preferred for the diagnostic evaluation of cervicitis and can be performed on vaginal, urine, or endocervical specimens. If a pelvic examination is being performed, an endocervical or vaginal swab specimen for NAATs can be collected by direct visualization. A wet mount evaluation to diagnose associated STIs (eg, trichomoniasis) is recommended, especially if the discharge is foul smelling or frothy; however, immediate specimen evaluation is required for optimal results. Alternative diagnostic tests for trichomoniasis are also available for females; vaginal, endocervical, or urine specimens can be tested using NAAT. The adolescent who is diagnosed with a new STI or engaged in other high-risk behaviors, such as unprotected sexual intercourse, multiple sexual partners, inconsistent or incorrect condom use, or young men who have sex with men, should undergo testing for other STIs as well, such as HIV, syphilis, and viral hepatitis.

Pelvic Inflammatory Disease

History

When considering a diagnosis of PID, the history should include a discussion of known risk factors, such as unprotected sexual activity; the number of sexual partners, especially new partners in the previous 2 months; a previous history of an STI or recent exposure to an STI; the type and consistency of contraceptive use; and the timing of the last menstrual cycle, because many young women present with PID during the first half of their menstrual cycle. The physician also should inquire about other symptoms that are often associated with PID: the onset, duration, quality, and location of abdominal pain; urinary symptoms that may be indicative of concomitant urethritis; intramenstrual bleeding; dysmenorrhea or dyspareunia; abnormal vaginal discharge; right upper quadrant pain; and systemic symptoms, such as nausea, vomiting, fever, and malaise. The classic symptoms of PID, which include pelvic or lower abdominal pain, vaginal discharge, fever, and abnormal bleeding, are not always present. More often, symptoms are nonspecific or vague, and the physician must maintain a high index of suspicion in any sexually active female with acute or subacute pelvic or lower abdominal pain.

Physical Examination

Classic signs of acute PID include fever with lower abdominal pain and tenderness of the cervix, uterus, or adnexa on bimanual examination. The clinical presentation can vary from vague discomfort to severe pain, however, depending on the particular patient. Therefore, before performing the pelvic examination a thorough physical examination should be completed to exclude other common causes of lower abdominal pain. This should include a review of the vital signs, evaluating for fever or tachycardia. The blood pressure also

must be reviewed carefully because hypotension can occur with a ruptured ectopic pregnancy, which may present with similar symptoms, including abdominal pain and vaginal bleeding. The abdomen should be assessed for tenderness and guarding. The location of the pain is particularly relevant because certain acute surgical conditions, such as appendicitis, ovarian torsion, and ectopic pregnancy, are important considerations in the differential diagnosis of PID. Additionally, right upper quadrant pain is consistent with perihepatitis (ie, Fitz-Hugh–Curtis syndrome), which can occur with a gonorrheal or chlamydial infection. In the presence of a chaperone, the speculum examination should be performed, looking for a mucopurulent endocervical exudate or any evidence of cervicitis (eg, cervical friability or erosion). The cervix should be carefully palpated for any evidence of CMT and the uterus for tenderness or adnexal masses on bimanual examination.

Laboratory Tests

The diagnosis of PID is based on clinical findings and a high index of suspicion, after other causes for pelvic or lower abdominal pain have been excluded. Previous CDC criteria for the diagnosis of PID included 3 major components: lower abdominal pain, CMT, and adnexal tenderness. Current recommendations outline 1 or more minimum clinical criteria and 5 additional criteria to support the diagnosis (Box 60.4). Particularly when evaluating an adolescent for PID, early conservative treatment and maximum sensitivity for subtle clinical findings are paramount to avoid a delayed or missed diagnosis. A NAAT for *N gonorrhoeae* and *C trachomatis* should be sent on the endocervical or vaginal swab specimen obtained during the pelvic examination.

Other laboratory studies to obtain include a complete blood cell count with differential and a sedimentation rate or C-reactive protein level, although in some cases the laboratory tests are normal. A urine pregnancy test should be performed to exclude the possibility of a concomitant intrauterine or ectopic pregnancy. Additionally, a urinalysis and urine culture should be obtained in the patient who reports dysuria. A serologic test for syphilis and HIV testing also should be offered to the adolescent. Testing for viral hepatitis is recommended in the patient who has not been immunized against hepatitis B or who has exposure to injection drug use, thereby placing the patient at risk for hepatitis C.

Laparoscopy may be performed to make a definitive diagnosis of PID or to obtain cultures directly from the fallopian tubes in cases in which the diagnosis is equivocal or the patient is not improving on standard antimicrobial therapy. Immediate consultation with a gynecologist is necessary for these challenging cases.

Imaging Studies

Transvaginal ultrasonography may help exclude diagnoses such as ectopic pregnancy or ovarian torsion and can aid in the detection of complications associated with PID, such as TOA. Fluid in the cul-de-sac may be evident on ultrasonography; however, it is not specific for the diagnosis of PID.

Box 60.4. Diagnosis of Pelvic Inflammatory Disease

Pelvic or Lower Abdominal Pain and ≥1 of the Following Minimum Criteria on Pelvic Examination

- Cervical motion tenderness
- Uterine tenderness
- Adnexal tenderness

Additional Findings

- Oral temperature >38.3°C (>101°F)
- Abnormal cervical mucopurulent discharge or cervical friability
- Presence of abundant numbers of white blood cells on saline microscopy of vaginal fluid
- Elevated erythrocyte sedimentation rate or C-reactive protein level
- Laboratory documentation of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*

Specific Criteria for the Diagnosis

- Inflammatory tubal mass or tubo-ovarian complex seen on magnetic resonance imaging or transvaginal ultrasonography, or evidence of pelvic infection (ie, tubal hyperemia) on Doppler ultrasonography
- Histologic evidence of endometritis on endometrial biopsy
- Laparoscopic abnormalities consistent with pelvic inflammatory disease

Derived from Workowski KA, Bolan GA; Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(RR-3):1–137.

Genital Ulcers

History

Likely the most important information to obtain from the adolescent with genital ulcers is whether the ulcers are painful. A painless chancre on the penis in males, around the mouth, in the oropharynx, or in females on the external genitalia is consistent with primary and secondary syphilis. If the lesions are painful or are associated with a grouped vesicular eruption, HSV-1 and HSV-2 is the likely cause. The presence of systemic symptoms, such as fever, chills, headache, or malaise, also is important to discern because these symptoms can occur with a primary infection with HSV-1 and HSV-2 or secondary syphilis. Generalized complaints, however, are associated with secondary syphilis in only 50% of cases. A history of adenopathy, whether localized or generalized, also must be noted, along with dysuria, which may be present in females with HSV-1 and HSV-2. Additionally, a history of a viral-like illness accompanied by a rash warrants further investigation because a diffuse maculopapular rash, especially on the palms and soles, is a classic sign of secondary syphilis. Because a nonspecific rash also can occur with primary HIV infection, all possible exposures to other STIs should be reviewed with the teenager.

Physical Examination

All adolescents who present with chancres, or ulcers, should undergo a complete physical examination. The skin, including the palms and soles, should be examined closely for any dull red to reddish-brown macular

or papular lesions. The oropharynx should be carefully checked for chancres or blisters. All lymph nodes should be palpated for pain, enlargement, or induration. Suppurative or fluctuant nodes often are associated with chancroid caused by *Haemophilus ducreyi*. The genital examination should focus on the appearance of the lesions, with the following questions in mind: Are the lesions ulcerative, clustered, and painful (ie, HSV-1, HSV-2, or chancroid)? Are they associated with grouped vesicles on an erythematous base (ie, HSV-1 or HSV-2)? Is tender inguinal adenopathy present (ie, HSV-1, HSV-2, or chancroid)? Or does the patient have a single, painless, indurated chancre with a clean base and a sharply defined, slightly elevated border (ie, syphilis)? The lymph nodes associated with this syphilitic type chancre often are nontender but enlarged. Other less common STIs produce genital ulcers that often are painful and deep and may be accompanied by some purulence. Adenopathy can be quite impressive with chancroid and lymphogranuloma venereum, as in the case of *C trachomatis*.

Laboratory Tests

The necessary diagnostic tests depend on the patient's clinical picture. However, all adolescents who present with a painless ulcerative lesion should undergo dark-field microscopy for syphilis or direct fluorescent antibody testing of the lesions, which is also available and quite specific. Nontreponemal serologic tests for syphilis, such as the Venereal Disease Research Laboratories (VDRL) or rapid plasma reagin (RPR) tests, should be done if direct examination is not available or the clinical appearance of the ulcer is nonspecific. In cases of early primary syphilis in which the VDRL or RPR may not be reactive initially, the test should be repeated in 1 week. Treponemal tests, such as the fluorescent treponemal antibody absorption test, should be used only as confirmatory tests and not for screening purposes. The physician must keep in mind that false-positive nontreponemal testing can occur in some clinical conditions, such as pregnancy, autoimmune disease, and HIV. In these instances, confirmatory treponemal testing is required.

Viral cell culture and PCR are the preferred diagnostic tests for individuals who seek treatment for painful genital ulcers or other mucocutaneous lesions likely caused by HSV-1 and HSV-2. Samples should be obtained from the base of a fresh unroofed vesicle. Herpes simplex virus-1 or HSV-2 serology for HSV-1 and HSV-2 is generally not helpful.

Because of the well-described correlation between genital ulcers and HIV, it is recommended that all patients with a diagnosis of syphilis be tested for HIV as well. Conversely, annual syphilis screening is not indicated for all teenagers but is currently recommended for the adolescent with multiple sexual partners; a history of injection drug use; a history of a male having sex with males; or a previously diagnosed STI. Additionally, the seroprevalence of syphilis in the health professional's particular community or specific patient population should be taken into account when contemplating more frequent screening.

Genital Warts

History

Risk factors for HPV infection should be assessed in all sexually active adolescents regardless of their immunization status. These factors include a history of multiple sexual partners, age younger than 25 years, a previous history of STIs, lack of consistent condom use, pregnancy, altered immune response, and tobacco use. Symptoms may include pruritus, pain, or dyspareunia, but often the condition is asymptomatic. The adolescent may palpate a lesion on the external genitalia, report local irritation, or note bleeding from larger, traumatized lesions, depending on lesion location.

Physical Examination

A complete pelvic examination should be performed on all sexually active female adolescents who report lower abdominal pain, vaginal discharge, or intramenstrual or postcoital vaginal bleeding, or who express concern with "something they felt" in the genital area. Before the speculum is inserted, the external genitalia should be carefully inspected for lesions. Genital warts (ie, condylomata acuminata) most commonly appear on squamous epithelium as irregular polypoid masses with an irregular, cauliflower-like surface that may coalesce into larger lesions. Usually these are located at the posterior introitus, labia minora, and the vestibule in females; they may be found on the cervix and in the vagina as well.

In males, warts are found more commonly on the circumcised penile shaft, glans, or corona, as well as under the foreskin of the uncircumcised penis. They also may appear as flat, flesh-colored papules on the scrotum and anus. Because the anus is a common location for lesions, it should be inspected carefully in males and females. Intra-anal warts are seen in persons who have receptive anal intercourse, but they also can occur in men and women with no history of anal sexual contact. *Condylomata plana* are subclinical lesions that are not grossly visible but are apparent on colposcopy and histology.

Condylomata lata are flat, flesh-colored warts that occur in moist areas (ie, anus, scrotum, vulva) and may be associated with other signs of secondary syphilis.

Laboratory Tests

The diagnosis of genital warts often is made by visual inspection and generally does not require confirmation by biopsy. A biopsy may be required in specific instances, however, such as with an uncertain diagnosis, in the case of a lesion that is not improving or that worsens with standard therapy, for an atypical lesion, in the immunocompromised patient, or for warts that appear pigmented, indurated, bleeding, or ulcerated. A definitive diagnosis of HPV infection is based on detection of viral nucleic acid or capsid protein. Tests that detect specific types of HPV DNA are available but are not routinely recommended because this information does not alter the clinical management of the condition, except in extraordinary circumstances.

Historically, suspicious areas of white epithelium identified by the application of 3% to 5% acetic acid or a specific vascular pattern consistent with HPV infection were biopsied. This procedure is no

longer recommended, however, because prospective studies have shown that many cervical and anogenital squamous intraepithelial lesions in adolescents resolve spontaneously if left untreated. For this reason, the American College of Obstetricians and Gynecologists and the American Cancer Society currently recommend that routine screening for cervical cancer should be performed starting at 21 years of age. Cervical Papanicolaou testing is no longer recommended by any major medical organization for individuals younger than 21 years, with the exception of adolescents with HIV infection, for whom screening is warranted 1 year after onset of sexual activity because of the high rate of progression of abnormal cytology.

All teenagers should be offered STI screening. Nucleic acid amplification tests for the detection of gonorrhea or chlamydia can be performed on urine, endocervical, or vaginal specimens. Additionally, a serum nontreponemal antibody test for syphilis (RPR or VDRL) is indicated. An HIV antibody test should be offered to all adolescents who are deemed at risk.

A urinalysis for asymptomatic hematuria is indicated in males with visible condylomata. Its presence is indicative of a urethral or meatal lesion.

Management

Although the details of health care delivery for adolescents differ by state, all 50 states and the District of Columbia allow health professionals to evaluate and treat adolescents for an STI without parental consent, except in unusual circumstances. Routine laboratory screening for common STIs is recommended at least annually in all sexually active adolescents and more frequently for those with additional risk factors. Gonorrhea, chlamydia, syphilis, chancroid, and HIV/AIDS are reportable diseases in every state, and a positive laboratory result is the impetus for reporting. Notification of all sex partners within 60 days of the onset of symptoms or diagnosis of infection or, if greater than 60 days, the last sexual partner, is generally anonymous and carried out by local public health officials. Contacts are informed that a partner has been diagnosed with an STI and are instructed to be evaluated and receive appropriate treatment.

Adequate and timely treatment of all sexual partners of patients diagnosed with an STI is extremely important to prevent reinfection. Because partners often are asymptomatic and do not seek treatment, however, and because persistent and recurrent infection rates are reported to be particularly high among adolescents, expedited partner therapy (EPT) is now advocated in many states. *Expedited partner therapy* is the practice of treating the sex partners of individuals with specific STIs without an intervening formal medical evaluation or professional prevention counseling. An extension of EPT, patient-delivered partner therapy, is another practical means of providing patients with medications or prescriptions for their presumed infected partners. Care must be taken when treating the female partners of men with gonorrhea or chlamydia without an examination because of the potential for undiagnosed PID in the female partner. Per CDC guidelines, in addition to providing medications, female partners should also receive instructions about the symptoms of PID and advice on when to seek additional medical care.

Antibiotic recommendations and dosing schedules for the inpatient treatment of PID are noted in Box 60.5, as well as in Chapter 59 (Table 59.2) and Chapter 145 (Table 145.1) for other infections. The outpatient management of PID in adolescents with mild to moderate disease is supported by the 2015 CDC sexually transmitted diseases treatment guidelines; however, individual physician judgment of the teenager's ability to adhere to an outpatient regimen is crucial to prevent short- and long-term sequelae. For additional details about specific conditions and therapies, consult Selected References at the end of this chapter, specifically the CDC publication "Sexually Transmitted Diseases Treatment Guidelines, 2015." To avoid reinfection, patients and their sex partners should avoid sexual intercourse for at least 7 days after all parties have been adequately treated and symptoms have resolved.

In addition to antimicrobial therapy, treatment of the adolescent with an STI should include preventive services and counseling on risk reduction in a nonjudgmental and developmentally appropriate manner. Additionally, the patient's primary language, culture, sexual orientation, sexual practices, and age should be taken into account. Adolescents with a first-time STI and those with recurrent STIs should be educated about disease transmission, consequences of delayed treatment, and methods for the prevention of acquiring

Box 60.5. Parenteral Regimens for the Inpatient Treatment of Pelvic Inflammatory Disease

Parenteral Regimen A

Cefotetan, 2 g IV every 12 hours

or

Cefoxitin, 2 g IV every 6 hours

plus

Doxycycline,[a] 100 mg PO or IV every 12 hours

Parenteral Regimen B

Clindamycin 900 mg IV every 8 hours

plus

Gentamicin loading dose IV or IM (2 mg/kg body weight), followed by a maintenance dose of 1.5 mg/kg every 8 hours. (Single daily dosing 3–5 mg/kg may be substituted.)

The above regimens are continued for 24–48 hours after the patient improves clinically. On discharge from the hospital, doxycycline is continued orally for a total of 14 days. Clindamycin, 450 mg PO 4 times a day, can be used as an alternative to complete 14 days of treatment.

When tubo-ovarian abscess is present, clindamycin or metronidazole with doxycycline is recommended rather than doxycycline alone.

Abbreviations: IM, intramuscularly; IV, intravenously; PO, orally.

[a] Doxycycline should be administered orally when possible because of the pain associated with IV infusion.

Derived from Centers for Disease Control and Prevention. Sexually Transmitted Diseases Treatment Guidelines, 2015. Atlanta: U.S. Department of Health and Human Services; 2015. https://www.cdc.gov/std/tg2015/clinical.htm. Accessed April 3, 2019.

new and recurrent infections (eg, abstinence, condom use, limiting the number of sexual partners, modifying sexual behaviors, asymptomatic viral shedding, pre-exposure immunization [eg, Gardasil 9, Cervarix]). The risk for acquiring other specific STIs, such as HIV, also should be addressed. The physician should spend additional time with the adolescent with recurrent STI and explore the reasons why preventive methods have failed in the past. Several factors are extremely important to consider, including an untreated or undisclosed partner, poor sexual judgment secondary to concomitant substance use or abuse, and nonadherence to previously prescribed treatment regimens.

Patient retesting in 3 months is recommended for gonorrhea, chlamydia, and trichomonas infections, even if the physician is certain the patient has been treated with an appropriate antibiotic regimen. Most posttreatment infections are the result of reinfection rather than treatment failure and occur because the sex partner did not receive treatment or from the initiation of sexual activity with a new infected partner. Because repeat infections can increase the risk for long-term complications associated with PID and because the rate of reinfection in adolescents is so high, the CDC recommends retesting all individuals in 3 months.

Prognosis

The prognosis is good in most cases in which STIs are diagnosed and managed in a timely manner, especially with the judicious use of observed single-dose oral therapy for uncomplicated chlamydial infection, which is the most common bacterial STI in adolescents. Acute complications of PID include TOA and Fitz-Hugh–Curtis syndrome, which can result in an unanticipated surgical procedure or prolonged hospitalization. Long-term consequences of PID are chronic abdominal or pelvic pain, ectopic pregnancy, and tubal infertility. Early administration of appropriate antibiotics and prevention of recurrent infection is crucial to minimize the manifestation of these long-term sequelae.

Currently, no pharmacologic agent exists for eradicating HSV-1 and HSV-2, although acyclovir, famciclovir, and valacyclovir are useful in managing the signs and symptoms of primary herpes and reducing the incidence and duration of recurrences. The long-term safety of HSV treatment with valacyclovir or famciclovir for longer than 1 year is unknown. Daily suppressive therapy to reduce the frequency of outbreaks may be warranted in patients with more than 6 outbreaks per year. Because recurrences often decrease over time, the need for suppressive therapy should be assessed annually.

The prognosis for HIV is variable, depending on the individual's disease progression at the time of diagnosis and adherence to antiretroviral therapy. The advent of new preventive therapies, such as HIV pre-exposure prophylaxis, has significantly reduced the risk of HIV infection in individuals at substantial risk (eg, those exposed to HIV through sex or injection drug use). When taken daily and consistently, a combination of emtricitabine and tenofovir (eg, Truvada, Descovy) can reduce the risk of permanent infection by up to 92%. These medications should be used in combination with other medications to manage established HIV infection as well.

CASE RESOLUTION

A diagnosis of HSV-1 and HSV-2 infection can be made clinically. The diagnosis can be confirmed by unroofing a vesicle and gently swabbing the ulcer to examine for HSV via PCR testing. The adolescent should be counseled about HSV and its general mode of transmission, the natural history of primary versus recurrent infection, and the role of antiviral agents. A urine sample also should be sent for NAAT for the detection of gonorrhea and chlamydia. A serum RPR or VDRL test should be performed as well as a thorough assessment for HIV risk. Testing for HIV should be strongly encouraged, allowing the patient time to ask questions or decline testing. The adolescent should be given a return appointment for 1 to 2 weeks hence to review laboratory results, discuss possible treatment options for recurrent HSV-1 and HSV-2 infection, and explore risk-reduction behavior. Depending on the results of the remainder of the STI screening tests, the adolescent should be followed every 3 to 6 months.

CHAPTER 61

Menstrual Disorders

Monica Sifuentes, MD

CASE STUDY

A 16-year-old girl presents with a 9-day history of vaginal bleeding. She has no history of abdominal pain, nausea, vomiting, fever, dysuria, or anorexia, and she reports no dizziness or syncope. Her menses usually lasts 4 to 5 days and, in general, occurs monthly. Her last menstrual period was 3 weeks ago and was normal in duration and flow. Menarche occurred at 14 years of age. She is sexually active, has had 2 partners, and reportedly uses a condom "most of the time." Neither she nor her current partner has ever been diagnosed with or treated for a sexually transmitted infection. She has no family history of blood dyscrasia or cancer, has no history of chronic illness, and takes no medications.

On physical examination, she is in no acute distress. Her temperature is 36.9°C (98.4°F). Her heart rate is 100 beats/min, and her blood pressure is 110/60 mm Hg. Her body mass index is at the 50th percentile. The physical examination, including a pelvic examination, is unremarkable except for minimal blood noted at the vaginal introitus.

Questions

1. What menstrual disorders commonly affect adolescent girls?
2. What factors contribute to the manifestation of menstrual disorders, particularly during adolescence?
3. What relevant menstrual history should be obtained from the adolescent?
4. What options are available for managing primary dysmenorrhea?
5. How is abnormal uterine bleeding managed in the adolescent patient?

Gynecologic concerns and symptoms are common reasons for adolescent girls to visit their primary care physician. The challenge for the pediatrician is to differentiate between an organic etiology, a functional condition, and psychogenic symptoms. When this cannot be readily done or if the physical examination is equivocal, multiple diagnostic procedures may be performed, often with variable results. Additionally, many pediatricians are uncomfortable evaluating gynecologic problems in adolescents and performing pelvic examinations, which contributes to this diagnostic dilemma. The purpose of this chapter is to review some of the more common gynecologic conditions affecting adolescent girls and to highlight the significant historical and physical findings associated with each problem. For a discussion of the infectious conditions that cause pelvic pain, see Chapter 60.

Epidemiology

The overall prevalence of menstrual disorders during adolescence is estimated to be 50% in the United States, with the most common gynecologic symptom being *dysmenorrhea*, or painful menstruation. At least 70% to 90% of women have some pain associated with menses; the extent of discomfort varies. Although most menstruating women report mild to moderate discomfort, severe dysmenorrhea occurs in 10% to 15% of women and has been reported to be responsible for significantly limiting activities of daily living, including school attendance, participation in athletics, and socialization with peers. Uterine anomalies or pelvic abnormalities (eg, endometriosis) occur in approximately 10% of female adolescents and young women with severe dysmenorrhea.

Prevalence estimates concerning premenstrual syndrome (PMS) are difficult to assess because most studies in adolescents are retrospective, and self-reports can be unreliable and misleading. In these studies, between 20% and 30% of older adolescents report significant PMS-type symptoms. An estimated 20% to 40% of adult women experience PMS symptoms sufficiently bothersome to impair daily functions, and 5% to 10% have debilitating symptoms that warrant the diagnosis of premenstrual dysphoric disorder (PMDD). Other menstrual problems in adolescents include abnormal uterine bleeding, primary and secondary amenorrhea, and vaginal discharge.

Several factors contribute to the occurrence of menstrual disorders in adolescence. The average age of menarche in the United States remains at 12.5 years (range: 9–16 years), although the age of onset of puberty has decreased in some racial groups and in children with obesity. Bleeding may be irregular or prolonged initially in young adolescents because most early menstrual cycles are anovulatory and irregular, especially during the first few years after menarche. Bleeding problems may resolve after ovulatory cycles are established; however, menstrual symptoms, such as lower abdominal pain, breast tenderness, headache, bloating, and vomiting, may predominate. Early sexual activity among adolescents and associated sexually transmitted infections (STIs) also may contribute to the presence of certain gynecologic conditions in this age group, particularly vaginitis, abnormal uterine bleeding, and pelvic pain.

Clinical Presentation

The adolescent with a menstrual disorder may present in a variety of ways. Specific symptoms include heavy menstrual bleeding, irregular periods, and painful menses, and more general symptoms include fatigue, dizziness, and syncope (Box 61.1). The adolescent with PMS may experience mood swings, stress, and nervousness accompanied by abdominal bloating and pain before menses. Additionally, the adolescent or her parent or guardian may have questions or concerns about delayed pubertal development and primary or secondary amenorrhea.

Pathophysiology

Puberty and the Normal Menstrual Cycle

Figure 61.1 depicts the menstrual cycle, which typically lasts for 21 to 35 days, with a mean length of approximately 28 days. Normal duration of menses is 4 to 7 days. Blood loss is usually 30 to 40 mL per cycle; most women do not lose more than 60 mL per cycle. Regular ovulatory cycles usually do not occur until 2 to 3 years after menarche, although 10% to 20% of cycles remain anovulatory as long as 5 years after menarche. It has been reported that girls with earlier menarche establish regular ovulatory menstrual cycles more rapidly than girls with later menarche.

One-quarter of females begin menstruating when they reach sexual maturity rating (SMR [ie, Tanner stage]) 3 of sexual maturation, but approximately two-thirds do not menstruate until they reach SMR 4 breast and genital development. Several other processes occur before the onset of menstruation. *Thelarche*, or the beginning of breast development, takes place approximately 2 to 3 years before menarche, and growth acceleration usually begins approximately 1 year before thelarche.

Dysmenorrhea

Dysmenorrhea often is accompanied by other symptoms, such as nausea, vomiting, diarrhea, fatigue, bloating, low back pain, and headaches. It can be classified as primary or secondary. Primary dysmenorrhea occurs in the absence of any pelvic pathology,

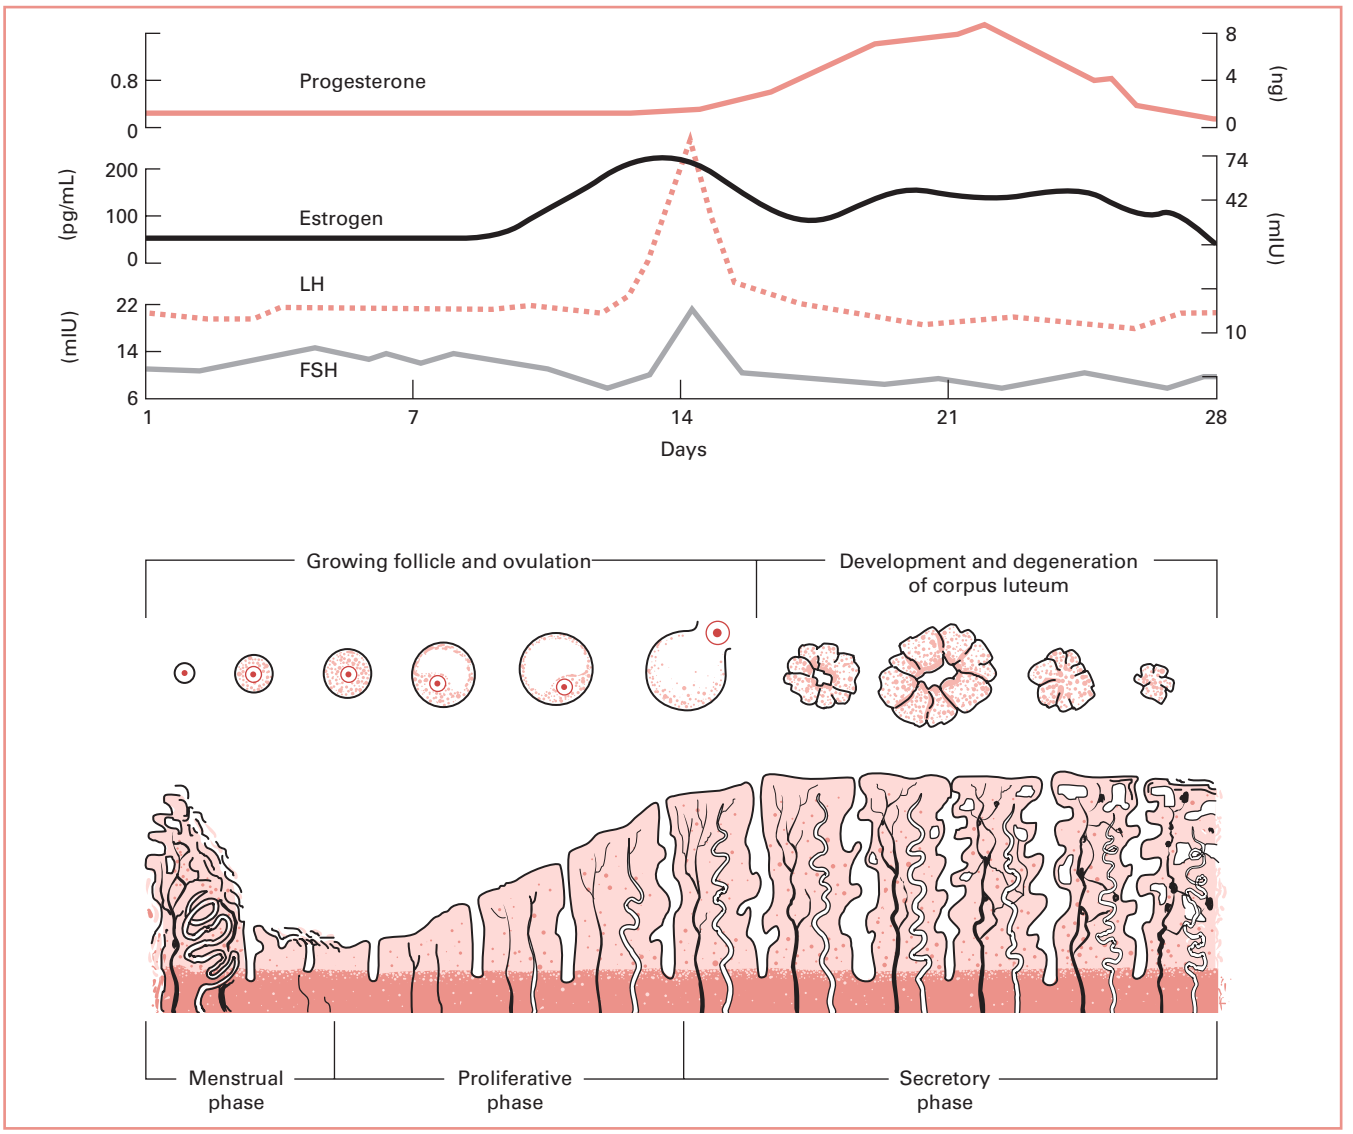

Figure 61.1. The normal ovulatory menstrual cycle.
Abbreviations: FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Box 61.1. Diagnosis of Menstrual Disorder in the Adolescent Patient

Primary Dysmenorrhea

- Painful menstruation
- Lower abdominal pain associated with menstruation, usually worse on the first few days of bleeding
- Associated back pain
- Pain sometimes accompanied by nausea, vomiting, fatigue, headache, bloating, and diarrhea
- Symptoms begin 6–12 months after menarche

Abnormal Uterine Bleeding

- Prolonged bleeding (>8 days) *or*
- Excessive bleeding (>6 tampons/pads per day) *or*
- Frequent uterine bleeding (≤21 days)
- No demonstrable organic etiology
- Normal laboratory studies, with the possible exception of anemia

Primary Amenorrhea

- No spontaneous menstruation in a girl of reproductive age
- Absence of menarche by age 15 years in a girl with normal pubertal development *or*
- Absence of menarche by age 13 years in a girl with no secondary sexual development *or*
- Absence of menarche within 1–2 years of reaching full sexual maturation (sexual maturity rating 5)

comprising 90% of adolescent menstrual pain, and most commonly occurs in older adolescents after ovulatory cycles are established. *Secondary dysmenorrhea* refers to painful menses associated with some underlying pelvic pathology, such as pelvic inflammatory disease (PID), endometriosis, ovarian cysts or tumors, Müllerian anomalies, or cervical stenosis. A complete list of causes of secondary amenorrhea can be found in Box 61.2. Endometriosis is the most common cause of secondary dysmenorrhea in the adolescent.

Numerous studies have shown that cell membrane phospholipids, endometrial prostaglandins, and leukotrienes play a role in the pathogenesis of primary dysmenorrhea. After ovulation, fatty acids build up in the phospholipids of the cell membrane in response to the production of progesterone. Arachidonic acid as well as other omega-6 fatty acids are released after the onset of progesterone withdrawal before menstruation. A cascade of prostaglandins and leukotrienes is initiated in the uterus during menses, which results in an inflammatory response. Prostaglandin $F_{2\alpha}$, which is produced locally by the endometrium from arachidonic acid, is a potent vasoconstrictor and myometrial stimulant that causes uterine contractions, resulting in tissue ischemia and pain. Prostaglandin $E_{2\alpha}$ causes hypersensitivity of the pain nerve terminals in the uterine myometrium. The cumulative effect of these prostaglandins may cause the pain of primary dysmenorrhea. Hormonal and endocrine factors also may play a role in the etiology of primary dysmenorrhea, because ovulatory cycles with estrogen and progesterone are necessary for development of the condition.

Box 61.2. Differential Diagnosis of Common Menstrual Disorders

Secondary Dysmenorrhea

- Endometriosis
- PID
- Uterine myomas, polyps, or adhesions
- Adenomyosis
- Ovarian cysts or tumors
- Presence of an intrauterine device
- Cervical stenosis or strictures
- Congenital malformations (ie, septate uterus, imperforate hymen)

Excessive Uterine Bleeding

- Ovulatory dysfunction: physiologic anovulation
- Complications of pregnancy: spontaneous/threatened/incomplete abortion, ectopic pregnancy, hydatidiform mole
- Infections of the lower and upper genital tract: endometritis, PID, cervicitis/vaginitis
- Blood dyscrasia and thrombocytopenia: von Willebrand disease, ITP, leukemia, platelet defects, aplastic anemia
- Endocrine disorders: hypothyroidism and hyperthyroidism, hyperprolactinemia, late-onset 21-hydroxylase deficiency, Cushing or Addison disease, PCOS
- Vaginal anomaly: carcinoma
- Cervical/uterine abnormalities: endometriosis, polyp, hemangioma, rhabdomyosarcoma
- Ovarian abnormalities: primary ovarian failure, tumors, cysts
- Systemic/chronic illness: IBD, malignancy, SLE, diabetes mellitus
- Foreign body: retained condom or tampon, IUD
- Medications: aspirin, anticoagulants, hormonal contraception, androgens, chemotherapy
- Trauma or sexual assault (ie, high vaginal laceration)

Amenorrhea (Primary and Secondary)

- Pregnancy
- Systemic abnormalities: endocrinopathies (hypothyroidism, Cushing syndrome), chronic diseases (IBD, sickle cell disease), poor nutrition (anorexia nervosa), obesity, intense exercise, stress, drugs (opiates, valproate)
- Hypothalamic lesions: tumors, infiltrative lesions (TB, CNS leukemia)
- Pituitary lesions: prolactinoma, drugs causing elevated prolactin (eg, marijuana, cocaine), cranial irradiation
- Ovarian failure: gonadal dysgenesis (ie, Turner syndrome); autoimmune failure associated with diabetes mellitus, adrenal insufficiency, thyroid disease, and celiac disease; radiation- or chemotherapy-induced oophoritis; galactosemia
- Congenital abnormalities of the reproductive tract: imperforate hymen, transverse vaginal septum, absence or abnormality of the uterus, complete androgen insensitivity syndrome (complete or partial receptor defects), Mayer-Rokitansky-Küster-Hauser syndrome
- Androgen excess: PCOS, benign ovarian androgen excess

Abbreviations: CNS, central nervous system; IBD, inflammatory bowel disease; ITP, idiopathic thrombocytopenic purpura; IUD, intrauterine device; PCOS, polycystic ovary syndrome; PID, pelvic inflammatory disease; SLE, systemic lupus erythematosus; TB, tuberculosis.

Most cases of primary dysmenorrhea begin 1 to 2 years after menarche, and symptoms gradually increase until patients reach their early 20s. Parity and advancing age are associated with a decrease in symptomatology.

Abnormal Uterine Bleeding

Abnormal uterine bleeding (formerly called dysfunctional uterine bleeding) is abnormal or excessive endometrial bleeding in the absence of any pelvic pathology. Menstruation is considered excessive if the cycles are short (≤21 days) and the bleeding is prolonged (>8 days). Although ovulatory dysfunction is the most common cause of abnormal or excessive uterine bleeding in adolescents, it is a diagnosis of exclusion. Other causes of abnormal bleeding should first be investigated by obtaining a thorough history, performing a complete physical examination, and obtaining laboratory studies as indicated.

Excessive uterine bleeding typically is the result of anovulatory, immature menstrual cycles. In adolescents, 50% of menstrual cycles are anovulatory within the first 2 years after menarche. If menarche occurs later in adolescence (ie, at SMR 5), the interval from anovulatory to ovulatory cycles reportedly lasts even longer. Most cases of abnormal uterine bleeding in adolescents are thought to result from the delayed maturation of the hypothalamic-pituitary-ovarian axis. Normally, a positive feedback mechanism manifests with rising estrogen levels, resulting in a surge in luteinizing hormone and follicle-stimulating hormone, which triggers ovulation. The progesterone-producing corpus luteum then stimulates development of the secretory endometrium, with subsequent shedding after approximately 14 days if no fertilization occurs (ie, menses). With anovulation, progesterone-producing corpus luteum is absent; thus, no development of a secretory endometrium occurs. Estrogen thus remains unopposed, and proliferative endometrium continues to accumulate. When the tissue can no longer maintain its integrity, it sloughs. Additionally, without progesterone the normal vasospasm that helps limit endometrial bleeding does not occur. As a result, bleeding is prolonged, frequent, and heavy.

Premenstrual Syndrome

Premenstrual syndrome refers to a group of physical, cognitive, affective, and behavioral symptoms that occur 1 to 2 weeks before menses, that is, during the luteal phase of the menstrual cycle, and resolve within 4 days after the onset of menstruation. Various mechanisms have been proposed, including an increased sensitivity to the normal cyclic fluctuations in steroid hormones and releasing factors and alterations in central neurotransmitters, such as endorphins, γ-aminobutyric acid, and serotonin. The exact etiology remains unknown, however, despite multiple studies with a focus on pinpointing the cause of this complex condition.

Amenorrhea

Amenorrhea is the lack of spontaneous menstruation in women of reproductive age. Similar to dysmenorrhea, it can be classified as primary or secondary. Traditionally, primary amenorrhea was defined by the following criteria: an absence of menarche by age 16 years in the girl with otherwise normal pubertal development, an absence of menarche by age 14 years in the girl with no secondary sexual development, and an absence of menarche within 1 to 2 years of reaching SMR 5 pubic hair. Causes of primary amenorrhea range from congenital anatomic anomalies to genetic and endocrine conditions. Because many of these disorders can be diagnosed and treated earlier than 16 years of age, however, guidelines have been modified to address when menstrual conditions should be evaluated. Current guidelines encourage a more proactive medical evaluation for girls who lack menses by age 15 years or more than 3 years after the onset of secondary sexual development. Additionally, absence of secondary sexual characteristics by age 13 years is considered abnormal (Box 61.3). A detailed discussion of each etiology that causes primary amenorrhea is beyond the scope of this chapter; see Selected References for more information.

Secondary amenorrhea is a state of 3 or more consecutive months of amenorrhea in the girl who has already established menstruation. The most common cause of secondary amenorrhea is pregnancy, which must be ruled out in all adolescents presenting with this symptom, regardless of their acknowledgment of sexual activity. Other causes include systemic illness, significant change in weight, stress, intense physical exertion, eating disorders (eg, anorexia nervosa), and certain medications, such as phenothiazines, glucocorticoids, and heroin. Polycystic ovary syndrome is another common cause of secondary amenorrhea in young adult women, but often it is characterized by a wide range of menstrual irregularities, including abnormal uterine bleeding, oligomenorrhea, and amenorrhea of perimenarcheal onset.

Box 61.3. Menstrual Conditions That May Require Evaluation

Menses That:

- Have not started within 3 years of thelarche
- Have not started by 13 years of age with no signs of pubertal development
- Have not started by 14 years of age with
  - Signs of hirsutism *or*
  - A history or physical examination suggestive of excessive exercise or eating disorder *or*
  - Concerns about an outflow tract obstruction or anomaly
- Have not started by 15 years of age
- Are regular, occurring monthly, then become markedly irregular
- Occur more frequently than every 21 days or less frequently than every 45 days
- Occur 90 days apart even for 1 cycle
- Last longer than 7 days
- Require frequent pad/tampon changes (soaking more than 1 every 1–2 hours)

Adapted with permission from American College of Obstetricians and Gynecologists Committee on Adolescent Health Care. Menstruation in girls and adolescents: using the menstrual cycle as a vital sign. Committee Opinion No. 651. *Obstet Gynecol*. 2015;126:e143-6.

Vaginal Discharge

Vaginal discharge can be normal (ie, physiologic), nonspecific, or related to a particular bacterial or viral pathogen. A thin, white discharge, known as *leukorrhea*, occurs approximately 6 to 12 months before the onset of menarche. A purulent, malodorous, or bloody discharge is considered abnormal, however. Etiologies are varied and may be infectious, inflammatory, or traumatic (see Chapters 59 and 60).

Differential Diagnosis

The differential diagnosis of common menstrual disorders is extensive and can be found in Box 61.2. Other etiologies of pelvic pain include mid-cycle menstrual disorders (eg, mittelschmerz), urinary tract infection, complications of unmanaged or inadequately managed PID, and abdominal conditions, such as inflammatory bowel disease and irritable bowel syndrome. Psychogenic pain also should be considered as a cause of recurrent pelvic pain and may be secondary to depression, anxiety, a history of sexual abuse, or another psychological condition.

Evaluation

History

A thorough medical and family history should be obtained from the adolescent girl with a suspected menstrual disorder because many nongynecologic conditions can affect menses. A complete psychosocial assessment, including a private, confidential sexual history, also should be performed without the parent or guardian present. The acronym HEADSS (home, employment and education, activities, drugs, sexuality, suicide/depression) serves as a useful tool when interviewing adolescents (see Chapter 4).

Most of the interview should focus on the gynecologic history (Box 61.4), including pattern of menstrual bleeding and any associated symptoms (Box 61.5). With primary dysmenorrhea, pain that

Box 61.4. Gynecologic History

- Age at menarche
- Date of last menstrual period
- Regularity of menses
- Duration and pattern of bleeding
- Amount of flow (ie, number of pads and/or tampons used per day and amount of saturation)
- Associated menstrual symptoms, such as bloating, headache, lower abdominal pain, and cramping
- Maternal and sibling gynecologic history
- Treatment of menstrual symptoms
- Sexual activity (consensual and nonconsensual)
- Age at debut
- Number of partners and ages
- Date of last sexual encounter
- Protected versus unprotected vaginal or anal intercourse
- Current method of contraception

Box 61.5. What to Ask

Menstrual Disorders

Dysmenorrhea

- What is the pain like?
- Does it always occur with menses?
- When did the pain first begin in relation to menarche?
- How frequently does the pain occur?
- How long does the pain last?
- Are any other symptoms associated with the pain (eg, nausea, vomiting, diarrhea, headache)?
- Do you miss a lot of school or work as a result of painful menses?
- Do the painful menses interfere with other activities?
- What do you do for the pain? Have you tried any medications or complementary or alternative remedies?
- Does a maternal or sibling history exist of painful menses?
- Does a family history exist of endometriosis?

Abnormal Uterine Bleeding

- What was the age at menarche?
- Do you have any symptoms of anemia (eg, fatigue, dizziness, shortness of breath)?
- Have you experienced any syncopal episodes?
- Do you have any history of blood loss in the urine or stool?
- Do you have any evidence of a bleeding disorder (eg, easy bruising, bleeding from the gums or nares)?
- Do you have any symptoms of pregnancy (eg, breast tenderness, morning nausea or vomiting, fatigue)?
- Have you knowingly been exposed to a sexually transmitted infection?
- Has your weight or diet changed markedly?
- Are you using any medications, such as aspirin, oral contraceptives, long-acting progestational agents, psychotropic medications, or anticoagulants?
- Do you have a history of a systemic illness, such as systemic lupus erythematosus, diabetes mellitus, or renal disease? Do you have a history of trauma?
- Is the bleeding cyclic in nature?
- Does breakthrough bleeding occur throughout the cycle?
- Does a family history exist of bleeding disorders, type 2 diabetes mellitus, polycystic ovary syndrome, or thyroid disease?

Amenorrhea

- Have you ever had a period?
- Have you noticed any other changes associated with puberty (eg, breast development, pubic hair, growth spurt)?
- Do you have any other symptoms, such as galactorrhea, weight loss, or hirsutism?
- Have you experienced significant changes or stressors in your life (eg, parental divorce, new school)?
- How often do you exercise?
- What is your typical diet, or do you have any dietary restrictions (eg, vegan, vegetarian)?
- Are you taking any medications, including contraception?
- Do you have a history of headaches or visual changes?
- Does the review of systems reveal anything suggestive of a chronic illness, such as Crohn disease?

radiates to the anterior thighs or the lower back is not uncommon, although other emergent etiologies, such as ovarian torsion, must be explored if the patient presents acutely. The color of the blood may be helpful when assessing excessive uterine bleeding. Brown or dark blood may be associated with a cervical obstruction or endometriosis, whereas red or pink blood occurs with most other conditions. More important, the timing of the bleeding is extremely significant. Cyclic bleeding beginning at menarche is more consistent with the presence of a blood dyscrasia. In contrast, breakthrough bleeding throughout the cycle may be indicative of an infection, endometriosis, or a polyp. The passage of blood clots on rising in the morning is not uncommon secondary to the vaginal pooling of blood while the patient is supine. Clots throughout the day, however, are not normal and require further investigation.

A thorough review of systems also should be performed, paying particular attention to recent weight changes, systemic illnesses, and chronic symptoms.

Physical Examination

A complete physical examination, including an evaluation for any stigmata associated with a systemic illness, must be performed in the adolescent girl with a suspected menstrual disorder. The patient's height and weight should be plotted on the growth chart and compared with previous measurements. Depending on the SMR, the health professional can then determine if the teenager should have experienced her expected growth spurt. Body mass index, calculated by dividing weight in kilograms by height in meters squared, also should be calculated and compared with previous values, especially in girls with amenorrhea. Vital signs, including orthostatic measurements, are especially important to review in the patient with excessive uterine bleeding or amenorrhea as the result of restrictive eating (eg, hypothermia, severe bradycardia, orthostatic hypotension). The skin should be inspected for any evidence of androgen excess (eg, hirsutism, acne), insulin resistance (acanthosis nigricans), bruising, pallor, or petechiae. The thyroid gland should be palpated for masses or any evidence of hypertrophy, and the abdomen and suprapubic area also should be palpated for tenderness, organomegaly, or masses.

In the presence of a chaperone, the SMR of the breasts should be noted and compared with pubic hair development, particularly in the adolescent with primary amenorrhea. Other signs compatible with gonadal dysgenesis include webbed neck, broad shield-like chest, short fourth metacarpal, and an increased carrying angle of the arms. The presence or absence of galactorrhea also should be noted by gently squeezing each nipple. With the patient in the lithotomy or frog-leg position, the external genitalia should be carefully inspected for clitoral size (normal clitoral glans width, 2–4 mm) and patency of the hymen via gentle separation/traction of the labia majora. Passing a saline-moistened cotton swab gently through the vaginal introitus can help determine vaginal length as well as the presence of a transverse or longitudinal vaginal septum. A bimanual vaginal or rectoabdominal examination may be performed in the adolescent with primary amenorrhea who is not sexually active to ensure the presence of a normal vagina, uterus, and adnexa. Typically, a speculum examination is not necessary for an adolescent with no prior sexual intercourse who is reporting abnormal uterine bleeding or simple primary dysmenorrhea. If the sexually active teenager is asymptomatic, screening tests for STIs, particularly chlamydia and gonorrhea, can be performed noninvasively using a voided urine sample or self-collected vaginal swab, and the pelvic examination can be deferred. In the adolescent who is sexually active and has abnormal vaginal discharge, intermenstrual bleeding, history of dyspareunia, or lower abdominal pain, however, a complete pelvic and bimanual examination is mandatory to evaluate for PID and its complications (eg, tubo-ovarian abscess).

Laboratory Tests

The performance of laboratory studies depends on the specific menstrual symptoms. No laboratory studies initially are necessary for primary dysmenorrhea because the diagnosis usually is based on a classic clinical history and normal physical examination. The same is true for PMS. The laboratory evaluation for primary amenorrhea is dependent on the presence or absence of associated secondary sexual characteristics. For more information on the diagnostic evaluation of primary and secondary amenorrhea, refer to Selected References.

In the patient with abnormal uterine bleeding, baseline studies must include obtaining hemoglobin or hematocrit. Other initial laboratory studies should include a complete blood cell count to evaluate the red cell indices and platelets, a reticulocyte count, and a urine pregnancy test. Further diagnostic studies depend on the severity of the anemia and findings on history and physical examination. These may include coagulation studies (eg, prothrombin time/partial thromboplastin time), erythrocyte sedimentation rate, and thyroid function tests. Other tests for the evaluation of a blood dyscrasia, such as a von Willebrand factor (measured with ristocetin cofactor activity and antigen), factor VIII, and fibrinogen, should be performed in the patient who presents with severe anemia, especially at menarche or shortly thereafter. The studies should be performed in consultation with a pediatric hematologist and obtained before the administration of any required blood transfusions or hormonal treatment (eg, estrogen-containing medications), which may affect the results of certain assays. If the patient is sexually active and a pelvic examination is performed, an endocervical specimen should be obtained for nucleic acid amplification testing for *Chlamydia trachomatis* and *Neisseria gonorrhoeae.* Nucleic acid amplification testing of the urine or a vaginal swab to screen for gonorrhea and chlamydia are also available (eg, ligase chain reaction, polymerase chain reaction). Follicle-stimulating hormone, luteinizing hormone, prolactin, thyroid-stimulating hormone, testosterone, free and total testosterone, and dehydroepiandrosterone sulfate studies should be performed in the patient with a history of chronic anovulation or in whom androgen excess is suspected (eg, polycystic ovary syndrome).

Imaging Studies

Transabdominal or transvaginal pelvic ultrasonography can be helpful in the patient with excessive uterine bleeding or amenorrhea if a mass is suspected or palpated on physical examination. Complex

congenital obstructive anomalies, such as a longitudinal vaginal septum with hemi-obstruction, cervical agenesis or stenosis, or a partially obstructing uterine septum, may require magnetic resonance imaging if pelvic ultrasonography is inconclusive. Plain radiography is not indicated. Magnetic resonance imaging of the head may be indicated in the adolescent with amenorrhea if the patient presents with central nervous system symptoms or has markedly elevated serum prolactin.

Management

Effective management of each of these adolescent gynecologic conditions is multifaceted and includes education of the patient and parent or guardian, reassurance about the ease of managing the condition, and appropriate medications for those conditions requiring therapy. Generally, for most gynecologic conditions a menstrual calendar can be quite helpful for confirmation of the severity of the bleeding and assessment of the pattern and duration of each menstrual cycle. Digital period tracking applications are available for download onto most smartphones to assist with monthly documentation of menses and associated symptoms.

Dysmenorrhea

General modalities in the management of primary dysmenorrhea include education about menstruation, proper nutrition, smoking cessation (as appropriate), application of heat (eg, heating pad), simple exercise and/or yoga, acupuncture, and pharmacologic therapies.

For mild to moderate symptoms of dysmenorrhea, over-the-counter nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, are appropriate for first-line pain management and can also reduce blood loss. Physicians most often suggest that patients use ibuprofen initially because it is both safe and efficacious when taken in appropriate doses and frequency. The dose is 400 to 600 mg every 6 to 8 hours. Ibuprofen should be taken at the onset of the menstrual cycle and continued for 24 to 72 hours or for the usual duration of symptoms. Any girl who is unable to take the medication at the onset of menses secondary to vomiting can be instructed to start the NSAID 1 to 2 days before menses is expected to occur.

For moderate to severe dysmenorrhea in the patient who is not sexually active and does not desire birth control, a faster-acting NSAID, such as naproxen, may be an alternative to ibuprofen (Table 61.1). The major mechanism of action of NSAIDs is the inhibition of prostaglandin synthesis. A loading dose of naproxen is recommended at the onset of therapy. Side effects of these drugs, which most commonly affect the gastrointestinal tract, are nausea, vomiting, and dyspepsia. These reactions can be minimized by taking the medication with food or an antacid. Other adverse reactions include renal effects; skin reactions, such as erythema multiforme and urticaria; and central nervous system effects, including headache and dizziness. Contraindications to NSAID use include peptic ulcer disease, clotting disorders, and renal disease. All NSAIDs should be administered with food and taken for 3 to 4 menstrual cycles before their efficacy is evaluated.

Table 61.1. Nonsteroidal Anti-inflammatory Drugs Used in the Management of Primary Dysmenorrhea

Generic	*Sample Trade Name(s)*	*Dosage*
Ibuprofen	Motrin, Advil (200 mg/tablet)	2–3 tablets every 6–8 hours for 24–72 hours
Naproxen sodium	Aleve (220 mg/tablet), Anaprox (275 mg/tablet), Naprosyn (250 mg/tablet)	2 tablets at onset, then 1 tablet every 8–12 hours
Mefenamic acid	Ponstel (250 mg/capsule)	2 capsules at onset, then 1 capsule every 6 hours or 2 capsules every 8 hours

Low-dose combination oral contraceptive is indicated for the adolescent with moderate or severe dysmenorrhea who is sexually active or in the patient whose symptoms are not sufficiently relieved by NSAIDs alone and whose own medical or family history does not preclude the use of estrogen. Oral contraceptives decrease the production and release of prostaglandins and leukotrienes by inhibiting ovulation as well as endometrial growth. Because the symptoms of dysmenorrhea are prevented only after several cycles of oral contraceptive pill (OCP) use, the patient should be advised not to expect complete resolution of symptoms during the first month of treatment. The adolescent with a classic clinical presentation of primary dysmenorrhea does not require a pelvic examination before initiating oral contraceptives. Even if an adolescent is sexually active, routine STI screening can be performed using a vaginal swab or urine-based nucleic acid amplification testing. Reevaluation after at least 3 cycles is indicated to document adherence and resolution or improvement of menstrual symptoms.

Thirty or 35 mcg of ethinyl estradiol-containing monophasic oral contraceptives should be used for a minimum of 3 to 4 months. If symptoms do not improve, an NSAID can be added to the treatment regimen. Oral contraceptives are more than 90% effective in cases of severe dysmenorrhea, and the physician should emphasize this hormonal benefit to the patient and the patient's parent or guardian. Although 20 mcg of ethinyl estradiol-containing OCP formulations are available, the literature remains inconclusive concerning the first-line use of these for primary dysmenorrhea.

Other combined hormonal contraceptives, such as the transdermal patch and the contraceptive ring, have been studied for the management of primary dysmenorrhea in adult women. The use of extended OCP regimens to reduce the hormone-free interval also has been reported to be beneficial in reducing painful menses. Specific studies in adolescents, however, are extremely limited. Long-acting reversible contraception also should be considered in the adolescent with primary dysmenorrhea who is unable to take combined oral contraceptives.

If dysmenorrhea persists despite the judicious use of NSAIDs and contraceptives, a search for other pelvic pathology (eg,

endometriosis) is warranted, and the patient should be referred to a gynecologist for further evaluation and possible diagnostic laparoscopy.

Abnormal Uterine Bleeding

The management of abnormal uterine bleeding depends on the severity and frequency of the bleeding, the severity of anemia, and the underlying etiology (Table 61.2). The goal of management is 4-fold: to control the bleeding, correct the anemia, replenish iron stores, and prevent further episodes of bleeding. The patient with mild or moderate anemia can be treated as an outpatient with weekly to monthly follow-up depending on how quickly the bleeding is controlled and the anemia resolves. Regardless of the etiology, hormone treatment generally is required to stabilize the endometrium and control future bleeding episodes, particularly if the patient presents with symptomatic anemia. Monophasic combined oral contraceptive pills (COCPs) are the mainstay of treatment for abnormal uterine bleeding in the patient with moderate anemia and/or who desires birth control. Other hormone regimens, such as progestin-only preparations (eg, medroxyprogesterone acetate), also can be used. This is especially important in the adolescent with a medical contraindication to estrogen or disinterest in COCP therapy. Supplemental oral iron therapy is also required for all teenage girls with anemia. Prescribing ferrous gluconate rather than ferrous sulfate may improve adherence because the former is less irritating to the stomach.
