EDITOR'S INTRODUCTION

This is the first encyclopedia of Caves and Karst Science and provides a unique, comprehensive, and authoritative reference source that can be used both by subjectspecialists who wish to obtain information from outside of their immediate area of knowledge and by non-specialists who wish to gain an understanding of the diverse and multi-disciplinary nature of caves and karst science. It will also be useful to cavers who wish to learn more about the environments in which they undertake their sport and to conservationists, engineers, planners, and others who are charged with developing and managing in a sustainable manner complex karst environments. The 351 entries were selected by a multi-disciplinary Advisory Board of leading scholars, all of whom are cavers. The entries cover a wide range of topics and each entry also includes both references and further reading to enable deeper study. While not intended as an atlas, there is a wide geographical coverage of all scientifically important karst areas, the level of detail (continent, country, region, or individual site or cave) reflecting the Advisory Board's opinions as to the importance of the locality. It is the first encyclopedia to cover all the disciplines involved in cave and karst science-archaeology, biology, chemistry, ecology, geology, geomorphology, history, hydrology, paleontology, and physics as well as exploration, survey, photography, literature, and art. The resources found in caves and in karst areas are outlined, including the underground water that supplies around a quarter of the world's population. Caves and karst environments are fragile and special places so there is appropriate consideration of conservation and management, including protected areas. Contributors are all leading authorities in their area and all entries were subject to review by the Editor, members of the Advisory Board, or other subject specialists. The term "cave" is commonly applied to natural openings, usually in rocks, that are large enough to permit entry by humans. The term is also sometimes applied to openings constructed by humans but this encyclopedia is confined to natural caves. The majority of these form parts of a wider landscape known as karst, defined by Derek Ford in this volume as "terrain with distinctive hydrology and landforms arising from the combination of high rock solubility and well-developed solution channel (secondary) porosity underground". As well as distinctive landforms and drainage, karst areas have distinctive biological attributes and provide a wide range of resources, together with particular problems for humans who wish to exploit them. Caves are natural museums, preserving important archaeological evidence as well as sediments and deposits that provide clues to past environments. They also present many challenges for explorers. Although several thousand kilometres of cave have been explored, it is certain that many passages have yet to be entered and these represent the only truly unknown parts of the Earth outside of the oceans. Each year several well-equipped teams undertake major expeditions to discover new cave but it remains the case that individuals and groups working steadily on smaller projects also succeed

in becoming the first humans ever to set foot in a particular passage. While the thrill of discovery drives many, caving has also become a popular recreational activity in many countries and many thousands more enjoy visits to commercially developed tourist caves.

To discover new cave it is usually necessary to have an understanding of the scientific contexts in which caves are formed while the discovery of new caves provides opportunities for new scientific discoveries. This synergy between science and exploration is one of the factors that makes the study of caves and karst so exciting. Caves are widely distributed, from within the Arctic Circle to the Antarctic and from below sea level to altitudes of several thousand metres. Karst is also widespread and it has been estimated that about a quarter of the world's population draw their water from karst rocks. Cave and karst science is multi-disciplinary, being undertaken by archaeologists, biologists, chemists, ecologists, geographers, historians, hydrologists, and physicists. It is also applied as conservationists, consultants, engineers, environmental managers, and planners require an understanding of the special characteristics of karst in order to manage and sustainably develop the many resources of karst areas.

Choosing the entries and authors

Given the above it is perhaps surprising that this is the first encyclopedia devoted to Caves and Karst Science. As such it seeks to describe all of the world's important karst areas and the most important caves. However, it is not an atlas and coverage is not, and could not have been, exhaustive. Instead, an initial list of sites was drawn up with the assistance of an appointed board of advisers who have very wide subject expertise and caving experience (see page ii and Notes on Contributors). The list was then widely publicized and suggestions for additional/ alternative sites sought from the cave and karst community before a final list was agreed. This comprises 100 entries on the world's most significant cave and karst sites, and regional discussions of the world's largest areas of caves and karst. In addition to assisting in the choice of important sites and areas the Advisory Board helped to draw up a list of topical entries considered to be of primary importance to their particular branch of science. Again there was wide discussion of the lists both between the Advisory Board and also via the encyclopedia web site.

Following the consultative process a final list was produced broken down by themes, although some entries fall into more than one field:

Archaeology, Art in Caves and Paleontology: 29 entries, from dating methods to major sites, and regional discussions of art in caves

Biospeleology: 78 entries on ecology and ecological processes, habitats, cave ecology & man, subterranean fauna, subterranean biodiversity, regional faunas, the world's richest cave faunas, evolution of subterranean fauna, and important subterranean taxa

Caves and Caving: 23 entries on cave media, caving, and the uses of caves

Cave and Karst Regions: 75 entries on the world's largest and most important areas of caves and karst together with 28 entries on individual caves and cave systems

Conservation and Management: 19 entries on topics such as environmental impact assessment, groundwater pollution, and tourist caves

Geoscience: 78 entries on caves and speleogenesis, climate of caves, deposits in caves, karst settings and landforms, processes and techniques, and pseudokarst

History: 27 entries on key events and personalities in the history of cave and karst science together with the history of cave exploration in particular regions of the world

Resources and Development: 22 entries on the resources of karst regions and some of the key problems in their exploitation

The next stage was to allocate a word limit for each entry and to seek suitable authors. Most entries were planned at 1000 words, although it was recognized that some would need to be longer, up to a maximum of 4000 words. The Advisory Board suggested some possible authors who were invited individually. Other authors were approached in more general terms and invited to offer to write entries that remained unassigned. The objective was to include the leading authorities on each topic from a range of different countries. All entries were read by the Editor and by selected members of the Advisory Board or other reviewers.

The finished work has a total of 351 entries on a wide range of topics. A thematic list, an extensive index, and cross-references are provided to help readers explore themes systematically. All the entries have bibliographies and/or suggestions for further reading, pointing the reader toward original research and textbooks that augment the overview approach to which an encyclopedia is inevitably limited. Most entries have either line diagrams expanding on explanations given in the text, or photographs illustrating type examples. There is also a section of colour pages illustrating the range of themes.

Entries and structure

The 351 entries appear in alphabetical order and are of several kinds (for the complete list of entries see page xi). Although each entry is self-contained, the links between entries can be explored in a number of ways. The Thematic List on page xv groups the entries within broad and more specific categories and provides a useful summary of related entries. Almost all of the entries have "See Also" links, both within the text and at the end of the entry, so the reader is encouraged to browse outwards from a starting node. Finally the Index provides a detailed listing of topics, organisms, and sites or countries that do not have their own entry but are discussed within the context of broader entries.

One aspect which came as a surprise to the Editor was the difficulty of deciding the exact titles of several entries and hence the point at which they would appear in the alphabetic listing. Following much discussion it was decided that all organisms would appear alphabetically by scientific name (hence "Chiroptera" not "Bats", and "Pisces" not "Fish") and that where the common name for a site commences with a local word for a cave or geographical feature then the entry should be under the location (hence "Draenen, Ogof Draenen, Wales" and "Encantado, Sistema del Rio, Puerto Rico"). We recognize that this may initially cause some confusion but if you cannot find an entry on a topic you expected to find you should be able to use the Thematic List or Index to locate the title of

the entry that contains the topic you are looking for. Thus, for the examples above the Index will contain cross references for Bats, Fish, Ogof Draenen, Rio Encantado, and Sistema del Rio Encantado.

Acknowledgements

My thanks are due to all the contributors who provided excellent material, adhered to length guidelines and submitted their work on time. I also thank those who caused me angst by submitting overlong scripts that needed serious pruning and those from whom the script was finally extricated months after the deadline. You know who you are...

Particular thanks are due to fellow cavers who supplied photographs for no reward other than seeing their work in print. Commitment to the wider good of caving is one of the marks of our sport.

The Editorial Advisory Board played a vitally important role in helping to decide what entries should be included and who should write them, as well as in reviewing the submitted essays. Special thanks are due to Paul Wood who reviewed all of the biology entries, many of which were written by scientists who do not have English as their mother tongue. Also to Tony Waltham who reviewed all of the entries on individual cave systems and on the world's largest and most important areas of caves and karst. Tony also edited many of the maps and photographs to ensure consistency and provided new maps and many photographs for entries where the author was unable to do so. As we approached the production phase Tony also provided a great deal of constructive advice on the choice of illustrative material, particularly in the colour section.

From start to finish the project has been overseen in an incredibly efficient manner by Gillian Lindsey, first at Fitzroy Dearborn and then at Routledge in New York. Without her commitment and drive the work may never have come to fruition and on behalf of myself and the members of the Advisory Board I offer her our very grateful thanks.

Special thanks for personal support during the editorial process are due to Ernest, Doreen, Cathy, Eilíse, and Owain Gunn, to Paul Somers and Lian, caver of the future, and to Sarah Davies.

A

ACCIDENTS AND RESCUE

Cave exploration is, by its nature, a potentially hazardous activity, although the relative risk of an accident, and its severity, clearly vary from cave to cave. In all but the simplest of cases, rescue of an injured person from a cave poses problems that are different from those encountered on the surface. A cave is a relatively hostile environment in which to perform a rescue: it is completely dark beyond the entrance zone and there may be other potential hazards, including water, low temperatures, constricted passages, and vertical shafts. Hence, there is a need for specialist rescue teams who are aware of the latest rescue techniques.

The French Cave Rescue Organization has records that have been kept from the early 1900s but it is believed that the world's first formally organized cave rescue team was founded in Yorkshire, England, in 1934 (Eyre & Frankland, 1988). At present, over 20 nations have active cave rescue organizations. The International Cave Rescue Commission within the International Union of Speleology provides a forum for cave rescue organizations to communicate with each other at their congresses and through the internet at http://netdial.caribe.net/~emercado/uis.htm.

Rescue organizations have training seminars and extensive practice rescue from caves. At the training seminars, often international events, experience gathered from real and practice rescues is exchanged and rescue equipment and techniques are demonstrated. Rescue records are published in national journals, often with full details and analysis. In addition, many organizations keep detailed records of their rescues and hence it is possible to generate statistics on the diversity of caving accidents that require rescue. Statistics from the United States show that the majority of incidents (c. 30%) involve vertical caving and rope work. This is followed by individuals who have become lost or have experienced light failure (18%); water problems including being trapped by flooding (14%); entrapment (10%); and explosion, rock fall, bad air, and medical problems, each making 5% or less (Hempel & Fregeau-Conover, 2001). Frankland (1991) gives statistics for the causes of injury or death to British cavers: falls (61%), rock fall (15%), drowning (12%), bad air (21%), and others (10%). A more detailed analysis of cave rescue statistics for the Yorkshire Dales area (Forder, 2001) showed that half of the incidents between 1935 and 2000 involved floods or falls and that falls accounted for a quarter of all fatalities, and floods 13%. Standing (1976) showed that 80% of British rescue incidents involved novices and in the United States, 90% of call-outs were for inexperienced or poorly equipped cavers (Hempel & Fregeau-Conover, 2001).

The above statistics illustrate that inexperienced and poorly equipped cavers are most at risk and that falls, usually off short, unprotected climbs or while vertical caving with ropes and ladders, are the most common accidents. In such falls lower limb fractures are the most common injury, followed closely and perhaps surprisingly by spinal fractures, almost entirely without spinal cord damage. Spinal injuries pose particular difficulties for the rescue team.

Rescue of the lost caver requires that the rescue teams have substantial local knowledge and the resources for rapid systematic searches of complex caves or several caves in an area. Speed in any rescue is critical because even if the cavers are not injured they are in danger from hypothermia. Lloyd (1964) found that death from hypothermia could occur within half an hour of the onset of symptoms. The prevention of hypothermia in the lost, trapped, or accident victim is a major consideration of the rescue team, who typically carry equipment such as thick neoprene exposure bags, heat packs, insulating systems, and warm-air rebreathing apparatus.

When a person is injured a factor critical to successful rescue is the time taken to alert the rescue organization. Nevertheless, the difficulty of the cave and the depth of the accident site mean that there may be hours or even days between an injury and the arrival of the rescue team. Hence, the availability of basic survival equipment and knowledge of first aid among the victim's group enhances the probability of a successful rescue.

Many cave systems flood and often flash flood. Special care is required in the lowest levels of caves and close to sumps as in these regions back-flooding can cause water levels to rise exceptionally rapidly. When floodwaters prevent safe exit the only option is to seek a position above the maximum water level, which can sometimes be deduced from foam or mud-coated walls or vegetation lodged in cracks and crevices. Some caves that experience frequent flooding of their entrance passages have designated points where trapped cavers may safely await rescue (e.g. Peak Cavern, England). It is usually advisable to wait until the rescue team arrives unless absolutely certain that the water levels have dropped sufficiently for a safe exit. It is not wise to move with or against a flood, and exceptionally hazardous to attempt to ascend or descend ropes or ladders when the cave is flooding. The worst caving disaster in Britain was in Mossdale Caverns in 1967 when six cavers lost their lives as a result of an unexpected flash flood. Guide books often contain information as to which caves are known to flood and a wise caver will check the weather before entering such caves. However, intense precipitation is not always predictable and in the Mossdale area on 3 May 1986, another flash flood resulted in six separate rescue call-outs. This time there was only a single fatality.

Rock fall or movement can trap a caver, especially when they are negotiating breakdown. Rescue of the trapped can be a frightening experience for the rescue team if the area remains unstable. Rescue of a person from bad air requires both a fast response and great care as accidents in bad air could result in the deaths of the rescuer as well as the victim. Rescue and recovery teams use breathing equipment or wait until the hazardous atmosphere has cleared. Bad air can arise from a number of sources: partial combustion of fuel in fires, stoves, or generators can result in accumulations of carbon monoxide as well as carbon dioxide, and explosives release a variety of exceptionally toxic gases. Less obviously, respiration in a confined space results in hazardous increases of carbon dioxide and reduced oxygen. For example, in England in 1976 six cavers were free diving a c.8 m sump in Langstroth Pot with a small air bell where a breath could be

taken halfway. Unfortunately they used up the oxygen in the air bell, replacing it with expired carbon dioxide, and there were three fatalities.

Every rescue situation is different and there is no formula for exactly what must be done. On expeditions in remote areas and in most vertical caves emphasis is placed on self-rescue, which in this context means that members of the victim's party organize the rescue. The cavers performing self-rescue must assess the degree of injury and the availability of outside rescue before attempting to remove the victim from the cave. Some rescues cannot wait for an outside team; for example, if the victim is trapped on rope hanging in a harness they should be released as fast as possible as death occurs rapidly to both the conscious and unconscious. If the cavers are trained in first aid and techniques of rescue, especially those needed for rescue in vertical caves (Warild, 1994), then the probability of a successful self-rescue is increased. However, an untrained group would probably fail to rescue a severely injured victim from deep in a cave. It should be emphasized that the death of a victim can be a harrowing experience for all. The most experienced rescuer should adequately package the body such that the object being handled by the recovery team is minimally visibly human.

Flooded passages (sumps) pose particular problems. Only fellow divers can rescue cave divers who have equipment failure or an accident; divers have also been used to bring out uninjured cavers trapped beyond flooded cave passages. Probably the earliest such rescue was in 1969 when a trapped and unconscious cavers in Meregill Hole, England, was brought through a sump with a diving mask held onto his face. He survived the dive, but died of hypothermia shortly afterwards. Subsequently there has been considerable research into the development of equipment for transporting injured or trapped cavers safely through flooded passages. Unfortunately very few cave diving incidents result in a successful rescue, and body recovery poses its own problems. In the United States the International Underwater Cave Rescue and Recovery team assists local law enforcement agencies and other rescue organizations by supplying specially trained divers to aid in rescues or recoveries.

Modern rescue teams have the benefit of state-of-the-art equipment; the ability to call out cave, mine, and other specialist rescue teams, and to transport experts and victims thousands of kilometres if necessary. No expense is spared if it is believed the cavers are still alive. For example, probably the world's longest, largest, and most expensive cave rescue took place in France in November 1999 when seven cavers were trapped by floods. Shafts were drilled to locate air spaces in which the cavers were likely to be waiting (a first) and the successful rescue took ten days.

ADAPTATION: BEHAVIOURAL

Of all phenotypic traits, behaviour plays the most immediate role in determining the ability of a group of individuals to survive during colonization of the subterranean (hypogean) environment. Changes in behaviour as a response to environmental change are thus crucial to understanding the phenomenon of adaptation to hypogean environments. In the following overview of current understanding of behavioural adaptations in caves, most of the examples presented come from studies of fish, the taxon on which most behavioural experiments have been performed.

Numerous animals colonize the hypogean environment by developing entirely new behaviours such as echo-location (e.g. bats and the nocturnal oilbird *Steatornis caripensis*), bioluminescence (e.g. the New Zealand glow-worm—actually a fly larva—*Arachnocampa luminosa*), or hibernation (e.g. a carp from China, *Varicorhinus [Scaphestes] macrolepis*). However, these types of behavioural modifications are the exception, not the rule. Most can be grouped into one of the following categories: feeding, reproduction, social behaviour (including aggregation, responses to alarm substances, and antagonistic behaviour), photoresponses, and circadian rhythms.

Feeding

Many cave animals have enlarged sensory systems that allow them to sense the presence of food. To improve their ability to find food, many cave animals move continuously in their environment; for example the troglomorphic form of the fish *Astyanax fasciatus* swims continuously. In studies, these fish also decrease the angle of their body relative to the bottom of the aquarium in order to increase the area of contact between food on the bottom and areas of their skin where there are larger numbers of chemoreceptors (Schemmel, 1980). Similar adaptations have been reported for the toothless blindcat *Trogloglanis pattersoni*, the Somalian cave fish *Phreatichthys andruzzii*, and the catfish *Trichomycterus itacarambiensis*. Coprophagy (feeding on excrement) is not uncommon in caves, and some animals specifically choose such environments. For example, larvae of the pyralid moth *Aglossa pinguinalis* are found inside caves in densities 700 times greater than at the surface. This is apparently due to the fact that in more exposed excrement they cannot compete with other coprophagous specialists, owing to a lack of parental care and slow growth rates for this species (Piñero & López, 1998).

Reproductive Behaviour

The use of chemicals to attract mates has been reported in a number of cave organisms, ranging from crickets to fish. This behaviour has yet to be studied thoroughly in natural conditions. Aggressive behaviour associated with reproduction has been observed to decrease, probably due to a lack of visual information (Parzefall, 2000) (see below).

Aggregation/Schooling

In general, all hypogean animals show a tendency to reduce organized forms of aggregation, from insects (Christiansen, 1970) to fish (Romero, 2001). Romero (1984, 1985a), for example, observed that individuals of *A. fasciatus* morphologically identical to the epigean populations of the same species actively entered a cave in Costa Rica for both feeding and to escape from predators (the fishing bat *Noctilio leporinus*). However, unlike the typical epigean *A. fasciatus*, the population did not form schools.

Responses to Alarm Substances

Many bony fishes contain an "alarm substance" in their skin that is released into the water when the skin is damaged, for example by biting. It is believed that this substance is sensed by conspecifics (members of the same species) of the individual that has been harmed, and thus they use the information to escape or seek refuge. Although the substance is produced by many hypogean fishes, the response to its release is either highly reduced or lost (Fricke, 1988).

Aggression and Antagonistic Behaviour

Aggression has been reported for many cave fishes, and some amphibia and crustaceans (Parzefall, 2000). Aggression is usually reduced, but antagonistic (confrontational behaviour without fighting) behaviour persists in many species, including amblyopsids (where the rituals decrease in complexity in parallel with the degree of cave adaptation, Bechler, 1983), the Ceguinho catfish *Pimelodella kronei*, and the Cueva del Guácharo blind catfish *Tricomycterus conradi*.

Responses to Light

Many blind, depigmented hypogean animals do show behavioural responses to light. Photoresponses are mediated by the pineal organ and—to a certain extent—by extrapineal organs (Langecker, 1992; see Adaptation: Morphological-Internal). They are termed scotophilia (the tendency to stay in the dark side of an aquarium under experimental conditions) and have been reported for many species of hypogean fishes (Romero, 2001). The behaviour of staying away from light is usually more common among recent invaders of the hypogean environment than among more troglomorphic species (Green & Romero, 1997). Also, the degree of scotophilia (in which the fish moves away from light) increases with development, as it does for epigean forms (Romero, 1985b). Although earlier authors made much of this behaviour as an indication

that these species maintain such responses in order to stay in caves, all available evidence suggests that such behaviour is an inherited relic from their epigean ancestors (Romero, 1985b).

Circadian Rhythms

This is a system also known as a "biological clock", which controls a series of physiological and behavioural responses in an organism. The rhythmicity generated by these clocks is usually triggered by light and temperature changes in the environment. Many cave animals show a reduction or total loss in their ability to generate biological rhythms even when exposed to light under experimental conditions (Lamprecht & Weber, 1992). As with the photoresponses mentioned above, circadian cycles are more reduced (or totally absent) in the more troglomorphic species (see also Adaptation: Eyes).

Acoustic Behaviour

Hoch (2000) found that the cave planthopper, *Oliarus polyphemus*, utilizes communication systems similar to those of its epigean ancestor, by communicating using substrate-borne vi brations, and also found that the cave environment seems to be especially suited to low-frequency sound transmissions. No acoustic communication has been demonstrated for hypogean fish, despite the obvious advantage of such behaviour. More research is needed in this area.

In summary, with the exception of a few very specialized types of behaviour, most cave animals tend to reduce or eliminate many of the typical responses of their epigean ancestors. To understand the role played by behaviour during hypogean colonization, ethological studies on hypogean organisms that have yet to achieve a troglomorphic state are probably the most important avenues to explore.

ADAPTATION: EYES

The lightless regions of caves, referred to as "the deep zone" by Howarth (1993), can harbour aquatic, terrestrial, and even flying organisms. Although troglophiles—and even some animals that occasionally visit caves—often show adaptations involving photoreceptors and sight, few generalizations can be made regarding their eyes. Cave animals such as bats generally possess poor eyesight, but are never blind; other animals that simply visit caves may have grossly enlarged eyes with highly sensitive photoreceptors (Jamaican cave frogs, for instance) or, as in the case of some millipedes, may lack eyes altogether. On the other hand, obligate cave-dwellers frequently have eyes that are reduced in size, and some have lost their eyes entirely. Thus, eyelessness has traditionally been regarded as a sure sign of a "troglobitic" lifestyle. However, with the discovery in New Zealand of cave harvestmen (*Hendea myersi cavernicola*) that possess large, functional eyes but display other typically troglobitic features such as a pale, nonpigmented body, it has become clear that troglobites need not necessarily be blind. The New Zealand cave harvestmen prey upon the luminescent larvae of the so-called glow-worm fly, *Arachnocampa luminosa*, which is a troglophile. For a predatory animal

like the cave harvestman, to be able to see its luminescent prey is an obvious advantage. Therefore, as with the occurrence of bioluminescence in mesopelagic organisms, an adaptation which has prevented the widespread evolution of eyelessness in the deep sea—only a few bathypelagic fishes completely lack eyes—provided that light sources still exist and sight still has a role to play, then even a troglobite need not be eyeless.

Notwithstanding the exceptions discussed above, it is clear that lack of light especially sunlight—is a powerful feature of most cave environments and, undoubtedly, has led to the reduction and even disappearance of eyes and their constituent elements in many cavernicolous vertebrate as well as invertebrate species. In the dark it is energetically demanding to maintain a functioning eye with its photopigments, optical structures, dark/ light adaptational mechanisms, nerve connections to the brain, and the ability to integrate and interpret visual signals. Moreover, it is a luxury that can become a handicap, because eyes can become injured, infected, or become a hindrance in locomotion. Consequently, eye degenerations in cave vertebrates are common among troglobitic fishes (see Table and Figure in Pisces: Amblyopsidae) as well as cave newts and salamanders, but nevertheless, tiny eye rudiments under the skin—often invisible from the outside—are usually present.

Embryologically, the eyes of cave fishes and amphibia at first develop quite normally, but then begin to exhibit developmental retardation. Arrested growth and differentiation follows, and finally programmed cell deaths occur. The grafting experiments of the French biospeleologist Jacques Durand showed elegantly and convincingly that this scenario does not depend on the presence or absence of light. He exchanged the larval eyes of the hypogean, aquatic cave salamander Proteus anguinus with those of the epigean Euproctes asper and observed that in both cases the donor eye behaved in the way that it would have done in the specimen of origin. The degeneration of the eye appears to be controlled by a cascade of regulatory genes; eight to ten genes are now thought to be involved specifically in the eye regression of the cave fish Astyanax *fasciatus*. Eye regression in cave vertebrates is mostly centripetal, which means that it commences peripherally with the cornea and lens, then affects retinal and perceptive structures, and finally engulfs nerves and the optic centres of the brain. Interestingly, cave fish are known to compensate for the loss of their visual system with enhancements to their lateral line organ and taste buds. Eyeless cave arthropods frequently exhibit elongated limbs, antennae, and body hairs, presumably to facilitate the detection of tactile stimuli, water or air currents. In arthropods with compound eyes, reduced eye size and a smaller number of facets are usually the first signs of eye regression: approximately 30 ommatidia are present in the eye of the cave opposum shrimp Heteromysoides cotti, three in the cave shrimp Typhlatya garciai, and none in Troglocaris anophthalmus.

Apparently the more rudimentary the eye, the more variable its appearance: the percentage of misshapen or malformed ommatidia increases, pigmentation becomes irregular, and cellular outlines as well as photoreceptive elements become increasingly less uniform. Such multifariousness in a rudimentary organ has been interpreted as support for Darwin's theory of natural selection, since organs deemed unnecessary—and which have therefore undergone regression—ought to be less and less affected by selection. Functionally, loss of colour-, shape-, and form-vision precede changes in the ability to detect flickering lights, to adjust the visual system to changes in ambient light intensity, and to protect the eye against photic damage. However, whether the latter

occurs as a consequence of the cave environment or has prompted a species to establish itself in the cave, needs to be examined from case to case. An entire book has been devoted to one species of cave crustacean, the amphipod *Gammarus minus*. It is interesting that numerous totally eyeless species of terrestrial cave insects and aquatic crustaceans exist, but that almost no cave crab is completely eyeless, either exhibiting only reductions in eye size or lack of pigment and facetation around the eye region as well. Eyeless cave arthropods need not necessarily be completely insensitive to light: extra-ocular photoreceptors (for example, the so-called tail photoreceptor in the sixth abdominal ganglion of the crayfish), may be able to convey information on ambient light levels.

Without daylight, the most important time-keeper to coordinate circadian or seasonal rhythmicities is absent in caves, and many troglobitic animals, whether with or without rudimentary eyes, are indeed non-rhythmic. However, strictly clock-controlled locomotion rhythms are known from some troglobites. Since eyes and photoreception cannot be involved, secondary or even tertiary signals, such as daily movements of cave bats; periods of increased production of faeces; or activity periods of bat guano flies probably are. The question of how long it would take an animal species to lose its eye in total darkness is hard to answer. Fruitflies kept in total darkness for more than 600 generations showed little change in eye size. However, selective pressures were absent in that particular experiment, and undoubtedly the presence of predators would have had some impact. It was estimated that the total loss of the compound eye in a troglobitic arthropod could require some 100000-1000000 generations. However, in view of the fact that deep-water hydrothermal vent shrimps apparently underwent a near-total loss of the dioptric (lens and corneal) elements (but not the photoreceptive cells) of their eyes in only 10000 generations, estimates for the time-scale of morphological changes in the eyes of cave organisms may need to be revised.

ADAPTATION: GENETICS

Any particular feature of an organism results from the interplay of genetics and the environment, but it is the genetic component that is passed on to succeeding generations, forming the raw material of evolution, which is, by one definition, simply the change in gene frequency through time. For a trait-whether behavioural, demographic, or morphological-to be adaptive in the cave environment, it must satisfy several requirements (Brandon, 1990), the most important of which are: (1) that some types are better adapted than others in the cave environment; (2) that selection has occurred; and (3) that trait differences are genetically determined. For many of the traits shared by obligate cave animals, the selective advantage is obvious. Thus, any increase in size or complexity of extra-optic sensory structures confers an apparent advantage in the darkness of caves, and any decrease in number of eggs produced confers an apparent advantage in the food-poor environment of caves. The third requirement-that trait differences are genetically determined-is more difficult to document. Purely environmental effects can mimic some of these adaptive changes. For example, colour differences between cave-dwelling and surface-dwelling crayfish (Procambarus simulans) are related to the availability of carotenoid pigment precursors, not genetic differences (Maguire, 1960). Starvation can also mimic some effects. Starving animals become emaciated, sometimes giving the appearance of a true cave animal. Even egg production is affected by starvation (Charlesworth, 1980).

There have been two studies that document the genetic basis of adaptation—Fong's study of the heritability of relative antennal length in cave and spring populations of the amphipod *Gammarus minus* (Fong, 1989; Jernigan, Culver & Fong, 1994) and Schemmel's study of taste-bud density and feeding behaviour in river and cave populations of the Mexican characin *fish Astyanax fasciatus* (Schemmel, 1974a, 1974b).

Schemmel found that density of taste buds was high in cave populations, low in surface river populations, and intermediate in phylogenetically young cave populations. In river populations the only area of dense taste buds is at the tip of the mouth, and this is enlarged in all cave populations, especially to the ventral side of the head (Wilkens, 1992). For the most part these differences were shown to be genetic because he measured the differences on long-term captive populations raised under identical conditions. Taking advantage of the captive populations at the Zoological Institute in Hamburg, Schemmel crossed several cave populations in order to learn more about the genetics of tastebud density differences. By considering the variability of the offspring of these

crosses, Schemmel showed that the differences in taste-bud density between river fish and cave fish were due to at least two or three taste-bud genes. The polygenes show an additive manner of expression, but there was a threshold effect, where the density increases abruptly, indicating gene interaction.

Fong studied a series of antennal characters in two spring and two cave populations of *Gammarus minus*. He measured both relative lengths and number of segments in 60-dayold individuals raised under constant darkness and constant temperature. As expected, all relative lengths and number of segments were larger in cave populations than in spring populations. Because he compared groups of siblings, Fong was able to measure heritability, the fraction of the variation that is attributable to genetic as opposed to environmental variation. Fong measured what is called broad-sense heritability (because it does not eliminate the variance due to the common environment of sibs, e.g. the maternal effect). Nevertheless, his results were striking. For the six antennal traits measured in four populations, heritabilities averaged 0.6, and in only one case in 24 was there no statistically significant heritability (Fong, 1989).

If these results are typical of cave organisms, then almost all cases of morphological change associated with isolation in caves have a strong genetic component. The kinds of morphological changes associated with starvation and the absence of pigment precursors listed above only mimic adaptation at a superficial level, and are not a general explanation for the adaptation of animals to the cave environment.

Fong and his colleagues (Jones, Culver & Kane, 1992; Culver *et al.*, 1994; Culver, Kane & Fong, 1995), were able to push the analysis of the genetic basis of adaptation much further because they were able to demonstrate that animals with larger antennae or more antennal segments had larger numbers of eggs and/or were more likely to mate than animals with smaller antennae or fewer antennal segments. Both mating propensity and egg number are components of fitness. This reconnects with the criteria for showing that a trait is adaptive—the differences must be genetic and selected for. In this case, the agent of selection is clearly life in darkness.

Eye reduction has a strong genetic basis in those species that have been carefully studied, including *Astyanax fasciatus* and *Gammarus minus* (Culver & Wilkens, 2000). However, the adaptive nature of these losses is not at all certain. At least in part, eye loss occurs due to the relaxation of selection in favour of maintaining eyes and the accumulation of selectively neutral, structurally reducing mutations. The work of Fong and his colleagues on *Gammarus minus* cited above also indicates that there is a selective advantage to eye loss, due to either energy conservation or simplification of neurological connections.

ADAPTATION: MORPHOLOGICAL (EXTERNAL)

Morphological adaptation is used to mean evolutionary modifications of the external morphology of lineages of organisms, which are associated with their existence in caves. While some of these modifications may be non-adaptive, most putatively increase their chances of survival or competitiveness in caves. Selected works describing such adaptations in specific groups and reviews of general cave adaptation are listed in the references and further reading. A good example of morphological changes can be seen in cave Collembola of the family Entomobryidae where members of the genera Pseudosinella and Sinella go through very similar evolutionary changes in the caves of Japan, North America, Central America, and Europe (Christiansen, 1961; see Figure 1). These involve increase of adult size, expansion of mesothorax and elongation of furcula, and associated muscle changes producing an enlarged mesothorax, all associated with increased jumping ability. They also involve elongation of legs (also probably associated with increased predation escape), elongation of antennae, and enlargement of antennal sensory organs (both probably associated with increased olfactory and tactile sensitivity). The most studied changes are major changes in the foot complex. These have been shown to be associated first with adhesion on smooth wet rock surfaces and penetration into wet clay, and then with movement over water surfaces. In addition, there is the much-debated loss of eyes and pigment.

Other excellent descriptions of morphological changes involved in lineages of caveadapted organisms have been given for a number of groups, all of which include eye and pigment reduction or loss. In each case there are more specialized changes. In Amblyopsid fishes (see Pisces: Amblyopsidae) these include hypertrophy of free motion sensing neuromasts and flattening of the head (see Figure 2D in that entry). Specialized changes in beetles of the family Cholevidae and the subfamily Trechinae include wing loss, cuticle thinning, elongation of appendages, narrowing of the prothorax, physogastry or (in some Cholevidae) narrowing of abdomen (see Insecta: Coleoptera). In Crustacea of the family Crangoncytidae (Amphipoda) the special changes include elongation of appendages (see Crustacea: Amphipoda).

It is notable that while earlier works suggested non-neoDarwinian explanations for adaptation in cave animals (Vandel, 1965) almost all recent work has been undertaken with the clear assumption of the applicability of the Darwinian core tenets. A possible recurrence of a view similar to that held by Vandel can be seen in the emphasis on phenoplastic adaptation put forward by Romero (see Evolution of Hypogean Fauna).

Troglomorphy

The term "troglomorph" (Christiansen, 1962) was created to designate phenotypic features that are characteristic of cave ani mal evolution, and served to identify caveadapted organisms without the unprovable and often erroneous assumption that they live only in caves implied by terms such as troglobite. While the term was originally used for morphological features, subsequent work has shown that it applies equally well to behavioural and physiological features. The Table summarizes some of the major morphological troglomorphic features.

Questions as to the adaptive nature of troglomorphic features are putatively answered by their convergent nature but many recent works have furnished more direct evidence (e.g. Christiansen, 1965; Culver, Kane & Fong, 1995 and references within).

Adaptation: Morphological (External): Figure 1. Stages of increasing troglomorphism in Collembola Entomobryinae. A. *Pseudosinella octopunctata;* B.*P. hirsuta;* C.*P. christianseni.*

Adaptation: Morphological (External): Figure 2. Various troglomorphic vertebrates showing head flattening. A. lateral and B. dorsal view of head of *Ophisternon inferniale* (Synbranchidae), after Vandel (1965); C. *Synocyclocheilus hyalinus* (Cyprinidae); D. *Speoplatyrhinus*

Troglomorphy is not universal among cave organisms. In order for it to occur two factors have to be present: 1) a strong selection pressure for the development of a particular characteristic, and 2) the genetic and physiological or behavioural ability of the organism to respond to this pressure. Many cave organisms lack one or both of these factors. The phreatobite entomostracan crustacea and the extremely edaphic Collembola, such as the members of the family Onychiuridae, rarely show morphological troglomorphy. In many other groups, troglomorphy is questionable or inconsistent (Culver, 1982). It is also absent in cave environments such as guano piles or large masses of organic debris which are extremely energy rich. Peck has pointed out that troglomorphy should not be expected in these cases since troglomorphy only occurs when organisms are exploiting large volume spaces such as the surface of cave walls or floors (Peck, 1973), or large bodies of water. Indeed it has been long noted that the troglomorphic features of cave Entomobryidae are most closely approached in two very different surface habitats. The foot structure is closest to that seen in aquatic Collembola but the body shape features are most similar to those seen in forms (largely tropical) which live above the litter or soil, in trees. It is interesting that something similar to troglomorphy has been found in phreatobites where small size and elongate body form are developed convergently (Boutin & Coineau, 2000).

Where troglomorphy does occur, it allows for a separate analysis of those features clearly affected by the cave environment and those which are unaffected by it. It also gives clear polarity for phylogenetic analysis and permits a measure, or least an indication, of the degree of cave adaptation of different groups of organisms (Christiansen, 1961; Poulson, 1986).

Troglomorphy also shows varying degrees of taxonomic localization. In all cases there is some degree of convergent or parallel evolution in different regions and taxonomic groups. This is

usually transgeneric or even transfamilial, as in the case of the foot structure of European, Japanese, and American members of the genera *Pseudosinella* (Figure 1) and *Sinella* of the family Entomobryidae. In this case, as well as in the case of the similar changes in the family Orchesellidae, the adaptive significance of these changes is well known (Christiansen, 1965). In many cases, as with the flattening of the heads of troglomorphic fish and Amphibia (Figure 2), this is not so. Some troglomorphic features are so general (elongation of appendages, loss of pigmentation) as to be considered virtually universal.

Studies of troglomorphic evolution have produced a number of interesting ideas. Most exciting of all are the works of Culver, Kane, and their collaborators on *Gammarus minus*, which unites genetic, population genetic, population dynamic, and ecological analysis to answer the question of whether troglomorphic changes are in fact adaptive (e.g. Kane & Culver, 1992; Richardson & Kane, 1988). These works indicate that the troglomorphic features which have been studied are subject to selection and are in fact adaptive.

ADAPTATION: MORPHOLOGICAL (INTERNAL)

Anatomical adaptations are the internal reflections of the morphological and behavioural modifications of subterranean animals. Total darkness, almost unique to the subterranean environment, favours those organisms that have developed or are in the process of developing non-visual sensory structures. These are represented by any structure employed in any kind of sensory reception: mechanical (air currents, touch), olfactory (smell), gustatory (taste), or auditory (sounds). These sensory structures tend to be more highly developed in cave animals compared to epigean organisms.

In the brains of cave fish the nervous centres responsible for non-visual sensations, memory, learning, and spatial orientation are hypertrophied and can be used to estimate the degree of eye regression, and of sensorial compensation in cave vertebrates. Telencephalon hypertrophy is the most homogenous feature in the cerebral development of hypogean fishes. The cerebellum of many subterranean fishes is larger and its dimension is related to the time since cave colonization. This part of the brain receives information from the lateral line, free neuromasts, and other nerve pathways. The degree of development reflects the locomotory activity of cave species. Sometimes, related stygobitic and stygophilic fishes co-exist in the same pool within a cave. American researchers who compared the brain of the highly adapted *Typhlichthys* sp. and the less adapted *Chologaster* sp. from the River Styx in Mammoth Cave (Kentucky) found obvious differences (Mohr & Poulson, 1966) (see Figure 1). The inner ear structures of hypogean fishes are also modified, generally being larger, and are used to maintain equilibrium by perception of body motion and position.

The pineal organ has a photoreceptive function in fishes and amphibians. It contains many photosensitive cells, similar to receptors within the eye, but also has neuroendocrine cells that synthesize and release the hormone melatonin in the presence of light. Thus, the absence of light in caves will induce the degeneration of the exterior parts of pineal photoreceptors of stygobitic animals. Some cavernicolous species with completely

reduced eyes can still have functional pineal cells. This has been clearly demonstrated in the fish *Astayanax fasciatus* (Langecker, 2000).

Mohr & Poulson, 1966, modified).

The development of sensory structures in the dark is relatively well documented for some subterranean species. In contrast, the development of other organs not directly linked to sight has been very poorly studied, for example exocrine glands, producing pheromones. Cave beetles from the sub-family Leptodirinae that possess several types of glands with varying degrees of development or involution (depending on the phyletic line) have been described. The sternal gland is a multicellular gland present in the males of several Leptodirinae species. The *Speonomus* spp. are characterized by enhanced development of this gland but in marked contrast, *Batysciola* spp. are characterized by reduction of the sternal gland (Juberthie-Jupeau & Cazals, 1984; Moldovan & Juberthie, 1998) (see Figure 2). In the latter case, there is also a change from a secretion with less volatile particles to a very volatile secretion. However, this gland is absent in beetles highly adapted to life in subterranean habitats.

In subterranean environments, food input is not uniformly distributed in space or time and the primary adaptation of animals living in hypogean habitats is the improved ability to accumulate and store large energy reserves. Their lipids contain twice the energy per unit weight compared to proteins and carbohydrates. The adipose tissue can increase through excessive feeding, increased feeding efficiency, and improved metabolic pathways favouring lipid deposition during food-rich periods (Hüppop, 2000). This has also been observed in epigean animals, for example hibernating birds and mammals. In several terrestrial and aquatic cave animals an increase in fat content has been observed. Exceptional development of the adipose tissue has been recorded

Adaptation: Morphological (Internal): Figure 2. Evolution of the sternal gland in two subterranean genera: *Bathysciola*—a soil species (top) and a cavernicolous species (bottom), and *Speonomus*—from different cavernicolous species: *S. delarouzei:* (top), *S. pyrenaus* (middle), and *S. hydrophilus* (bottom). UG=unicelluar gland, S=sternite, G=sternal gland.

in springtails, Leptodirinae beetles, remipedes, and shrimps. For example, cave beetles can survive for several months without feeding. In cave decapod crustaceans, the hepatopancreas, a major lipid storage organ, is larger than that of other decapods and lipids are also deposited in oleospheres, specialized compartments within the hepatopancreas. An interesting example is that of the larvae of the most highly adapted cave beetles from the Leptodirinae family that hatch from large, yolk-rich eggs, do not feed at all, have an atrophied and non-functional digestive apparatus, and break down the lipid reserves to protein (Deleurance-Glaçon, 1963). The adult digestive apparatus of soil and cave species only display differences linked to the presence of the chitinous spines in proventricular and mesenteric caecums. Cave animals accumulate large volumes of fat reserves in the internal spaces occupied by other structures in epigean species, such as the wing muscles and the sternal gland, and which are completely absent in subterranean species.

The storage of lipids in fish has been extensively studied. The primary organs used for storage are the subcutis, muscles, viscera, orbit of the reduced eyeball, and cranium. An interesting example is provided by two Texas cave fishes *Trogloglanis pattersoni* and *Satan eurystomus* (Siluriforme), whose swim bladders are totally reduced and their place filled by fat deposits (Langecker & Longley, 1993). This allows the maintenance of a small body, which is advantageous for animals living in subterranean crevices.

Food scarcity and stability of the environment also help explain the tendency for paedomorphosis and neoteny in some subterranean vertebrates. Besides the morphological features that characterize this retardation of somatic development, some anatomical changes have been observed in cave fish and amphibians, including reduced muscles and ossification. Together with a reduced metabolic rate, oxygen consumption and accumulation of lipids are all characteristic of hypothyroidism. In some subterranean fish underdevelopment of the thyroid has been recorded. However, in *Proteus anguinus* the thyroid is highly developed and in this instance we probably observe the insensivity of the tissues to thyroxin, the hormone secreted by the thyroid (Langecker, 2000).

There have been relatively few detailed studies of anatomical adaptations to subterranean life and much remains to be learnt from the organisms that inhabit hypogean habitats.

ADAPTATION: PHYSIOLOGICAL

In subterranean ecosystems, the main environmental factors influencing physiological adaptations in cave organisms are darkness, lack of food, and also hypoxic conditions. These factors have a high selective value in regard to adaptive features such as a drastic reduction in eye size and a reduced metabolic rate compared with that of surface-dwelling relatives. To study the physiological adaptations of cave organisms to the subterranean environment, it is necessary to compare troglobites with troglophilous and epigean species. Studies have been carried out on aquatic and terrestrial invertebrates and vertebrates by investigating oxygen consumption and metabolic responses.

Oxygen Consumption

The most meaningful information on metabolic rate is given by measuring the oxygen consumption of the organism's whole body rather than just part of it. In most comparisons, hypogean species show generally lower metabolic rates than their epigean relatives. For example, the hypogean crustaceans *Stenasellus virei*, *Niphargus virei*, and *N. rhenorhodanensis* have a reduced metabolic rate because they show O_2 consumption rates in normal oxygenation 1.6–4.5 times lower than the epigean *Asellus aquaticus* and *Gammarus fossarum* (Hervant *et al.*, 1998). The same was found with salamanders, among which the obligate cave-dweller *Proteus anguinus* has an oxygen consumption as low as one-eighth that of the facultative cave-dweller *Euproctus asper* (Hervant *et al.*, 2000).

Reduced activity and decreased metabolic rates are a response to a selection pressure to economize on energy use because food and oxygen are in short supply (Culver, 1982; Malard & Hervant, 1999). Usually, cave animals have a higher basal metabolic rate than interstitial fauna. Culver & Poulson (1971) showed that individuals of *Stygobromus emarginatus* inhabiting more open water have higher activity rates than those of *S. spinatus* living deeper in the gravels of the stream bed. In the same way, Mathieu (1980, 1983) found interstitial *N. rhenorhodanensis* to be less active than cave-adapted ones.

A low metabolic rate is also an adaptation to a dysoxic environment. During periods of hypoxic stress, hypogean crustacean species possess a lower critical pO_2 (oxygen partial pressure) than epigean ones, which may indicate that these organisms are better adapted to low O_2 tensions (Hervant *et al.*, 1998), and probably maintain a more efficient aerobic metabolism for a longer time in declining pO_2 pressure instead of partly switching to anaerobic metabolism. Post-hypoxic recovery results in a high oxygen debt (the excess O_2 consumed during post-hypoxia). The main expla-

Adaptation: Physiological: Oxygen consumption of the epigean *Gammarus fossarum* and *Asellus aquaticus*, and of the hypogean *Niphargus virei*, *N. rhenorhodanensis*, and *Stenasellus virei* during long-term starvation and subsequent feeding at 11° C and in darkness. Values are means ± standard deviation for *n*=8–10 animals (modified from Hervant *et al.*, 1997).

nation for the smaller O_2 debt shown by hypogean species is the lower energetic expenditure during hypoxia, due to a decrease in movement and ventilation rates.

During long-term starvation, the respiratory—but also locomotory and ventilation rates are drastically reduced in hypogean crustacean species, whereas epigean species show a smaller decrease in these rates and respond by a marked and transitory hyperactivity (Hervant *et al.*, 1997) (see Figure). During such a long-term starvation, the troglobite vertebrate *Proteus anguinus* shows a slight increase in oxygen consumption, after which its respiratory rate decreases. By contrast, the epigean *Euproctes asper* shows an immediate and high increase in its rate of respiration, which decreases later to a value similar to that for well-fed individuals (Hervant *et al.*, 2001).

Metabolic Adaptations

The physiological adaptations of cave animals may also be understood by examining intermediary and energy metabolism. Both epigean and hypogean animals respond to long-term severe hypoxia with classic anaerobic metabolism, characterized by a decrease in ATP and phosphagen, the use of glycogen, and the accumulation of lactate (Hervant *et al.*, 1995; 1996). Compared with epigean crustaceans, the hypogean amphipod *N. virei*, which uses coupled fermentation of glycogen and amino acids, stores large amounts of glycogen and arginine phosphate. After severe hypoxia, *N. virei* appears to implement a strategy of lactate removal quite different from that observed in epigean crustaceans, favouring lactate-supported gluco- and glyconeogenesis and rapid glycogen replenishment, instead of rapid lactate removal via oxidative pathways.

The metabolic response to prolonged food deprivation in epigean amphipods appears to be monophasic, showing an immediate and large decline in all energy reserves. In contrast, hypogean amphipods display successive periods of glucidic, proteo-glucidic, and then lipidic-dominant catabolism during food deprivation. Lipids and proteins are the most metabolized substrates, whereas glycogen contributes little energy (Hervant *et al.*, 2001).

This high degree of storage, the rapid restoration of fermentable metabolic fuel without feeding, and the ability to reduce glycolytic flux and energy expenditure due to a decrease in locomotion and ventilation activity, allow hypogean species to survive harsh conditions, and consequently are very good adaptations to the subterranean environment.

Sensory Functions

It is generally assumed that the distinctive morphology of cave animals results from selection for increased sensory organs on appendages, which in turn results in lengthened appendages to compensate for eye and pigment cell degeneration (Culver, 1982). A good example of such adaptations is given by the amphipod *Gammarus minus*, which can be found in large caves and in springs in Virginia. Cave-dwelling *G. minus* populations have smaller eyes and longer antennae than surface populations, and they also have smaller optic ganglia and larger olfactory lobes in their central nervous system. In some other species of arthropods, the antennae of hypogean species are relatively short compared to those of their epigean relatives (Culver, 1982). It has also been demonstrated that the blind crayfish *Orconectes australis packardi* learns about its environment using both tactile and chemosensory cues, mainly located on the antennae but also elsewhere on the body (Li & Cooper, 2001).

A classic example of sensory compensation and cave adaptation in general is also provided by primitive vertebrates, one obvious feature being the hypertrophy of the lateral line system observed in cave fishes or amphibians. This is clear in the amblyopsid cave fishes, where, because of differences in neuromast morphology, some species are more sensitive to general water movement, and others are more sensitive to the direction of the current (Poulson, 1963). Hypertrophy and differential sensitivity certainly confer an increased ability to find food and detect predators in an environment where food is scarce.

AFRICA, NORTH

The African continent is poor in limestone outcrops in general, but the northern zone has abundant karst and Algeria has the longest and deepest cave systems in Africa (Boll Maza, 18.6 km, Anou Ifflis, -1170 m, Anou Boussouil, -805 m). For a long time Morocco had the continent's deepest cave (Kef Toghobeit, -722 m) and one of the longest cave networks (Wit Tamdoun, 17.5 km). There is very good potential for further discoveries in both countries. Tunisia has only a few karstified massifs, which are not very well known. Libya possesses a few areas of interesting gypsum karst, and Egypt has very few caves. Climates of North Africa vary with annual rainfalls ranging from >1000

mm in high mountains (Rif and Atlas ranges) to <150 mm in the Sahara. Karst morphology is equally variable.

Morocco

In Morocco, less than 1000 caves have been discovered, but the country has more than 100000 km² of karst terrain (see Figure 1). There are three geological domains north of the Saharan border, which correspond to three orogenic phases: (1) the Anti-Atlas domain near the Saharan border has folded Precambrian rocks forming mountains ranging from 2000 to 3000 m in elevation; (2) the Atlas domain is a second range with Caledonian, Hercynian, and Alpine structures; it is the largest of the three domains and has very different stratigraphies and lithologies; and (3) the Rifin domain, the smallest and youngest domain from the late Alpine. These three domains are separated by major fault zones. Karst landscapes, especially on limestone, are well represented in these three domains. Paleozoic limestone occurs in the Anti-Atlas domain (18000 km²) where it is more than 300 m thick in the western part, becoming thinner in the east. Superficial karst forms are developed, but caves are rare.

Lias limestone and dolostone form the largest karst terrain in Morocco, 30000 km^2 in extent, mainly in the Middle and High Atlas ranges. These formations are large reservoirs that sustain the base flow of Morocco's major rivers. They measure up to 500 m thick in the calcareous High Atlas. Alpine karst is well developed with karren, dolines, poljes, and shafts in the higher altitudes of the High Atlas with good rainfall (600 to 1000 mm annual rainfall) and snow cover during winter. One of Africa's deepest caves, Kef Toghobeit (-722 m), is also developed in this formation, in the Rif (Northern Morocco). In the Middle Atlas, lower than the High Atlas, the karst landforms are also dense and various, but the limestones facies are not very

Name	Region	Length/Depth
Wit Tamdoun	Tazroukht, Agadir	17500 m
Rhar Chara	Middle Atlas, Taza	7650 m
Kef Aziza	Central Atlas, Bou Denib	3950 m
Kef Toghobeit	Rif, Bab Taza, Chaouene	3918 m
Rhar Chiker	Middle Atlas, Taza	3865 m
Kef Toghobeit	Rif, Bab Taza, Chaouene	-722 m
Kef Tikhoubaï	Middle Atlas, Taza	-310 m

Africa, North: Table 1. Major Caves of Morocco.

Africa, North: Figure 1. The main karst regions and locations of the major caves in the Moroccan and Algerian sectors of the Atlas Mountains in North Africa.

good for cave development. The more frequent landforms are poljes developed upon the limestone plateaus. Among the other types of closed depressions are "issianes", shallow basins due to superficial corrosion following the truncation of paleovalleys, and large dolines whose origin lies in the dissolution of underlying Triassic salt beds. In the fresh volcanic landscapes, rugged holes are scattered across the outcrops of basaltic sheets. Some may be related to the collapse of lava tunnels, but most are interstratal karstic collapses into the underlying limestones (Martin, 1981, and see photo in Dolines entry).

Middle and Upper Jurassic limestones are also very common in the High Atlas, Middle Atlas, and Eastern Morocco (c. 20000 km²). They are thinner and are less homogenous. Some interesting karst landforms have been described on these limestones including "wave karst", a succession of small parallel dry valleys with asymmetrical dolines on the Ait Abdi pleateau (Azilal), which are aligned with the main wind direction due to control by snow accumulations (Couvreur, 1974; Perritaz & Monbaron, 1998). On this plateau, an ancient cave network with vertical shafts suggests that climates were wetter in the past. Radiometric dating of speleothems yielded ages between 3200 and 220000 years, and some beyond the range of the U-Th method (>400000 years). The lateral flow is conducted by an interstratal network, inactive and dry in the upper part, but active at the base near the regional aquiclude, attesting three karstification phases. Morocco's longest cave, the Wit Tamdoun underground river, is developed in Malm limestone, in the Western High Atlas, near Agadir.

Nearly everywhere in Morocco, karst springs are associated with calcareous tufas. Some deposits are very large and form attractive landforms, especially where they obstruct valleys. The Ouzoud cascades and the Imi n'Ifri natural bridge (Azilal) are wellknown examples.

Algeria

In Algeria people have used caves over a long period of time as shelters, sanctuaries, and sheepfolds. Cave wall paintings have been discovered in the shelters in Tasslli N'Ajjer, in the southern part of Algeria. Many caves are still used today by shepherds (Collignon, 1997). The first modern cave explorations were by French scientists and speleologists at the beginning of the 20th century. In 1948, Anou Boussouil, then 505 m deep, was briefly the world's second deepest known cave, and the Tafna underground river was Africa's longest known cave in 1933. During the war for independence (1954–62), explorations could not be made, but caves were widely used as refuges, arsenals, or small hospitals. Systematic explorations by French and Belgian immigrants began again after 1973. Expeditions were organized by European cavers and geologists, and Algerian caving groups were founded, but the civil war that began in 1991 again stopped exploration. There are many small limestone ranges scattered throughout northern Algeria, and four terrains have been found to contain significant karst—the Oran Meseta (plateau), the Tell mountain ranges, the Constantine tabular massifs, and salt and gypsum diapirs.

The Oran Meseta are large karstic plateaus in western Algeria comprising some 6000 km² of mostly Jurassic limestone and dolostone between 800 m and 1500 m in elevation. Large underground rivers, siphons, and the main Algerian poljes are found there. In the Tlemcen and Saïda mountains, about ten streamsinks and springs have been dived, from which the country's largest underground rivers can be reached (including Tafna, 18.6 km of large galleries). These rivers are generally of low gradient and represent some of the region's main water resources, especially during the dry summer season. Some caves are used as pumping stations and speleologists have significantly contributed to their exploitation at Rhar El Khal and Hassi Dermam.

The Tellian Atlas contains many small karst areas, of which Djurdjura and Babors, composed of Jurassic and Eocene limestones folded into one another, are the most spectacular. The highest parts (*c*. 2300 m) are all composed of limestone. Classical high mountain range karst landforms (karren, snow pits, dolines, perennial underground ice) are well developed, in areas with the highest rainfalls in the country (more than 1000 mm a^{-1}). In 1950, Anou Boussouil, a large pit in the Djurdjura, was explored to a depth of 505 m (the world's second deepest pit at that time). In 1980 it became Africa's deepest cave (-805 m). New groups of cavers came to Djurdjura and discovered Anou Ifflis (-1170 m, Africa's only cave >1000 m deep) and about 20 other pits, of which three are over 200 m deep.

In the Constantine region, Cretaceous neritic limestone with many dolines and shafts forms small anticlines that overlook the surrounding eastern Algerian plains in a terrain of 18000 km² where it is more than 300 m thick in the western part, becoming thinner in the east. Superficial karst forms are developed, but caves are rare.

In most of northern Algeria, Jurassic limestones overlie Triassic sequences with abundant salt and gypsum layers in anticlines,

Name	Region	Length/Depth
Rhar Bou Maza (Tafna)	Tlemcen	18600 m
Kef El Kaous	Traras	4160 m
Anou Boussouil	Djurdjura	3200 m
Anou Ifflis	Djurdjura	-1170 m
Anou Boussouil	Djurdjura	-805 m
Anou Achra Lemoun	Djurdjura	-323 m

Africa, North: Table 2. Major caves of Algeria.

Africa, North: Figure 3. The AA4 shaft on the Ait Abdi plateau in Morocco's Central High Atlas, that descends into a cave is rich in speleothems that are evidence of more humid climates in the past. (Photo by Luc Perritaz)

diapirs, or salt domes. The Djebel Nador, in the east of the country, possesses one of the largest diapiric structures in Africa. In such zones there are abundant dolines and pits. The rock is weak and roofs are often collapsed in many places, dividing long galleries into many smaller caves. In Algeria some of the world's deepest gypsum caves (e.g.

Dahredj Ghar Kef in Djebel Nador, 2450 m long, 212 m deep) and salt caves (El Outaya, -55 m) have been discovered. Salt outcrops are quickly dissolved by rainwater, and caves exist only in very dry regions with active diapiric uplift.

Algeria is tectonically active and has many thermal springs. Some of these hydrothermal flows cross the limestone massifs, where they have produced caves with cupolas and calcite and gypsum encrustations (especially when water contains carbon dioxide and hydrogen sulfide). The small Biban massif in the Tellian Atlas has some wonderful caves (Rhar Es Skhoun, Rhar Amalou, Rhar Medjraba) with very rare speleothems, but exploration is hindered by the high temperatures.

Tunisia

In spite of the fact that a large portion of the Tunisian landscape is composed of limestone (or dolomite), there are only a few karstified ranges (for example djebels Zaghouan Oust, Ben Saïdane, and Fkirine, see Figure 1). In addition to this, the carbonates are relatively thin, except in the djebels Serdj, Bargou, Taboursouk, and Cap Bon. The Djebel Serdj (1357 m high) has been extensively explored and contains the country's largest cave networks: the Rhar Ain et Tsab cave (2700 m long, 160 m deep) and the Mine cave (also called Rhar Djebel Serdj cave, 1700 m long, 267 m deep). Lhopiteau (1980) grouped Tunisian caves into oasis caves (mainly short and dry); many types of southern djebel caves (in climatic transition zones); northern Tunisia caves (very similar to European ones); gypsum caves (small and not deep, with good mineral concretions); and thermal springs and caves.

Libya

In spite of the desert climate, which is unfavourable for karstification, some remarkable caves have nonetheless developed. A gypsum karst is associated with the Upper Jurassic Bir al Ghanam formation, extending 100 km southeast of Tripoli to, and beyond, the border with Tunisia. The formation, which is 400 m thick and horizontal, consists of two gypsum beds separated by an essentially dolomitic bed. Both the upper and lower gypsum beds are karstified and contain numerous caves. Some 7 km of passage has been surveyed, including Umm al Masabih cave (3593 m long). The caves are mainly linear, carrying ephemeral streams (active several hours a year during rain-generated floods), and they display vadose morphology. Bedding planes and joints both play a role in passage development. In the karst, the upper gypsum is removed by erosion and the plateau surface lies on the more resistant dolomite. Underlying caves cause collapse features, and many of these contain cave entrances and swallets (Klimchouk *et al.*, 1996).

Egypt

About half the area of Egypt is on outcrops of limestone and chalk, but there is minimal karst development in the harsh desert climates. A low plateau of Mesozoic and Tertiary limestones separates the Nile Valley from the sand seas of the Western Desert, and the same limestones extend eastwards to the north end of the Gulf of Suez. Across most of these areas, karst landforms are barely seen in terrains of bare rock escarpments and aeolian dune fields (Stringfield, LaMoreaux & LeGrand, 1974). The few small springs and caves are known because they provide water and shelter in the desert; typically, the location of St Antony's Monastery, east of Cairo, is due to its karstic spring and caves

(only a few metres long). In the Western Desert, the Farafra oasis is famed for its spectacular "White Desert", a basin 100 km across distinguished by thousands of pinnacles of snow-white chalk that stand clear of the orange desert sand (Waltham, 2001). These are relict karst features, mostly pinnacles 2–4 m tall, but there are small areas of towers 10–15 m tall. They were formed in wetter climates of the late Tertiary, and are now being degraded by thermal shattering and aeolian sand abrasion. Travertines in the nearby Kharga oasis, which are now dry and largely predate 750000 years ago, are probably contemporary with the pinnacle and tower karsts. In the Eastern Desert, about 70 km southeast of Beni-Suef city, an unusual cave in alabaster was intersected by blasting. Sannur Cave is a crescent-shaped chamber which at 275 m is the largest cave in Egypt (Günay *et al*, 1997).

AFRICA, SOUTH: ARCHAEOLOGICAL CAVES

The archaeological caves of South Africa are remarkable in that together they contain a long history of evolution of hominids (hominins, by some authorities), beginning with the Australopithecines at over three million years ago, through to the first tool users in the early Stone Age (ESA; 2.5 million to 250000 years ago), the middle Stone Age (MSA; 250000 to 22000 years ago), *Homo sapiens* in the MSA (at least 100000 years ago) and the late Stone Age (LSA; 22000 to 2000 years ago) and up to the historical period (see Figure 1). The Iron Age in southern Africa is marked by the arrival of the taller Bantutype peoples—farmers—into an area that had been predominantly bushman territory. The bushmen, mainly hunter-gatherers, are also noted for their rock art, and they currently live in the drier areas of southern West Africa.

The first Australopithecine to be uncovered was the Taung child skull found at the Buxton Lime Quarry, in the Kalahari Desert, near the Namib border in 1924. This site is not a cave but a very large set of tufa (travertine) deposits, and the skull was unearthed by blasting operations, along with fossil baboons and other fauna. Raymond Dart at Witwatersrand University, Johannesburg, assigned the skull to a new genus, *Australopithecus africanus* (meaning "southern ape" for the genus and "of Africa"

Africa, South: Archaeological Caves: Figure 1. Southern Africa locations of caves mentioned in the text. "X" marks the Australopithecine

sites north of Johannesburg. "+" signs represent *Homo* and later cave sites. Langebaan is an open-air site that has provided a rich source of mammalian fauna for the late Miocene. It has been used to aid faunal dating of Makapansgat and other Australopithecine sites.

for the species name) claiming a "missing-link" status for it. It took more than 30 years for the skull and similar finds to be accepted by British authorities, such as Sir Arthur Keith (of Piltdown fame), as being germane to the evolution of humans. By the association of the faunal remains at the site to similar dated fauna of East Africa, the Taung skull is currently reckoned to be about 2.4 to 2.6 million years old. Berger & Clarke (1995) have reconstructed an interesting story of how the skull and other fauna may have resulted from eagle predation.

The Australopithecine caves of South Africa formed in Proterozoic dolomites and, in addition to the usual clastic infill, originally contained massive amounts of pure speleothems in the form of stalagmites and flowstones. In the early part of the 1900s these speleothems were mined for gold extraction in the Witwatersrand goldfields around Johannesburg and Pretoria. The Australopithecine fossils turned up with the speleothems and with the unwanted breccias. Among the hominid finds was the skull, "Mrs Ples", at Sterkfontein, blasted out of a flowstone in two pieces. Robert Broom, who came to be in charge of the acquired site, assigned it to *Plesianthropus transvaalensis*. Later, Robinson reassigned it to *Australopithecus*. Sterkfontein has turned out to be a rich site: the latest find, by Ron Clarke and Nkwane Molefe, being an almost complete skeleton known as "Little Foot" from the Silberberg Grotto near the bottom of a shaft inside the cave (Clarke, 1998). By magnetostratigraphy, the skeleton is currently assigned an age of between 3.30 and 3.33 Ma BP (Partridge *et al.*, 1999).

Across the shallow valley from Sterkfontein lies the mined site of Swartkrans. The fossil hominid sites of Sterkfontein, Swartkrans, and Kromdraai were declared a World Heritage Site in 1999. Swartkrans too contained Australopithecus remains, although the skulls of many of the finds are more robust than the early finds at Sterkfontein. The Swartkrans skulls possess a sagittal crest, more robust jaws and more massive molar teeth, indicating a more powerful masticatory action than the gracile Australopithecines of Sterkfontein and Makapansgat. The robust species are referred to either as Australopithecus robustus or to a new genus, Paranthropus robustus. There are active debates as to how distinct these genera are from each other and which of these or the East African Australopithecines is a direct ancestor to the Homo lineage. The later, long, excavation at Swartkrans was largely the work of C.K. "Bob" Brain, of the Transvaal Museum, Pretoria, who went about reconstruction of the stratigraphy in a painstaking enterprise (see Figure 2). Brain also tested Dart's ideas about the nature of the remains at another site, the Makapansgat Limeworks Cave. This huge cave is in the Northern Province (old Transvaal) about 300 km north of the Johannesburg group. Dart had been shown shattered animal long bones that seemed to have been burned artificially. From these, he pictured a savage Australopithecine culture using bones, teeth, and horns as weapons and tools and using fire inside the cave, and he coined the term "osteodontokeratic" (bone-teeth-horn) culture. It was later shown that the burnt appearance was due to infiltration by manganese dioxide, which is black. Brain carried out a series of heating experiments on bone to show how different stages of burning might appear on site. He and others also investigated hyena dens to show, firstly, that the thick bone accumulations at the Limeworks Cave and elsewhere were due to animal denning and, secondly, that the marks on the bones (when properly prepared from the matrix in the laboratory) were due to hyena tooth marks and the gnawing of other animals such as porcupines.

The study of how buried bones and artefacts result in their present state is known as taphonomy, and Dart and Brain are thus two of the earliest researchers to promote cave taphonomy. As an interesting example of a story in taphonomy, Brain showed fairly convincingly that the puncture marks on one of the juvenile Australopithecine skulls resulted from being dragged by a leopard to the cave site. The upper canines of a leopard closely fit the puncture marks in the top of the skull cap (calvaria). This in turn has implications on whether the cave functioned as an Australopithecines' "home" site, in the way that baboons often use caves, or was a leopard (or felid) lair (Brain, 1981).

The later deposits of Sterkfontein, Swartkrans, and other caves have yielded remains of tool-making *Homo*, variously suggested to belong to either *H. habilis*, *H. erectus*, or *H. ergaster*. The remains occur together with some of the earliest ESA stone tools in the form of simple choppers of Oldowan type (Clark, 1993).

How are the remains and artefacts dated? The two main problems with all these sites is that they are very difficult to unravel stratigraphically and the deposits in which they lie are not readily amenable to direct, radiometric, dating. This is in contrast to their East African Rift, and Ethiopian, counterparts where there is often simple "layer-cake" stratigraphy and where there is often recognizable inter-site stratigraphic correlation. Riverine and lake sediments can be dated by magnetostratigraphy, and ash horizons are datable by potassium-argon (K-Ar) dating (or Ar-Ar dating).

The Johannesburg group of Swartkrans, Sterkfontein, Drimolen, Kromdraai, Gondolin, Coopers, and Gladysvale are mainly eroded rift systems to the surface (avens from below), with complex collapse phases of breccias and flowstones with uncertain contacts and rapid lateral changes of facies. Sterkfontein and other caves still possess streams flowing sluggishly under a low gradient. In most cases, the miners got there before the archaeologists, and their excavations reveal some relationships but obscure and confuse others. Magnetostratigraphy of the sediment and flowstone successions is also an uncertain game, since the various polarities that are recorded in the deposits are stretched and compressed due to different depositional rates and can therefore be fitted to almost any part of the global polarity time-scale (GPTS). As for radiometric methods, there are no ash deposits (no nearby volcanoes) and so Ar-Ar cannot be used. The hominid-bearing speleothem deposits are not less than 500000 years old, and so they are beyond the range of the U-Th method. Electron spin resonance (ESR) techniques have been tried at Sterkfontein, but the ages are thought to be tentative, mainly because of the difficulty of estimating reliably the longterm dose rates (see Dating Methods: Archaeological) (Schwarcz et al., 1994).

Africa, South: Archaeological Caves: Figure 2. Plan and section of Swartkrans Cave (from Brain, 1993, with permission). The section shows the cave in its present state of partial excavation.

The Makapansgat Limeworks Cave is different in that it appears to have operated as a huge resurgence to a mountain river system, probably in the late Miocene (ending at about 5.1 million years ago). Toward the end of its life about 3–3.5 million years ago, it contained an estimated 60000 tonnes of speleothems and thick layers of sediments and breccias. The present 2 ha cavern is an eroded remnant estimated to be about half its original height, revealing speleothems at the surface. Nearly all the speleothems have been mined out, although, interestingly, some distinctive subaqueous, mammillary, deposits are still in place. A number of Australopithecine remains were retrieved from miner's breccia dumps, and a 1 m thick bone breccia band, known as the "Grey Breccia" contained a dense assemblage consisting of over 80% bovid bones, the rest being baboons, equids, large felids, hyenas, Australopithecus, and smaller animals.

At about the same time as the Limeworks dumps were being sorted, from about 1945 to the 1960s, some of the Witwatersrand researchers (Van Riet Lowe, Kitching, Tobias, Hughes, Malan, and others) were working at another mine site about 1 km up the valley-the Cave of Hearths. Under the direction of Revil Mason, a long sequence of early Homo occupation layers were uncovered, containing stone tools from the ESA, MSA, LSA, and up to historic times. The Cave of Hearths, together with Wonderwerk Cave, Northern Cape, and Montagu Cave in the Western Cape, is one of the few South African caves to contain artefacts of the Acheulian culture (MSA) (Deacon & Deacon, 1999). As Mason blasted his way down through the calcite-hardened breccias he uncovered hearth-like structures firstly in the upper layers and then toward the base. Tentative claims were made for the earliest known use of fire although this still remains to be substantiated. This site has undergone recent reappraisal, chiefly by a team from Liverpool University (England). The lowermost archaeological layers are normally magnetized, showing that they are less than 780000 years old. The sediments contain no associated speleothems in the unexcavated sediment left as a witness section that might lend themselves to U-Th dating, and they are probably too old for thermoluminescence or optically stimulated luminescence dating. In comparison to Wonderwerk Cave, the Cave of Hearths has a much lower density of faunal material, and this suggests that it probably did not operate as a home base in the way that was once thought likely.

In 1925, a poorly excavated skull, with a brain capacity of 1280 ml and with some Neanderthal-like features, was unearthed from a fissure in a dolomite cave at Kabwe (the Broken Hill lead-zinc quarry), in Zambia. The maxilla shows dental caries and abscessing, and Bartsiokas & Day (1993) have suggested that the skull displays evidence of lead poisoning.

Those sites of the Middle Stone Age that contain not only artefacts but also human remains are relevant to the question about the transition of *Homo erectus*, associated with the Acheulian hand-axe technology, to *Homo sapiens* associated with the Upper Paleolithic (in Europe) and more sophisticated stone tools of the preformed core type (in Europe, the Levallois technique). Migration of *Homo erectus* out of Africa (the migration known popularly as "Out of Africa I") is thought to have occurred between 1.5 and 2 million years ago. In Europe, these hominids were succeeded, probably ancestrally, by the Neanderthals. When and where the first anatomically modern humans appeared also finds its answers in Africa. Several DNA studies suggest that humans appeared in Africa at about 200000 years ago. In South Africa, there are several caves containing modernlooking skeletal remains, including Klasies River (Mouth) Cave and Border Cave.

Klasies River Cave, near Port Elizabeth, is a set of openings, 6 to 18m above sea level. It was excavated by Wymer and Singer from 1967 to 1968 (Singer & Wymer, 1982) and then again by H.Deacon in the 1990s. The human remains uncovered included jaws, teeth, and fragments of crania (Rightmire & Deacon, 1991) that have been dated faunally and by ESR to between about 115000 to 60000 years ago (Klein, 1999). In Europe, by contrast, the first anatomically modern humans (AMH; old term, Cro-Magnon) succeeded the Neanderthals from about 40000 to 30000 years ago (Eastern Europe to Iberia). It should be realized that although this discussion restricts itself to evidence from cave sites, there is a broader picture of hominid evolution and culture from all African sites. Although many archaeologists and paleoanthropologists are.persuaded by the origin of modern humans by replacement out of Africa ("Out-of-Africa II") there is a sizeable minority that thinks that modern humans evolved more or less in every region of the Old World (including, possibly, Australia which appears to have witnessed the first entry of humans about 40000 to 60000 years ago). Milford Wolpoff is the chief dissenting voice on the Out-of-Africa II migration, but see also, for example, Smith (1992) and, for the argument itself, see Delson et al. (2000).

Near the Cape, around 1910, John Hewitt excavated a rock shelter at Howiesons Poort and uncovered a fine, small, and distinctive stone tool technology of the MSA that was not to be approximated till the late Stone Age (22000 to 2000 years ago; Deacon & Deacon, 1999). The fine blades appear to have supported hafted tools, and the Howiesons Poort technology has been found at many other sites in southern Africa, including Klasies River Mouth Cave and in Nelson's Bay Cave, between the Cape and Port Elizabeth. At Rose Cottage Cave, excavated currently by Lyn Wadley of Witwatersrand Archaeology Department, there was occupation before and after Howiesons Poort times. Dated to between 70000 and 60000 years ago (Vogel, 2001), the Howiesons Poort culture is used as a marker horizon in southern African sites as far north as Lake Eyasi in central Tanzania and west to the Apollo 11 Cave in Namibia (Deacon & Deacon, 1999).

Many archaeologically important cave sites are situated on the southern coast, and they are important as recorders of the use of seafood. Sea levels were high around 125000 years ago during interglacial isotope stage 5e, and this appears to have resulted in the scouring of the Klasies River Mouth Cave openings. After that, as sea levels fell, the evidence suggests that the caves were occupied sporadically by hunter-gatherers who scavenged and hunted seals and penguins and also lived off shellfish.

The fact that the MSA human skeletal remains are thought to be modern has suggested to some anthropologists that fully modern humans came out of Africa at least by 120000 years ago (the "Out-of-Africa II" event—see Carmel Caves, Israel: Archaeology). The aforementioned Howieson's Poort MSA technology has also featured in this issue (Parkington, 1990). A reconstruction of ash layers, tools, various adornments, and other cultural evidence on site, has prompted Deacon & Deacon (1999) also to suggest that, "They were probably the direct ancestors of the Later Stone Age peoples"—and that must include the Bushmen of today. In effect, the Bushmen of southern Africa may well be the direct descendants of the earliest humans. This adds impetus to the great interest in old and new Bushman wall paintings.

AFRICA, SUB-SAHARAN

Sub-Saharan Africa has 42 countries, climates ranging from humid tropical to arid, and a predominance of ancient Precambrian rocks. Although only a small proportion of the area is karst, and many of the karst areas have never been fully explored, the subcontinent has many significant sites: caves with early hominid remains dating to 4.5–5.0 Ma, the largest underground lake in the world and the fourth deepest siphon, a 305 m deep cave in quartzite, the sixth and ninth longest lava tube caves in the world, caves in pyroclastics that are frequented by elephants and buffalo to lick salt from their walls, and a cave with 5 m speleothems in the floor of an active volcanic crater. It also has an example of the rare labyrinth karst landform, human-induced subsidence into karst cavities as a result of gold-mining activities, and a sea cave in quartzite with large carbonate speleothems and the remains of the first modern humans.

Caves: The two longest caves in sub-Saharan Africa are Sof Omar in Ethiopia and Apocalypse Pothole in South Africa, both of which are maze caves. Sof Omar (see separate entry) is 15.1 km long but only 1.2 km of this is river passage, the remainder being in a maze formed near the resurgence, giving the cave a total of 42 entrances. Apocalypse Pothole in dolomite has 12.1 km of mapped passages. The deepest caves are Mwenga Mwena (Zimbabwe) in quartzite (-305 m), and Bushmangat (South Africa) in dolomite (-295 m). Cango Cave (5.3 km long) in the Western Cape of South Africa is the most important tourist cave and is possibly the best decorated.

The sub-continent has spectacular cenotes, as well as caves with large underground lakes. In the Otavi Mountains of Namibia are the cenotes of Aikab, Aigamas, Guinas Lake, and Otji-

Africa: Sub-Saharan: Figure 1. The

main karst areas of sub-Saharan Africa. Nations are numbered:

1=Mauritania.

2=Mali. 3=Senegal.

4=Gambia. 5=Guinea Bissau.

6=Guinea. 7=Sierra Leone.

8=Liberia. 9=Ivory Coast.

10=Ghana. 11=Burkino Fasso.

12=Togo. 13=Benin. 14=Niger.

15=Nigeria. 16=Chad.

17=Cameroon.

18=Central African Republic.
19=Equatorial Guinea. 20=Gabon.
21=Congo. 22=Zaire. 23=Sudan.
24=Ethiopia. 25=Eritrea.
26=Djibouti. 27=Somalia.
28=Kenya. 29=Uganda.
30=Rwanda.
31=Burundi. 32=Tanzania.
33=Mozambique. 34=Malawi.
35=Zambia. 36=Zimbabwe.
37=Botswana. 38=Angola.
39=Namibia. 40=South Africa.
41=Lesotho. 42=Swaziland.

koto Lake (see Figure 2), and also underground lakes at Harasib and Dragon's Breath. The latter, discovered in 1986, may have the largest underground lake in the world, 260×180 m, more than 90 m deep, and 60 m below ground. Harasib Cave is the fourth deepest cave on the subcontinent (-210m) with a lake 135×35 m and 90 m deep. Lakes in Aikab, Guinas, and Aigamas

Africa: Sub-Saharan: Figure 2. Otjikoto Lake, a cenote in the Otavi Mountains of Namibia. (Photo by Tony Waltham)

are $120 \times 100 \times 63$ m deep, $145 \times 70 \times 120$ m deep, and $115 \times 0 \times 40$ m deep. Guinas is one of two sites with the multicoloured indigenous fish, *Tilapia guinasana*, while Aigamas is the only site with the catfish, *Clarias cavernicola*. Otjikoto Lake, 100 m in diameter and 75 m deep, is a National Monument because during World War I German troops dumped Krupp ammunition wagons and field guns into the lake before surrendering to British troops. Today this military equipment is an underwater museum at depths of 48–52 m. Divers have recovered speleothems up to 130 ka old from depths up to 40 m in the Otavi lakes, indicating much lower ground water levels in the past. The Wonderhole at Chinhoyi Caves, northwest of Harare, Zimbabwe, is a circular cenote 46 m in diameter and 190 m deep, with a 144 m deep lake—the Sleeping Pool. Bushmangat in the Gaap Plateau dolomites of the Northern Cape, South Africa, contains a lake 30×12 m at the surface and 264 m deep, making it the fifth deepest siphon in the world. The lake widens to 247×75 m in plan extent at a depth of 100m.

Three of the five deepest caves in sub-Saharan Africa are in the Chimanimani Mountains of eastern Zimbabwe in quartzite: Mawenga Mwena (-305 m), Jungle Pot (-221 m), and Bounding Pot (-194 m). Big End Chasm has the world's largest chamber in quartzite: 90 m high and 70×15 m in plan. The famous Klasies River Mouth sea caves on the South African Tsitsikama coast are also in quartzite. They contain the oldest remains of anatomically modern humans, dating to more than 100 ka (see entry Africa, South: Archaeological Caves), and also house carbonate speleothems up to 1 m in diameter and 4 m high, deposited by dripwaters draining from shell-rich aeolian sands on the surface above the cave.

The largest and most important caves in East Africa are in volcanic rocks. Kenya has the sixth longest lava tube cave in the world, Leviathan Cave, 12.5 km long and 3–10 m in diameter; the ninth longest, Mount Suswa, at 11.0 km; and six of the top 60. Almost 100 lava tube caves are known in the Chyulu Range between Nairobi and Mombasa, while Mt Suswa has 40 caves in an area of 3 km² that are segments of a complex braided tube system with up to 3 levels of passages, and 67 entrances. Passages are 6–10 m in diameter increasing to 20–30 m where collapse has occurred. The 19th longest lava tube cave in the world is Ubuvomo bwa Musanze on Mt Ruhengueri in Rwanda at 4.6 km and 210m deep, while nearby Ubuvomo bwa Nyrabadogo is 1.5 km long. All are developed in pahoehoe lava flows and various caves have lavafalls 10m high, lava stalactites and flowstones, rare silica dripstones and flowstones, calcium phosphate deposits beneath bat guano, and bones of rhino, giraffe, leopard, baboon, and antelope.

In 1990, Hades Cave was discovered in the crater floor of Oldoinyo Lengai in northern Tanzania, the world's only active carbonatite volcano. The cave, 20–30 m in diameter and 5–8 m deep, was formed by the collapse of the 0.5–1.0 m thick roof of an old spatter cone. Pale yellow stalactites 1–4 cm in diameter and up to 5 m long stretched from the ceiling, probably formed from lava spatters that stuck to the roof of the void. As there was considerable volcanic activity within 100 m of the cave, it probably did not survive for long.

There are also numerous small caves in tuffs and agglomerates; these are up to 300 m long but have breakdown chambers up to 100 m wide, the best known being Kitum and Makingen caves on Mt Elgon in Kenya. The entrances to these caves are behind waterfalls and are frequented by elephant and buffalo for the salt they contain, as seen by tusk marks on the walls.

Many dolomite caves in southern and eastern Africa are water-table caves formed by solution in the upper part of the phreatic zone. Lowering of the water table focused solution deeper in the dolomite and left upper passages aerated and open to the surface via vertical shafts allowing the influx of soils and making them death traps for animals falling into them. In Botswana, Angola, Namibia, and South Africa caves of this kind contain fossiliferous, cemented breccias of middle Miocene to Holocene age that include baboon, hominoid, and hominid remains. At Berg Aukas, Namibia, remains of two hominoids, 13 and 9–10 Ma old, were recovered from sediments in dolomite fissures. Several dolomite caves northwest of Johannesburg, South Africa, including Sterkfontein, and Makapansgat Limeworks near Potgietersrus, contain important fossils. Basal breccias at Sterkfontein in the upper, older part of the cave are more than 4 Ma old, and an almost complete hominid skeleton recovered from the cave is 3.30–3.33 Ma old.

Surface karst varies considerably across the region in response to both the climate and the rock lithology. In the humid tropics, rare labyrinth karst has formed in the Tanga limestone of Tanzania, with fissures up to 15 m deep and 1-2 m wide isolating sharp pinnacles and ridges and in places coalescing to form internal closed depressions. Cone and tower karst with depressions occurs in an area including parts of south Congo, western Zaire, and Angola. Elsewhere on the subcontinent doline karst is more typical with occasional uvalas and poljes. Coastal limestones in Western Cape, South Africa, have closed depressions up to 20 km long, dry valleys, large springs, and extensive dry phreatic cave systems. Hundreds of shallow dolines, dry valleys, and depressions up to 8 km long dot the covered karst near Alexandria, Eastern Cape. The Gaap Plateau, Northern Cape Province is pockmarked by closed depressions with ephemeral lakes typically 3-5 m deep and 100-500 m long, while strings of dolines 5-10 m deep mark old stream drainage lines. There is also doline karst in calcrete 5–10 m thick in the upper catchments of the Tsondab, Gaub, and Kuiseb rivers of the central Namib Desert where annual rainfall is only 150-250 mm. This karst extends from the escarpment westwards for 40–50 km with dolines up to 25 m across and 2–3 m deep.

Lusaka, the capital of Zambia, sits atop a marble plateau with dolines 10–100 m across and up to 10 m deep. Almost everywhere the marble is buried beneath a shallow layer of lateritic gravel. As there is no surface drainage, the marble surface is susceptible to flooding after very heavy rains when infiltration capacity is exceeded. The worst flooding was in 1926 when the whole township was flooded and boats were rowed down Cairo Road in the city centre. Despite construction of flood drains the city was flooded again in 1978–79. In areas where the lateritic gravels have been excavated, marble pinnacles 3–10 m high have been exposed (see Figure 3). The pinnacles are disappearing rapidly as they are being broken into pieces for sale on the street as aggregate.

The Rand gold mining area of South Africa, west of Johannesburg, is perhaps the bestknown area of karst in the subcontinent. Gold is found in beds of quartzite and conglomerate overlain by 1220 m of dolomite largely hidden beneath 9–150 m of unconsolidated sediment. The dolomites are divided into water compartments by a series of vertical syenite dikes. To facilitate mining, groundwater was pumped from the Venterspost compartment in 1955, and from the Oberholzer and Bank compart-

Africa: Sub-Saharan: Figure 3. Marble pinnacles exposed from beneath lateritic gravel in Lusaka, Zambia. (Photo by George Brook)

ments in 1960 and 1972, the watertight nature of the dikes making it possible for each compartment to be de-watered independently. By 1957 sinkholes appeared in the Venterspost compartment by compaction of surficial sediments (up to several km long) and by their collapse into subsurface cavities. In 1962 a vertical-sided sinkhole, 55 m across and 30 m deep, formed in the Oberholzer compartment, engulfing the crushing plant of the West Driefontein mine and causing 29 deaths. As sinkholes continued to develop, some small towns had to be evacuated. In 1964 the West Driefontein mine was extended into the Bank compartment which had not been de-watered. On 26 October, 1968 a fissure opened up in the roof of the workings beneath the Bank compartment and a torrent of water flowed in. Fortunately, 13500 men were evacuated safely but it took 26 days to stem the flow of water. The source of the inrush was the saturated, cavernous dolomites of the Bank compartment with 850 m head. Following the disaster the Bank compartment was de-watered.

Evaporite karst is unusual in sub-Saharan Africa but is well developed in gypsum and anhydrite on the northern Haud Plateau in Somalia. Shallow solution dolines up to 100 m in diameter are common, while many collapse dolines up to 50 m in diameter and 15m deep lead into caves 0.5–20 m below the surface, such as Ail Afwein (1275 m long) and Las Anod (1455 m long). Many caves contain water that is used for camels and goats.

Gypsum speleothems and crystals are common, and hyenas occupy many entrances. On the limestone Baidoa Plateau in southern Somalia there are several 1–3 km long structural/erosional basins with lakes including those at Ted, Moragavi, and Burdo. In the east, the plateau has a thick soil cover and some of the numerous shallow depressions contain perched water bodies.

Quartzite karst has developed in eastern Mpumalanga Province, South Africa (see Silicate Karst) where dolines with pinnacled slopes occur along abandoned streamlines in 20-25 m of quartzite resting on granite. Seventeen caves up to several hundred metres long are known, some with vertical shafts to 20 m deep and chambers 60×25 m and 15 m high. Most have water flowing through them, disappearing and reappearing several times. Small limonite stalactites and flowstones are present. Quartzite karst has also developed in the Cape Peninsula of South Africa including numerous small caves, with Ronan's Well the longest at over 700 m.

Spring and waterfall tufas occur in semiarid and arid parts of sub-Saharan Africa. Notable are the massive, relict, perched spring and waterfall tufas in South Africa, Namibia, and Somalia, and there are smaller examples in southeastern Zimbabwe. Since the Miocene, thick masses of tufa have accumulated along the dolomite Gaap Escarpment of South Africa, particularly in gorges cut back into the scarp. Individual tufa masses such as Gorrokop are 1.8 km long and average about 30 m thick. At Buxton-Norlim, in 1924, the famous type specimen of the species Australopithecus africanus was discovered in the Thabaseek tufa carapace, which was being quarried for lime. Smaller waterfall tufas about 45 m across and 10m high, but up to 1200 m across and 30 m high, occur as plugs in incised valleys of dolomite areas in Northern and Mpumalanga Province. Numerous massive waterfall tufas occur at different elevations in the Naukluft Mountains of Namibia, a dolomitic nappe complex. The Blässkranz tufa, 500 m long and 150m high, becomes a huge waterfall after uncommon heavy rains. Large waterfall tufas also occur in Kaokoland near Warmquelle, in the Kuiseb River Valley where average annual rainfall is less than 50 mm, and in the Swartkloof Mountains of southwest Namibia. The largest tufas in Somalia are around the southeastern edge of the Baidoa plateau at Deileb Wanei and Isha Baidoa. At Isha Baidoa the tufa is more than 20 m thick and extends for hundreds of metres along the escarpment. In northern Somalia relict spring and waterfall tufas up to 300 m long and 40 m high are found at several locations in the Golis Mountains and on the Gulf of Aden coast.

AFRICA: BIOSPELEOLOGY

Africa spans temperate to tropical latitudes, with a great variety of different ecosystems, making it an extremely varied continent with high levels of biodiversity. Few zones have been explored from a biospeleological perspective, nonetheless the results obtained so far show considerable subterranean diversity. Biospeleological research began in the first decades of the 20th century and was concentrated in eastern (Ethiopia, Kenya, and Somalia), northern (especially Morocco), and southern (Namibia and South Africa) Africa, and on Madagascar. Several researchers explored these territories and collected a large amount of zoological material.

The French zoologists C.Alluaud and R.Jeannel were among the first to research in detail the subterranean fauna of Africa. In 1911–12 they visited several African countries where they collected a large amount of troglobitic material, and the first African stygobites. The results of their research were published in *Biospeologica* (Jeannel & Racovitza, 1914), where the first review of several African caves and their fauna can be found. In the 1950s, French scholars led extensive research in Madagascar, while more recently activity has been re-established in northern Africa by French and Moroccan researchers and, in southern Africa, by Namibian and South African researchers. At the beginning of the 20th century and later, in the 1970s, Italian researchers collected and presented data on biospeleological aspects of Ethiopia and Somalia. In the rest of the continent biospeleological research has been sporadic and scattered.

African caves host almost all animal taxa, with many troglophiles and trogloxenes, but only a few troglobites. Stygobites, stygophiles, and stygoxenes on the contrary are numerous and are primarily restricted to karstic areas developed in the limestone deposited during Cretaceous (c. 100 million years ago) marine invasions. In some cases, such as Amphipoda and Isopoda of eastern and southern Africa, these are apparently the only representatives of the taxa in the region.

Although the continent has not been extensively explored from a biospeleological perspective, the list of African subterranean-dwelling animals is long. Excluding Protozoa, flatworms, worms, and all hyporheic (interstitial spaces within the sediments of a stream bed) and marine interstitial (living in the spaces between sand grains) taxa, the subterranean African diversity is presented below by taxa.

Mollusca

A number of terrestrial and aquatic snails and clams are reported from African caves, although no true troglobitic species are known.

Crustacea

The presence of Copepoda in subterranean waters in Africa has been reported from almost every explored area; however the reports are scattered and fragmentary. Ostracoda is a widely distributed taxon in subterranean waters, although few species are strictly stygophilic or stygobitic. A single stygobitic species has been found in Zaire and several others in the wells of Somalia. Of the Malacostraca, several African forms of Bathynellacea have been described, mostly interstitial. Several species of Thermosbaenacea are reported from African subterranean waters (Morocco, Somalia, South Africa, and Tunisia). The first to be described was *Thermosbaena mirabilis* from the El Hamma hot springs in Tunisia. No stygobilic Mysid (Mysidacea, or Opos- sum shrimps) is present in Africa, though stygophilic species are reported from Kenya, Madagascar, Aldabra, and Zanzibar Islands. A single species of Spelaeogriphacea, *Spelaeogriphus lepidops*, has been described from South Africa.

There are many stygobitic Isopoda species distributed in eastern, western, northern, and southern Africa belonging especially to the Cirolanidae and Stenasellidae families. Some of them show a striking aspect such as the *spiny Acanthastenasellus forficuloides*, known from a single female specimen collected in Somalian subterranean waters. Subterranean species of African terrestrial Isopoda are mostly troglophilic. Only termitophilous taxa show true troglobitic adaptations.

Amphipoda has many stygobitic species, belonging to several families (Hadziidae, Salentinellidae, and Gammaridae being the most represented), distributed in eastern, western, northern, and southern Africa.

Of the Order Decapoda (shrimps), several stygobitic and stygophilic species of the Athyidae family are found in Kenya, Madagascar, Somalia, Tanzania, and Zaire. One species of the Palaemonidae, *Typhlocaris lethaea* from Libya and several stygoxene decapods of the Penaeidae and Athyidae families are also present in African caves.

Onychophora

Only two true troglobitic species of velvet worms exist in the world, of which one, *Peripatopsis alba*, lives in a South African cave.

Arachnida

The best-represented arachnid orders in African caves are the Scorpiones (scorpions), Pseudoscorpiones (pseudoscorpions), Solifugae (sun-spiders), Araneae (spiders), Opiliones (harvestmen), Amblypigi (whip spiders), and Acari (ticks and water mites). It is impossible to enumerate all the Arachnida that can be found waiting for their prey in African caves. Numerous parasitic ticks live on bats, and terrestrial taxa that are associated with guano, predate on eggs or insect larvae, feed on fungi, or scavenge are common in caves. Several water mites (Halacarids and Hydracarids) can be found in subterranean waters.

Myriapoda

Centipedes (Chilopoda) are often present in caves, although no troglobites are reported so far from Africa. Millipedes (Dipolopoda) are present with a few troglophilic and trogloxene species in caves. In Somalia specimens of *Graphidostreptus gigas* were found in Showli Berdi cave.

Hexapoda

Although numerous species of springtails (Collembola) have been found in African caves, only two species from Madagascar are described as true troglobites: *Cyphoderopsis madagascarensis* and *Troglobius coprophagus*. Only one Diplura genus, *Anysocampa*, is reported from the Ethiopian region. A single species is truly troglobitic in Zaire, *Austrjapyx leleupi*.

Insecta

Only one species of silver fish (Thysanura) is reported from South Africa as troglobitic, Lepidospora makapaan. Cavernico-lous or troglophilic Orthoptera (crickets) are present in most African caves, they are mostly scavenger and detritus feeders. They belong to only two families, the Phalangopsidae and Rhaphidophoridae. The fleas (Siphonaptera) are well known to any speleologist and to those working in African caves in particular. They cannot be considered true cavernicoles because they are all parasites of vertebrates such as bats, and belong to the subterranean world only because of this specialization. No troglobitic species of wasps or bees (Hymenoptera) are known but many nest at the cool and dark entrance of many caves in Africa. They are quite aggressive, especially the bees, thus making some caves a risky place to enter. Beetles (Coleoptera) are the most diversified insect taxon to have colonized the subterranean environment. They are present in African caves especially with many carabids (ground beetle), cholevids, curculionids (snout beetle), pselaphids, staphilinids (rove beetle), and even with aquatic forms of the Hydrophilidae and Dytiscidae families (diving beetle). Only one earwig (Dermaptera) species is known from Africa. This is the first ever described species of a troglobitic earwig, Dyplatis milloti. Of cockroaches (Blattodea), only the family Nocticolidae has troglobitic species in Africa, where several troglophilic species are present. Cicadas and aphids (Homoptera) have very few cave representatives in Africa: one species of Hypochthonellidae in Zimbabwe and only one troglobitic species of Cixidae in Madagascar. Only a few species of moths (Lepidoptera) of the families Oecophoridae, Plutellinae, Alucitidae, and Noctuidae have been so far reported from African caves, but they cannot be considered troglobitic species. The four reported African species of troglobitic flies (Diptera) have guanophagous (feeding on bat guano) larvae and haematophagous (blood-sucking) adults.

Fish

Eight species of cave-dwelling fish were described in Africa between 1921 and 1959: *Caecobarbus geertsii(former Zaire); Uegitglanis zammaranoi* (Somalia); *Phreatichthys andruzzii* (Somalia); *Barbopsis devecchii* (Somalia); *Typhleotris madagascariensis* (Madagascar); *Clarias cavernicola* (Namibia); and *Typhleotris pauliani* (Madagascar). The first cave-dwelling fish, a small cyprinid discovered in 1921 in the Belgian Congo, was the first subterranean fish in the world to be officially protected (by the Belgian colonial authorities). Somalia has the highest cave fish diversity in Africa, with three species. Italian interest has remained strong and these species have been extensively studied in recent years.

Amphibia and reptiles

Several toads and frogs searching for cool, humid places rich in insects, can be easily found in African caves. No troglobitic snake or lizard has been recorded in any African cave. Most of the reptiles enter the caves to feed on bats, bird eggs, or mice as is the case with *Naja* sp. (cobra), *Bitis* sp. (puff adder), and *Varanus* sp.

Birds

Several species of swallows (*Apus* sp.) inhabit the entrances of African caves, but so far none is reported to have adaptations like those observed for Asian species, which use echolocation deep in the cave. Only one other bird has been reported to nest inside caves in Africa, *Picathartes orea* (bald picathartes) of Gabon.

Mammals

Several species of mammals spend part of their time in caves. Bats are certainly the bestrepresented group: several insectivorous and frugivorous bats roost in African caves, often forming huge colonies. Other mammals, especially the Insectivora and Rodentia such as the Hystricidae (Old World porcupines), may be found in caves, even in the deeper zones. The signalled presences of Carnivora especially felids such as the African wildcat (*Felis lybica*) or the leopard (*Panthera pardus*) are numerous. The African elephant *Loxodonta africana* has been documented to enter the Kitum Cave (Mt Elgon, Kenya) and to dig with its tusks the salt that can be found there.

AGGTELEK AND SLOVAK KARST, HUNGARY-SLOVAKIA

The Aggtelek and Slovak area comprises a major karst region, in which the caves have been designated as a World Heritage Site, approved in 1995. It straddles the southern foothills of the Carpathians, and consists of the Aggtelek National Park and Biosphere Reserve in Hungary (19708 ha) and the Slovak Karst Protected Landscape Area and Biosphere Reserve in Slovakia (36165 ha), together with the nearby Dobšina Ice Cave. Topographically, the main block comprises a series of rolling plateaux in thick limestones and dolostones, dissected by a few deep river valleys. Relief ranges from altitudes of 200 to 900 m. Geologically, it is a part of the Szilice Overthrust in the Carpathians, displaying complex, highly deformed structure. More than 700 solution caves are known. The climate is humid continental, with mean annual temperatures between 5 and 12°C and 600–1000 mm precipitation, depending on altitude. Natural vegetation is an oak, hornbeam, and beech deciduous forest.

Aggtelek-Domica Region

The principal karst area is shown in Figure 1. The limestone (Wetterstein Formation) and dolostone (Guttenstein Formation) are platform deposits of Triassic age, uplifted and deformed during the Cretaceous. Denudation commenced in the late Cretaceous under tropical or subtropical conditions, forming *terra rossa* soils, with some bauxites in karst depressions. In the mid-

Aggtelek and Slovak Karst: Figure 1. Outline map of the cave systems within the Aggtelek karst beneath the border between Hungary and Slovakia. Tertiary (Miocene), the region was partly buried by deposits of the Pannonian Inland Sea, chiefly sands and clays from the mountains further north. Erosion has since exhumed the higher ground, which now forms a rounded massif to altitudes of 450-500 m, above remaining clay lowlands at *c*. 300 m. Kecso River (Figure 1) entrenched the massif, permitting early springs to drain to it, at an altitude of *c*. 270 m. A knickpoint has receded through the Kecso valley, lowering modern spring levels to 220-230 m. The region experienced severe cold at times during the Quaternary, with solifluction and other periglacial features indicating periodic loss of natural forest cover, although there was no growth of glaciers (Zambo, 1993).

It is important to appreciate that the modern (post-Pannonian) karst has developed upon an older, well-fissured subtropical karst that remains partly buried. The principal surface karst landforms are shapely solution dolines, 10–100 m in diameter and up to 30 m in depth. Larger examples retain Pliocene sediments at their bases, covered by a few metres of colder climate brown or black earths, with up to one metre of man-induced erosional detritus on top. A few have become blocked, creating ponds. Modern dissolutional activity is studied intensely in Beké Doline, a major karst monitoring site (Zambo & Ford, 1997). There are also extensive subsoil karren, frequently exposed by erosion.

The principal caves are excellent examples of dendritic river cave development of the water table-shallow phreatic type (Ford, 2000). Baradla-Domica Cave (24 km long) is the lengthiest, an underground linking of six streams that collect on the clays and sink at the limestone contact (Figure 1), plus rivulets from the overlying karst. The entrance galleries at Aggtelek and Domica have a complex, multi-level structure, apparently due to Quaternary episodes of clastic filling, with paragenesis and incomplete re-excavation (Bolner-Takacs *et al.*, 1989). The main trunk passage is slightly sinuous and *c*. 7 km long. It descends through the highly deformed strata, at a regular gradient of 4–8 m km⁻¹ Its cross-sectional area *decreases* downstream, despite the addition of tributary streams, due to progressive undercapture to modern springs downstream of the Kecso River knickpoint. Flood overflow now reaches a sinkpoint in a boulder pile beneath the Oriasokterem (Giants' Hall) breakdown chamber, on average once every two years. The spring cave is constricted; flood discharge there is *c*. 20 m³ s⁻¹.

The cave is profusely decorated with calcite speleothems, including stalagmites and bosses up to 10 m or more in height or girth. U-series dating has established that most growth is no older than the last interglacial (c. 125000 years BP); the cave was partly filled with alluvial debris during the succeeding Würm cold phases and some larger stalagmites were toppled by extreme flooding. There is also significant condensation corrosion damage to speleothems in tall chambers, which can function as cave climate chimneys.

Beké Cave (6.4 km long), Szabadsag (3.4 km long), Kossuth (1.3 km long), and Vass Imre (1 km long) are similar, low gradient river caves but with lesser catchments and smaller passages. Beké Cave is noted for the erosional effects of aggradation that it displays, such as multiple, undulating corrosional-corrasional notching in the rock walls. Beké, Kossuth, and Vass Imre are sites of long-term hydrologic, hydrochemical, and cave climatic studies.

Higher on the plateaux, 162 steep swallet caves or vertical shafts beneath dolines are known, reaching depths of 100–250 m. Sixty collapse caves are also recorded. Miners

discovered relict hydrothermal caves in some isolated limestone blocks at the extremities of the karst, including the spectacular Ochtina Aragonite Cave (in Slovakia) and Rákóczi Cave, which are open to tourists.

Baradla Cave was one of the earliest centres of biospeleological research. More than 500 troglobite and troglophile species and sub-species are now known from here and other caves of the region, some of them unique. There are 21 species of bats, many of which winter in the caves.

History

The earliest surviving published reference on Baradla Cave is from 1549 AD. Guided visits took place quite frequently during the 18th century. The first accurate map, 1794, showed 2170 m of passages from the Aggtelek entrance. In 1825, the county engineer, Imre Vass, passed a downstream obstacle to extend the known cave, publishing a striking map, with 7.9 km of galleries, in 1829. Tourism increased vigorously in the following years. A partly artificial entrance was engineered alongside Voros-to (Red Lake, a pond doline) in 1890, permitting 6 km through-trips from Aggtelek. A second tunnel, in 1930, allowed entrance or exit at the downstream end of the cave, at Jósvafő. The connection between Baradla and Domica Cave was discovered in 1932.

Dobšina Ice Cave

Dobšina (German: Dobschau) Ice Cave is first known to have been entered in 1870, via a small collapse doline at an altitude of 969 m in a north-facing slope. This gave access to a series of breakdown chambers containing large, perennial ice masses and descending to a depth of c. 110 m (Figure 2). The discovery attracted great attention, was opened for tourists the following year, and fitted with electric lighting as early as 1884. In 2000, it was added to the World Heritage List, as an adjunct of the Slovak Karst. The cave is the truncated, relict, upstream end of the Stratenska Cave system, an 18.3 km, multi-level river cave in the Wetterstein limestone (Tulis, 1986). Breakdown and sedimentation have separated the Dobšina end (1232 m of passages) from the remainder with a seal that is nearly airtight and watertight, although there is limited through drainage.

The main ice body is a "textbook" example of a glacière. It largely fills two chambers, has a volume of c. 110 000 m³ and a maximum thickness of 26.5 m, making it the largest compact

Aggtelek and Slovak Karst: Figure

2. A sketch long section of Dobšina Ice Cave drawn by Dr. Johann E.Pelech (1879). It indicates the principles of the *glacière* or cold trap very well. The direction of the arrow indicates north. (A) External visible hollow in the limestone. (B) Actual entrance. (C, D) Upper portion of the Cavern with the three Ice Pillars, the Ice Saloon, Ice Tent, and Ice Hillock. (E) Lower portion of the Cavern, the Corridor with the Ice Wall. Near (G) the Cavern contracts, and is filled with fragments of rock; through these the water flows away. (J). The great Ice Mass. (M) The Limestone Rock. At (H) the top of the ice is in contact with the roof of the Cavern, thus dividing it into two parts, the Upper and Lower Stages. (Pelech, 1879)

Aggtelek and Slovak Karst: Figure 3. Tunnel cut through the ice in Dobšina Ice Cave. (Photo by John Gunn)

glacière in a show cave. It has an extensive flat floor, sometimes used for skating parties, and large ice stalagmites, columns, and draperies. The glacière accreted from films of flowing water in regular wet season layers because the sealed cavity is a cold trap, receiving dense cool air in winter that cannot be displaced by the warmer air of other seasons. Measurements in the 1880s found that the annual range of air temperature was -0.15 to -0.86° C around the glacière, in contrast to a mean annual temperature of approximately $+6^{\circ}$ C outside the cave.

There are 515 m of tourist paths to display the ice, including a tunnel cut through it that reveals the layered structure (Figure 3). Modern ice behaviour is closely monitored to prevent degradation due to visitors. Between 1981 and 1990, floor ice was observed to increase by 3-115 mm a^{-1} at different locations, much of the water deriving from the melt of nearby wall ice at 1-27 mm a^{-1} . The mass was also deforming plastically (flowing) at rates of ~10 mm a^{-1} horizontally and up to 27 mm a^{-1} vertically downwards (Lalkovic, 1995).

AGGTELEK CAVES, HUNGARY-SLOVAKIA: ARCHAEOLOGY

The Baradla-Domica Cave System, one of the most important archaeological sites in Central Europe, where artefacts of the Neolithic Bükk culture have been found, straddles the boundary between northeastern Hungary and southern Slovakia. The cave system is almost 25 km long and is the most important landform of both the Aggtelek (Hungary) and the Slovak karst. It was excavated by the erosive activity of the underground Styx River, mainly in Middle Triassic (Ladinian) Wetterstein limestone. However, there are substantial cave deposits consisting of gravel and cave loam. The Baradla-Domica caves probably served as temporary or permanent dwellings for paleolithic hunters. In the Middle Ages they also provided sanctuary from the invading Tartars and Turks. But the people of the Bükk culture inhabited the caves for the longest period—during the Middle Neolithic, *c*. 6000–4500 BC.

The Bükk culture derives its name from the Bükk Mountains in northeastern Hungary, which was the main centre from which it spread. The people subsisted by farming, animal husbandry (especially sheep and goats), the obsidian trade, and textile and ceramic production. Their ceramics include some of the finest examples of Central European Neolithic pottery. Apart from their settlements on the river terraces and hillsides, the people also favoured caves as dwelling-places. From this point of view, the Baradla-Domica Cave System (especially the Domica Cave in Slovakia) represents the most important archaeological site for the Bükk culture.

The first archaeological discoveries in the Domica Cave sediments were made in 1926. However, the first archaeological research only began in 1932–33, about 50 years later than in the Hungarian Baradla Cave, where Jenő Nyári had already begun work in 1876–77. Jaroslav Böhm led the research at Domica Cave in the 1930s, in cooperation with American archaeologists (V.J.Fewkes and his team). The Hungarian scientists Hubert Kessler and Maria Mottl also excavated in this cave during World War II (in 1940). New research into the cave settlement was initiated by the Archaeological Department of the Slovak Academy of Sciences in 1956 (by Juraj Bárta) and continued in 1963 (Bárta, 1965; Lichardus, 1969).

A large quantity of new data on the occupancy of the Domica Cave have been collected during this research. The finding of paleolithic leaf-shaped stone "spike" (tool) of the Szeletian culture in allochthonous sediments was especially noteworthy. This is evidence of the presence of prehistoric hunters in the cave or nearby. However, a substantial proportion of the cave artefacts date back to the Neolithic Period. In the cave, six cultural hori zons (Domica Ia, Ib, IIa, IIb, III, and IV) have been found (Lichardus, 1969). These horizons cover the time span from the end of the Early Neolithic to the Middle-Late Neolithic boundary. The painted ceramics of the older Neolithic cultures (a sphere from the Starčevo-Karanovo-Kriš culture and pottery shards from the Gemer painted ceramics culture) have been found in the Domica Ia to IIa horizons, whereas artefacts of the Bükk culture have been excavated only from younger horizons (Domica IIb to IV) (Bárta, 1965; Lichardus, 1969).

Unlike the painted ceramics, the basic motif of the Bükk culture line pottery is a spiral, sculpted decoration, often encrusted with white, yellow, and red pigment. Round vessels predominate, with amphora-like vessels being less common. Bone tools (awls, smoothers, comb-like tools, grinders, rods, a bone ring, pendants, needles, and daggers), stone tools (polished axes and splintered blades), and earthen spindles (evidence of the textile production) have also been found here. Post-holes, connected with the Bükk culture and also known from the Baradla Cave, suggest that dwellings were constructed inside the caves. Several fireplaces were also found, some of which served as sources of charcoal for radiometric dating. On the basis of radiocarbon analysis, the Bükk culture charcoal layer was dated to 6122 ± 75 BP (4120 ± 75 BC). This is in good agreement with the age (6492 ± 100 BP, 4490 ± 100 BC) obtained by radiocarbon dating of samples from the Bükk culture settlement of Arkatul, near Korlát in Hungary (Bárta, 1965).

The unique discovery of three geometrical Neolithic charcoal drawings in 1931 was the most important find both in the Domica Cave (Benický, 1945) and the whole cave

system. These drawings (see Figure)—the only prehistoric murals found in Central Europe—may represent symbols of fertility, and a stylized female figure. They are situated in the back of the cave section known as the "Sacred Corridor", which has a shape of a female lap. The way in which the drawings are located in this part of the cave is presumably related to a sacred site in which religious ceremonies could take place. The corridor was separated from the other cave spaces in two places, probably by some kind of curtains fastened to wooden beams. Traces of post-holes on the cave floor tend to confirm this theory (Bárta, 1965).

From the anthropological point of view, only two human jawbones (one of which belonged to an elderly individual) have been found in the Domica Cave, whereas a Neolithic burialground with 13 human skeletons has been discovered in Baradla Cave. The individuals were buried in a crouched position, face down, and were covered by large flat stones. Along with these

Aggtelek Caves: Archaeology: One

of three charcoal drawings in the "Sacred Corridor" of the Domica Cave. (Reproduced by the permission of the Slovak Museum of Nature Protection and Speleology in Liptovský Mikuláš, Slovakia.) human bones, footprints of Neolithic people were preserved on the floors of both caves. Unfortunately, these footprints were inadvertently destroyed during the first exploration of the cave system.

It is known that the Domica Cave was settled by the Bükk people, especially during the winter, when it was warmer in the cave than outside (the average temperature in the cave is 10°C). The cave could have served as a religious site and/or a ceramics production centre. Artefacts of the Bükk culture have also been discovered in other caves of the Baradla-Domica system (e.g. Baradla Cave, Čertová pec Cave, etc.), but their importance is not as great as those in Domica Cave. However, because of the presence of unique karst phenomena and rare archaeological finds, the Baradla-Domica Cave System was registered as a UNESCO World Heritage Site in 1995.

AKIYOSHI-DAI KARST AND CAVES, JAPAN

The Akiyoshi-dai (plateau) karst is located in Yamaguchi Prefecture, in the western part of mainland Honshu, the largest of the Japanese islands, and is the most famous and largest karst plateau in Japan. Permo-Carboniferous limestones crop out over an area of some 130 km² in one of the main caving regions in Japan. The limestone plateau is shaped like a parallelogram, measuring 17 km in an eastnortheast-westsouthwest direction and 8 km in a northnorthwest-southsoutheast direction, and is surrounded by mainly clastic facies of Permo-Carboniferous age. The western part is covered by Triassic and the northern part by Cretaceous rocks.

The limestone plateau is at altitude of 100–400 m with a gently undulating surface and is mostly surrounded by steep marginal slopes. The valley of the Koto River cuts through the central part of the area from north to south, and divides the Akiyoshi-dai (plateau) into two areas: Higashino-dai in the east and Nishino-dai to the west. About 2200 dolines have been located, and the mean doline density for the total area is *c*. 20 per square kilometre on the plateau. The highest doline density is 140–160 per square kilometre in the central part of the Higashino-dai (Miura, 1991). There are also 81 karst springs and 429 caves distributed all over the plateau. About 45 km² of the Akiyoshi-dai Plateau was designated a Quasi-National Park of Japan in 1955, and 13.8 km² was designated a Special National Monument of Japan in 1964, based on its great significance to the geological sciences.

The Akiyoshi Limestone Group, which forms the Akiyoshidai Plateau, has a total thickness of *c*. 770 m, ranging in age from early Carboniferous (late Tournasian) to late Permian (Guadalupian), and yields abundant fusulinids, bryozoans, crinoids, brachiopods, corals, and other fossils. There is no terrigenous clastic material in any part of the succession. The limestones were deposited in five main environments: talus slope, true reef, beach, marginal lagoon, and central lagoon. The limestone rests conformably on a greenstone succession of alkaline volcaniclastic rocks. The reef complex was formed above a ridge as the result of submarine volcanic activity (Ota, 1977). The northwestern part of the Akiyoshi limestone complex is inverted (recumbent folded and subsequently overturned structures) and the southwestern part displays the normal succession (Schwan & Ota, 1977). In the Carboniferous limestone belonging to the upper part of the *Millerella yowarensis* zone, emergence surfaces with evidence of paleokarst are known to occur (Nagai, 1993).

The caves developed in the Akiyoshi-dai limestone plateau can be divided into three groups on the basis of elevation: highaltitude (higher than 250 m above sea level), middle altitude (250–130 m above sea level) and low-altitude (lower than 130 m above sea level) caves. The high-altitude caves are mostly pits at altitudes of 320–280 m on the Choujagamori Plain. The middle-altitude caves range from an altitude of 160 to 180 m, and occur mostly on the Wakatakebara Plain. The lower-altitude caves mostly open at the foot of the plateau (Kawano, 1983).

Akiyoshi-do Cave is the longest cave in the plateau and is designated a Special Natural Monument of Japan. It is one of the lower-altitude caves, with a natural entrance at the foot of a 50 m high limestone cliff; the entrance is 20 m high and 8 m wide. Before the 1960s, the known passageway of Akiyoshi-do Cave was c. 2 km long including the tourist route, but underwater explorations by various teams have since revealed that it is more than 7.5 km long. A connection was also found between Akiyoshi-do Cave and Kuzuga-ana Cave, and the combined cave system is currently over 8.5 km long. The tourist route, 1 km long, in Akiyoshi-do Cave runs parallel to an underground stream, and passes a complex of 500 terraced rimstone pools (see Figure), large stalagmites, and large columns.

Akiyoshi-dai Karst and Caves, Japan: The terraced gour pools of Hyakumai-zara in the main stream cave of Akiyoshi-dai. (Photo by Akiyoshi-dai Museum)

Taisho-da Cave lies in the northern part of Higashi-dai Plateau and opens at an altitude of 159 m of the northern foot of Mt Mana. Taisho-do Cave is designated a Natural Monument of Japan. The cave is complex, developed with three passage levels and is 1000 m in total length. The upper-level passage (at an altitude of 180-175 m) includes a large chamber containing many speleothems and notches at an altitude of 178 m on the cave walls. The middle level (at an altitude of 175-160 m) is a labyrinthine passage. The lower-level passages (at an altitude of 160-120 m) reach to the water table. Within these three levels, many phreatic solution features (bore passage, natural bridges, pillars, pockets, and anastomoses) are developed. Taisho-do Cave consists of a phreatic cave system linked with Sano-ana Cave, Inugamori-no-ana Cave, and Current-mark-no-ana Cave. The total length of these caves is *c*. 2200 m. (Nakagawa *et al.*, 1979).

Takaga-ana Cave is located on the northern part of Nishinodai Plateau. The vertical entrance shaft of 42 m in a collapse doline is located at an altitude of 241.6 m. Takaga-ana Cave lies in the middle-altitude group and is the second-longest cave in the Akiyoshidai Plateau. It is a complex cave with shafts and passages on four levels at heights of 180 m, 170–160 m, 140–130 m and 90 m levels. The main cave passages are more than 1500 m long, developed at the 170–160 m level. The total surveyed length including the 41 branch caves is 4525 m, and the volume is *c*. 120000 m³, developed along many fissures. The cave is decorated with numerous speleothems of various types. *Macaca* (macaques), *Lutra* (river otters), *Paleoloxodon naumani* (an extinct elephant), and other vertebrate remains have been obtained by surface collection of the cave deposits (Shuho-cho *et al.*, 1981).

Recently, polluted waste waters have sometimes been detected in the groundwaters of the Akiyoshi-do Cave. It is obvious that the pollution is derived from domestic waste water from the tourist hotels and installations built on the surface of the Akiyoshi-dai Plateau. It is essential that the pollution is prevented by dealing with the waste-water problem and periodically monitoring the groundwater in the caves.

ALPINE KARST

Alpine karst is the solutional landscape occurring at high altitudes throughout the mountains of the world. It is distinctive primarily by virtue of localized colder conditions resulting from the altitude, often resulting in restricted vegetation, seasonal snow and snow melt, and past and present glaciers. Exceptionally steep hydraulic gradients develop between upland recharge areas and adjacent valleys. Alpine conditions do not particularly favour karst development: runoff is seasonal, dissolution subdued by reduced biological activity, and past and present geomorphic processes compete and hinder evolution of karst.

Hydrology

Alpine environments are characterized by strong climatic gradients; average temperatures decline by about 6°C per km elevation and upland areas capture additional precipitation, much of which may be in the form of snow. Many alpine karsts therefore experience a strong spring-summer freshet, supplemented only so far as snow patches, glacier ice, and summer rainfall sustain runoff. Meltwater from snow and ice initially contains little dissolved gas or minerals and hence does not have much inherent capacity to dissolve limestone. Carbon dioxide solubility is higher under cold conditions, but partial pressures of gases are reduced under lower atmospheric pressures. Furthermore, poorly developed or skeletal soils combined with a limited growing season result in little enhancement of solutional capacity from soil CO_2 during infiltration.

Groundwater hydraulics under mountains are strongly influenced by relief. Saw-tooth (dissected cuesta) terrain characterized by continuous slopes between peak and valley tends to develop recharge in the upper fraction and discharge throughout the lower fraction with respective linkage of the highest and lowest components. More classical alpine terrain of cirques, dissected plateaus, and entrenched valleys exhibits much deeper circulation and strong groundwater convergence in valleys below.

Processes

Alpine karst processes reflect the seasonal hydrology and subdued chemistry. For much of the year cold conditions may limit runoff, and lack of soil water storage may result in intermittent rather than sustained summer flows. Alpine snow banks are important in sustaining infiltration and stream flow. Closed depressions preferentially accumulate and sustain snow into the summer, and the resulting meltwater may enhance their development in otherwise dry summer conditions.

Much solutional potential may be expended on preferential dissolution of fine carbonates generated by glacial abrasion, and present in glacially derived soils. Evapotranspiration losses are low in comparison with many other environments and hence the runoff percentage tends to be high, although this is more than compensated for by low pCO_2 in the absence of biogenic sources. Hence, karst denudation rates are not high, and alpine karst generally develops quite slowly, unless there is substantial runoff or a supplementary source of acidity. Oxidation of crushed pyrite to produce sulfuric acid is one such process. Two factors, currently poorly understood, are the impact of initial freshet water that is chemically enriched (especially where acidic air pollution is high),

and the very rapid kinetics of dissolution arising from water containing no dissolved minerals.

Cold conditions, seasonally abundant water, rapid runoff, and steep gradients strongly sustain other geomorphic processes, most of which can be viewed as competing with karst development. Frozen ground may allow accumulation of massive ice and perennial snow in surface shafts. This effectively cuts off the water supply and may prevent exploration, although in the Julian Alps explorers have been able to penetrate over 200 m down ice-filled shafts by following narrow routes at the contact between ice and the rock walls. Frost shattering of susceptible materials can devastate surface karst forms and choke closed depressions. Mass movement by solifluction, creep, rockfall, and debris flows may also obscure karst features, or restrict groundwater recharge.

Glaciers play an ambiguous role in alpine karst where many closed depression are both karstic and glacial in development. Closed depressions tend to be preferred sites for snow accumulation and glacier development, and glacier erosion at valley heads tends to produce overdeepened (closed) cirques that may function in a similar way to dolines following ice-melt. The bed temperature of most alpine glaciers is fixed at melting point. As a result, glaciers protect the ground from freezing and so permit groundwater recharge at altitudes otherwise sustaining permanently frozen ground. They may also prevent frost shattering, and scour accumulated debris from surfaces. As a result the finest alpine karst terrain is largely found in areas recently exposed by glacier retreat. Small circular glaciers may coexist with active karst, as they produce little debris. However, more active, extensive glaciers generate large quantities of till that accumulates in lower reaches as moraines. Much alpine karst is obscured by a mantle of such glacial deposits that not only neutralize solutional erosion, but may also preclude groundwater recharge, and support lakes which act as sustained traps for fine sediments. Glacial action is particularly enhanced by the steep topographic and climatic gradients of alpine regions. At higher altitudes, erosion dominates, generally disrupting surface catchments (especially closed depressions) and truncating shallower karst systems. At lower altitudes, glaciers tend to deposition and the resulting glacial, fluvioglacial, and glaciolacustrine sediments occupy valley floors, raising local base levels and often burying karst springs.

Karst Landforms

The composition of carbonate mountain ranges reflects the regional geological history. As most mountains are developed at plate margins, the carbonates of mountain ranges may be considerably thicker than is found in plate interiors. Intense folding, faulting, and alteration of rocks are common in mountain ranges, resulting in varied juxtaposition of various grades of carbonate with insoluble silicates, and sometimes containing exotic minerals arising from hydrothermal and volcanic activity. Many of the features of alpine karst may be linked to the active tectonics associated with mountain development. Valleys and poljes may occupy down-faulted blocks or zones of weakness; horizontally bedded blocks form plateaus. Tilted blocks tend to generate saw-tooth ridges that may be separated by strike-aligned valleys developed in weaker strata; regional karst drainage is often along the strike of such blocks discharging into larger, cross-cutting glacial valleys. Carbonate tectonic units in the European Alps

Alpine Karst: View across the dipping limestone pavements on the Slovene side of Monte Kanin. (Photo by John Gunn)

may contain independent karst systems isolated from adjacent rocks by the impermeable fault surface.

The paucity of surface vegetation due to glacial erosion, soil erosion, and the harsh climate renders alpine karst features more easily seen and appreciated than in other environments. Solutional features like karren are often well developed in suitably massive, pure carbonates, and the resulting lapiaz or limestone pavements can cover many square kilometres (see figure). Such surfaces are composed of numerous, structurally controlled closed depressions, indicating highly fragmented recharge. Larger closed depressions may occupy tectonic structures, or may occupy cirque floors or valleys previously overdeepened by ice. However, many alpine closed depressions act as agents of their own burial. They are filled with clastic deposits generated by weathering, mass movement, glaciation, and runoff, and the sink points are unable to carry the coarse materials involved. In time, if the terrain stabilizes, suffosion dolines may develop in the fill, eventually leading to reopening of the ponor. For example, Medicine Lake, Jasper National Park, Canada occupies a karst depression blocked by a rock slide, glacial deposits, and river sediments. It has failed to develop a significant ponor due to continuous infilling of nascent openings.

Alpine Caves

The fundamental features of alpine caves are those of any cave system, although there may be considerably greater vertical development and longer preservation of ancient passages. Vertical shafts are common underground, and are often exposed at the surface, truncated by glaciation and filled with shattered rock and sediment. They are the most common alpine cave entrance, but relatively few provide access to a cave system. Vadose channels may downcut rapidly, rather than widening, creating narrow meandering canyons linking sequences of shafts, as at Krubera Cave (see separate entry). Phreatic sections may also develop considerable vertical range, including dramatic upwards flowing segments to phreatic loops, reflecting the fracture frequency, and the tendency to deep groundwater circulation in alpine terrain.

Mountains are dynamic landscapes at the time scale of karst development. Tectonic, climatic, and geomorphic patterns may change many times during evolution of cave systems. Changes to the alpine terrain and base level will alter patterns of recharge and discharge, disrupting the fundamental trajectories of cave system development. Recharge shafts may entirely lose their surface catchment and become relict. Springs developed at the valley floor may become perched above base level as a consequence of later entrenchment, and the associated passages become progressively abandoned. Passage infill and overflows may develop in response to alluvial infilling of the valley floor, for example the more than 60 separate springs recognized in and below Maligne Canyon, Jasper National Park, Canada. Within the cave system, phreatic conduits may be abandoned and reactivated as a response to cycles of valley deepening and infilling, or glaciation of the recharge surface and valleys. Reorganized surface recharge may form new vertical shafts, graded to a new local base level and cutting directly through former passage networks. These are type examples of invasion vadose caves (see Speleogenesis: Unconfined Settings). Backfilling in valleys may result in these shafts becoming flooded, and overflows may reactivate ancient phreatic or choked conduits. Such rejuvenation and reactivation are normal in many karst regions. However, in alpine karst, thick carbonates, the great vertical range of cave development, and the marked transitions in controls over time may result in more radical changes and permit greater preservation of cave systems than in lower relief regions. Multilevel passages, shaft complexes, and a wide suite of clastic and mineral deposits provide a tantalising record of the past environment.

Exploration

The great relief of alpine regions permits development of the great deep caves of the world, and the complex history of many alpine caves makes them extraordinarily extensive. In many cases, active streams occupy relatively few of the known passages. The possibility of ever greater depths of exploration has attracted considerable interest from speleologists. However, apart from relief, there is no common form for deep alpine caves. Some are simple shafts (e.g. Epos Chasm, Astraka Plateau, Greece), or are developed along simple contacts or fractures (e.g. Krubera). Some are developed into complex horizontal networks, linked by shafts (e.g. Gouffre Berger, see Vercors entry). Others are trunk systems gathering water from a number of distinct subcatchments (e.g. Pierre Saint-Martin, see separate entry). The challenge is often to gain entry to the system, for the recharge surface may be disrupted. In fact, many great caves are not entered by hydrologically prominent depressions, for these are often infilled. Rather, inconspicuous shafts, lacking any surface catchment often survive to permit explorers to

enter (e.g. Yorkshire Pot, Alberta, Canada). A number of alpine caves have been explored from the lower entrance. In some (e.g. Castleguard Cave, see separate entry) exploration has required only persistence, as all the large shafts are descents, despite penetrating upstream. In others, extraordinary technical virtuosity has been required to push exploration up vertical shafts (for examples see entries on Dent de Crolles and on Siebenhengste). Fortunately, upward exploration, often pursuing the cave wind, may reveal upper entrances, permitting more ready access to the inner reaches of the system (e.g. Hölloch, see separate entry, and Nettlebed Cave, New Zealand).

Alpine cave exploration is almost always highly technical, requiring skill and equipment to tackle the vertical sections. Not only is there a considerable quantity of equipment to transport, but the length of many trips demands establishment of under ground camps. In many systems, water also poses a challenge, in some cases by the intensity of flow, in others by closure of passages by floods. Exploration may be restricted to wintertime when there is much less runoff. Low temperatures mean that ice may form, preventing access, or possibly converting a difficult wet section to a straightforward frozen pool.

Resources

Alpine karst aquifers may be used in water supply and power generation. For example Vienna (Austria) obtains at least 60% of its water from alpine karst. However, the strong seasonality of flow, lack of quality protection, and poor moderation of recharge may render the water resource of limited value. Quarrying poses a threat in some regions as many alpine caves are developed in carbonates attractive to the aggregate and cement industries. Much alpine karst lacks surface expression, but retains its hydrological function. Reservoirs may prove ineffective, if built on such terrain. Surface karst is often extremely fragile, although nature may be the primary vandal. However, economic development of alpine terrain often results in wholesale destruction of karst surfaces for development of roads and alpine resorts, and significant compromise of water quality.

ALTAMIRA CAVE, SPAIN: ARCHAEOLOGY

Located 2 km south of the village of Santillana del Mar (Santander), near the north coast of Spain, the cave of Altamira, nicknamed the Sistine Chapel of Cave Art, was decorated at various times between *c*. 16000 and 14000 years ago. First discovered by a hunter in 1868, it was visited in 1876 by a local landowner, Don Marcelino Sanz de Sautuola, who noticed some black painted signs on a wall at the back, but thought little of them. In 1879 he returned to do some excavating and, while he was digging in the cave floor, searching for prehistoric tools and portable art of the kind he had recently seen displayed at a Paris exhibition, his 8-year-old daughter Maria was playing in the cavern. Suddenly she spotted the cluster of great polychrome bison paintings on the ceiling.

Her father, at first incredulous, became more interested when he found that the figures seemed to be done with a fatty paste, and noticed a close similarity in style between these huge figures and the small portable depictions from the Ice Age which he had seen at the Paris exhibition; he therefore deduced that the cave art was of similar age, but his attempts to present his views and his discovery to the academic establishment met with widespread rejection and accusations of naivety or fraud. Sanz de Sautuola died prematurely in 1888, a sad and disillusioned man (see Art in Caves: History).

Altamira Cave is 296 m long, comprises a series of chambers and passages, and ends in a very long, narrow section known as the "Horse's Tail". Although the site is best known for its magnificent decorated ceiling, its galleries contain an abundance of engravings, including some particularly fine deer heads identical to some engraved on deer shoulder-blades in the cave's occupation layers. There are also some meandering finger tracings, some of which form a bovine head. One remarkable feature is a series of masks, where natural rock-shapes were turned into humanoid faces by the addition of eyes and other details; most of these masks can only be noticed when one is leaving, rather than entering, the "Horse's Tail".

The great hall, with its high vault, has engravings and also some red compartmentalized quadrilateral signs, similar to those of the cave of El Castillo in the same region. The cave also has black paintings (black figures often occur in different zones from red figures), some stencilled hands, and some (far rarer) positive painted hand prints.

To the left, as one enters Altamira, is the great hall of paintings, measuring about 20 m by 10 m. The floor has been lowered in order to allow visitors easier access and viewing of the very low ceiling on which a score of large painted animals are spread: there are 18 bison, a horse and a hind, the latter being 2.5 m in length—the biggest figure in the cave. They are polychromes, done in ochre, manganese, and charcoal. Most animals are standing, but a few natural bosses in the ceiling are occupied by curled-up bison, which thus appear three-dimensional. Two or three painted figures on the ceiling have often been described as boars (a very rare animal in Ice Age art) but they are now seen as streamlined bison (especially since one has horns).

The curled-up bison on the bosses have been described as sleeping, wounded or dying, falling down a cliff, or as clear pictures of females giving birth. Currently the dominant

view is that they are males, rolling in dust impregnated with their urine, in order to rub their scent on territorial markers, even though one of them has udders! In fact, they may simply be bison drawn to fit the bosses—they have the same volume, form, and dorsal line as those standing around them, but their legs are bent and their heads are down. Some researchers see this chamber as a symbolic pound, with a bison-drive depicted on the ceiling (the curled-up animals at the centre are dead, while those around them stand and face the hunters—there are male humans engraved at the edge); another interpretation is that the ceiling is a depiction of a bison herd in rutting season.

Although the Altamira ceiling has sometimes been taken as a single accumulated composition, it actually comprises a series of superimpositions: researchers have distinguished five separate phases of decoration, beginning with some continuous-line engravings, followed by figures in red flat-wash, then some multiple-line engravings, some black figures, and finally the famous polychromes. The multiple-line figures are identical to some portable specimens from the cave, dated to 14480 years ago, so it is clear that the two earlier phases pre-date them, while the black figures and polychromes are younger. Charcoal used in some polychrome bison on the painted ceiling has produced radiocarbon dates from 14820 to 13130 years ago. The cave was probably blocked shortly after this period.

Sanz de Sautuola saw the ceiling as a unified work, and many subsequent researchers have declared that one artist of genius could have done all the cave polychromes. Recent detailed observations have confirmed these intuitions that one expert artist was probably responsible for at least all the polychrome bison on the ceiling. The different radiocarbon dates, if accurate, may indicate subsequent retouching.

The occupation layers at Altamira have yielded material from the Mousterian; the Solutrean, including classic shouldered-points and the engraved deer shoulder-blades; and the early Magdalenian, with perforated antler batons, and antler spear-points with complex decorative motifs. The Magdalenian fauna is dominated by red deer, and has abundant seashells reflecting the cave's proximity to the coast; seal bones occurred in the Solutrean layers. Between the Solutrean and Magdalenian periods, the cave was used by cave bears for hibernation. Altamira's wealth of occupation material and of portable and parietal art (literally art on walls) suggests strongly that it was an important regional focus at times, perhaps the scene of seasonal or periodic aggregations when people from a wide area might meet for ritual, economic, and social activities.

Altamira became a World Heritage Site in 1985. In July 2001, a magnificent facsimile of Altamira Cave, constructed a few hundred metres from the original, was opened to the public; it not only contains a perfect replica of the decorated ceiling, with every crack, engraving and painting on it, but places it in its original context by reconstructing the whole of the cave entrance chamber and its gaping mouth, which has not been seen since it collapsed towards the end of the Ice Age.

AMERICA, CENTRAL

Central America, here defined as the isthmus between the United States and South America including the Yucatan Peninsula, contains many significant carbonate karst landscapes, with a regional karst area totalling about 431300 km², or 17% of the total land area (Figure 1). Over 90% of Central America's karst is in Mexico, particularly in the southern and eastern states of Oaxaca, Guerrero, Chiapas, Pueblo, and Tamaulipas, and on the Yucatán Peninsula. Significant karst also occurs in Guatemala, Belize, and Honduras.

Geologically, the bulk of Mexico, excluding the Yucatan, is related structurally to North America and not to the remainder of Central America. The carbonate rocks of Central America range in age from Quaternary to Jurassic, representing discontinuous carbonate deposition over more than 200 million years. Considerable geologic, topographic, and environmental hetero geneity characterizes the region, but Central America contains a number of dramatic karst landscapes. These include cockpits, towers, dry valleys, dolines of various types and sizes, cenotes, and extensive cave systems, together with an impressive marine karst landscape (Table 1). The world's second longest barrier reef is located off the Caribbean coast of the Yucatan, Belize, and Honduras.

Karst landscapes in Central America have been, and still are, influenced by tectonic, eustatic, and climatic changes (Gardner, 1987) and they have also undergone significant alterations as the result of human activity (Day, 1993).

The most extensive Central American carbonate karst areas are in Mexico, in the Sierra Madre Oriental, in the Yucatan Peninsula, and in the Southern Mountains. The Sierra Madre Oriental includes some 130000 km^2 of rugged, mountainous

America, Central: Figure 1. The main karst regions in Central America, and the location of significant caves referred to in the text.

karst with extensive dolines and deep shafts punctuating an elevated plateau, bounded by steep escarpments and dissected by deep canyons. The Southern Mountains are a structurally complex range that extends into Guatemala. They include the Huautla Plateau and the Chiapas Highlands, in a karst area extending over 60000 km², and a similarly sized area further west in northern Guerrero. In the Yucatán, over 115000 km² of Tertiary and Quaternary carbonates give rise to a subdued karst landscape, characterized by shallow dolines, low residual hills, cenotes, and flooded cave systems.

Another extensive karst area, including cockpit and tower karst developed in Cretaceous and Tertiary carbonates, extends through the Peten of east central Guatemala into western Belize, covering nearly 15000 km², and there are also significant elevated karst areas in the Alta Verapaz and Huehuetenango Departments of Guatemala. Honduras

has three major karst areas, covering approximately 10000 km²: the Montana Santa Barbara in the northwest, the Cordillera Agalta in central Honduras, and the Sierra de Colon and Cordillera Entre Rios in the southeast bordering Nicaragua. The karst in Montana Santa Barbara and Cordillera Agalta has received only moderate scientific attention, and the karst on the Sierra de Colon has received little attention, due to its remoteness and dense vegetation. The folded limestone mountains of the Sierra de Colon extend across the border into neighbouring Nicaragua. The Cretaceous carbonates of the Atima Limestone of the Yojoa Group are several hundred metres thick and are heavily karstified. There are also significant carbonate karst areas elsewhere in Nicaragua and throughout Costa Rica (Mora, 1992; Peacock & Hempel, 1993; Troester *et al.*, 1987). In Panama, there is karst in the northwest along the border with Costa Rica, in the Archipielego de Bocas del Toro, in central Panama in the Maje Mountains near the Rio Chepo o Bayano, and in the eastern Darien Department (Reeves, 2000). El Salvador has less than 300 km² of karst, located along the border with Honduras and Guatemala, south of Anguiatu.

Considerable topographic variation characterizes the karst of Central America as a whole, although three distinct karst terrain styles—doline, polygonal (cockpit/cone), and tower—are recog-

America, Central: The areas of karst and significant landforms in Central America.

America, Central: Figure 2. A corner of the extensive calcite dripstone deposits in the Gruta del Palmito in the Bustamente karst of northern Mexico. (Photo by Andy Eavis) nized. Dry or underdrained valleys and subdued depressions or dolines occur throughout the region but have received little scientific attention. Cockpit, cone, and tower karst occurs in southern Mexico, Belize, Guatemala, Honduras, and Nicaragua. Variations of these types occur throughout Central America and are not restricted to the areas described above. Flooded shafts, cenotes, are the characteristic surface landform across the northern Yucatán Peninsula.

The karst rocks range from pure, dense, hard, fractured, crystalline limestones, some much altered from their original state, to impure, powdery, soft, porous, amorphous carbonates. Their depositional environments were highly variable, but the low-lying limestones of the Yucatán Peninsula were formed as extensive carbonate platforms and reefs analogous to those off the Caribbean shore today. Some interior karstlands, especially in mountainous areas adjacent to volcanoes, are mantled by volcanic ash. Some carbonates, particularly in Belize and Guatemala, are brecciated as a result of extreme tectonic disruption or meteoric impact. Others have been extensively folded and faulted as a consequence of orogenic mountain building. Karst landscape elevations range from sea level to an altitude of 3000 m; some are mountainous and restricted in area, others planar and extensive; some are hydrologically isolated, while others receive allogenic surface drainage from higher, adjacent non-karst terrains.

There has been considerable but disparate cave exploration and scientific karst research in Central America. Some of the longer and deeper cave systems have been explored and studied extensively, but other potentially significant karst areas have received little attention. The history of cave exploration dates back to the pre-Hispanic Maya, who penetrated some caves for considerable distances as part of ceremonial and ritual practices, and made extensive and varied uses of caves. Modern cave research started in the 19th century with, for example, the exploration of the Gruta de Palmito in Nuevo Leon, Mexico, between 1835 and 1875. Exploration of the Guerrero caves began in earnest in the 1930s, with the traverses of the underground rivers of Chontalcoatlan and San Jeronimo. More recently, the Grupo Espeleologico Mexicano, which was formed around 1960, and the Association for Mexican Cave Studies, formed in 1962, have promoted cave and karst research throughout Mexico, increasingly with international cooperation. The Yucatán karst (see separate entry) has received considerable attention in the context of differential dissolution in groundwater mixing zones and has become famous for its very long underwater cave systems.

Widely published scientific research has been conducted in some other Central American karst areas, notably in Belize (see Veni, 1996) and Costa Rica (Peacock & Hempel, 1993; Troester *et al.*, 1987), but overall the regional karst offers considerable scope for future research. The karst areas of Honduras and Nicaragua warrant further study, although this may be hindered by problems of access.

Extensive cave systems occur through Central America, although the best known are those in the Sierra Madre Oriental, the Southern Highlands, the Yucatan Peninsula, Guatemala, and Belize. The Sierra Madre Oriental includes many famous deep and long cave systems, including Sistema Purificacion, 94 km long. Sistema Cuetzalan is an extensive, dendritic river cave system with over 35 km of passage and as much again in adjacent caves not yet connected. Sótano de Las Golondrinas (see separate entry, Golondrinas and the Giant Shafts of Mexico) is the most famous of many large bellshaped daylight shafts. In Puebla, at the southern tip of the Sierra Madre Oriental, there is another group of significant deep cave systems including Akemati (1130 m deep) and Ocotempa (1063 m deep).

The Southern Mountains, including the Huautla Plateau, the Chiapas Highlands and northern Guerrero, constitute another of the world's premier cave areas. Sistema Huautla (see separate entry) is 56 km long and at 1475 m deep the deepest cave in the western hemisphere, while, on the opposite side of the Santa Domingo Canyon, Sistema Cheve is 1386 m deep and drains to a canyon-floor resurgence 2540 m below the Cheve entrance (Hose, 2000). Spectacular river caves in Chiapas include the resurgence system of Veshtucoc (5 km long and 380 m deep), while the Sumidero Yochib is a challenging system over 3 km long and over 200 m deep with polished canyons containing waterfalls and deep plunge pools. The Guerrero karst includes well-known caves, such as hoyo de San Miguel (455 m deep), the very well decorated show cave grutus de Juxtlahuaca (5 km), and the river caves of Rio Chontalcoatlan (6 km), and gruta del Rio San Jeronimo (6 km). In Quintana Roo, the extensive water-filled conduit caves of the coastal Yucatan have been a focus of research into carbonate dissolution in freshwater-seawater mixing zones (Back *et al.*, 1986).

In Belize the caves of the Chiquibul River System are particularly well known (see separate entry, Belize River Caves). The Chiquibul Cave System contains four segments, three in Belize (Cebada Cave, Actun Tun Kul, and the Kabal Group), and the fourth (Xibalba) in Guatemala, with a total length exceeding 50 km. There are also extensive river caves in Guatemala, including the Sistema del Rio Candaleria in Alta Verapaz, with 12 km of passages in seven segments and at least 55 entrances (Bordier, 1976).

Central America's natural karstland vegetation varies from xerophytic scrub to wet tropical broadleaf forest, including both deciduous and evergreen trees, although much of the original forest has been cleared, with only fragments remaining in remote karst areas. The region also supports one of the world's most diverse wildlife assemblages, and specifics of the regional karstland ecology warrant additional studies. Regionally, levels of endemism and species diversity are high, particularly in terms of plant species and terrestrial vertebrates.

Human impacts on Central American karst landscapes and caves have been long-term and severe, in particular through forest clearance, species introduction, agriculture, degradation of water resources, and industrial activities, including mining, quarrying, and construction (Day, 1993). Important archaeological sites, both surface and subterranean, are significant facets of karstlands throughout Central America. Mayan archaeological sites within karst areas include Tikal (in Guatemala), Caracol (in Belize), and Chichen-Itza (in Yucatan). The Mayan cave art in Naj Tunich, Guatemala is less well known but no less significant. Pre-Hispanic influence on regional karst areas was extensive, particularly in terms of forest clearance and agricultural activities.

Contemporary threats to the Yucatan karst include hotel expansion along the coast, illegal quarrying activities, and the potential impacts of inappropriate attempts to restore quarried areas. Groundwater contamination, as a result of inadequate sewage disposal practices, is a perennial problem in the Yucatan (Back, 1999). In Belize, adverse impacts range from agricultural expansion to increasing tourism. Forest reserves continue to be logged, despite local opposition, and quarrying of limestone for construction projects is ongoing. In Guatemala and Honduras, major threats include the exploitation of floral and faunal resources, the establishment of settlements within protected areas, and unclear or

ineffective legislation. Overall, about 10% of the Central American karst has been designated as some form of protected area, including 68% of the karst in Belize. However, no karstlands are yet designated as protected areas in Nicaragua or El Salvador, and much of the most significant Mexican karst is not protected.

AMERICA, CENTRAL AND THE CARIBBEAN ISLANDS: BIOSPELEOLOGY

Central America (including Mexico) and the Caribbean Islands encompass a vast area ranging from the temperate zone in the north to the tropics in the south. The hypogean fauna is highly diverse and contains species derived from northern and southern elements and from freshwater and marine ancestors. The subterranean fauna of much of this area is poorly known with large areas still essentially unexplored. This is especially true of south

ern Central America where remoteness and a long history of political instability have prevented any comprehensive study of the fauna.

Volcanic deposits cover much of southern Central America but extensive limestone outcrops occur in Belize, Guatemala, Honduras, Nicaragua, Costa Rica, and Panama. Lava tubes occur in all of the countries of this area except for Belize. No biospeleological studies have been conducted in Nicaragua and only a few guano-associated species have been reported from El Salvador. The only cave system in Panama that has been extensively surveyed is the Chilibrillo Caves. This large bat cave contains no troglobitic fauna. Several studies have been conducted in Costa Rica, but only one troglobite (a phalangodid harvestman) and one stygobite (a pseudothelphusid crab) have been described from caves. Studies in the caves of Honduras have produced a few troglobites but only one collembolan has been described. The interstitial habitat has produced stygobitic mites in Costa Rica and copepods in El Salvador and Honduras.

American, Canadian, French, and Italian biospeleologists have studied areas of Guatemala. A few caves have been investigated in the provinces of Izabal and Petén but no troglobites or stygobites are known here. However, the highland provinces of Alta Verapaz and Huehuetenango have a rich fauna of troglobites and stygobites. The troglobitic fauna includes pseudoscorpions, spiders, millipedes, collembolans, entotrophs, crickets, and carabid and leiodid beetles. All have close affinities with the fauna of southern Mexico. The stygobitic fauna includes triclad planarians, amphipods, isopods, and crabs. The triclad and amphipods are of marine origin, whereas the isopods and crabs are derived from freshwater ancestors.

The troglobites of Belize are closely related to the fauna of the Yucatan Peninsula, but include an unusual endemic millipede and two genera of Opiliones not otherwise represented by troglobites in Mexico. Other troglobites include schizomids, spiders, pseudoscorpions, and crickets. The stygobitic fauna includes two species (a pseudothelphusid crab and a pimelodid catfish) of freshwater origin. These genera also contain species in southern Mexico. The remaining stygobites have been obtained from anchialine habitats off the coast of Belize and include Remipedia, copepods, and cirolanid isopods. These species have affinities with other anchialine species from the coast of Yucatan and the Caribbean Islands.

Reddell (1981) detailed the history of biospeleological studies in Mexico. The Association for Mexican Cave Studies continues study in various parts of Mexico. Recent work under the direction of José Palacios-Vargas from Mexico City has resulted in major faunal discoveries. Approximately 300 troglobites and 140 stygobites have been described from Mexico but many more will probably be recorded. Few areas of the country have been adequately sampled and large areas remain unexplored. In particular, many of the numerous isolated mountain ranges in northern Mexico have yet to be visited. One lava tube in Veracruz contains a prolific fauna and other volcanic caves probably contain fauna of interest. Recent discoveries of endemic stygobites in caves and springs in northern Mexico suggest that many additional species await discovery and description.

The distribution and composition of the cavernicole fauna of Mexico is a result of a combination of past climatic and geological history and the complex physiography of the country. The majority of the terrestrial fauna is composed of species closely related to taxa still inhabiting the surface. A few species in the extreme north of Mexico are
identical to or congeneric with species found in Texas to the north. Numerous species in northern Mexico occupy caves in isolated mountain ranges surrounded by desert. Of special interest are two families of millipede, the Cambalidae and Trichopetalidae, which are common elements of the southeastern United States fauna but occur only in caves in Mexico. These appear to be relicts derived from leaf litter inhabitants of forests that once extended along the Gulf Coast south into Veracruz. These forests are now restricted to high elevations in Mexico, but some species of these families are now restricted to caves at both high and low elevations, with the more highly cave-adapted species found in lowland caves.

The aquatic fauna in Mexico is derived both from freshwater and marine ancestors. The freshwater groups include some dugesiid flatworms, hydrobiid snails, asellid and stenasellid isopods, crayfish, palaemonid shrimps, pseudothelphusid crabs, dytiscid beetles, and fishes. Two species of earthworm and one trichonisicd isopod appear to have become secondarily adapted to freshwater in caves. The marine derivatives include species that are apparently relicts of the vast Cretaceous marine embayment that covered much of Mexico. These species presumably became adapted to freshwater as the seas retreated. This fauna includes amphipods, isopods, mysids, and alpheid shrimp. A large number of species have been described from the caves of the Yucatan Peninsula (see separate entry), largely as the result of diving. Although some of the species inhabiting groundwater in this area are fully adapted to freshwater, others have been found only in anchialine habitats. These latter species have their closest affinities with the fauna of the islands of the Caribbean. Among notable groups inhabiting these waters are remipedes, copepods, ostracods, cirolanid isopods, mysids, amphipods, and fishes.

The nutrient-rich caves of the lowlands in the eastern foothills of the Sierra Madre Oriental, Oaxaca, Veracruz, and Tabasco contain a preponderance of troglophiles, many associated with bat guano. The troglobitic fauna include species apparently derived from taxa inhabiting leaf litter and include large isopods, arachnids, centipedes, millipedes, thysanurans, and histerid beetles. The spiders (particularly the Pholcidae) are well represented, but troglobitic schizomids, pseudoscorpions, and ricinuleids are also known. One tarantula from the family Theraphosidae is a troglobite in the lowland caves of Oaxaca. The stygobitic fauna includes species of both freshwater and marine origin. The freshwater derivatives include snails, palaemonid shrimp, crayfish, and fish. The marine derivates include dimarcusid flatworms, cirolanid isopods, mysids, and alpheid and atyid shrimps. Of special interest are several species of fish. Two species of the ictalurid genus Prietella have been found in caves along the eastern slopes of the Sierra Madre Oriental and one in the extreme north of Mexico near the border with Texas. One pimelodid catfish of the genus Rhamdia has been found in caves in Oaxaca. Two species that possess troglomorphic populations are of special interest. The poeciliid Poecilia mexicana displays varying degrees of eye and pigment reduction within Cueva de Villa de Luz, a remarkable sulfur-based chemoautotrophic cave ecosystem (see separate entry). The characid Astyanax fasciatus has apparently colonized caves many times in the states of San Luis Potosí and Tamaulipas and has become the best-studied cave fish in the world. This reflects the ability of subterranean populations to fully interbreed with surface ancestral populations and the ease with which it can be raised in captivity.

High elevation caves throughout Mexico are typically more nutrient-poor and contain a much more diverse troglobitic fauna than caves at lower elevations. The fauna of the Sierra Madre Oriental includes trichoniscid isopods, scorpions, schizomids, amblypygids, pseudoscorpions, opilionids, numerous species of spider, centipedes, millipedes, collembolans, campodeid entotrophs, silverfish, phalangopsid crickets, and beetles. Troglobitic beetles, which are absent from lowland caves, are especially speciose with numerous species of carabid beetles belonging to several genera. The family Leiodidae also contains troglobites in this area. Many genera reach their northern limits in the isolated mountain ranges of Durango, Nuevo León, and Coahuila. Several schizomids, ricinuleids, spiders, pseudoscorpions, opilionids, centipedes, millipedes, thysanurans, and carabid beetles are now relicts at higher elevations on mountains surrounded by desert. Stygobites found at higher elevations include dugesiid flatworms, earthworms, amphipods, isopods, and dytiscid beetles. The troglobitic fauna of the highlands of southern Mexico typically contains the same groups as that of the Sierra Madre Oriental but includes several families of spider and millipede that reach their northern limits of distribution in extreme southern Mexico. Pseudothelphusid crabs have also been found in Chiapas. The stygobitic fauna includes a number of unusual species, including a polychaete worm from a cave in Guerrero.

The troglobitic fauna of the Yucatan Peninsula includes trichoniscid isopods, scorpions, amblypygids, pseudoscorpions, spiders, millipedes, collembolans, and phalangopsid crickets. The stygobitic fauna is particularly rich and includes remipedes, copepods, ostracods, thermosbaenaceans, mysids, amphipods, cirolanid isopods, and fish. The fish *Ogilbia pearsei* is a marine relict, whereas the eel *Ophisternon infernale* is presumably of freshwater origin.

Numerous species of bat inhabit Mexican caves. These include carnivorous, piscivorous, insectivorous, and haematophagous species. Attempts to eradicate vampire bats in southern Mexico have led to the destruction of many colonies of all species. Other vertebrates occurring as trogloxenes in Mexican caves include frogs, salamanders, lizards, snakes, and rodents.

The cavernicole fauna of the Caribbean islands is generally poorly studied although the fauna of Cuba has been fairly well documented and research in Jamaica and Puerto Rico has considerably extended our knowledge of the troglobitic fauna of these islands (Peck, 1999; Peck et al, 1998). Very little is known about the terrestrial cave fauna of the island of Hispaniola. The aquatic fauna of many of the islands is now well understood due to the extensive studies by a number of researchers studying the interstitial and subterranean fauna. Extensive diving in many caves has greatly expanded our knowledge of the anchialine fauna (Illiffe, 2000; see also Walsingham Caves, Bermuda: Biospeleology). A troglobitic onychophoran from Jamaica is only one of two in the world, the other being in South Africa. The only troglobitic isopod recorded from the Caribbean Islands is an undescribed species from Jamaica. With few exceptions, the troglobitic arachnids from the Caribbean islands are represented by endemic genera. Troglobitic schizomids are known from Cuba and Jamaica, amblypygids from Cuba, pseudoscorpions from the Dominican Republic, Cuba, and Jamaica, opilionids from Jamaica, and spiders from Cuba, Jamaica, and Mona Island. Of special interest are troglobitic mygalomorph spiders from Cuba (Barychelidae) and Jamaica (Dipluridae). Two species of troglobitic centipede are known from Cuba. The absence of troglobitic millipedes from the Caribbean islands is puzzling. The troglobitic insect fauna of the Caribbean islands is far more limited than on the mainland. Collembola are known from Cuba, Guadeloupe, Haiti, and Jamaica, thysanurans on Cuba, pentacentrid and phalangopsid crickets on Cuba, roaches on Cuba, Jamaica, and Puerto Rico, fulgoroid homopterans on Jamaica and possibly Mona Island, and carabid beetles on Jamaica.

The stygobitic fauna in the Caribbean is almost entirely derived from marine ancestors. The only exceptions appear to be some copepods and crayfish on Cuba and elmid beetles on Haiti. Many mites have been sampled from the interstitial zone below rivers in Cuba and Haiti. There is a remarkable diversity of species inhabiting both freshwater and anchialine habitats in the Caribbean islands. With the exception of triclad planarians on Jamaica and in the Venezuelan Islands, polychaetes in the Bahama Islands and Netherlands Antilles, and a chaetognath in the Bahama Islands, the invertebrates all belong to the Crustacea. Remipedes have been found in the Bahama Islands and Turks and Caicos Islands; themosbaenaceans in Cuba, República Dominicana, Guadeloupe, Jamaica, Puerto Rico, Venezuelan Islands, and Virgin Islands; ostracods in the Bahama Islands, Cuba, Haiti, Jamaica, and Turks and Caicos; copepods in the Bahama Islands, Barbados, Cuba, Guadeloupe, Haiti, Jamaica, Netherlands Antilles, and Venezuelan Islands; cumaceans in the Bahama Islands; isopods in the Bahama Islands, Cayman Islands, Cuba, Dominican Republic, Guadeloups, Haiti, Jamaica, and Netherlands Antilles; amphipods in the Bahama Islands, Barbados, Cayman Islands, Cuba, Dominican Republic, Guadeloupe, Haiti, Jamaica, Leeward Islands, Netherlands Antilles, Puerto Rico, Turks and Caicos, Venezuelan Islands, and Virgin Islands; mysids in the Bahama Islands, Cuba, Dominican Republic, Jamaica, and Puerto Rico; grapsid crabs in the Bahama Islands and Jamaica; and shrimps in the Bahama Islands, Cayman Islands, Cuba, Dominican Republic, Guadeloupe, Jamaica, Leeward Islands, Mona Island, Netherlands Antilles, Puerto Rico, and Turks and Caicos. Stygobitic fish, all belonging to the genus Lucifuga, have been found only in the Bahama Islands, Cuba, and Jamaica.

The stygobitic fauna of the Caribbean islands exhibits many puzzling distributional patterns, with some genera endemic to a particular island whereas others are widespread throughout the Caribbean, including Belize and the Yucatan Peninsula. Some genera also occur in the Galapagos Islands, some on both sides of the Atlantic Ocean, and a few have recently also been found in Australia. The distribution of many of these taxa clearly indicates a great age for some lineages.

The subterranean fauna of Central America and the Caribbean islands is severely threatened by a variety of pressures. The greatest threat in many areas is deforestation with resultant erosion, loss of habitat for bats, and reduction in sources of nutrient input into caves. The construction of extensive resorts along the Caribbean coast of Mexico and on many of the islands of the Caribbean has destroyed some caves and led to severe problems with pollution from inadequate sewage disposal facilities. Many caves in Mexico lie in or near small villages that routinely dispose of trash and raw sewage directly into entrances. A proposal to dispose of sewage from cities into wells in northern Yucatan threatens the entire water supply of the Peninsula. Overpumping, especially along the Caribbean coast of the Yucatan Peninsula and some Caribbean islands, threatens to diminish groundwater supplies but also increase the salinity of caves that open onto the coast. Although national parks and other nature reserves exist in some areas, these form only a limited part of the area needed to protect the natural subterranean biodiversity of this region.

AMERICA, CENTRAL: ARCHAEOLOGICAL CAVES

The geographical area discussed here corresponds with the region known to archaeologists as Mesoamerica. It includes the area of pre-Columbian high cultures in central and southern Mexico, all of Guatemala, Belize, and the western portions of Honduras and El Salvador.

For Mesoamerican cultures, caves were perhaps the most sacred features in the natural landscape. Their importance is a reflection of a basic Amerindian religious focus on the Earth as a sacred and animate entity. Growing out of that focus was a fundamental concern with place. In central Mexico, the Nahuatl word for community, *altépetl*, literally means "water-filled mountain". The glyphic rendering is a mountain with a cave at its base. A people were identified with their place, their sacred mountain, and its cave. In many Maya languages the name for the principal indigenous deity translates as "hill-valley", and the deity is considered to be the owner of that "hill-valley". In a very real sense, the landscape is personified and deified. The word for cave in many indigenous languages translates as "stone house" because caves were seen as the residence of the deities. This may be the reason that I6th-century Yucatec Maya used the term *actun* for both caves and stone buildings like temples. Neither is this the only case. In Maya inscriptions, pyramids were called "hills" and represented sacred mountains. Thus, place

and its surrounding landscape were so important that the dominant human constructions, pyramids and temples, were models of mountains and caves.

Historical Development of Cave Archaeology

The archaeological investigation of caves in Mexico and Central America has a long history, dating back to the travels and descriptions of John Lloyd Stevens and Frederick Catherwood in the 1840s. Formal archaeological investigations that met or exceeded the standards of the day were initiated before the end of the 19th century at a number of sites in the Maya area. Henry Mercer published *Hill-Caves of Yucatan* in 1896, Edward Thompson wrote *Cave of Loltun* (1897), the *Caverns of Copan* was published by George Gordon (1898), and Eduard Seler reported on Quen Santo (1901) in the Guatemalan Highlands.

During the period between the world wars, cave studies languished, with the only noteworthy studies being the British Museum Expedition to Pusilhá in the Maya area (Gruning, 1930; Joyce *et al.*, 1928; Joyce, 1929) and the Cueva Encantada, Morelos (Arellano & Müller, 1948; Müller, 1948) in Central Mexico. During this period, cave studies disappeared as an important element of the archaeological literature and never again approached the discipline's highest standards of field methodology.

After World War II, the situation slowly improved, with sound scientific studies being produced by the Carnegie Institution of Washington's Mayapan Project and by David Pendergast in Belize. At the same time, a number of high-profile discoveries focused attention on the often-spectacular cave remains. The most impressive was the opening of a blocked passage at Balankanche near Chichen Itza, which revealed dozens of elaborate incense burners and other artefacts, all in their original context. The study of the cave was noteworthy for the recording of a modern Maya cave ritual that coincided with the beginning of the study (Andrews, 1970). Two caves containing Olmec paintings were discovered in Guerrero, but unfortunately no archaeological study accompanied the recording of the artwork. Finally, the discovery of a cave beneath the Pyramid of the Sun at Teotihuacan was probably the single most important cave discovery in Central Mexico, because it engendered a great deal of rethinking of the importance of caves. In the Maya area, the discovery of Naj Tunich served to launch cave archaeology as a recognized subdiscipline (Brady, 2000).

While cave investigation has a 150-year history, no attempt was made to synthesize the data and produce a coherent statement on the function of caves until the publication of J.Eric Thompson's *The Role of Caves in Maya Culture* in 1959. Thompson's views, however, were not widely circulated until the appearance of a revised version of his original article (Thompson, 1975). Thompson's synthesis is noteworthy because, with the exception of the use of cenotes as sources of drinking water, all of his major functions are religious. Furthermore, habitation, the function most frequently proposed by field archaeologists, was discarded completely. That same year, Doris Heyden (1975) published the first synthesis in English on Central Mexican cave use. Heyden's discussion is noteworthy because she is the first to propose that a cave was of such importance that it determined the placement, size, and orientation of one of the largest structures in all of Mesoamerica. Interestingly, neither Thompson nor Heyden ever did archaeological work in caves. By the late 1980s a new trend was notable as archaeologists specializing in caves began to dominate theoretical discussions, using data that they had collected in the field (Bonor Villarejo, 1989; Brady, 2000; Stone, 1995)

The Role of Caves in Legitimizing Settlement

The founding of a new settlement in Mesoamerica was a matter of great cosmological importance and was always accompanied by ritual. After their conquest, the Spanish found that the easiest way to map a community's boundaries was to have the foundation ritual reperformed, because this ceremony formally established those boundaries. As a result, there are many descriptions of such rituals. It is clear from these descriptions that indigenous people searched for a particular landscape configuration that had cosmological significance and in which caves were central. Angel García-Zambrano (1994:218) notes that these caves, "when ritually dedicated to the divinities, became the pulsing heart of the new town, providing the cosmogonic referents that legitimized the settlers' rights for occupying that space and for the ruler's authority over that site."

From 1990 to 1993 a cave survey was carried out at the Maya site of Dos Pilas in the Peten area of northern Guatemala, in order to determine if a relationship between surface architecture and caves could be detected. The study found a far more pervasive pattern of locating site architecture in relation to caves than reported for any other site. Relationships are present on three levels. Two of the site's three large public architectural complexes are built directly over caves. Hieroglyphic inscriptions at the largest complex appear to refer to the cave in the toponym, or place name. The third complex may be aligned with a cave feature (springs), and there is the possibility that a cave also runs below it. At a nearby site, a cave runs beneath the central plaza, and the architecture was laid out so that a skylight entrance could be utilized as an important religious feature. A number of important, but secondary, complexes also appear to be formed around large caves. Finally, small residential complexes and even individual house structures are associated with small caves generally less than 10 m in length (Brady, 1997; Brady *et al.*, 1997). Thus, it appears that the caves at Dos Pilas structured the site layout from the largest public architectural complexes down to individual house mounds.

While the Dos Pilas data are the most systematic and compelling, a number of examples of cave/architecture relationships have been recorded. The earliest example was Edward Thompson's discovery in 1896 of a cave beneath the centre of the Ossario at Chichen Itza (Thompson, 1938). Other early examples were reported at Tulum (Lothrop, 1924:109), Cozumel (Mason, 1927:278), and Polol (Lundell, 1934:177). Because the importance of the caves was not appreciated, no attempt was made to interpret what appears to be a clear and widespread pattern.

Artificial Caves

As noted above, within Mesoamerica there is a widely shared conceptual landscape in which caves are a major feature. Interestingly, most of the volcanic areas of Mesoamerica have few if any natural caves. In these areas the conceptual landscape is imposed on and reproduced in local landscapes by the excavation of artificial caves. In recent years, large numbers of these have been documented in the Maya Highlands (Brady & Veni, 1992) and in Central Mexico (Manzanilla, López & Freter, 1996; Medina Jaen, 2000).

Artificial caves offer clear proof that the relationship between architecture and natural caves noted at Dos Pilas and other sites was deliberate, because artificial caves replicate

the same patterns. These features are also important because their form reflects the decisions of their makers. Several of the elaborate artificial caves appear to be models of the seven-chambered cave of origin, suggesting that this may be what all the caves in site centres are meant to represent. The association of other artificial caves with sacred locations and pilgrimage sites adds another dimension to our understanding of the role of caves. The presence of the cave would appear to be one of those markers that alerts visitors to the fact that this a place of supernatural power.

Artificial caves appear to be constructed along fairly regular plans, so they are clearly an architectural form in their own right. Some of the caves reflect construction on a monumental scale, requiring as much or more labour input as pyramidal structures. The truly massive scale of some constructions is of central importance, because the lavish expenditure of resources should alert archaeologists to the fact that the focus of such attention is somehow central to the concerns of the society.

Caves and Ritual

The preceding sections have dealt with caves that were located in political core areas and so were the focus of large-scale public rituals. To this could be added the many pilgrimage caves. The vast majority of all caves, however, are located in peripheral areas, but these almost invariably show some type of ancient utilization. This suggests that these features, no matter how small or how remote, were never overlooked.

What type of rituals were carried out in these caves? The rural Mesoamerica religious tradition, which is still very much alive, suggests that the rituals revolved around the agricultural cycle. Villages often make processions to ask the permission of the Earth Lord before clearing and burning fields, and perhaps again at the time of planting. The discovery of small corn cobs, four to five centimetres long, at many caves indicates that ceremonies for the offering of the first young ears may have been widely practised. The Day of the Cross (3 May) is celebrated throughout Mesoamerica. Occurring just before the onset of the rainy season, the celebrations traditionally include petitions for rain. The ceremonies are often made in a cave, because rain is considered to be a terrestrial rather than a celestial phenomenon. Rain, clouds, and lightning are formed within caves and then sent by the rain deities into the sky. Special rituals are undertaken in cases of drought, which are usually interpreted as a supernatural punishment for some oversight or infraction. Thus, rituals involving caves appear to occur at every significant point in the agricultural cycle.

Besides providing rain and fertility, the earth is also the source of disease and pestilence. In Yucatan, rituals are performed to keep the evil airs from escaping from caves/cenotes. Curing ceremonies often involve cave rituals. In many cases, the diseasecausing agent may be removed by a shaman passing an egg over the person's body or sucking out a poisonous intrusion. The disease-bearing object will then be returned to its source in the cave. Not surprisingly then, caves are often thought to be places of witchcraft where disease can be given to an enemy.

Caves appear to have been used by all segments of society in pre-Columbian Mesoamerica. These features carried a variety of meanings. As the place of human origin they were connected to the miracle of creation and were the focus of group identity. The association with the earth made them sacred places where earth deities could be propitiated and petitioned for the basic necessities of agrarian life. They were frightening places as well. From caves, the deities could send drought and disease to punish humans for misconduct. The huge artefact assemblages recovered from caves suggest that the visitation for all these purposes was heavy and prolonged.

Show Caves

There are a number of show caves open to the public in the region but only a few of the better developed can be mentioned here, and many of the large caves, such as the Chiquibul System, have not been excavated professionally. In northern Mexico near Ciudad Madera, Chihuahua, the Cuartena Casas (Forty Houses) Archaeological Zone is formed around a series of cliff dwellings related to Southwestern rather than Mesoamerican culture. The sites were occupied from about 950 AD until perhaps the 14th century and appear to be related to Casas Grandes (Paquimé).

In Central Mexico, the most famous cave is the man-made tunnel under the Pyramid of the Sun at Teotihuacan, which has been discussed in detail by Heyden (1975). Special permission is needed, however, to get access. Another man-made cave at the site of Xochicalco, Morelos, is open to the public. The main cave appears to have been used as a solar observatory. The position of the sun was charted by sunlight entering through a hole in the ceiling.

In the Maya area, Balankanche Cave near the World Heritage Site of Chichen Itza has regular tours in an assortment of languages. Both the cave and the original context of many of the artefacts were heavily modified in opening the cave to tourism. Loltun Cave, near Oxkutzcab is one of the most impressive caves with large passages. The site is noteworthy for its rock art (Thompson, 1897) as well as a sequence of use dating back to the end of the Pleistocene. Finally, the Cave of Bolanchen, Campeche, made famous by Frederick Catherwood's painting of the use of a huge ladder in the 1840s, has been the subject of a good deal of archaeological investigation (Zapata Peraza, Benevides Castillo & Peña Castillo, 1991).

In Guatemala, the Cueva de las Pinturas, 20 km south of Flores, Peten, contains a large polychrome inscription and substantial architectural modifications dating to the Preclassic. Just across from Flores in Santa Elena, parts of Actun Kan are open to the public. The cave, formerly known as Jobitzina, is quite extensive with another entrance on the opposite side of the hill in which the cave is located. In Alta Verapaz, Lanquin Cave has long been a tourist destination but is also sacred to the Q'eqchi' Maya. Finally, the man-made caves at Utatlan can be visited but are often in use by the K'iche' Maya.

In Honduras, Tauleve, a show cave near Lake Yojoa, is sacred to the Lenca who conduct ceremonies at the cave on April 24. The Talgua Cave (Cave of the Glowing Skulls) near Catacamas is now open to tourism but visitors are not allowed to enter the chambers containing archaeological material. In Belize, visitors can see many intact vessels in their original context at Actun Chichem Ha, near San Ignacio.

AMERICA, NORTH: ARCHAEOLOGICAL CAVES

Archaeological cave sites in North America occur from Alaska to the Yucatan Peninsula. The only significant area lacking archaeological caves is the Canadian Shield. The two most significant areas of prehistoric deep cave use occur in the karst regions of the Central Lowlands of the United States and the Mayan cave region of southern Mexico and Central America (see America, Central: Archaeological Caves). Most archaeological caves are prehistoric habitation sites, where people sought shelter under cliff overhangs, or rock shelters and cave entrances. A significant number of cave sites, however, contain evidence of human activity far beyond the reach of daylight, that includes the mining of minerals and stone resources, drawing pictographs and petroglyphs, placement or burial of the dead, and performance of rituals.

In North America, as in all parts of the world, humans have used the natural shelter afforded by cave entrances for everyday activities: processing food, cooking, making tools and clothing, and, undoubtedly, other social activities. Many cave entrances contain deeply stratified deposits, some dating to the earliest, well-accepted occupation of the Americas, *c.* 10000–12000 years BP. Deeply stratified cave deposits were used to define regional cultural chronologies in many regions of North America, thus making them important sites in the history of archaeology.

Two important cave sites, with late Pleistocene Paleoindian occupations, are Wasden/Owl Cave, Idaho, and Bluefish Caves, Yukon. Owl Cave is a collapsed lava tube with a large bison bone bed, stone tools, and worked bone, ¹⁴C dated between 8200 and 7800 BP. Underlying this strata, is a bone bed of broken and modified mammoth, bison, and camelid remains, with a fluted, Paleoindian point association (Miller, 1982). Bluefish Cave I contains an early deposit of stone tools and other artefacts, with the remains of mammoth, bison, horse, and other mammals. Bone collagen ¹⁴C dates range from 25000–12000 BP, and the tool assemblage is similar to late Pleistocene tool traditions known from Siberia (Cinq-Mars, 1978). The associa tion between the human artefacts and Pleistocene animal bone, however, is still problematic.

Three important stratified cave sites in the western United States are Ventana Cave, Arizona, Danger Cave, Utah, and Bat Cave, New Mexico. Ventana Cave is a deep rock shelter formed by a seep spring in volcanic agglomerate. Completely excavated in the 1940s (Haury, 1950), the cave yielded stratified deposits from the late Pleistocene to historic Tohono O'odham (Papago) Indians. The earliest deposit contained bones of extinct Pleistocene fauna and a few human artefacts, suggesting a possible Paleoindian occupation. Later ¹⁴C dating of this layer established that it was early Holocene (c. 10600–8800 years BP) in age, and that the early tool industry was more closely related to later Archaic occupations than Paleoindian. Danger Cave is a dry cave that has a long history of excavation, beginning in the 1930s (Jennings, 1957). A stratified sequence of occupations dating from 10500 BP up to historic Indian occupations, was used to define the Desert Archaic tradition, a successful hunting and gathering way of life adapted to the desert and mountain environments of western North America. Bat Cave also has a long sequence of occupation (c. 10500 BP to historic times); however, it is best known because it contains the earliest association of maize with human occupation outside of Mesoamerica (Dick, 1965). Re-analysis of the deposits, and direct ¹⁴C dating of the maize remains, confirmed its spread into North America by 3500-3000 BP.

In central and eastern United States, three important stratified cave sites are Russell Cave, Alabama, Dust Cave, Alabama, and Graham Cave, Missouri. Russell Cave is a true limestone cave that is now a US National Monument. Excavated in the 1950s and 1960s, archaeological deposits in the entrance were more than 9 m deep, dating from 9000 to 400 BP (Griffin, 1974). The deposits yielded a wealth of chronological information on tool and artefact manufacture, especially during the Archaic Period (*c.* 9000–3000 BP). Ongoing excavations at nearby Dust Cave, with deposits dating from 10500 to 3250 BP, are yielding new information on the depositional context, paleoenvironment and human subsistence during this early time period, as well as more traditional information on prehistoric tool manufacture and use. Graham Cave is an unusual cave, formed in sandstone, which also contains early archaeological deposits, primarily dating from 9700 to 7000 BP (Logan, 1952). Prehistoric occupation spans the transition from the late

Paleoindian to Archaic Period hunters and gatherers in an important ecotone between the western prairies and eastern hardwood forests.

In the eastern United States, the first evidence of deep cave exploration by prehistoric Indians is dated *c*. 4600 BP. In a remote passage of a cave in Tennessee, approximately 1.5 km from the entrance, were found some 275 foot impressions in a soft mud floor. A thin scatter of cane torch charcoal (*Arundinaria* sp.), and charcoal smudges on the walls and ceiling of the passage, were used to date this prehistoric exploration. It appears from the footprints that nine individuals (possibly in two separate trips) travelled to the end of this passage and then returned. A number of other cave sites in Tennessee, Kentucky, and Indiana, contain evidence of prehistoric exploration dating prior to 3000 BP. Based on the limited remains found in these caves, the objective of these early cave trips appears to be simply exploring. However, these early prehistoric cave explorers were apparently adept at penetrating remote and demanding cave passage and successfully returning to the entrance.

A number of new activities begin to appear *c*. 3000 BP, in the record of prehistoric cave use in the eastern United States. Third Unnamed Cave, Tennessee, contains evidence for quarrying chert cobbles from a remote sandy-floored passage, testing and reducing the cobbles by knapping, and the engraving of petroglyphs onto the limestone ceiling and walls (Simek, Franklin & Sherwood, 1998). The petroglyphs are primarily geometric: rayed circles, semi-circles, checkerboards, chevron patterns, and numerous other enigmatic groups of lines. Wyandotte Cave, Indiana, was explored in prehistoric times and variously mined for chert and aragonite. The exploration and possibly chert mining occurred earlier, *c*. 4150–2200 BP, but the mining of a large aragonite stalagmite appears to date *c*. 2200–1150 BP (Munson & Munson, 1990). Artefacts made of Wyandotte Cave aragonite have been identified at several sites in the Midwestern United States, suggesting that this cave resource was widely valued.

The most extensive prehistoric mining activity in the caves of North America is found in Mammoth Cave and Salts Cave, Mammoth Cave National Park, Kentucky. Dating *c*. 3000-2200 BP, several kilometres of both caves were systematically mined for gypsum (CaSO₄'2H₂O) in the form of crusts and flowers battered from the walls and ceiling, and selenite needles dug from the floor sediments. In more limited quantities, mirabilite (Na₂SO₄·10H₂O) is also present in the caves and appears to have been collected in prehistoric times. It is not clear why so much effort was spent mining sulfate minerals, although gypsum may be made into a white paint or paste and the crystals themselves can be quite spectacular. Mirabilite, if ingested in sufficient quantities, is a medicinal cathartic.

The archaeology of Mammoth and Salts caves is well known for the perishable remains preserved in the dry passages: unburned torch material, cordage, woven foot wear, twined textile fragments, gourd containers, wooden bowls, digging sticks, mussel shell scrapers, and climbing poles are commonly found in the mined passages (Watson, 1969; 1974). Historically, at least two desiccated prehistoric bodies were found in the cave, both appearing to be mining accident victims. One is a *c*. 45-year old man killed by rock fall, and the other a *c*. 9-year old boy who appears to have died from a fall. Also among the dry remains preserved in the caves, are hundreds of human paleofaeces (hence the strong suggestion that mirabilite was consumed in the cave for its cathartic effect), which is an unparalleled source of material for the study of prehistoric diet and parasitic

infection during this time period. There are also a small number of enigmatic charcoal pictographs and petroglyphs found in Mammoth and Salts caves, associated with the mining, although the rendering of glyphs appears to have been a minor activity.

During later prehistoric periods in North America (c. 2000 BP to historic times), native groups appear to have used caves increasingly for ceremonial or ritualistic settings, including use as burial sites and decoration of the walls and ceilings with glyphs. The Copena culture of northern Alabama and Georgia used caves to inter individuals with elaborate burial items, including artefacts made of imported copper, galena, mica, marine shell, and steatite (Beck, 1995). Vertical shafts or pit caves, with surface openings, were used to deposit bodies in many areas of North America. This is not a very well-studied phenomenon, but the greatest concentration of burial pit caves is reported from southwest Virginia and east Tennessee. Human remains, incorporated into talus cones at the base of pit openings, are complex depositional environments awaiting more detailed, systematic study.

So-called "cave art", in the dark zone of caves, is turning out to be widespread in the eastern United States. Pictographs, petroglyphs, and mud-glyphs, found in numerous caves, contain an array of geometric shapes, but increasingly zoomorphic, anthropomorphic, and iconographic elements dominate the art. Some of the art appears related to motifs found on artefacts widespread in the southeastern United States, and mythological figures of historic Indian groups, such as Cherokee underworld creatures (Faulkner, Deane & Earnest, 1984). The performance of rituals or shamanistic acts, associated with the drawing of cave art, has been inferred for many of these late prehistoric deep cave sites.

One of the best archaeological examples of the use of an inner cave setting for ritual behaviour, is Feather Cave, New Mexico. An inner room of the cave, rediscovered in 1964, contained some 400 perishable artefacts in their original position, thought to be at least 600 years old. The room contained a large assortment of miniature bows, reed arrows, crook pahos (prayer sticks) and other artefacts, along with pictographs adorning some walls (especially hand prints outlined in white clay-like pigment). The site was interpreted, with the help of elders from the nearby Pueblo Indians, as a Mogollon sun and earth shrine visited during biannual solar ceremonies, similar to Pueblo ceremonial caves still in use today (Ellis & Hammack, 1968). Parallels may also be drawn between Pueblo ceremonial caves and concepts regarding caves and supernatural beings in Mesoamerican cultures. It is debatable whether parallel beliefs between cultures are due to diffusion of religious ideas, or similar geological features (in this case caves) influence similar concepts among different cultures.

The ritual use of caves is also a renewed topic of interest in Mesoamerican archaeology. Classic Maya sites (c. 1700–1050 BP) appear to be associated with important caves, often incorporat-ing local caves into the settlement layout. From these new cave discoveries, a more complete picture of ancient Maya ritual practice is emerging. As in the case of the historic Cherokee in the eastern United States, and Pueblo groups in the southwestern United States, belief systems of modern Maya Indians provide a link between sacred cave use and ritual knowledge in the present to the beginning of prehistoric concepts of caves a millennium or more in the past.

AMERICA, NORTH: BIOSPELEOLOGY

Faunal Distributions: a Result of History

North America—Canada and the continental United States (northern Mexico is discussed in the entry on America, Central & the Caribbean Islands: Biospeleology) contains a diverse and widely distributed cave fauna. The current distribution of cavernicoles is the result of interwoven historical parameters such as glaciation, shifting of vegetative communities, moisture (or aridity), and the rise and fall of shallow inland seas. Continental drift (elements of the North American cave fauna have holarctic affinities) and the availability of suitable caves—typically in limestone, but also lava tubes and other types of caves—play a role in explaining the current biogeographic setting.

Pleistocene glaciation is a factor limiting the northern extent of the range of many North American troglobites and stygobites, especially terrestrial taxa. Most terrestrial cavernicoles see their greatest diversity south of the maximum reach of Pleistocene glaciation (see biodiversity map of United States in colour plate section). Notable exceptions occur, such as Castleguard Cave in western Canada where a troglobitic mite (*Robustocheles occulta*) is thought to have survived the Pleistocene in this cave beneath the Columbia Ice Field. Distributions of aquatic faunas, too, are sometimes limited by the glacial history—for example, the troglobitic flatworms of the genus *Sphalloplana* are found almost exclusively to the south of the maximum extent of Pleistocene glaciation. Among the aquatic taxa there are a number of lineages that seem to have survived the episodic advance and retreat of glaciers in the groundwater. Distributions of various amphipod crustaceans (e.g. species of *Stygobromus* and *Bactrurus*) are especially indicative of such a history.

The Pleistocene climatic fluctuations have influenced not only through the direct impacts of glaciers, but also through shifts in vegetative zones. Much of the North American terrestrial troglobite fauna has affinities with epigean leaf-litter/soil communities. Faunal elements associated with moist leaf litter typical of cooler montane forests may have entered caves during cooler periods when such forests extended further south and to lower elevations. As the forests retreated north and to higher elevations some taxa—especially those with features that preadapt them to life in caves—were isolated from their epigean ancestors.

The relatively depauperate fauna of western North America is explained only in part by somewhat lower densities of caves. Here, the more extreme aridity of the climate may have had much the same influence on terrestrial troglobites as glaciation had on the cave fauna of the northern parts of eastern North America. Arid western caves may have historically lacked the capacity to sustain populations of terrestrial troglobites because of both insufficient moisture and a lack of suitable energy input in the form of organic debris entering the caves from the more sparse vegetative communities in this arid climate. Finally, forest leaf litter communities in the southwestern United States are thought to have historically lacked a diverse community of cool/ moist adapted invertebrates through most of the Pleistocene. Such ancestral, pre-adapted, taxa are thought to have been precursors to many of the terrestrial troglobitic arthropods of the eastern United States.

The aquatic fauna of North American caves is also influenced by ancient seas. Stygobitic freshwater isopods of the largely marine family Cirolanidae occur in southern Texas caves (and southward into Mexico) and an endemic cirolanid (*Antrolana lira*) is also known from a small area in Virginia. These taxa may be relicts that were able to adapt to the freshwater cave environment as ancient shallow seas receded. Other aquatic cavernicoles have clear links to extant epigean aquatic taxa which co-occur in the same region. Stygobites in these groups may represent more recent invasions from the surface.

Richness and diversity of the fauna

There are approximately 1300 to 1500 described species of troglobites and stygobites in North America (north of Mexico). Approximately 70% of these are terrestrial, the remainder aquatic. Recent estimates as high as 6000 species have been made when undescribed taxa are included. Such estimates generally ignore microbes, protozoa, and fungi. The richness of the North American stygobite and troglobite faunas is not equally distributed among major taxonomic groups.

Among the vertebrates, troglobites and stygobites are found only among the fish (six or seven species) and salamanders (at least ten taxa). Several species of stygobitic fish occur in the family Amblyopsidae with several species across the eastern United States (*Amblyopsis rosae* in the Ozark Plateau and *Amblyopsis spelaea* and *Typhlichthys subterraneus* in the Interior Low Plateaux). The most extremely troglomorphic species among them is *Speoplatyrhinus poulsoni*, endemic to a very small area in northern Alabama. Two small catfish species are known from the large aquifer of the Edward Plateau. The grotto sculpin, *Cottus* sp. (Cottidae), of southeastern Missouri is likely to be described as a species distinct from a closely related surface relative.

The salamander fauna of North American caves includes a number of troglophiles and troglobites, dominated by members of the family Plethodontidae. Among these are *Haidetriton wallacei* (Florida and Georgia), *Typhlotriton spelaeus* (Ozark Plateau), two species and several subspecies of *Gyrinophilus* (Interior Low Plateaux and Appalachians), the Cave Salamander, *Eurycea lucifuga*, and several plethodontid salamanders in the Edwards Plateau (see Edwards Aquifer: Biospeleology, and photo of Texas Blind Cave Salamander in Amphibia).

Many North American bats are trogloxenes, and utilize caves as roost sites for overwintering, for migration stopovers, as maternity sites, and as bachelor roosts. Those species that roost in large colonies produce large deposits of guano that serve as an energy-rich food source for a guanophillic community that includes a variety of flies, beetles, mites, millipedes, and other invertebrates. Among the more significant largecolony bat species are two eastern North American species, the Indiana Bat and the Gray Bat, and, further south, the Mexican Free-Tailed bat. All three species can congregate in large colonies which sometimes number many thousands of individuals. A variety of other bat species, especially in the genera *Myotis, Pipistrellus,* and *Eptesicus,* are frequent inhabitants of North American caves.

Other trogloxenic vertebrates regularly utilizing caves include packrats (*Neotoma spp.*), mice, Turkey Vultures (*Cathartes aura*), and Eastern Phoebes (*Sayornis phoebe*), all of which commonly nest in or near the entrances or twilight zones of caves. Raccoons (*Procyon lotor*), who commonly venture deeper into caves, may leave behind significant deposits of faeces which can comprise an important energy input into some caves.

North America's invertebrate cave fauna includes a variety of insect, myriopod, arachnid, and crustacean species. Other groups of cavernicolous organisms—generally less well studied than the macroinvertebrates and vertebrates—include aquatic oligochetes (Annelida), branchiobdellidans, horsehair worms, entocytherid ostracods, copepods, and a variety of bacteria, fungi, and protozoans. Among the flatworms (Turbellaria), stygobites are known in several genera, including *Macrocotyla* and *Sphalloplana*.

Few molluscs are adapted for life in caves. Several groups contain stygobites, and the hydrobiid genus *Fontigens* is notable among these, as it includes several stygobites found in caves of the eastern and southeastern United States.

The arachnid fauna of North America is diverse and fascinating. Several genera of opilionids are troglobites, including *Phalangodes* and *Bishopella* in the eastern United States, *Texella* species in the Edwards Plateau and Guadelupe Mountains, and *Cryptobunus* in the west. Some of these species are troglobites and others are troglophiles. A number of other opilionids may be found in caves, such as the Holarctic genus *Sabacon*. The common genus *Lieobunum* includes trogloxenes that occur in caves from Canada to Texas (and into Mexico). A southwestern species, *Lieobunum townsendii*, frequently occurs in huge aggregations of many hundreds of individuals in or near cave entrances. This species forages above ground at night, and thus may function as an important energy source for some caves.

Mites of caves are not well studied. The family Rhagidiidae occurs in caves across much of North America and includes several troglobites. Pseudoscorpionida is one of the more diverse cavernicolous arachnid groups. There are more than 20 troglobitic pseudoscorpions in the Appalachians alone. Some cave pseudoscorpions are notably larger than their surface relatives. Troglobites occur in several families. *Apochthonius* (Chthoniidae) is one of the more diverse genera, with troglobites found in caves across the United States. As with many of the arachnid groups, there are a number of species that are endemic to one or few sites.

Across much of the United States the spider families Linyphiidae, Leptonetidae, and Nesticidae contain troglobites. Other families (e.g., Telemidae and Dictynidae) contain numerous cave-adapted species in certain regions. In the eastern United States there are several cave-limited *Islandia* and *Nesticus* species. In Texas, the genera *Eidmanella*, *Neoleptoneta*, and *Cicurina* contain a variety of troglobites, and the genus *Cicurina* (Dictynidae) includes epigean species, troglophiles, and narrowly endemic troglobites. In the western United States (California), the genera *Telema*, *Blabomma*, and *Cybaeozyga* each contain several troglobites. The most commonly encountered troglobitic/troglophilic spider in the eastern United States is the widespread linyphiid, *Phanetta subterranea*. Several pholcids are common troglophilic spiders. The common troglophilic spider *Meta ovalis* is one of the more obvious arachnid inhabitants of caves in eastern North America, and is closely related to a European species.

The stygobitic crustaceans include more than 30 decapods—primarily crayfish species (especially *Orconectes* and *Procambarus*) but also three narrowly endemic species of freshwater paleomonid shrimps. Troglobitic crayfish are known from the Ozark Plateau and the Interior Low Plateaus, but the group is most diverse in the aquifers of Florida, where up to three species coexist. One notable decapod community outside of Florida is the faunal assemblage of Shelta Cave (Huntsville, Alabama) where three species of crayfish and a shrimp (one of the three stygobitic *Palaemonias* species) are known.

The amphipod fauna of caves and other groundwater in North America is diverse and dominated by crangonyctid and gammarid taxa. Among the genera frequently encountered are *Crangonyx, Stygobromus, Bactrurus,* and *Gammarus*. Detailed studies of *Gammarus minus* and other Appalachian cave fauna are the basis for some of the theoretical framework of current studies of aquatic cavernicoles in North America.

Several other amphipod families occur in North American caves and groundwater, most notably in the Edwards Aquifer of Texas.

In addition to the cirolanid isopods mentioned above, there are many stygobitic or phreatobitic species of the asellid isopod genus *Caecidotea*. *Salmasellus* occurs in a few caves of western North America. Cave-adapted terrestrial isopods of the family Trichoniscidae may also be found in caves of the southeastern and western United States.

Of the myriopods, only the millipedes contain an abundance of troglobites. Troglobitic millipedes are frequently encountered in caves throughout the eastern United States and occur in caves across the country. Genera with troglobites include *Pseudotremia, Cambala, Tingupa,* and *Scoterpes,* but there are a number of others. The centipedes commonly encountered in North American caves are troglophiles.

Among the hexapods, there are a number of troglobites among the springtails (Arrhapolites, Tomocera, Sinella, Pseudosinella, and Oncopodura are examples of genera containing troglobites) and diplurans (e.g. Litocampa, Haplocampa, Eumesocampa).

Troglophiles and trogloxenes are found in several insect orders. The colourful moth *Scolioptrix libatrix* over-winters in caves, and other moths are associated with guano deposits. Flies of the families Heleomyzidae, Phoridae, Sphaeroceridae, and Mycetophilidae are frequent in caves. In the eastern United States the larval stage of the fungus gnat *Macrocera* builds webs to entrap prey. Mosquitoes (Culicidae) of several genera over-winter in caves across much of North America.

Cave crickets (e.g. *Haedenoecus* spp.) and camel crickets (*Ceuthophilus* spp.; Figure 1) are important components of many North American cave communities, and several species may co-occur in a single cave. Trogloxenic *Ceuthophilus* species forage outside of caves at night and rest in the caves during the daytime. Faeces, bodies, and eggs of these animals comprise an important energy source for terrestrial cave communities. In the western United States, some lava tube caves contain another interesting orthopteran, *Grylloblatta* (Grylloblattodea).

Hymenoptera are generally not important components of North American cave communities, with the exception of the Red Imported Fire Ant (*Solenopsis invicta*). This introduced species forages in caves of the Edwards Plateau (and perhaps elsewhere in the southeastern United States) and is thought to have a negative impact on cave communities.

America, North: Biospeleology: Figure 1. *Ceuthophilus cunicularis*, a trogloxene in central Texas caves. Cave crickets are important components of many North American cave communities. (Photo by Steve Taylor, courtesy of Natural Resources Branch, Fort Hood, Texas)

Insect troglobite diversity is greatest in the beetles. Several staphylinids occur in caves, with the troglophile genus *Quedius* being the most frequently encountered. Spider beetles (Ptinidae) include some troglobitic species (e.g. *Niptus*), and the mold beetle family Pselaphidae is rich in troglobites, especially in the widespread genus *Batrisodes*, but also several other genera. Mold beetles occur in many caves of the Appalachians, Interior Low

Plateaux, and Edwards Plateau. Aquatic beetles occur in the Edwards Aquifer. The Leiodidae is one of the important cave beetle families, with more than 18 troglobites in the genus *Ptomaphagus* in the southeastern United States. Much of the cavernicole diversity in the Coleoptera occurs in the Carabidae, with many troglophilic and troglobitic species especially in the genera *Pseudanophthalmus* which is especially rich in species in the Appalachians and Interior Low Plateaus and *Rhadine* (Figure 2) which is most diverse in the Edwards Plateau and occurs in caves throughout much of the southwestern United States. Several species of beetles in each of these two genera are closely associated with cave or camel crickets, and prey upon the eggs of those crickets.

North America's cave fauna is threatened by a variety of environmental problems associated with human activities. These problems, discussed in greater detail in the entry

Conservation: Cave Biota, include 1) microbial contamination and organic enrichment of karst aquifers through inadequate treatment of human, livestock, and poultry waste; 2) increased sedimentation of subterranean streams resulting from deforestation, agricultural activities, and development; 3) spills of toxic materials (e.g. petroleum and acids) from pipelines, tanker trucks, and freight

America, North: Biospeleology. Endangered species utilizing caves in the continental United States (excludes spring and groundwater taxa). Modified after Elliott (2000).

trains; and 4) reductions in recharge, resulting from increased impervious cover (buildings, roads, parking lots). Continued human population growth also increases impact visitation to caves (habitat degradation), as well as increased rates of cave destruction through quarrying and filling of caves. In the continental United States, 23 troglobitic invertebrates, one fish, one salamander and six bats—all taxa that utilize caves—are currently listed as federally endangered (see Table). In addition, a variety of other cave-dependent species have been proposed as candidates for federal recognition.

AMERICA, NORTH: HISTORY

Canada and the United States have karsts and pseudokarsts in many differing terrains, with differing landforms, and with differing spelean histories. In broad terms, the United States has about a dozen major calcareous karst areas and one in gypsum. Canada has almost as many in carbonate rocks, and several in gypsum (see entries on Canada and United States of America). The density and types of caves and other features vary markedly between the areas, and many of their subordinate units have their own history of exploration and study, and of significant events.

The study of cave exploration in the United States and Canada began in the 18th century with a simple mention of caves as curiosities. Longer accounts followed, largely in locally oriented tourist guides and early travel books and articles. Gazetteers pulled together scattered accounts, but these tended to be oriented toward specific localities. Eventually, caves were studied as interesting features of natural history; the study of caves for their own sake came relatively late. When a distinctly American speleology began to arise in the 19th century, it too was oriented toward local caves and their specific patterns and features. Thus it was largely independent of evolving European concepts, and perhaps somewhat suspicious of them.

In 1832 the erratic genius Constantine Rafinesque chose an inopportune time to utilize some of these European concepts. In the first systematic effort in American speleology (a classifica tion of the caves of Kentucky) he began with his own observations on swallet and resurgence caves, rock shelters and crevice caves, and saltpetre caves with huge passages. To these he added Buckland's theology-based antediluvial concepts of bone caves, and a brand-new concept of limestone as a lava-like rock extruded from caves through crater-like dolines. At least in part, Buckland soon abandoned the antediluvial theory, and hardly anyone else ever thought of limestone as an extruded rock.

At the north end of the Appalachian Highlands karst area, Kastning has shown how a host of little-remembered figures contributed significantly to American speleology through local observations and reports (Kastning, 1981). To some degree, similar unsung participants contributed to equivalent progress in other karstic areas. Benchmark papers (e.g. those of Nathaniel Shaler, William M.Davis, and other well-known later speleologists) thus evolved naturally from a broadly based continuum, rather than as isolated studies.

Shaw (1992) mentions several writers who, in addition to Constantine Rafinesque, merit special note in this period: W.S. Blatchley, H.C.Hovey and his son E.O.Hovey, Edmund Lee, David Owen, Louisa Owen, and Charles Wright. These notables were a small fraction of the potential list. Not all were obscure. Not all were academics. But all were fluent in English. Early French and Spanish reports (for example, on what now is Florida Caverns, in 1693), were almost entirely unknown to pioneer American speleologists.

In the United States, the first wave of interest in caves was based largely on the pioneers' need for nitrates to manufacture gunpowder. The second wave began in Kentucky, Indiana, Virginia, and New York in the 1880s, peaked around the turn of the century, and ebbed at the time of World War I. The third began to gain momentum in the 1930s and 1940s and achieved unprecedented success after World War II.

The Europeans founded their initial settlements along the Atlantic coast and its rivers, with littoral and riverside caves being the first to be found. Important riverside caves included Cave-in-Rock on the Ohio River, Indian Cave on the Tennessee River and the largely forgotten Carver's Cave in what is now St Paul, Minnesota. Away from the rivers, small caves in Pennsylvania and in the Virginia highlands were recorded in the 1740s and 1750s.

The names of well-educated "founding fathers" of the United States are prominent in this early period. George Washington left his signature in a small cave near what is now Harpers Ferry, West Virginia. Thomas Jefferson made the first map of a US cave (Madison's Cave, Virginia) and a later edition of his celebrated book (1853) *Notes on the State of Virginia* reproduced the third and fourth American cave maps—of Madison's Cave and what now is Grand Caverns, Virginia, and of Mammoth Cave, Kentucky (Figure 1). Jefferson consistently used scientific principles to evaluate aspects of caves. His studies of remains of a ground sloth from Organ Cave, West Virginia—the first ever discovered—led to its scientific name: *Megalonyx jeffersoni*.

In the mid-18th century, "long hunters" (hunters from pioneer settlements who stayed away from home for up to several months at a time) and a few hardy settlers began making gunpowder from nitrates in caves in what was then western Virginia (see Gunpowder). During the American Revolution, several of these caves were briefly pressed into full production. Around the turn of the century, Mammoth Cave and dozens of others were explored for nitrates, with production eventually reaching a very large scale until the Kentucky producers were devastated by the New Madrid earthquakes. Then the entire nitrate market collapsed at the end of the War of 1812.

American cave explorers followed in the footsteps of early cavers of the French and Spanish eras, but apparently without learning anything from them. Constructive plagiarism by fledgling American literary and scientific journals and travel books kept literate Americans somewhat informed about European caves and concepts. But 20 years after the collapse of the nitrate industry, "cave hunting was little else than a bizarre and venturesome underground diversion" (Clarke, 1914).

Canadian caves were even less celebrated. One cave near Lake Ontario was mentioned (fancifully and apparently second hand) in Winterbotham's 1796 *View of the United States of America*. Two others were reported in Quebec, in 1822 and 1823, with a new discovery in Ontario in 1824 and a flowery account of a cave in Nova Scotia in 1836. Gibb's landmark: *On Canadian Caverns*, however, did not appear until 1861. The now-famous Steam Cave at Banff was not seen by a European until 1875 and most of the other long-famous Canadian Rockies caves were not encountered until after 1900. The hell-roaring Nakimu Caves were discovered in 1904; within a few years they were developed in an early version of ecotourism. Alpinist A.O. Wheeler led North America's first real alpine cave exploration in 1911, down 76 m of pitches in Arctomys Cave.

America, North, History: Figure 1.

1811 sketch map of Mammoth Cave, Kentucky, as reproduced in the 1853 edition of *Notes on the State of Virginia* by Thomas Jefferson. William R.Halliday Collection.

America, North, History: Figure 2. Horace C.Hovey, father of American speleology. From an 1871 portrait by a photographer named Thompson. William R.Halliday Collection.

In the rebel southern states of the United States, the American Civil War (1861–65) precipitated a renewed wave of exploitation of saltpetre caves, and interest heightened throughout the reunited nation. Notable academic geologists, archaeologists, and biologists like Nathaniel Shaler and A.S.Packard, published landmark reports in 1876 and 1888.

However, it was a middle-aged clergyman, Horace C.Hovey, who triggered the second major wave of American speleology. Beginning in 1878, his writings had an impact unmatched in American spelean history. Hovey began caving as a youth but pursued it only intermittently. Nevertheless he dominated American speleology for 35 years. To the public he brought genial, unexaggerated accounts with which each reader could identify. His timing was fortunate: cave diggers broke through into Virginia's magnificent Luray Caverns shortly after publication of his 1878 article. When the news broke, *Scientific American* magazine rushed him to Luray for a scoop, and suddenly Hovey had enough material for his famous 1882 book *Celebrated American Caverns*. It became the most influential American cave book of all time. Almost overnight he became "final in experience and judgment in that phase of science now designated by the unlovely term speleology" (Clarke, 1914).

Hovey never travelled west of Arizona's Grand Canyon, but his wave of enthusiasm swept across the entire country. Show caves sprang into existence as far away as California. Back home in Indiana, W.S.Blatchley published the first state-wide report on caves. In 1900, E.S.Balch followed with *Glacières, or Freezing Caverns*, the first exhaustive American work on cave meteorology.

The Hovey wave ebbed during World War I, but a new wave of interest began in 1925 when Floyd Collins died in a detached part of Mammoth Cave. Later that year, members of the Explorers Club light-heartedly sought the end of Virginia's Endless Cavern, with considerable publicity. Publicity also was building at Carlsbad Cavern, where the ill-fated Nicholson Expedition of 1930 provided another prolonged media event—and triggered the creation of Carlsbad Caverns National Park. Raconteur Russell Trall Neville lectured widely in the 1930s, and Clay Perry's books and articles about American caves brought still further cave consciousness to a wide audience.

In the scientific world, notable papers by Weller (1927) and William M.Davis (1930) strongly stimulated speleogenetic thought in the United States. Within a few years, Swinnerton, Gardner, and Malott all provided the beginnings of a new, ongoing flood of papers expanding Davis's concepts in specific localities. That of J Harlen Bretz in 1942 was especially significant. From it, ordinary American cavers learned to read the silent language of speleogenetic sequences. More recently, contribu-tions by William B.White, Arthur Palmer, and Ernst Kastning are among many meriting special mention.

State-wide cave reports began to appear. Ralph Stone's *Caves of Pennsylvania* was published in 1930. Soon it was followed by McGill's *Caves of Virginia* and W.E.Davies's *Caves of West Virginia* and *Caves of Maryland*. Bretz's *Caves of Missouri* and many others followed.

The word "speleogenesis" broke into print in 1960 at a symposium where the old concept of speleogenetic cycles was laid to rest (Halliday, 1960). (Kyrle had used its German equivalent by 1923.) Also advanced at that symposium was a then-heretical concept: not all karstic caves have precisely the same origin.

Extensive US participation in international speleological congresses accelerated in 1981 when the 8th was convened in Kentucky. The purely American brand of speleology became more and more internationalized. With an extensive publication programme culminating in the appearance of the internationally edited book *Speleogenesis* in 2000, the National Speleological Society took on a leadership role in international speleology.

The National Speleological Society was founded in 1941. After World War II, the third wave of American speleology rose to new heights. The number of recorded caves skyrocketed; 8000 are now listed in the state of Tennessee alone. New US depth records were repeatedly broken in the Rocky Mountains, then surpassed by Lechuguilla Cave at 478 m (the vertical ranges of long lava tube caves don't count; see Volcanic Caves). That depth wasn't much by world standards, but the Cave Research Foundation of especially dedicated explorers (an offshoot of the National Speleological Society) pushed the mapped length of Mammoth Cave to 587 km by 1996, by far the greatest in the world. And a barely separate segment of its system—Fisher Ridge Cave—reached 161 km in 2001.

Opened in 1986 by two years' digging, the crystalline magnificence of Lechuguilla Cave somewhat distracted attention from its statistics. With 176 km currently mapped, it became the third longest in the United States.

The explored length of "little" Jewel Cave in South Dakota increased rapidly to 204 km, surpassing neighbouring Wind Cave (just over 160 km). Even California, not renowned for its caves, was found to have a long cave: Lilburn Cave at 27 km and another which is 367 m deep (Bigfoot Cave).

Progress in conservation has been no less important. Most Americans think in terms of national parks and monuments rather than World Heritage Sites, but three caves or groups of caves have been designated as national parks (Mammoth Cave, Carlsbad Caverns, and Wind Cave). Four others are national monuments: Jewel Cave, beautiful little Timpanogos Cave in Utah, Oregon Cave, and Russell Cave in Alabama (primarily an archaeological reserve, but also with notable karstic features). When Mount St Helens National Volcanic Monument was created, the Caves Basalt Lava Flow comprised one of its three units, and many other American and Canadian national parks and monuments are karstic or pseudokarstic.

In Canada, cave studies in the 20th century followed a somewhat different route. The arrival of Derek Ford and other keen British cavers at McMaster University provided an international scientific flavour long lacking in the United States. They also brought in their special skills and determination, and experience in alpine karsts. Soon a secondary Canadian centre of speleology was spun off to Calgary, and the famous Nakimu Caves soon lost their status on the list of deep Canadian caves. In the 1960s and 1970s, three of the five deepest caves in Canada were discovered, explored and/or studied in the Canadian Rockies: Arctomys Cave, Castleguard Cave, Yorkshire Pot, and later, Close to the Edge Cave. Castleguard Cave—Ford's speciality and Canada's longest—was mapped for 20.1 km. A member of his team found that it ends with ice plugs from a major glacier overhead. Even in the remote Northwest Territory, Quebec cavers and members of Ford's group found several caves over 1 km long in the isolated Nahanni National Park. Here, Grotte Valerie is notable for its exceptionally diversified underground climate.

Meanwhile in Quebéc, the vigorous and well-organized Société Québecois de Spéléologie was formed in the early 1970s, with a distinct French flavour (Beaupré & Caron, 1986). It soon became noted for excellent scientific and educational programmes, but found itself frustrated by the lack of large caves in Quebéc. Its activities soon became thoroughly international.

Another caving centre developed in and near Victoria, British Golombia. With an initial impetus in the early 1960s from Clarence Hronek in Vancouver and Seattle's

Cascade Grotto of the National Speleological Society, several vigorous groups emerged in the 1960s, 1970s, and 1980s. Vancouver Island now has the greatest number and density of caves in any Canadian region, including five each from the dozen longest and dozen deepest caves in Canada.

Cave diving in the continental United States began to come of age in 1953, in enormous underwater cave passages in Florida. Pleistocene mastodon and other paleontological remains were found at the start of a huge underwater borehole at Wakulla Spring. Here, current explorations are more than 5 km from the entrance, with an average depth of nearly 100 m *en route*. Garry Salsman and Wally Jenkins are acclaimed for early achievements here. The nearby Woodville Karst Plain system may be far larger, with more than 20 interconnected spring entrances and a claimed underwater length of 32.9 km in 2001. The longest recorded underwater traverse in Florida appears to be 4268 m, between Big Dismal Sink and Cheryl Sink. Elsewhere, cave diving in the remarkable karstic springs of the Ozark Plateau has shown that several are outlets of other huge karstic conduits at depth, reached by underwater corridors sloping uniformly downward from the swirling springs. In Nevada, however, the National Park Service forbids diving in the amazing Devil's Hole, so its remarkable depth remains unmeasured. The late Sheck Exley is widely credited with the primary role in advancing American cave diving, with Bill Stone noted for technological advances.

Biologists initiated systematic study of gypsum caves in Kansas in the mid-20th century. In the great gypsum karst of Texas, David Belski subsequently began an extensive geomorphological project, still ongoing. Interest in crevice caves and other limestone landforms resulting from deeply buried gypsum karst in northeastern Arizona is largely recent. In Canada, gypsum caves are widespread but interest in them has been desultory. An apparently world-class example in Wood Buffalo National Park is full of very cold water, and the others all seem to be less than 300 m long (D.Ford, personal communication, 2001).

Interest in American and Canadian pseudokarst and pseudokarstic caves has been sporadic. William R.Halliday, Donald Davis, Louise Hose, and the Colorado, San Diego and Southern California Grottoes (Chapters) of the National Speleological Society have provided notable leadership. The smooth, waterpolished surfaces of Greenhorn Cave and other granite stream caves of California have been appreciated by local cavers, but the talus caves in the Pinnacles National Monument have received more publicity. Regions especially noted for piping caves include Oregon's John Day country, Texas's Palo Duro Canyon, and the Anza-Borrego area of southern California.

More than a century ago, Israel Russell found lengthy glacier caves in Alaska, with a subglacial river about 50 km long coursing beneath the entire width of the Malaspina Glacier's piedmont. Direct scientific observation in Alaskan glacier caves shows a lack of progress since the 1970s. The Paradise Ice Caves—large glacier caves on Mount Rainier—were commonly visited by 1908, and its summit geothermal firn caves saved the lives of the first party to ascend it. The geothermal summit caves of Mount Rainier and Mount Baker were primarily investigated by Eugene Kiver in the 1970s. The glacier containing the Paradise Ice Caves shrivelled, re-expanded, and then disappeared completely during the last decades of the 20th century, though in 2001, the caves were reported to be re-forming in firn.

AMERICA, SOUTH

Compared with other continents, South America contains relatively small areas of carbonate, probably less than 2% of its total surface. Carbonate karst is concentrated within the ancient plateaux of central Brazil and in a few scattered areas of the Andean countries, although some small bodies of carbonate rock are dispersed throughout the continent (Figure 1). Nevertheless, there are some important South American karst areas with significant caves (see Table), including the world's best-developed quartzite karst (see Quartzite Caves of South America).

Venezuela is second only to Brazil in the area covered by karst scenery. The Roraima quartzite occupies a major part of the country's southern sector, hosting impressive vertical caves on the top of quartzite towers (known locally as tepuis), which rise abruptly from the rainforest. Many deep fissure-like caves and massive shafts occur in this area. Carbonate karst is concentrated in the northern coastal mountains of the Andean zone, the location of *c*. 95% of all caves recorded in Venezuela. In this area, karst is developed in carbonate rocks of Jurassic-Tertiary age, mostly as isolated outcrops usually of local extent, surrounded by noncarbonate rocks. The most significant karst is developed in five areas: Oriental, Central, Falcon, Andes, and Perija. In the Oriental area, the best-developed karst occurs in the Caripe-Mata de Mango area in the state of Monagas, where about 30 caves are developed in Cretaceous limestone. Venezuela's most celebrated cave, the 10 200 m long Cueva del Guácharo is located in this area, protected since 1949 by the Alejandro de Humboldt Natural Monument. The central part of this area hosts significant caves in the metamorphosed limestones of the Cordillera de la Costa (Coastal Range), for example, the 4292 m long Cueva Alfredo Jahn.

In the Falcón area, karst occurs in the San Luis and Serranía Churuguara mountains. The former area shows well-developed karst topography on Oligocene reefal limestones. Many deep caves occur within this zone, such as the 305 m deep Haitón del Guarataro. The Andes area shows Cretaceous reefal limestone at Humocaro, La Azulita, and Guaraque. The karst region of the Sierra Perijá, close to the Colombian border, has recently yielded major caves. In this area, lower Cretaceous limestones outcrop in a very wet rainforest environment. Many active caves exist in the area, including Venezuela's longest known cave, the 18200 m long Cueva del Samán and many other important caves such as Cueva Sumidero La Retirada (6080 m long), Cueva los Encantos (4600 m), and Cueva los Laureles (4300 m).

America, South: Figure 1. Main areas of carbonate and quartzite karst in South America.

Little is known about karst in Surinam, Guyana, and French Guyana. Carbonate rocks appear to be absent, although the Roraima quartzite does extend towards Guyana. Short caves in granite and under laterite (ferricrete) layers have been noted in French Guyana.

Over a hundred caves have been recorded in Colombia. Carbonate karst occurs mainly within the Cordillera Oriental, where isolated karst areas contain a number of significant caves. The best-known area lies in the Santander Department, where some major vertical caves have been recorded, among them the renowned Hoyo del Aire, a 120 m deep, 100+m wide pit which gives access to a massive passage terminating at a depth of 270 m, and the 4926 m long Sistema Hermosura, Colombia's longest cave. In southern Colombia, a small karst area hosts the Cueva del Indio (3507 m long) and the important Cueva de los Guácharos (1000 m long), both of which have been protected since 1960 by the Cueva de los Guácharos National Park. One significant sandstone cave has been explored in the Tolima area—the Cueva del Cunday, which is 850 m long and 160 m deep.

Carbonate karst in Ecuador is concentrated mostly in the Oriental sector of the Andes. The Cretaceous limestones of the Napo, Pastaza, and Morona Santiago provinces host most of

America, South: The longest and deepest caves of South America, as at January 2003.

the c. 400 caves known so far. The Napo Province hosts many caves, including the 2460 m long Cueva de San Bernardo. The Pastaza Province is home to several caves, but difficulties of access have precluded systematic exploration. The deepest and longest caves in Ecuador are located in the Morona Santiago area. The Cueva de los Tayos de

Coangos is 4800 m long and 201 m deep. The same region contains the 2305 m long Cueva de Shimpiz. Important lava caves occur in the volcanic Galápagos Islands. Most of the 67 caves that were recorded up to 1988 are concentrated in Santa Cruz Island, including the 3010 m long Cueva del Cascajo and the partially commercialized 2331 m long Cueva de Gallardo, the most important lava tube cave in South America.

Carbonate crops out in many areas of Peru, although some of the best-developed karst lies in the northern and central region. The country is noted for its high-altitude karst, some of which occurs as high as 4800 m in altitude. In the northern portion of the country, significant caves occur in the Cajamarca area, one of the most important being the hydrological system known as Uchkopisjo, with a combined length of 2350 m. The San Andrés de Cutervo area has been a National Park since 1961 and contains, among other caves, the Gruta de los Guácharos (1134 m long and 180 m deep) and the 334 m deep El Tragadero (Figure 2). Southeast of the town of Cajamarca there is a highaltitude karst area (4000–4200 m in altitude) with an extraordinary collection of deep pits, many with depths around 200 m. The area near the town of Tarma (Central Peru) hosts the Millpu de Kaukiran, the second deepest carbonate cave in South America (407 m deep and 2141 m long). Its resurgence is the Gruta Huagapo, the longest Peruvian cave at 2396 m in length. Ongoing exploration in an area in south-central Peru has yielded South America's deepest carbonate cave, Sima Pumacocha, which is 638 m deep.

There are only a few karst areas in Bolivia, but the most well-known area is the Torotoro Karst near Cochabamba, which comprises Cretaceous limestones hosting the Gruta Umajalanta, the deepest and longest cave in the country at 4.6 km long and 164 m deep. Other nearby caves include the resurgence of Chiflonkkakka and the 154 m deep Caverna Huayllas. The area belongs to the Torotoro National Park, which was established in 1989. There are some areas of gypsum and sandstone karst in the country, which host respectively the 413 m long Gruta de San Pedro and the 350 m long Gruta San Miserato. Precambrian carbonates also occur near the border with Brazil, at Puerto Suarez. These outcrops have received little attention to date and no significant caves have yet been noted.

The most important karst zone in Paraguay is located near the border with Brazil, where Precambrian dolomites form a

America, South: Figure 2. The large open sink of the Rio Charcay at the Tragadero de San Andes in the high Andean karst of Peru. (Photo by Chris Birkhead)
cone karst with isolated hills above the alluvial plain of the Paraguay River and its tributaries. A number of caves have been explored in this area, none of which is of a significant length. Uruguay is of little speleological importance due to the near absence of carbonates. The best-known cave in the country is the 41 m long Cueva de Arequita, developed in granite and located near the town of Minas.

The Chilean karst is characterized by extreme climatic conditions. Limestone, gypsum, and salt are known to outcrop in the hyper-arid Atacama Desert (precipitation of around 1 mm a^{-1}) in northern Chile. Surface karst features have been noted in these rocks, and the Cueva del Valle de la Luna, in salt, comprise two separate caves respectively 500 and 250 m in length. At the southern end of Chile, the Patagonian region hosts some spectacular marble karst, especially on the islands of Diego de Almagro and Madre de Dios (see Patagonia Marble Karst, Chile), under high precipitation (*c*. 7000 mm a^{-1}) and extreme conditions of wind and temperature. Unique wind-controlled karren have been observed, and recent exploration in the Madre de Dios has yielded the 376 m deep Perte du Futur. Near Puerto Natales, the celebrated Cueva Mylodon is probably South America's best-known paleontological site. The cave is a massive passage 200 m long and 100 m wide, developed in conglomerate, where well-preserved ground sloth and human fossil remains have been studied since the end of the 19th century.

Only 1000 km² of Argentina is made up of karst, which is a fairly small area for such a large country. The most important carbonate and gypsum areas occur in the provinces of Mendoza and Neuquén. The two most important carbonate areas are the Las Brujas region, near Malargüe, Mendoza, with the 1343 m long Cueva de las Brujas, a cave of supposedly hypogene origin (Forti, Benedetto & Costa, 1993), and the Cuchillo Cura area in Las Lajas, Neuquén, home of the country's longest cave, the 3433 m long Sistema Cuchillo Cura. Gypsum karst occurs in La Yesera del Tiromen and Curymil, both in the Neuquén Province, and at Sierra de Reyes and Sierra de Cara Cura in the Mendoza Province. The most significant gypsum cave in Argentina is the 853 m long Cueva del León in Las Lajas, Neuquén. Some lava caves also exist, such as the Cueva de Doña Otilia in Malargüe, Mendoza, at 838 m in length.

Brazil contains the largest area of karst in South America. Carbonate karst occupies c. 200000 km², mostly distributed in the southern half of the country. The majority of the karst develops over Precambrian carbonates, under a seasonal climate (with a rainfall of between 500 and 2000 mm a⁻¹). The Bambuí karst (see Bambuí Karst, Brazil) is the largest carbonate area in the country, hosting about half of the c. 3500 known caves, including some of the country's most significant caves. The Una Karst, located mostly within a semi-arid area, in northern Bahia State, is home to the longest cave in South America, the 97 km long Toca da Boa Vista (see entry on Boa Vista, Toca, Brazil) besides significant caves in the vicinity of the town of Iraquara. In southern Brazil, the outcrops of the Açungui Group contains many major active caves in tropical rain forest, including the world's tallest cave entrance at Gruta Casa de Pedra (215 m, Figure 3). Caves in this area are generally very well decorated (Figure 4), and most of this area is protected by the Upper Ribeira and Jacupiranga State Parks (Karmann & Ferrari, 2000). In western Brazil, many caves have been identified in the isolated carbonate hills of the Corumbá and Araras Groups, including important

America, South: Figure 3. Part of the entrance to Casa de Pedra cave, Ribeira karst, Brazil. The entrance is thought to be the highest in the world at 215 m. The stream-sink at the bottom left leads to a fine river passage. (Photo by John Gunn) flooded caves near the town of Bonito. Other important carbonate areas include Cretaceous limestones of the Apodi Group in the northeasternmost part of Brazil, and karst developed over freshwater carbonates of the Caatinga Formation, in northern Bahia State.

Brazilian quartzite caves occur mostly in the eastern portion of the country (see Quartzite Caves of South America), and comprise the deepest and longest caves known in this type of rock. Sandstone karst is widespread throughout Brazil, from the

America, South: Figure 4. Fallen stalactite block in Casa de Pedra cave, Ribeira Karst, Brazil. The block appears to have detached slowly and rotated through 180° landing upside down on the floor. (Photo by John Gunn) southern provinces to Amazonia. The best-developed areas lie in rocks of the Furnas and Botucatu formations, including the 1400 m long Caverna Aroe Jari at Chapada dos Guimarães, Mato Grosso State. In Amazonia, the Prainha area has some long sandstone caves, such as the 1297 km long Gruta Planaltina. The longest sandstone cave in Brazil is currently the 1633 m long Toca das Confusões in the semi-arid region of the state of Piauí. Another cave of note is the 1600 m long Caverna dos Ecos, developed in mica schists (Karmann, Sánchez & Fairchild, 2001). Caves in granite, talus, bauxite, and under laterite have also been recorded.

AMERICA, SOUTH: BIOSPELEOLOGY

South America, with an area of 17800000 km² mostly within the tropical zone and a high diversity of physiography from lowland forests to semi-desert high mountains, encompasses several regions of biological megadiversity. The subterranean fauna was therefore predicted to be accordingly rich and diversified due to the diversity of potential

colonizers. Intensive, systematic biospeleological studies started late in comparison with Europe and North America. However, rapid progress has been made in the last 30 years.

In 1799, the naturalist Alexander von Humboldt made the first written reference to a South American cave animal, the oilbird or "guácharo" (*Steatornis caripensis*), from caves in Venezuela. Other naturalists travelling throughout the continent in the 19th century occasionally mentioned cave animals, especially bats and birds. By the end of that century, the first South American troglobite, the blind catfish—*Pimelodella kronei*, was described from caves in southeastern Brazil. During the first half of the 20th century, biospeleology in South America was mainly restricted to occasional descriptions of taxa from caves scattered across the continent. Extensive studies started in the 1950s and 1960s, with foreign expeditions to several countries in addition to efforts by some native biologists, especially in Venezuela, and later in Brazil. Brazil currently has the best-studied cave fauna in South America, following intensive studies starting in the 1980s that ranged from faunistic surveys to community studies and to investigation of the biology of different taxa.

Based on such studies, ecological and evolutionary patterns began to emerge, revealing that differences with respect to temperate cave ecosystems were less than previously assumed. Although the taxonomic composition of subterranean communities differ as a consequence of biogeographic factors, ecological and evolutionary mechanisms and processes appear to be similar. Caves with huge amounts of guano produced by very large colonies of bats and echo-locating birds, frequently cited as characteristic of tropical regions, are not as common in South America as generally assumed. As observed in temperate areas, many caves studied in South America are oligotrophic, with food resources for cavernicoles represented by vegetal debris, relatively small guano piles, and dead and living epigean organisms accidentally entering caves or carried in by water (streams or percolating water).

The most frequent subterranean taxa found in continental South America are presented here, organized by ecological affini-ties. Some taxa are distributed throughout the continent, whereas others are restricted either to fully tropical, warm caves (>22°C) to the north of Tropic of Capricorn, or to subtropical to temperate caves in southeast Brazil, Uruguay, and Chile.

South America is remarkable for its chiropteran (bat) diversity, only equalled by that in Southeast Asia. Many bat species frequently use caves, especially phyllostomids that include frugivorous, nectarivorous, insectivorous, carnivorous, and haematophagous species. In inhabited karst areas with livestock, vampire bats may be particularly numerous in some caves. Different kinds of bat guano support distinct communities of invertebrates; it is noteworthy that vampire bats, with their distinctive black guano due to their specialized diet based on blood, are exclusively neotropical. Other trogloxene mammals include didelphids (e.g., the four-eyed opossum, *Philander opossum*, the river otter (*Lontra longicaudis*), and rodents such as the water rat (*Nectomys squamipes*), spiny rats (*Proechmys*), and agouti (*Agouti paca*). In northwest South America, oilbirds form large, noisy colonies nesting in some caves. Their "guano", actually a mixture of faeces and regurgitated, partially digested fruits, supports rich communities of detritivorous invertebrates. Barn owls and some other birds are observed in caves throughout South America, but never far from entrances. Among invertebrates, it has been shown that large opilionids (harvestmen) of the genus *Goniosoma* form trogloxene populations in southeast Brazil, reproduce near the entrances, and leave caves regularly to feed.

Most terrestrial invertebrates regularly found in South American caves are omnivorous/detritivorous troglophiles. Conspicuous macroinvertebrates include phalangopsid crickets, mainly Endecous, cockroaches (in warm caves), harvestmen, and millipedes; rhaphidophorid crickets, typical of North temperate caves, have been found in Chile. Their predators are mainly spiders, which present a high diversity in South American caves-33 out of 54 families occurring in the neotropical region have been recorded in Brazilian caves. The most frequent are large wandering ctenids (mainly Ctenus), sicariids (Loxosceles), and web-building pholcids, theridiosomatids (mainly Plato), and theridiids. Additional predators are centipedes, reduviid bugs and, in fully tropical caves, amblypigids (especially the large Heterophrynus) and scorpions. Among detritivores, cave millipedes are also diversified in South America, including Polydesmida (e.g., chelodesmids), pseudonannolenids, and spirostreptids. Most cave harvestmen are gonyleptids, especially pachylines; cosmetids, agoristenids, and cranaids are found in fully tropical caves.

Soil animals are typically found in sediment banks, concentrating in plant debris and animal matter deposited on these banks or on rocky surfaces. These include earthworms (e.g., enchytraeids), the ubiquitous springtails (isotomids, paronellids, entomobryids, arrhopalitids) and mites, campodeid diplurans, oniscidean isopods (mainly phylosciids, platyarthrids, and styloniscids), millipedes, larvae of tineid moths, larvae and adults of beetles such as cholevids (usually on animal matter), and ptilodactylids. Their predators include predaceous mites, beetles (e.g., carabids, pselaphids, histerids, staphylinids), pseudoscorpions (mainly chernetids), small spiders (e.g., ochyroceratids, hahniids), centipedes, and, in tropical caves, schizomids. Some species are mainly found in guano, certain taxa being restricted to or showing strong preference for particular kinds of guano (e.g., *Acherontides* springtails, larvae of *Drosophila, Fannia*, and *Psilochaeta* flies in vampire bat guano; cydnid and lygaeid homopterans, and lithobiomorph centipedes in frugivorous bat guano).

As expected in view of their overall diversity, beetles and flies are the most diversified cave insects in South America. Several families of small to medium-sized predaceous and detritivorous beetles have been recorded. As in temperate karst areas, the predaceous carabids and the detritivorous cholevids are among the commonest cave beetles; however, the subgroups that contribute with the highest diversity in most temperate caves—trechines within carabids, bathysciines within cholevids, including many troglobitic (exclusively subterranean) species—are rare in South American caves. Several familes of dipterans have been recorded in South American caves, including psychodids, chironomids, keroplatids, sphaerocerids, phorids, milichiids and muscids.

Nymphs and larvae of flying insects such as chironomid flies, mayflies, and caddisflies live in cave streams. Their adults, which may attain very high population densities at certain times of the year, are captured in the webs of spiders and of larvae of keroplatid flies. In addition to immature insects, the aquatic fauna includes adult heteropterans (e.g., veliids) and beetles (e.g., elminthids, dytiscids), molluscs such as hydrobiid gastropods, and crustaceans. Among crustaceans, amphipods, mainly bogidiellids and hyalellids, are frequent in both streams and phreatic water bodies throughout South America. Other crustacean taxa have more localized distributions:

spelaogriphaceans in phreatic water bodies from southwest Brazil; Calabozoa isopods in phreatic waters from Venezuela and northeast Brazil; the anomuran *Aegla* in cave streams of southeast Brazil; and crabs mainly in northwest South America. Shrimps are rare in South American caves, usually as accidental or trogloxene occurrences.

The total diversity of terrestrial troglobites in South America is moderate, much lower than the observed in Northern hemisphere temperate caves especially for some groups such as spiders and beetles. The great majority of South American terrestrial troglobites evolved from soil animals—several springtails, isopods, a few campodeid diplurans, rare thysanurans, chthoniid pseudoscorpions, a few, generally small spiders, beetles (mainly pselaphids and carabids), and polydesmida diplopods. Other terrestrial troglobites are harvestmen (gonyleptids in Brazil, agoristenids in Venezuela, a triaenonychid in Argentina), a few cockroaches (Venezuela and Brazil) and a cixiid homopteran (Argentina).

On the other hand, South America is relatively rich in aquatic stygobites, including both stream-dwelling and phreatobic crustaceans (syncarids, amphipods, isopods, spelaeogriphaceans, decapods such as *Aegla* anomurans, and pseudothelphusid crabs), hydrobiid gastropods, a few planarians, and fishes. South America is distinguished by its richness of stygomorphic fishes. At least 19 exclusively subterranean species are known, mostly Siluriformes (catfishes). The most frequent are catfishes of the genus *Trichomycterus* from Brazil, Venezuela, Colombia, and Bolivia; armoured catfishes of the genus *Ancistrus* from Brazil and Venezuela; and heptapterine catfishes from Brazil. In addition, several epigean stygomorphic species (with reduction of eyes and pigmentation) have been found in turbid rivers of the Amazon Basin.

While the cave fauna is better known in Brazil, the interstitial aquatic fauna has been better surveyed in countries such as Venezuela, Argentina, and Chile. A diversified stygobitic crustacean fauna including several species of copepods (mainly harpacti coids), ostracods, syncarids, isopods (e.g., protojanirids in Argentina) and amphipods (bogidiellids, ingolfiellids), in addition to hydracarians, have been found in interstitial habitats.

As proposed for temperate karst areas, paleoclimatic fluctuations resulting in periodic elimination of epigean populations and, consequently, isolation of troglophilic populations in subterranean habitats (which they colonized during more favourable periods) and subsequent allopatric speciation, have been evoked as a major cause of diversification of the South American troglobitic fauna, at least for terrestrial taxa. In the case of aquatic troglobites, there is evidence that other isolation mechanisms such as stream capture, or even parapatric or sympatric speciation, may also be important.

AMERICA, SOUTH: HISTORY

The relationship between man and caves in South America precedes the arrival of the first Europeans at the end of the 15th century. South American inhabitants did not appear to have strong cultural ties with caves and karst features in the same way as the Maya of Central America and Mexico (see America, Central: Archaeological Caves), but nevertheless there is numerous evidence of use of caves by prehistoric civilizations. Throughout the Brazilian karst, cave entrances were used as shelters from the end of the Pleistocene/beginning of the Holocene, and many of the country's most important archaeological sites are located in karst areas. Some caves were apparently used as burial sites, as large numbers of human remains have been located in selected sites within caves. In Venezuela, the indians of Caripe have hunted the Guácharo or oil bird (*Steatornis caripensis*) inside caves since at least 3500 BP (Perera, 1976). The vocabulary of some indian cultures in eastern Brazil also records a few words that designate karst features, such as *itararé* ("hollow rock") and *anhonhecanhuva* ("water that sinks").

Following European colonization there were some sparse references to caves, mostly in Venezuela, during the period 1500–1700. The majority of the descriptions refer to caves with some kind of indian usage. The first recorded reference to a Venezuelan cave dates from 1548 when Diego de Vallejo and others entered a cave in the state of Trujillo (Urbani, 1989). In 1579, in the same area, Alonso Pacheco and others gave a description of Indian rituals in a cave (Urbani, 1993). The Cueva del Guácharo (Venezuela) has the longest and richest history of any cave in South America. It was probably first visited in 1659, and the first published reference dates from 1666 (Urbani, 1996). Since then, numerous visitors of varied scientific relevance have described the cave, among them Tauste (first description of the cave in 1678), Jiménez Perez (1773), Ibarra (1795), Humboldt and Bonpland (1799), Grisel (1834), L'Herminier (1834), Codazzi (1835), Bellerman (first paintings of the cave in 1843), and Lisboa (first sketch of the cave in 1866) (Urbani, 1999). In 1691, Francisco de Mendonça Mar, a peasant of strong religious inclination established a shrine at a cave by the São Francisco River (presently known as Bom Jesus da Lapa), eastern Brazil, which has since become very popular as a pilgrimage site. Other caves in Brazil became centres of pilgrimage from the 18th century onwards. The Portuguese colonial government in Brazil financed the excavation of saltpetre in hundreds of caves throughout the country for the manufacture of gunpowder. Saltpetre exploitation in Brazil reached its climax during the 18th and 19th centuries, not ending until early in the 20th century.

Numerous naturalists and travellers, mostly Europeans, described caves in South America during the late 18th and 19th centuries, among them Ferreira, Eschwege, Pohl, Spix and Martius, Saint Hilaire, Lund, Liais, Fonseca, and Krone in Brazil; Goudot and Boulin and Cuervo in Colombia; Darwin at Galápagos Islands (Ecuador); Humboldt, Marcoy, Castelnau, and Raimondi in Peru; Berg in Uruguay; and Humboldt, Codazzi, Lisboa, Funk, Goering, Sievers, Scharfernorth, and Marcano in Venezuela. Among them, at least four deserve special mention. Alexander von Humboldt was the forerunner of cave science in Venezuela, following his visit (together with Bonpland) to the Cueva del Guácharo in 1799. Humboldt explored the first 422 m of this famous cave and described scientifically the unique Guácharo in his *Personal Narratives of Travels to the Equinoctial Regions of America during the years 1799–1804*. Humboldt also made a pioneering visit in 1802 to the Uchkupisjo caves in Peru.

In Brazil, the Danish naturalist Peter Wilhelm Lund laid the foundations of Brazilian cave science during intensive research in the caves of central Minas Gerais state from 1834 to 1844. Lund explored over 1000 caves in search of fossil bones. He hired the Norwegian Peter Andreas Brandt, a merchant turned cartographer and painter, who was responsible for surveying the caves and drawing caving scenes. At least 30 cave maps and cave and karst paintings have been preserved in Danish museums. Besides his more immediate interest in vertebrate paleontology, Lund was the first to suggest that cave saltpetre has its origins in nitrates in the soil above the cave, an explanation not adopted again until the 20th century. Lund also published valuable data on karst landscape, cave origin, cave sedimentation, and fossil emplacement in his series of "memories", published in Danish and translated partially in other languages (Lund, 1840).

The intrepid Father Romualdo Cuervo may well be considered the pioneer of vertical caving in South America after descending suspended in a basket, in 1851, the 120 m deep entrance shaft of Hoyo del Aire in Colombia. The Venezuelan chemist Vicente Marcano was the main explorer of Venezuelan caves in the 19th century, studying over 30 caves between 1883 and 1890. His immediate interest was the study of guano deposits for use as a fertilizer.

The 20th century saw the beginning of organized caving in South America. Several people made important contributions in both exploration and scientific studies of caves, including the first description of a troglobitic fish (in Brazil) by Miranda Ribeiro in 1907. In 1937 the first caving club of South America, the still active Sociedade Excursionista e Espeleológica (SEE), was founded in the town of Ouro Preto, Brazil. Other clubs followed in the 1950s and 1960s, such as the Speleology Section of the Sociedad Venezolana de Ciencias Naturales, formed in 1952, later evolving to the Sociedad Venezolana de Espeleologia in 1967. In Brazil, many of these earlier groups were emulated by expatriate cavers of European origin, mainly French. The 1960s also saw the

foundation of national caving bodies, the Sociedad Peruana de Espeleologia (now defunct) in 1965 and the Sociedade Brasileira de Espeleologia in 1969.

Cave exploration had a great impetus from the 1960s to the present. Most of the major caves of the continent were explored during this period by enthusiastic local caving clubs and foreign expeditions. The contribution of European expeditions was particularly significant in countries such as Colombia, Peru, Bolivia, and Ecuador, and they are responsible for the majority of what is known about karst and caves in these countries. Argentina also experienced a rapid growth of its speleology from the early 1970s, when many active clubs were formed. In 2000 the Federación Argentina de Espeleología was founded.

The present status of cave and karst research and exploration in South America varies between countries. Well-organized (but small) local caving communities exist in Argentina, Brazil, and Venezuela, with incipient or non-existent local speleology in the remaining countries. Cave and karst research is performed in a few universities and established postgraduate programs allow the regular production of theses on karst related topics. Cave exploration remains restricted mostly to the upper classes of financially debilitated countries, aided by frequent foreign expeditions. Nevertheless, the technical level of both exploration and science is equal with what is done in more developed countries, although performed on a much more restricted scale. Cave preservation is increasingly a topic of concern in South America. Several conservation areas have recently been designated to protect karst resources. In 1997 the Brazilian government created a centre for the protection and management of caves (CECAV), the first of its kind in South America.

AMPHIBIA

The characteristic features of amphibia (frogs, salamanders, and gymnophiona) include a slimy skin that is not well suited to prevent desiccation, and a body temperature corresponding directly to ambient temperature. It is not surprising therefore that amphibia are commonly encountered in the entrance or twilight zone of caves, which are characterized by high air humidity and buffered temperature changes. Many amphibia visit caves occasionally as temporary shelter from unfavourable environmental conditions outside, such as summer drought or winter frost. Caves are also used as breeding sites by some species. However, the impact of those visitors on the cave ecosystem is low since they only make a small contribution to the subterranean food web. More important for biospeleology are the troglophilic salamander species which are rarely found far from caves, and can also feed on subterranean invertebrates. Well-known examples are the Pyrenean salamander Euproctus asper, members of the genus Hydromantes in southern France, northern to central Italy, Sardinia, and California, the long-tailed salamander Plethodon longicauda, the common cave salamander P. lucifuga, the slimy salamander P. glutinosus, the purple salamander Gyrinophilus porphyriticus, all from the eastern United States, and Eurycea neotenes from Texas. The high number of amphibian species which can be observed occasionally in caves is in marked contrast to the low number of obligate cave dwellers or troglobites, which cannot survive outside caves. Only ten amphibian troglobitic species or subspecies are known and all are salamanders (see Table 1). Troglobitic members are restricted to two families, the Proteidae and the Plethodontidae. The Proteidae comprise six species, but only one is troglobitic. This is the famous blind cave salamander *Proteus anguinus* (see Amphibia: *Proteus*) from the Dinaric karst. The family Plethodontidae comprises about 246 species and is distributed mainly from North America down to northern South America, with a few members in Europe. However, the nine troglobitic taxa are restricted to the United States. Cave salamanders share some morphological characteristics with the other group of troglobitic vertebrates, the cave fishes (see Pisces entry). Advanced cave-adapted forms have reduced eyes and body pigmentation, a slender body, and a comparatively large, anteriorly depressed, shovel-like head with a large mouth. Cave plethodontids show a trend to markedly elongated thin legs, giving them a fragile appearance. With the exception of *Proteus* which may reach up to 40 cm in length, all other cave salamanders are small, rarely exceeding 15 cm.

Amphibians are generally characterized by a life cycle with two stages: an aquatic larvae which metamorphoses into a terrestrial adult after some time. With the exception of only two species, Gyrinophilus subterraneus and the cave salamander Typhlotriton spelaeus, all other troglobitic salamanders usually attain sexual maturity without metamorphosis, i.e. they remain aquatic for the whole life and retain some larval characteristics, such as the feathery external gills and a fin-shaped tail. Because of the blood in the capillaries the external gills appear brightly red and are in sharp contrast to the whitish body. The persistence of a larval body form in the adult is called neoteny. It seems that this life strategy is advantageous in subterranean habitats since approximately half of all known neotenic salamander taxa are troglobitic. However, the reasons for this adaptation are still not fully understood and may even differ between the species. Food scarcity in the caves may play an important role. Salamanders tend to eat any prey they can handle. In caves these are usually crustaceans, insect larvae, snails, and worms, but occasionally also other salamanders-even cannibalism has been observed. Although troglobitic vertebrates are usually small they are nevertheless the largest predators in the subterranean community and therefore at the top of the food chain or web. Hence, the energetic costs of metamorphosis might be too high and selection would act towards prolonging the larval phase. Another argument might be that food scarcity in the terrestrial habitat is usually stronger than in the aquatic habitat. Accordingly, neotenic salamanders that remain aquatic can exploit the more reliable food source. Climate may also have an influence on the development of neoteny. For example, the neotenic troglobite *Eurycea tridentifera* lives in caves of the Edwards Plateau in central Texas.

Typhlotriton spelaeus	Southwestern Ozark Plateaus (Springfield and Salem Plateaus) of southwest Missouri, southeast Kansas, northeast Oklahoma, and northwest Arkansas, United States

This area is not very suitable for amphibians because it is very dry. Therefore, a surfaceliving close relative, Eurycea neotenes, can only survive in damp headwater canyons, springs, and cave entrances. This troglophilic species exhibits a remarkable plasticity in its life cycle because some populations are completely neotenic while others have a variable proportion of metamorphosed animals. It seems that the reliability of spring discharge is the decisive factor. Only under conditions of a permanently sufficient discharge is metamorphosis an advantageous strategy. Springs with strong discharge fluctuations only support neotenic populations and if the discharge becomes too low the animals retreat into the underground spring. The evolution of the permanent cave dweller Eurycea tridentifera potentially started this way. A very remarkable life cycle can be observed in the cave salamander or Ozark blind salamander Typhlotriton spelaeus. This species has the largest distribution area of all troglobitic plethodontids and can be found in food-rich caves of the southwestern Ozark Plateau. T. spelaeus still exhibits metamorphosis as a life history characteristic. The larvae possess well-developed functional eyes and a marked body colouration. They usually live in cave entrances or even outside where they feed on small invertebrates. With the onset of metamorphosis after 2-3 years the animals retreat deep into the cave. Colouration becomes pale and the eyes are overgrown by the eyelids. In addition, the photoreceptors in the retina degenerate, i.e. the animal becomes blind. Also as adults the animals stay close to the water. They feed on terrestrial insects, isopods, and snails. It is thought that all troglobitic salamanders lay eggs instead of giving birth to free-living larvae. The internal insemination probably happens via a spermatophore which has been produced and deposited by the male and is taken up by the female. Not all troglobitic salamanders live in "real" caves, i.e. in caverns accessible to man. Some, like the Georgia blind salamander Haideotriton wallacei or the Texas blind salamander Typhlomolge rathbuni inhabit groundwater and are usually found only in wells after pumping activities. T. rathbuni is regarded as the most cave-adapted and phylogenetically oldest troglobitic plethodontid with a supposed Miocene origin. It shows the highest degree of eye reduction and the longest limbs. The animals move very slowly, stalking around on their

thin legs with the large head held high to sense every possible prey organism in the surrounding. Like all aquatic salamanders, *T. rathbuni* possesses well-developed sensory organs for smell, taste, mechanoreception, and even electroreception. If disturbed the animal swims away and tries to hide.

Most salamanders encountered in caves are legally protected and should not be collected. They are potentially at risk due to restricted distribution and low population sizes. Water pollution and excessive groundwater pumping are serious threats for these fascinating animals.

AMPHIBIA: *PROTEUS*

Proteus anguinus anguinus, popularly called the blind cave salamander or "human fish" due to its pink skin, is the sole species of the genus *Proteus*, and is only found in Europe. It is the largest, most remarkable, and world-famous model for troglobites. The distribution of *Proteus* is entirely within the Dinaric karst; nearly 200 localities, from the lower reaches of the Isonzo-Soča River in Italy in the northwest through to the southern part of Slovenia to the Trebišnjica River in Herzegovina in the southeast are known (Sket, 1997). As noted in Folklore and Mythology, *Proteus* were once considered to be the offspring of dragons.

Proteus is an obligate neotene and preserves some larval or immature characters in adulthood; the major reason for cessation of its metamorphosis, as in other obligate neotenes, probably lies in the insensitivity of its tissues to thyroid hormones. (Neoteny is retention of some larval or immature traits in adulthood; metamorphosis is a series of postembryonic changes involving structural, physiological, biochemical, and behavioural transformations.) *Proteus* retains three pairs of outer gills, two pairs of gill slits, an integument with many larval characteristics, and typical visceral skeletal elements. It has an extended, narrow body and a reduced number of digits, that is three on the anterior legs and two on the posterior legs. *Proteus* shows some general troglomorphic characteristics: specialization of the sensory organs, elongation of individual body parts, especially the disproportionate growth of the head in length, reduced eyes, skin

depigmentation, slow metabolism, resistance to starvation, increased lifespan, and probably the reduction of intraspecific aggressive behaviour. Proteiids characteristically possess no maxillae (i.e. the upper jawbones in vertebrates). Absence of maxillae is clearly paedomorphic (the phenomenon in which larval or immature features of ancestors become adult characteristics of descendants).

Proteus anguinus parkelj ssp. nov. from southeastern Slovenia differs from *Proteus anguinus anguinus* in its dark pigmentation, better-developed eyes, and many other morphological characteristics. This black, non-troglomorphic form was discovered in 1986 and has been attributed to a subspecies (Sket & Arntzen, 1994). Further research on the distribution and the racial polymorphism within *Proteus* is in progress. However, allozyme analysis also revealed the probability of speciation within this genus.

The embryonic development of *Proteus* takes about 130 days at 11°C, and larval development takes about 100 days at the same temperature (Durand & Delay, 1981). The water temperature in its natural habitat varies from 8°C during the winter to 11°C in the summer and autumn. They reach sexual maturity in about their 16th year. Owing to their slow metabolism, their lifespan may be as long as 70 years. Nutritional research on *Proteus* in its natural environment has proved that it is carnivorous, and has determined the main organisms on which it feeds, i.e. Crustacea, Insecta larvae, and Gastropoda. Its extraordinarily low metabolic rate, typical of troglobites, reflects its complete adaptation to conditions in cave habitats (Istenič, 1986).

Those sensory organs that have not undergone regression and for which proper stimuli are expected to be found in the underground waters of the Dinaric karst include the inner ear, the lateral line system, and sensory receptors that detect variations in the Earth's magnetic field, all of which are worthy of study (Bulog, 1989a, 1989b; Istenič & Bulog, 1984; Schlegel & Bulog, 1997; Bulog & Schlegel, 2000). In *Proteus*, these sensory organs, including the chemoreceptors, obviously play an important role in orientation, searching for prey, intraspecies communication, and mutual recognition.

Little is known about the hearing of *Proteus*, but occasionally observed reactions to sounds have suggested a hearing capacity, especially underwater. This would be of adaptive value in dark caves—in order to recognize particular sounds and to locate prey. Recently performed behavioural studies on the hearing ability of *Proteus* (Bulog & Schlegel, 2000) indicate that unpigmented specimens showed the greatest sensitivity to sounds at *c*. 1.5 kHz, while the black specimens were most sensitive to sounds at about 2 kHz. The fact that *Proteus* reacts spontaneously and consistently well to sounds demonstrates the biological significance and adaptive value of its underwater hearing.

The lateral-line sensory system is an aggregation of epidermal sensory organs scattered over the head and along the body in fish and aquatic amphibians. It includes ciliary mechanoreceptive neuromasts and electroreceptive ampullary organs. The discovery of ampullary organs in *Proteus* indicated that it is a candidate for passive electroreceptivity, which may play an important role in animals in underground water habitats (Istenič & Bulog, 1984). Behavioural experiments have confirmed that *Proteus* is sensitive to weak electric fields (Schlegel & Bulog, 1997).

Recently, some behavioural evidence of sensitivity to the orientation of the Earth's magnetic field has also been found. It is not yet known whether the magnetic field is detected by electroreceptors, or if the magnetoreceptivity is based on a different sensory mechanism.

The visual system undergoes some degree of regression in most cave animals. Among different changes in the eye structure, such as degeneration of the lens and optic nerve, it often includes changes in the structure of photoreceptor cells. Continuous darkness is known to result in the degeneration of outer segments in the retinal as well as in pineal photoreceptors. *Proteus anguinus anguinus* has small eye rudiments, seen as black dots, which lie buried deeply under the skin. The retina, lens, and vitreous body are strongly reduced in size and complexity in comparison to non cave-dwelling salamander species. Although eye development begins normally in the embryo, in the larval stage it is retarded and the degeneration becomes soon evident (Durand, 1971). Light and electron-microscopic studies of the retina of dark-coloured *Proteus* specimens led to the initial comparative analysis of the differentiation of these sensory organs (Bulog, 1992).

Proteus anguinus anguinus has a zone of less-pigmented skin on the anterior-dorsal part of its head. This zone is even more obvious on the head of the black subspecies *Proteus anguinus parkelj*. These pale areas are very sensitive to directional pointsource illumination and are located above or in front of the pineal gland. The pineal organ of the lower vertebrates is a photosensitive organ with many functions. Mediated by the pineal hormone melatonin, it controls circadian rhythms, gonadotropic activity, and body colour changes. It contains photoreceptor cells, which in their general features resemble retinal photoreceptors. In cave animals, which live under conditions of permanent darkness and constant temperature, the role of the pineal organ as a circadian pacemaker would be expected to become biologically useless.

Proteus has played a significant role in biospeleological study, both in the wild and in captive populations. The comparison of *Proteus anguinus anguinus with* its non-troglomorphic relative, the sighted and black-pigmented *Proteus anguinus parkelj*, is expected to provide new evidence about the development of photoreceptor structures in cave animals. The species is unfortunately threatened by water pollution and unscrupulous international dealers, despite being listed in the CITES convention, which prohibits trade in rare wild animals. The species is also protected under Slovenian law, and listed as vulnerable in the World Conservation Union (IUCN) Red List of Threatened Species.

ANCHIALINE HABITATS

Anchialine (anchihaline) cave habitats are located in water-filled voids near the coast, where there is a demonstrable marine influence shown either by mixohalinity (different brackish salinities) or by the presence of marine-derived animal species (Sket, 1996). The hydrological connections to the sea—as well as to the land—are underground, and there is restricted contact between the water body and the open air. Anchialine cave waters may function as corridors to open anchialine pools (Holthuis, 1973). The distinction between anchialine and marine caves is not always clear. A cave with euhaline (purely marine) water should only be considered as an anchialine habitat if it contains troglomorphic species. Riedl's (1966) concept of the marginal cave also included a theory about its origin, which differs from the archialine cave concept.

Most bodies of anchialine cave water have been observed in tropical to warmtemperate regions. The caves mostly developed during sea-level lowstands in the Pleistocene (see Speleogenesis: Coastal and Oceanic Settings); they retained the freshwater influx from the land, while the subsequent sea-water influx changed their ecology. Anchialine habitats in coral reefs and coastal lava fields have a different origin, but a similar morphology. Blue holes, anchialine pools, metahaline pools and some other habitats may exhibit some characteristics of anchialine cave waters. In particular, some stygobites may be present in these habitats, due to a diminished number of competitors in the generally unfavourable conditions of anchialine habitats.

Ecological Conditions

Besides the mixohalinity itself, one of the most striking abiotic characteristics of anchialine waters is their stratification (Figure 1). The primary stratification is in salinity; the extreme upper and lower layers may be limnic and euhaline (marine) respectively. This depends on the influx intensities of fresh and marine water, and therefore will change throughout the year or even within one day.

Great differences in the densities of waters of variable salinities prevent any mixing of layers, which might otherwise be expected during changes in temperature. Stratification is usually gradual, with a thin layer of rapid transition (the halocline) between the denser and the less-dense layers. This stable salinity and density stratification also allows stratification in other characteristics. Consumption of oxygen by animals and bacteria, particularly on the bottom, causes oxygen depletion. This deficit may be neutralized by exchange with sea water at the bottom and by diffusion from the surface in the uppermost layers, and therefore remains most extreme in the halocline layer, where there is least mixing. Accumulation of hydrogen sulfide may coincide with the oxygen deficit. If the water body is exposed to temperature changes associated with the atmosphere at the land's surface, a temperature inversion may occur in the winter, with the upper layers being the coolest (Sket, 1986).

Anchialine Cave Habitats:

Ecological stratification in the anchialine lake of the cave Šipun near Cavtat, Croatia, in September 1975. Depth in metres; temp, temperature in °C; Sal, salinity in ppt.; Ox, oxygen content in mg l^{-1} ; S, Saxurinator sketi (Gastropoda); O, Oligochaeta; A, Acanthocyclops venustus, T, Thermocyclops dybowskii, and D, Diacyclops antrincola (Copepoda); Sa, Salentinella angelieri, Hf, Hadzia fragilis, and N. Niphargus salonitanus (Amphipoda); Mh, Monodella halophila (Thermosbaenacea); M, Metacyclops trisetosus (Copepoda); Ab, Ammonia beccarii (Foraminifera); C, Caecum glabrum (Gastropoda): F. *Filogranula annulata*. The population density is measured in estimated relative values.

Fauna

The main biological characteristic of this habitat is the presence of stygobitic species together with species of marine provenance. The unfavourably diverse and variable degree of mixohalinity further reduces the number of species that can colonize these

habitats. On the other hand, contact with the faunistically rich marine ecosystem potentially increases diversity.

The number of species known from anchialine cave waters increased from less than 30 in the 1960s (Riedl, 1966) to *c*. 150 in the 1980s, and close to 400 species in the 1990s. The Table shows species numbers by groups; numbers of known taxa are still increasing rapidly, especially for copepods, but also for amphipods and other groups. Similarly to hypogean waters in general, crustaceans are by far the most prevalent group in anchialine waters. This is evident in the list of known species as well as within any local fauna. Since some crustaceans are larger (except for vertebrates) and more numerous than most other cave inhabitants, Crustacea are also the most important group in relation to biomass. In the Šipun Cave (Cavtat, Croatia; Figure 1) which exhibits a complete salinity range from limnic to polyhaline, nine crustacean species and only six other species have been found. The ratios of individuals and biomass between crustacea and other species is even more striking—at least 10:1. In Cave C-28, on Cape Range Peninsula, Australia, only five species have been found below the pycnocline (the thin layer of a rapid density change), with all but one (a fish) being crustaceans. In the anchialine waters of Quintana Roo, Mexico, 12–14 species have been identified, all of which are crustaceans.

It is difficult to assess exactly the number of anchialine species. While the distinction between anchialine cavernicole and interstitial fauna is seldom ambiguous, it is often questionable if a non- or slightly troglomorphic animal is anchialine or only a marinebenthic generalist. As in freshwater cave habitats, some (here necessarily euryhaline, or able to live in waters of a wide range of salinities) stygoxenes and stygophiles occur in anchialine waters. Another facultative presence—again euryhaline—are stygobitic species from freshwater caves. A very common non-specialized marine species in anchialine caves in the Caribbean is the fish *Eleotris pisonis*, and freshwater species include the copepod

Crustacea		Other groups

Tanaidacea	2		

Anchialine Habitats: Approximate numbers of essentially anchialine species known in the 1990s (according to Sket, 1996).

Isopoda	30–35
Amphipoda	80–95

Diacyclops bicuspidatus odessanus and amphipod *Niphargus hebereri*, both found in anchialine caves on the Dinaric coast. It may be fortuitous that some of these animals may be known only from anchialine caves, without necessarily being confined to them.

Most stygobitic (and usually troglomorphic) species are related to and probably derived from the extant shallow-marine fauna—most amphipods (e.g. Hadziidae) and shrimps (e.g. *Typhlatya* spp.). Representatives of some groups show close phylogenetic relationships to deep-sea species. These include the cavernicole Tantulocarida, Mictacea (*Mictocaris halope* in Bermuda), Decapoda Anomoura (*Munidopsis polymorpha* in the Canary Islands) and some other decapods, and some Ostracoda (*Danielopolina* spp.). The only higher taxonomic group limited to anchialine caves and therefore of a non-identifiable origin seems to be the Remipedia. Some specialized inhabitants of anchialine caves which are unquestionably invaders from fresh waters are known mainly from the Dinaric coast; for example, the amphipods *Niphargus salonitanus* and *N. pectencoronatae*.

General Comments

Some characteristics of anchialine fauna make them very important for understanding the colonization of less favourable habitats, such as non-marine and hypogean waters. The largely anchialine shrimps *Typhlatya* spp. are among the few members of the mainly circumtropical freshwater family Atyidae, which are still marginally marine. Amphipoda in anchialine waters are globally represented primarily by the family Hadziidae and only a few other species, although a huge variety of amphipod groups come into contact with these habitats. A number of groups are represented circumglobally (resembling the extension of the ancient Tethys ocean), including Remipedia, Thermosbaenacea, genera *Typhlatya* (Decapoda), and *Spelaeomysis* (Mysidacea). The strictly stygobitic species—such as *Niphargus hebereri* from the Dinaric coasts—may build dense populations in sunlit areas if no epigean competitors are present. Some delicate elements—such as Thermosbaenacea—may show different apparent salinity preferences, depending on the presence or absence of competitors.

ANNELIDA

Annelida or annelids are segmented, usually worm-like animals without articulated legs. The body consists of a chain of body segments, or somites; in front of them is the head lobe or prostomium, behind is an anal lobe or pygidium. A paired ventral nerve cord extends along the body with a pair of ganglia in each somite. The mouth and the anus are close to both ends of the body, connected by a straight intestine.

The main groupings of annelids are Polychaeta and Clitellata. The predominantly marine Polychaeta are characterized by pairs of bifurcated limbs or parapodia on each somite, with appendages called rami on the parapodia, each ending with a bundle of chaetae (bristles). Polychaetes are gonochoristic, i.e. they have separate sexes. Clitellata lack parapodia, and are hermaphroditic. The basal subgroup of clitellates is Oligochaeta, where bundles of, or single chaetae, are still present in the wall of each somite and the coelomic cavity is normally segmented. Leeches (Hirudinea) developed from within oligochaetes. They are devoid of chaetae and their coelomic cavity is restructured into a system of tubes that replaces the primary circulatory system. Leeches possess an oral and a caudal sucker, used for locomotion.

Polychaeta or polychaetes are principally a marine group with few freshwater representatives, the latter being mostly hypogean. The free-swimming and worm-like "Errantia" (names within quotation marks are not real taxonomic units) are represented in marine, anchialine, and fresh cave waters, mostly in the tropics, by representatives of the family Nereididae. Nereids have short antennae and palpi on their prostomia, their evertible mouth cavity has strong, deeply forked, cuticular jaws. *Namanereis hummelincki* is a stygobitic nereid from marine or anchihaline habitats in the Caribbean while *N. beroni* has been recorded from a cave at an altitude of 1600 m in Papua New Guinea. Representatives of the "Archiannelida" family Nerillidae are common in interstitial marine waters and anchihaline caves. They may be a few millimetres long, usually with two palpi on the prostomium and with up to ten somites. Some *Nerilla* species are benthic, others are stygobitic or in the marine interstitial

Annelida: Figure 1. (A) Polychaeta: *Troglochaetus beranecki;* (B) Polychaeta: *Marifugia cavatica;* (C) Hirudinea: *Dina absoloni*. Reproduced with permission from Botosaneanu (1986).

habitat. *Troglochaetus beranecki*, 0.5 mm long, is widely distributed in fresh interstitial or cave waters in Europe, from Finland to northern Italy; it has been known since 1921. Similar species have been found in Japan and recently in North America.

The only known stygobitic representative of the substratebound "Sedentaria" group is the cave tube worm, Marifugia (*Marifugia cavatica*), the only freshwater species of the family Serpulidae. Marifugia secrete a calcareous tube of less than 1 mm external diameter; the first few centimetres are attached to the substrate, while the youngest parts are erect. Apically, feathery ciliated tentacles function as gills for respiration and filter feeding. The ontogeny starts with a ciliated, free-living larva which soon attaches to the substratum and develops a tiny tube. Marifugia are present patchily throughout the whole Dinaric karst. While some authors consider it to be an ancient marine relict in caves, it has recently been suggested to have invaded cave waters via extensive Pliocene-Pleistocene freshwater lakes in the region.

Oligochaetes are a group found in the soil, in freshwater, and in marine water. They possess chaetae, whose shape and position are taken into consideration when carrying out a systematic study, as are the position and morphology of the genital organs. Some aquatic (Haplotaxidae, Lumbriculidae, Naididae, Tubificidae, and Parvidrilidae), semiaquatic and terrestrial families (Enchytraeidae, Lumbricidae, and Ocnerodrilidae) are found in caves. The Lumbricidae are found in humid soil, wet guano, and in the sediment of underground watercourses and gours. They are generally considered to be trogloxenes. The terrestrial Ocnerodrilidae are found only in South American caves. The Enchytraeidae are common in cave waters with genera such as Enchytraeus, Cernosvitoviella, and Marionina. The Haplotaxidae are also present with the three genera Delava, Haplotaxis, and Villiersia, D. bureschi being largely distributed in Europe. The Naididae are present in caves with ubiquitous species; the Pristina and Pristinella genera comprise stygophilic species and some stygobitic species, found only in the Antilles. Lumbriculidae and Tubificidae exhibit a high level of diversity and comprise many stygobitic taxa. The presence of freshwater species belonging to the marine genera of Tubificidae (Tubificoides, Spiridion, Aktedrilus, Abyssidrilus, Gianius, and Phallodriloides) highlights the links between some groundwater taxa and their relatives in marine habitats.

The recently discovered holartic family of Parvidrilidae, which has only two species (the European stygobitic *Parvidrilus spelaeus* and the North American interstitial *P. strayeri*) highlights the relationship between this family and the Gondwanian Phreodrilidae.

The biodiversity of underground oligochaetes is rather high: up to 100 stygobitic species have been identified worldwide. Some subterranean Oligochaeta show characters probably related to their adaptation to a subterranean way of life, such as a reduction in body size (for example the stygobitic species of Phallodrilinae and Parvidrilidae), or in body diameter on the gonadal region, due to the shifting or the asymmetrical bending of the spermathecae.

Hirudinea (leeches) are represented in caves only by few blood-sucking species. These include troglophilic, mollusc-sucking representatives of the family Glossiphoniidae, such as *Glossiphonia complanata* in the Postojna-Planina Cave System, Slovenia. There are also some land leeches, Haemadipsidae, which suck bats, for example *Leiobdella jawarerensis* in Papua New Guinea and a *Haemadipsa* sp. in Yunnan, China; both are without skin pigmentation but retain pigmented eyes.

All eyeless cave leeches are predators of small invertebrates, for example *Haemopis* caeca of Haemopidae in Movile Cave, Romania. Most, however, belong to the family Erpobdellidae, moreover to the genus *Dina* or its phylogenetic vicinity. The epigean and troglophilic species *D. krasensis* is endemic to southwestern Slovenia and Croatian Istra, with a partially depigmented population in the Postojna-Planina Cave System. The oldest known (by Johansson, 1913) stygobitic leech *D. absoloni*, is eyeless and widespread in southeastern parts of the Dinaric karst. Other stygobitic *Dina* species and probably *Trocheta* species have developed from southeastern France—northern Italy—Dinaric karst—Bulgaria—Georgia. The *Dina-related Croatobranchus mestrovi* from cold (5°C) shafts in the Croatian Mt Velebit is extremely modified. It exhibits unique extendible tentacles around its mouth and *c*. 10 pairs of finger-shaped gills

along the trunk. Undescribed stygobitic erpobdellid leeches have been found in Texas and Japan.

ANTARCTICA

The first caver on Antarctica was probably Emile Racoviță, who arrived in the Peninsula in January 1898. An ice cave entrance appears in a photo taken during the Scott expedition in 191.1, but it wasn't until the mid-1970s that the first cave exploration took place. During the Tazieff expedition to Mount Erebus, some fumarole caves were explored in the volcano, near the US MacMurdo base. In the 1980s, some classic glacier caves, created by water flow, were explored in the Schirmacher Oasis, near the Russian base of Novolazarevskaya (Queen Maud Land). The caves, in the glacier front, consist of some outflow conduits draining internal glacier waters. Later, in 1985, other fumarole caves were explored on Mt Melbourne, by Italian glaciologists. These early explorations were made during the course of research with other objectives and the first caving expedition to Antarctica was in March 2000, when small ice caves (moulins) were explored in the Collins Glacier on King George Island, South Shetlands.

Karst phenomena in glaciers develop where the average yearly temperature is around 0°C, either at high altitudes or at high latitudes (see Glacier Caves and Glacier Pseudokarst). The whole Antarctic continent has an average yearly temperature well below zero; only the edge of the Peninsula and the surrounding islands are not far from the isotherm at 0°C. Hence there are only minor examples of typical glacial karst phenomena, such as moulins and bedières. However, there are also glacier caves in other parts of the continent, that are not formed by simple waterstreams, but by water flow, volcanic heat, local thermal imbalance, and by ice fractures.

Water Flow

Most glacier caves are formed by runoff, where melt water enters the glacier through a "moulin". These caves are endoglacial because they are excavated inside the glacier core. Antarctica is too cold to allow the formation of large, meltwater rivers. For example, the ablation zone in Collins Glacier (King George Island) has a very limited extension (up to 100 m above sea level) but in spite of this, small (<50 m deep) moulins are formed on the sides of the main ice stream falling into the sea. Also the streams are very small, with a typical discharge of 11 s^{-1} . In some regions of the main continent, yet to be explored, the seasonal runoff may be stronger and the interaction of meltwater streams with very cold ice may create morphologies different from the typical temperate glacier karst, in which small water streams can flow away almost everywhere.

Volcanic Heat

Some glacier caves form by volcanic heat released at fumaroles. These caves are subglacial and are carved on the contact of ice with rock. This cave type is well known in Iceland, where "warm" (0°C) ice tolerates the presence of meltwater. In contrast, the caves seen in Antarctica, on Mt Erebus and Mt Melbourne, formed in ice at -30 to -40° C, and so the water was immediately refrozen. However, strong airflow permits active sublimation, resulting in vapourization of ice in warmer areas and crystallization on cooler zones near the cave entrances. The main interest of these caves, explored for about 100 m, is in their biological material. They are temperate oases surrounded by an extremely adverse environment (the maximum yearly temperature is -20° C) and they host some endemic bacteria. All the areas around these fumarole caves are protected to avoid contamination: visitors are forbidden and special care is necessary to explore the caves.

Thermal Imbalance

Some very large caves have formed at the contact between cold glaciers flowing from the Plateau (-20° C) and warmer sea ice (at -2° C). The contrast in ice temperature results in strong differences in equilibrium vapour pressure in the adjacent atmosphere (~100 Pa at -20° C, and ~500 Pa at -2° C). In a closed cavity, separating two such contrasting ice bodies, the resulting vapour pressure gradient will result in significant sublimation and redistribution of ice. Marine salt probably plays a role, but further studies are necessary to understand these caves that can play a role in the breaking of floating ice tongues.

Ice Fractures

Crevasses in ice are largely tectonic in origin and are not normally classed as glacier caves. Crevasse depth depends upon temperature. For soft, temperate ice (0°C), the ice plasticity is high and the crevasse depths range from 25–30 m. However, when the ice temperature is lower, crevasses may be much deeper: at -50° C (ice temperature of the Antarctic Plateau) the crevasses reach 3–400 m. If these crevasses act as cold traps and are filled with the coldest winter air (-80° C), the depth may increase up to 700–1000 m. However, to date this has not been confirmed by exploration.

Although most of Antarctica is covered by ice, about 3000 m of horizontally bedded sedimentary rocks, ranging in age from Devonian to Jurassic, are exposed in the central Transantarctic Mountains. On the western flank of the Queen Elizabeth Range, beneath Mount Counts, the Lower to Middle Cambrian Shackleton Limestone crops out and is unconformably overlain by the Pagoda Formation (made up of tillite, sandstone, and shale). Lindsay (1970) describes a large depression, thought to be a doline, and a cave up to 6.2 m wide and 5.5 m high, that is completely filled with sediment of pre-Permian age. The site is remote and difficult to access but it is likely that similar paleokarstic deposits, and even open caves, may be discovered in the future.

APPALACHIAN MOUNTAINS, UNITED STATES

The Appalachian mountains extend for 3000 km from Alabama (United States) to Newfoundland (Canada). They contain significant limestone and dolostone formations, especially in western and southern areas, and commonly these are less than 300 m in thickness. There are many sinking streams because of the juxtaposition of carbonates with other rocks, and a large number of extensive cave systems have been found in strata that vary from flat-lying to steeply dipping.

The northern half of the Appalachians, north of New York, consist of relatively flat uplands with isolated mountain ranges. The Proterozoic and Paleozoic strata contain few carbonates and no long caves. The southern half of the Appalachians consist of a series of parallel mountain ranges with local relief of several hundred metres, and is divided into four zones. The eastern two zones, the Piedmont and the Blue Ridge, consist largely of Proterozoic and Lower Paleozoic metamorphosed sedimentary and volcanic rocks, with few carbonates and no long caves. The two western zones, the Valley and Ridge and the Appalachian Plateau, have many extensive caves, and more than 10000 caves have been documented in these two zones. The locations of the caves at least 5 km in length are shown in Figure 1, and are clearly clustered in certain areas.

The Valley and Ridge zone consists of long parallel ridges and valleys. Lower Paleozoic limestones and sandstones form the ridges and shales form the valleys. Stratal dips are often steep, with the result that many caves have linear patterns, being elongated along the strike. The caves of Burnsville Cove in Virginia are typical. Over 80 km of caves have been mapped within a small area in a 230 m sequence of Silurian and Devonian limestones. The principal caves are the Butler—Sinking Creek Cave System (28 km), which is largely formed along a synclinal axis, and the Chestnut Ridge Cave System (22 km), which is partly formed along the adjacent, parallel, anticlinal axis.

The Appalachian Plateau is an extensive area of mostly flatlying Carboniferous strata. The plateau is known in the north as the Allegheny Plateau and in the south as the Cumberland Plateau. Upper Carboniferous shales and sandstones outcrop across most of these plateaus, and are underlain by Lower Car-

boniferous strata which include limestones. The most extensive caves have been found in the 40–90 m thick Monteagle Limestone (from Alabama to Kentucky) and the 100–400 m thick Greenbrier Group (in West Virginia). Most of the long caves in the Monteagle Limestone are close to the western edge of the Cumberland Plateau. The outcrop of the Greenbrier Group varies in width from less than 100 m in northern West Virginia to more than 10 km in the south. In the latter area the strata dip gently to the west. Streams that sink along the eastern edge of the limestone have formed distinctive caves at the contact between the limestone and the underlying shale, with vadose passages being incised into the shales. These "contact caves" include Organ Cave (64 km), Scott Hollow Cave (43 km), and The Hole (37 km). Nearby are caves that have been formed by streams sinking at the top of the limestone, and these include Friars Hole Cave System (72 km) and Culverson Creek Cave (33 km).

Friars Hole Cave System is the longest known cave in the Appalachians (Figure 2). It is located close to the boundary of the Valley and Ridge and Appalachian Plateau zones, and bears features typical of caves in both zones. The entrances of the cave are found in a series of small limestone inliers along Friars Hole, a 200 m deep valley. A series of streams flow off predominantly

Appalachian Mountains: Figure 2.

Outline map of the Friars Hole Cave System in the Appalachian karst.

shales, with minor sandstones and limestones, and drain an area of 86 km^2 . These streams sink where they reach the Union Limestone, a 50 m thick member of the Greenbrier Group, which has a structural dip of 2°. The Union Limestone is composed principally of sparites and micrites, but has four impure beds which are 1–3 m in thickness and have a clay content of about 50%. The 30 m thick Pickaway Limestone underlies the Union Limestone. The sinking streams descend through the vadose zone in a stairstep fashion, descending joints and then flowing downdip to the northwest, perched on the impure beds for distances up to 100 m before descending on another joint. Much of the complexity of the cave is due to the large number of such inlets, and more than 250 have been mapped, of which about 100 currently carry water.

The recharge to the cave throughout its history has been dominated by flow from the sinking streams of Hills Creek and Bruffy Creek, which together provide more than half the recharge of the cave. These streams sink several kilometres to the northeast of the cave, and the water is seen in the cave as Rocky River, a large strike-oriented passage. A second drainage, in the central part of the cave, includes the streams sinking at the Snedegars, Toothpick, Rubber Chicken, and Crookshank entrances. The cave stream descends to the lower Pickaway where it is 80 m stratigraphically below the top of the limestone, but the cave is 188 m deep because it extends almost 2 km downdip from the cave entrances. There is a third major stream in the southern part of the cave, which includes the stream sinking at Friars Hole Cave. All three cave streams flow to a spring which lies 10 km to the southwest on Spring Creek.

The water table has dropped 130 m since the earliest passages in the cave were formed. Uranium series and paleomagnetic dating of speleothems puts the age of the earliest passages at about four million years, and since that time a series of strike-oriented trunk passages has formed in succession. Most of these major passages are roughly rectangular in shape, with heights and widths of 5–10 m. Many were formed at the intersection between low-angle thrust faults and either the Union-Pickaway contact or at the impure bed which is 5 m above it. As the water table dropped, old trunk passages were abandoned and new ones were formed, usually at the same stratigraphic horizon, but several hundred metres downdip and thus at a lower elevation. The exact sequences and interrelations of these major relict passages are difficult to determine because only a small fraction of the passages in the drainage basin have been found. Many major passages in the cave terminate at sediment blockages or breakdown. The complexity in Friars Hole Cave System is caused by multiple sinking streams with their associated loads of clastic rocks, a lithology of interbedded pure and impure limestones, and a long history of karstification, and is typical for major caves in the Appalachians.

ARACHNIDA

The Arachnida are one of the most important groups inhabiting subterranean environments. Not only are they extremely abundant and widespread, but also include a large number of species, several of which show troglomorphic adaptations. Most arachnids are active predators and are involved in the ecological equilibrium of the subterranean food web.

The class Arachnida consists of 11 extant orders, nine of which include cavernicolous species. The Orders Araneae and Acari are the main groups and each has a separate entry. They have colonized subterranean habitats worldwide and their adaptation to the hypogean world has yielded a large number of troglomorphic species. An entry on Minor Groups includes the Orders Opilionida and Pseudoescorpionida, which are abundant in most subterranean habitats, but include fewer troglomorphic species, and the Orders Scorpionida, Amblypygi, Schizomida, Palpigradida, and Ricinulei, which are scarce in subterranean environments, although no less interesting. The Orders Uropigia and Solifuga are the only groups that do not have cavernicolous representatives.

Several factors have influenced the adaptation of Arachnida to subterranean environments: the particular physical characteristics of this environment, the scarce energy available, and the fact that Arachnida are primarily predators. This adaptation has involved morphological changes as well as changes related to their life cycles. From a morphological perspective, the main adaptive changes are the reduction and loss of ocular structures, a marked or total loss of pigmentation and the lengthening of appendages. When considering life cycles, adaptation to the subterranean environment is reflected by a reduced metabolic rate, which results in the loss of the nocturnal rhythm, a lengthening of their life cycle, and a low reproductive rate.

CARLES RIBECA

ARACHNIDA: ARANEAE (SPIDERS)

Spiders are one of the most common groups inhabiting subterranean environments. They are predators, and are usually abundant inside caves, from the entrance to the deepest galleries. Not all species occurring in caves are exclusive to the subterranean environment: around 25–30% are accidentals (trogloxenes) and appear in or around the entrance zone; around 50% of the species are regularly found in caves but also occur in the epigean environment (troglophiles); and between 20–25% are strictly cavernicolous (troglobitic). These troglobitic species are the most interesting from a taxonomical and evolutionary perspective since they are, in many cases, the living representatives of ancient evolutionary lineages that are now extinct in the epigean environment.

The main morphological adaptations of troglobitic Araneae species are the reduction and loss of eyes, a remarkable or total depigmentation, and the lengthening of appendages. Their adaptation to the subterranean environment also affects their life cycle. Generally, they show a lengthening of their embryonic and post-embryonic development, as well as their adult life. Several interesting studies on this subject have been performed on troglomorphic species belonging to the genera *Phaneta* and *Anthrobia* in the United States (Poulson, 1981) and *Telema, Leptoneta,* and *Troglohyphantes* in Europe (Juberthie, 1985; Deeleman-Reinhold, 1978). In general, when compared to their epigean relatives, cavernicolous species show a low metabolic rate and decreased activity. Their reproductive effort is diminished, the number of eggs per brood is lower, and the eggs are considerably larger. As a result, cavernicolous species have adapted their biological parameters to the environment they inhabit: they regulate their energetic expense according to the amount of energy available in the subterranean environment.

Distribution

Spiders are very abundant in all subterranean habitats worldwide. Nevertheless, the number of species in each cave varies according to the latitude and biogeographical region. Caves in temperate climates rich in organic matter can host up to ten different species. In contrast, caves in subpolar regions are much poorer in energetic resources as well as in diversity. The areas richest in troglomorphic species are those of temperate climates, mainly Mediterranean: the Mediterranean region, central and southern United States, Mexico, Japan, and Korea. In the southern hemisphere, they are abundant in South Africa, Australia, and in several regions in continental Asia, although these are less known. Tropical areas show a high biodiversity but host a low number of troglomorphic species. Possibly, when the large karst areas in Asia, Africa, and South America are explored, the number of troglomorphic species will increase considerably.

Main Troglomorphic Groups and Species

The Order Araneae includes three Suborders: Liphistiomorpha, Mygalomorpha, and Arachnomorpha. Currently, there are 40000 spider species known, which are grouped into more than

Arachnida: Araneae: Figure 1.

Spermophorides justoi (Araneae: Pholcidae), a troglobitic spider from caves of El Hierro, Canary Islands. The Spermophorides genus has other cave-dwelling species occurring in Tenerife and La Palma. (Photo by Pedro Oromi)

120 different families. Half of the families have troglomorphic species, giving just under 1000 troglomorphic species in total.

The Suborder Liphistiomorpha occurs in Southeast Asia, from Japan to Vietnam, and comprises the spiders that are considered the most primitive: they have a segmented opisthosoma (rear part of body). This suborder does not include a large number of species, and only two are troglomorphic: *Liphistius batuensis*, from Batu Cave, Malaysia, and *Liphistius langkawi* from Thailand.

The Suborder Mygalomorpha is common in tropical areas. Some species colonize warm regions in temperate climates, although it is absent from cold climate zones. Species collected inside caves are generally nocturnal, living under rocks found in the entrance zone of caves. Although they may be abundant, most are trogloxenes, some are troglophilic, and a few are troglomorphic—all of which occur in tropical regions. Examples from the American continent and the Caribbean area include *Speleoctenizia ashmolei* from Ecuador, *Masteria pecki* from Jamaica, three species of *Euagrus* and six species of *Speleopelma* from Mexico, and *Troglotele caeca* from Cuba. Only one species has been described in Africa: *Aporoptychus stercoricola* (Guinea). From Australia and New Zealand there is *Troglodiplura lowryi* and *Hexatella cavernicola* respectively, and *Masteria caeca* from Asia (Philippines).

The Suborder Araneomorpha comprises most of the known spider species and is well represented in the subterranean environment. Many of its families are cosmopolitan, or worldwide in distribution, such as the Pholcidae, which are abundant in most caves of tropical and temperate regions in both hemispheres. Most Pholcidae species are troglophilic, but some are troglomorphic. The most common genera that include troglobitic species are *Pholcus* and *Spermophorides* (see Figure 1) in Europe; *Physocyclus, Modisimus, Anopsicus, Metagonia, Pholcophora,* and *Psilochorus* in Mexico, Jamaica, and Belize; *Priscula* in Venezuela; *Coryssocnemis* in Ecuador; and *Artema* in New Guinea.

The Telemidae are an interesting family since their troglomorphic species are distributed across temperate as well as across tropical regions. This fact suggests that the Telemidae are an ancient family, and some of their representatives can be considered as living fossils. *Telema tenella*, one of the most studied troglomorphic species, occurs in the eastern Pyrenees (France and Spain) and is the only Telemidae found in the European continent. Some other troglobitic species are *T. niponica* from Japan and *T. mayana* from Mexico, *Cangoderces lewisi* and *Apneumonella oculata* from the African continent, and several species belonging to the genus *Usofila* from the United States and New Caledonia.

The Leptonetidae are small spiders inhabiting small rock piles on the floor of caves as well as cracks and rough areas on the walls. Most species are troglomorphic. The most important genera in Europe are *Leptoneta*, *Teloleptoneta*, *Paraleptoneta*, *Protoleptoneta*, *Sulcia*, *Barusia*, and *Leptonetella*, which are distributed across the northern side of the Mediterranean basin, from the Iberian Peninsula to Turkey. In Asia, the main genera are *Leptoneta*, *Saturana*, *Falcileptoneta*, and *Masirana* (occurring in China, Japan, and Korea). American species belong to the genera *Leptoneta*, *Archoleptoneta*, *Neoleptoneta*, *Appaleptoneta*, and *Callileptoneta* (United States, Mexico, and Brazil)

Species belonging to the family Ochyroceratidae are spread across the southern hemisphere and they occupy the same niche as the Leptonetidae in the northern hemisphere. Ochyroceratidae are abundant among fallen leaves and vegetal litter in forest undergrowth, and are also common in caves, where several troglomorphic species have been described. Most of the troglomorphic species belong to the genera *Ochyrocera*, *Theotima*, *Fageicera*, and *Speocera* in South and Central America, the West Indies, and Hawaii; *Speleoderces* from Africa and *Simonicera*, *Psiloderces*, *Althepus*, *Theotima*, and *Speocera* from Asia.

The Dysderidae are a family with a Palaearctic distribution. They comprise several troglobitic species belonging to the genera *Dysdera* (see Figure 2), *Speleoharpactea, Harpactea, Stalita, Folkia, Stalagtia, Minotauria, Rhode,* and *Rhodera*. Troglomorphic species occur on the northern side of the Mediterranean basin, in North Africa, and in the Canary Islands.

The Linyphiidae are one of the most widespread spider families in the epigean environment. A large number of troglomorphic species are found in the northern hemisphere, most of them belonging to the genera *Troglohyphantes*, *Lepthyphantes*, *Porrhomma*, *Centromerus*, *Caviphantes*, *Thypholyniphia*, *Icariella*, and *Troglodytia* (Europe), *Walkenaeria* (Canary Islands), *Phanetta*

Arachnida: Araneae: Figure 2.

Dysdera unguimmanis (Araneae: Dysderidae) is by far the most troglomorphic among the eight cavedwelling species of the genus occurring in Canary Island caves. (Photo by Pedro Oromi)

and Anthrobia, (United States), Meioneta (Hawaii), Allomengea and Jacsonella (Korea), and Dunedinia (Australia).

The Nesticidae are spread across the northern hemisphere, as the Leptonetidae, but have also been recorded in Brazil. The main genera that include troglomorphic species are *Nesticus* (Europe, United States, China, Japan, Korea, and Ceylon), *Canarionesticus* (Canary Islands), *Typhlonesticus* and *Carpatonesticus* (Europe), *Gaucelmus* and *Eidmanella* (United States and Mexico), and *Nesticiella*, which is distributed across Japan, Russia, China, Vietnam, Central Africa, Hawaii, and Fiji.

The Agelenidae are abundant in tropical regions. Several troglomorphic species have been described in temperate areas: they belong to the genera *Tegenaria*, from the Western Mediterranean region, and *Cicurina* and *Blabomma* from Mexico, United States, Japan, and Korea.

The families Clubionidae, Liocranidae, Gnaphosidae, Lyco sidae, and Prodidomidae are poorly represented in subterranean environments, and most species are epigean. Nevertheless, some extremely troglomorphic exceptions exist, such as *Agraecina cristiani* from Movile Cave in Romania, *Brachyanillus liocraninus* from Spain, *Berlandia tenebricola* from Tanganyika (Clubionidae); two *Lygromma* species from the Galapagos Islands and *Herpsillus suavis* from Cuba (Gnaphosidae); and *Lycosa howarthi* and *Adelocosa anops* from Hawaii (Lycosidae).
The Theridiidae are a set of species closely related to vegetation and ground fauna. They are common in tropical caves. Most species are troglophilic, but there are some troglomorphic species such as *Achaearanea mundula*, and a few more belonging to the genera *Coscinidia* and *Stemops*, from New Guinea, as well as to *Steatoda* and *Pholcomma* from Australia. Some troglomorphic species from the genus *Theridion* have been described in oceanic islands (Azores and Galapagos).

Hickmania troglodytes, from Tasmania, deserves special attention: it belongs to the Austrochilidae family, considered the most primitive within the Suborder Araneomorpha.

The genera *Meta* and *Metellina* of the family Metidae are troglophilic, inhabiting caves in temperate regions worldwide. Several species belonging to *Loxosceles* (Loxoscelidae) and the families Theridiosomatidae, Ctenidae, Oonopidae, Tetrablemidae, and Anapidae, are also troglomorphic, inhabiting tropical caves.

ARACHNIDA: ACARI (MITES AND TICKS)

Acari (mites and ticks) and spiders are the most diverse and abundant groups of Arachnida in the subterranean environment. Over 45000 Acari species are recorded, and more than 1000 have been reported from caves. Most Acari found in caves are troglophilic. Considering their environment and their lifestyle, Acari occurring in subterranean habitats can be divided into three groups.

Acari Terrestria

This group includes those Acari that are totally or optionally free living and they are the most common and abundant group in subterranean environments and occur in most caves. Several species live in close relation to guano deposits, common in many caves. Bat guano may support densities of between tens of thousands and millions of Acari individuals per square metre. These are generally guanobitic, although some species are bat parasites during some periods of their lives, tending to be ecologically and evolutionarily related to the caves they inhabit. Some authors consider them as recent cavernicolous species (eucavernicolous). Another set of species comprises the typical ground species associated with other organic detritus. They are generally predators that consume Collembola and other microarthropods, eggs, and insect larvae, but can also feed on fungi or may be detritophagous or necrophagous. This second group includes many species for which only a few individuals are known and therefore neither their biology nor their ecological requirements have been reported. These forms are considered troglophilic or troglobitic depending on their external morphological characteristics. A lengthening of appendages and a lack of pigmentation are the most conspicuous adaptations to the subterranean environment.

Among the Acari terrestria the Notostigmata (Opilioacarida) are considered the most primitive group, showing abdominal segmentation. They are cosmopolitan and comprise 20 species, four of which have only been reported from caves (*Opilioacarus orghidani* and *O. vanderhammeni* from Cuba and *Siamacarus dalgeri* and *S. withi* from Thailand).

The Mesostigmata (Gamasida) are common and abundant in most biotopes. All are eyeless and the most common groups in caves are predators, but some are saprophagous or guanophagous. Some species are parasites of small rodents and insectivores. Most species can be considered as troglophilic, but there are several troglomorphic taxa, such as *Eugamasus cavernicola* (Parasitidae), a European neotroglobitic species, and 31 of the 50 species belonging to the family Uropodidae that have been reported from caves.

The Prostigmata (Actinedida) include seven different families. Most species are troglophilic, but there are several troglobitic taxa such as *Bonzia brownei* from England and *Ischnothrombium diploctenum* from Cuba. *Proterorhagia oztotloica* (Proterorhagiidae), from Mexican caves, shows an extraordinary adaptation to the subterranean environment. It has lost all pigmentation, its lateral eyes are absent, and its legs and chelicerae are lengthened. It displays highly developed sensorial setae.

The family Rhagidiidae includes 22 troglomorphic species belonging to the genera *Rhagidia* and *Poecilophysis;* they are cosmopolitan and predators. The North American genus *Foveacheles* includes several troglobitic species, as does the genus Rubostocheles. *Flabellorhagidia* and *Troglocheles* also comprise troglomorphic species, and *Troglocheles vandeli*, from France, is one of the most highly evolved troglomorphic species.

The Astigmata (Acaridida) also include some cave species. They tend to be saprophagous and/or fungivorous, or associated with bat guano. Most species can be considered troglophilic, although some are troglobitic. The Cryptostigmata (Oribatida) is the most common group recorded in the subterranean environment.

Acari Parasiti

Parasitic Acari that live in association with bats and other little mammals are common in caves; their evolution is related to that of their hosts. The Acari parasiti can be subdivided into three groups: (i) temporary parasitic species that are only known from caves and are adapted to the subterranean environment; (ii) temporary or periodically parasitic species that do not display any adaptation to the subterranean environment; and (iii) permanent parasites evolutionarily related to their hosts but not to the subterranean environment.

The first group interests us the most and includes ticks, Trombiculids, and some guanobites. They spend most of their adult life in cracks on the walls or in guano and they look for a host only for feeding. Generally, their parasitism is not extremely specific and they parasitize almost any bat species. Most species are well adapted to parasitic life but they do not display adaptations to the subterranean environment. Nevertheless, some species show an extraordinary morphological and physiological adaptation to the subterranean environment. Some Ixodid species, which are parasites of Chiroptera, show a noticeable lengthening of their appendages and develop at a relatively low temperature (15°C). About 30 cavernicolous species are known within the family Argasidae (Metastigmata). The families Spelaeorhychidae (specific Chiroptera parasites), Trombiculidae, and Wenhoekiidae (Prostigmata) include 210 species, most of them troglophilic.

The second group, comprising temporary or occasional parasitic species that do not display adaptations to the subterranean environment, parasitize rodents and insectivores (Family Laelapidae) or they may be specific Chiroptera parasites. They are exclusively haematophagous. Almost 100 species have been reported, and all of them are considered as troglophilic.

The third group's occurrence in caves is accidental and they are considered trogloxenes. They parasitize hairs, exocuticles, endocuticles, the cornea, nose, mouth, stomach, and intestines. Several authors think their coexistence is very ancient.

Hydracarina

Subterranean Hydracarina (or water mites) are primarily interstitial, although some may also inhabit the water table (Limnohalacaridae and some hydrachnellas). Most species found in the subterranean interstitial environment come into caves from epigean watercourses. The true subterranean Hydracarina (stygobites) originate from epigean watercourses but have adapted to the subterranean environment (hyporheic interstitial environment). They are closely associated with the grains of sand that are more or less in contact with the water flow. All subterranean Hydracarina are predators, feeding on insect larvae (mainly Chironomidae), copepods, ostracoda, and other aquatic microinvertebrates.

Adaptive characteristics shown include absence of visual structures (cornea and retina); a marked diminishment of pigmentation, although in some species the ocular pigment remains; and reduced size but a body elongation—some highly evolved species show a worm-like aspect that helps them move between the grains of sand. Unlike terrestrial cavernicolous species, subterranean Hydracarina show a shortening of the first three pairs of legs; the first pair of legs tend to be used as feelers. The fourth pair, far more robust, are used for moving. The stygobites have also reduced their reproductive effort: they produce fewer eggs per brood.

The Hydracarina (Suborder Actinedida) comprises ten superfamilies. The superfamily Hydrachnellae is the most abundant in the subterranean environment (several hundred species). The superfamily Halacaroidea includes 20 stygobitic species. The superfamily Stygotrombioidea includes 19 species, all of which are stygobitic. Several other superfamilies have subterranean representatives including Trombidioidea, Eylaioidea, and Hydryphantoidea.

ARACHNIDA: MINOR GROUPS

The following section provides a brief overview of Arachnida that occur relatively infrequently or are poorly represented in subterranean environments.

Scorpionida

The Order Scorpionida includes about 1300 species grouped into nine families, five of which (Chactidae, Vaejovidae, Diplocemtridae, Chaerilidae, and Ischnuridae) have troglomorphic representatives. The first records of cave-dwelling scorpions were from Sumatra (*Chaerilus cavernicola*) and Malacca (*Chaerilus agilis*). Three species have been recorded in Europe, although none of these can be considered as troglobitic. *Belisarius xambeui*, endemic to the eastern Pyrenees (France and Spain), shows a slight loss of pigmentation as well as a lack of its central eyes and a marked reduction of laterals, but it inhabits both hyogean and epigean habitats. The highest number of troglomorphic species is found in the Mexican karst, where ten species have been recorded. In addition, troglobitic species have been recorded from Ecuador, Sarawak, and Australia (the recently described Ischnuridae: *Liocheles polisorum*).

Pseudoscorpionida

The Order Pseudoscorpionida is composed of about 3000 species distributed worldwide, with the exception of polar areas. Pseudoscorpions are abundant in most subterranean habitats, and a large number of troglophilic species have been described. Troglomorphic species are not numerous, but they cannot be considered as scarce. The most common families in the subterranean environment are Neobisiidae, Chthoniidae (see Figure), Bochicidae, Vachoniidae, and Syarinidae. A spectacular lengthening of appendages, the absence of eyes, and a complete loss of pigmentation are common adaptations to the

subterranean environment. In some cases, due to the fact that life cycles are unknown, it is difficult to distinguish troglophilic from troglobitic species.

Troglomorphic species are abundant in the Mediterranean climate zone of the northern hemisphere (Mediterranean basin, United States, Mexico, Japan, and Korea). There are also records from South American caves, the West Indies, Australia, and Tasmania, although they seem to be less abundant. The presence or absence of cavernicolous pseudoscorpionida remains unknown in many regions of the world, and therefore the current distribution map will probably be modified in the future.

Opilionida

Harvestmen (Order Opilionida) are common and abundant in many subterranean habitats. About 5000 species are currently known, and 125 of these can be considered as cave dwellers, including 80 troglobitic species. The Order Opilionida is divided into three Suborders: Cyphophthalmi, Laniatores, and Palpatores.

The Cyphophthalmi are small and have similarities with Acari, possessing short legs and hard integuments. Just over 100 species have been described, of which 12 are troglobitic. The main family with cavernicolous representatives is the Sironidae. They inhabit temperate areas in the Northern hemisphere and

Arachnida: Minor Groups.

Tyrannochthonius superstes (Pseudoscorpiones: Chthoniidae), can be found in the lava tubes of Tenerife, together with other pseudoscorpions well adapated to cave life. (Photo by Pedro Oromí) include 22 species, all of them eyeless, of which ten troglobitic species occur in Europe. The Pettalidae include 41 eyeless species of Gondwanic distribution, with only one troglomorphic species, *Speleosiro argasiformis* from South Africa. Other families with troglomorphic representatives are Troglosironidae (*Troglosiro aelleni*) from New Caledonia and *Neogovea mexasca* (Neogoveidae) from Mexico.

The Suborder Laniatores is the most abundant, occurring in most regions of the globe, but appears to be more abundant in tropical zones. Its species are humicolous and lapidicolous, with large, spinous, and prehensile pedipalpi. The main groups including troglobitic species are the Phalangodinae (50 troglobitic species), which inhabit temperate and tropical areas in America, Europe, and Asia, and the Assamiidae, distributed across tropical regions of Africa and Southeast Asia. The Triaenonychidae, which includes 20 troglobitic species, have an austral distribution (Australia, New Zealand, Africa, and South America) although they also have a representative in the United States. The Trabunidae, which occur in Europe, United States, and Japan, include some troglomorphic species that are relicts from the ancient fauna that colonized the European continent. Finally, the Gonyleptidae and the Agoristeridae, with a Neotropical distribution, are abundant in South American caves, but they have very few troglomorphic representatives.

The Superfamily Palpatores is cosmopolitan, although it is notably more abundant in the Palaearctic region. The most important groups belong to the families Nemastomatidae, which has nine troglomorphic species in Europe plus two in the United States, and Ischyropsalidae, which has more than ten troglobitic species in Europe.

Finally, the Suborder Phalangodidea is constituted by the typical long-legged harvestmen, with a cosmopolitan distribution. Within this group, there are no troglomorphic representatives, although they are common and abundant in the threshold zone of caves.

Amblypygi

Amblypygi (whip spiders) are largely nocturnal and colonize caves readily. They are distributed across the tropical regions of America, Africa, and Asia. Their main features are a flat body and large, powerful, and spinous pedipalpi. The first pair of legs (antenniform legs) are very long, with sub-segmentation of both the tarsi and the tibia, which are used as feelers. Most genera include epigean and cavernicolous species, some inhabiting both hypogean and epigean environments. Some genera, such as *Stygophrynus*, appear to be restricted to caves. About 40 species, among over 100 Amblypygi species known, have been reported from caves. Nevertheless, only a few can be considered as troglobitic.

There are no real differences between epigean and cave species with the exception of a few cave species that have reduced eyes. In some cavernicolous species, the pedipalpi may be extremely elongated. In others, medial eyes are reduced in size (*Paraphrynus baeops*) or even absent (*P. velame*). Many species of *Paraphrynus* inhabiting Mexican caves show reduced medial eyes. A few *Charinus* species also have reduced eyes. *C.* (*Speleophrynus*) tronchonii has no median eyes and the lateral eyes partially reduced, and *C.* (*Speleophrynus*) bordoni is completely blind, both taxa being from Venezuela. A similar eye reduction has occurred in the genus *Tricharinus* from Surinam and Jamaica. The cave-dwelling African *Paracharon caecus lacks* eyes, but also inhabits termite nests.

There are also troglobitic species (*Charinides cubensis and C. wanlessi*) in Cuba. Other troglobitic species are known from Venezuela, Guinea, Zanzibar, Tanzania, and Bardera in Somalia.

Schizomida

The Order Schizomida includes more than 100 species with lucifugous (light-avoiding) and hygrophilic behaviour that are spread across the intertropical region. They are small, between 2 and 8 mm long. Their dorsal scutum is divided into three parts: pro-, meso- and metapeltidium. The opistosome has a long, multiarticulated flagellum that varies between species. They show a marked sexual dimorphism. The first pair of legs is long and thin, and used as feelers. Most Schizomida are endogean (inhabiting the soil zone immediately below the surface) and it is very difficult to tell troglobitic species from endogean ones.

A total of 32 species have been reported from caves, of which 25 can be considered as troglobitic. Most cavernicolous species belong to the genus *Schizomus* and troglomorphic species have been described from Mexico (Chiapas, Tamaulipas, Veracruz, and Yucatan), Guatemala, California, Cuba, Jamaica, Puerto Rico, Ecuador, Venezuela, Tanzania, Zanzibar, Rodriguez Island, and Angola. *Schizomus* is the most diverse and widespread genus. The genus *Agastoschizomus* also includes troglobitic species: *A. lucifer*, from Sierra de El Abra, and *A. huitzomolotitlensis* from El Sotano de Huitzomolotitlam, San Luis de Potosí, both from Mexico. Cave species have also been reported from Africa and Asia: *Trithyreus parvus* from Gabon and *T. pileti* from Batu Caves. Only one species is known from India, and two from Japan.

Ricinulei

The Order Ricinulei includes only about 30 species that are distributed in tropical and subtropical areas in the American continent and Western Africa. They are small (10 mm), flat, slow, eyeless, and cryptic (coloured to camouflage) and have a preference for humid environments. The only characteristic identifying troglobitic species is a slight lengthening of their appendages, which makes it very difficult to assign them to a clear ecological category.

Known species are grouped into three genera: *Ricinoides* (seven species from Western Africa), *Cryptocellus* (21 species from tropical and subtropical America), and *Heteroricinoides*, (two species from Venezuela and Colombia). There are ten cavedwelling species, of which nine belong to the genus *Cryptocellus* (eight from Mexico and one from Cuba); the tenth cave-dwelling species is *Heteroricinoides bordoni* from Venezuela. This group has not been reported from African caves.

Palpigradida

The Order Palpigradida comprises the smallest and most difficult to find Arachnida: they rarely reach 2 mm in length. They are agile and extremely fragile. Their most conspicuous characteristic is a long flagellum used as a feeler. Their pedipalpi are ambulatory and the first pair of legs is antenniform. All palpigradida are blind and totally depigmented. They are thought to be of intertropical origin.

The Palpigradida includes about 80 species, 27 of which have been found only in caves (21 from Europe, one from Cuba and five from tropical Asia). These 27 species can

be considered troglobitic: since all palpigradida are blind and lack pigmentation, it is difficult to distinguish between endogean and cavernicolous species. Generally, cavernicolous species tend to be bigger than endogean species, and they also show notably longer appendages (particularly the chelicera).

From a taxonomical perspective, the Palpigradida are divided into two families: the Protokoeneniidae, with two genera (*Protokoenenia* and *Triadokoenenia*), and the Eukoeneniidae, with four genera (*Eukoenenia*, *Allokoenenia*, *Koenenioides*, and *Leptokoenenia*). With the exception of Triadokoenenia and Leptokoenenia), the remaining genera are found in caves. The largest and most modified species belong to the genus *Eukoenenia*, which comprises the species that are most adapted to subterranean environments.

ARCHAEOLOGISTS

An archaeologist is defined as one who makes a "study of human antiquities, especially of the prehistoric period and usually by excavation" (*Concise Oxford Dictionary*). This entry reviews the life and work of eight of those who had the greatest influence on understanding the development of the human race before historical records began, using evidence from caves. No aspect could be more crucial than the antiquity of humankind. Until the 1850s, it was normal to believe that humans were a recent addition to the world. There was too little time since the Crea tion, then thought to have been some 6000 years ago, for humans to have existed at the same time as extinct animals, those destroyed in the biblical Flood. Georges Cuvier, with all his authority, had in 1812 expressly denied the existence of such early humans. So, included here is a succession of people who gradually came to realize that deposits in caves contradicted this belief. None of these researchers were what would now be called archaeologists. They were either geologists, priests, or doctors, taking an interest in this branch of natural history. Nevertheless, the work was archaeological and some of the most important ever to have taken place. Three more conventional archaeologists are also described.

Johann Friedrich Esper (1732–81)

Esper (Figure 1) was the parish priest of Uttenreuth, near Erlangen in Germany. Excavating during 1771 in the Bavarian cave of Burggaillenreuth, he found human bones together with those of cave bear and other extinct animals (Esper, 1774, p.26). He considered very carefully whether or not they were contemporary with each other, but concluded that he had insufficient evidence for such a momentous interpretation.

...I do not, however, suppose without adequate reason that these human remains are of the same age as the other animal petrifactions. They must have come together with the others by chance.

This extract is translated from the original German version of Esper's book; in the French version published in the same year, the sense was reversed by mistake to say that the human and animal remains were of the same age.

John McEnery (1796–1841

McEnery was the first person to convince himself that early humans were contemporary with extinct animals. His excavations in Kent's Cavern (Devon, United Kingdom) took place between 1825 and 1829, but none of his findings was printed until many years later and even now some of them remain unpublished. What he did and found, however, is known, as are his conclusions and also the opinions of Buckland with whom he was in touch.

McEnery was born in Ireland. Although his name is often spelled as MacEnery, he himself wrote it as McEnery. He was ordained as a priest in 1819 and in 1822 became chaplain to the family living at Torre Abbey in Torquay, where he remained until his early death. The existence of bones in the nearby Kent's Cavern was already known but they had not been seriously studied before McEnery (1825–28?; 1869). He left lengthy notes

Archaeologists: Figure 1. J.F.Esper.

Archaeologists: Figure 2. William Buckland.

Archaeologists: Figure 3. P.C. Schmerling.

Archaeologists: Figure 4. William Pengelly.

Archaeologists: Figure 5. William Boyd Dawkins.

Archaeologists: Figure 6. The Abbé Breuil in 1919 or before.

on his work, which are in the library of the Torquay Natural History Society. Most of them were published in 1869, showing that he had found human bones and teeth, flint tools, pottery, and charcoal, as well as bones and teeth of *Homotherium latidens* (sabre-toothed tiger), rhinoceros, hyaena, and bear.

What is not immediately obvious is McEnery's own opinion. Did he or did he not believe that the human remains were of the same age as the animal bones found with them? What he wrote in his manuscript notes, intended as a basis for publication, conflicts with the opinion he expressed in private letters to Buckland.

It must be remembered that this young (30 years old in 1826) and inexperienced excavator was exposed to two of the world's authorities of the day, both of whom were opposed to the idea. Cuvier, already mentioned, identified some of his specimens and McEnery visited him in Paris. Buckland, with whom McEnery was in close contact, was deliberately cautious, believing that the apparent association at the same level in the deposits could be explained by supposing that humans had dug pits in which their bones and artefacts were found. These two must have been powerful influences on the young man, whose theological training may also have had an effect. This is what he wrote in his manuscript (McEnery, 1869, p.226):

I am persuaded that if due attention is paid to the place in which these remains occur—and the manner that they are intermingled with the soil and bones reputed fossil, it will be in every case found...that they are not coeval neither with one or the other but that they had been added subsequently to the deposition of the former and commingled with them into a common heap by causes such as operated here I mean the visits of man, or according to their position by the disturbing action of running waters.

Had I not devoted so long a period to personal examination of all the circumstances attending this delicate question, in common with others I should have fallen into the error of supposing human remains to be contemporaneous because conjoined with the deposit of mud and bones.

However, what were presumably his true views, forthright and unconstrained by any intention of publication, are contained in two letters written to Buckland in 1828 or 1829 and never previously published (McEnery, 1825–28?):

Nothing could give me greater pleasure than to concur with you in this and in every other point, but it would not be just to truth to give up the impressions of three years observation without the fullest conviction to the contrary.

Hitherto I had rather bowed to your high authority than to evidence. But the matter is now clear as day.

William Buckland (1784–1856)

Buckland (Figure 2) was one of the most influential geologists of the 19th century, but only a small part of his work related to humankind. At Oxford, his lectures were so highly regarded that a new chair of geology was created for him. His sense of fun drew many listeners and it also prompted humorous drawings relating to his cave interests. Having seen the Burggaillenreuth cave where Esper had worked, he was keen to investigate the newly found cave of Kirkdale in Yorkshire, but no human remains were involved. The fact that the cave contained bones of animals too large to get through the entrance and that they were nearly all broken and chewed, led him to conclude that hyaenas, the other occupants, had taken them there as food. This unconventional idea (Buckland, 1822) earned him the Royal Society's Copley Gold Medal. Buckland's only involvement with human remains in caves was in Torquay, as already described. He himself had expected that humankind would be found coeval with extinct animals but he did not accept that the Kent's Cavern evidence was convincing enough for such a contentious conclusion.

Philippe Charles Schmerling (1791–1836)

Although McEnery had been excavating in the 1820s, it was Schmerling who, in 1833, first published a definite statement that the human remains he had found were contemporary with those of extinct animals. Schmerling (Figure 3) trained as a doctor in Belgium and in 1825 began to practise in Liege. Only four years later he gave up medicine as a result of a chance meeting with some fossil animal bones that some of his patients' children were playing with. They came from a cave at Chokier, opened by quarrying and not previously disturbed. Stimulated by these, he spent the next four years exploring more than 40 similar caves. Besides 60 species of animals, he found fossil human bones, together with chipped stone tools and carved bones. They lay beneath flowstone floors, scattered and abraded just like the animal bones that were with them, so they could not have been buried later into an earlier deposit, as Buckland had supposed at Kent's Cavern. At Engis, a child's skull, known now to be a Neanderthal, was next to a mammoth tooth, and a Cro-Magnon skull was with rhinoceros teeth.

Schmerling published his findings in great detail and concluded (1833, p.66): "There can be no doubt that the human bones were buried at the same time and by the same cause as the other extinct species." Charles Lyell visited Schmerling and referred to his discoveries but it was only later that he accepted their significance. At first he had insisted that coexistence could only be proven if the remains were found together in stratified deposits, but he afterwards acknowledged that Schmerling's specimens had been found "under circumstances far more difficult to get over than any I have previously heard of" (Lyell, 1881, 1:401–02).

William Pengelly (1812–94)

Pengelly's great contribution to archaeology was his careful and precisely recorded excavation, carried out in a Brixham cave in Devon in 1858–59, which was sufficient to convince the doubters that humankind and the extinct animals there really were contemporary. The lesson was reinforced by the much more extensive excavations he directed in Kent's Cavern from 1864 to 1879. There is some analogy here with Darwin's achievement, in making evolution generally accepted by means of massive evidence. Darwin, however, had to argue his case; with Pengelly the evidence largely did it for him.

Pengelly (Figure 4) had only an elementary school education and was largely selftaught, yet his researches brought him Fellowship of the Royal Society. He started a school in Torquay and later took private pupils, who included members of European royal families. He studied geology and also did an immense amount of detailed work on such diverse subjects as dialect and rainfall, and he reprinted all he could find written about Devon caves, amounting to many hundred pages. His publication of the McEnery (1869) manuscript is the most accurate available.

When the Brixham cave was found in 1858, it had been sealed since prehistoric times and its flowstone floor, beneath which the deposits were excavated, was undisturbed. It was this, coupled with his system of excavation, close supervision and accurate recording, which made his findings accepted. A grid system fixed the location of every object and the dig followed the stratification layers (Prestwich, 1874). The Kent's Cavern excavation was less important in that it came second, and previous disturbance of the deposits made it more complex, but the facts and their publication year by year to the wide audience of the British Association for the Advancement of Science members, helped the antiquity of humankind to become generally recognized. McEnery's conclusions of 40 to 50 years before were vindicated and Lyell, who had been sceptical of Schmerling's opinion, was converted.

William Boyd Dawkins (1837–1929)

At last here is someone who was known as an archaeologist who worked in caves, in contrast to the geologists and others, whose crucial evidence for the antiquity of humankind had been archaeological. Boyd Dawkins (Figure 5) was not associated with the same vital breakthrough but he was, on the other hand, better known than many of his predecessors. His work, his writing and his long career, meant that he was regarded as *the* cave archaeologist for much of the 19th and 20th centuries, though more of his work was on Pleistocene animals rather than on humans.

Boyd Dawkins became interested in geology while at Oxford and in 1861 was appointed to the Geological Survey of Great Britain. In 1866, he was elected FRS and from 1874 to 1909 he was Professor of Geology and Anthropology in Owen's College, Manchester, the predecessor of Manchester University. Inspired by Pengelly's results at Brixham, he excavated in the Wookey Hole Hyaena Den, finding Mousterian tools together with extinct animals (Dawkins, 1862–63). His classic book *Cave Hunting* (1874), brought together facts on the physical aspects of caves, as well as their contents in many European countries. He himself carried out many cave excavations until 1903, when he was 66 years old, but still he was more concerned with mammal remains than human.

Henri Édouard Prosper Breuil (1877–1961)

Finally we come to a man who was widely acclaimed throughout his long life, for work in a special field of cave archaeology. It was he who founded, early in the 20th century, the new study of prehistoric cave art (see separate entry, Art in Caves: History). Ordained priest in 1900, the Abbé Breuil (Figure 6) was lecturer in Prehistory and Ethnography in the University of Fribourg 1905–10, Professor of Prehistoric Ethnography at the Institut de Paléontologie Humaine in Paris from 1910, and Professor of Prehistory at the Collège de France 1929–47. He was elected a member of the Institute de France in 1938, received gold medals from the Society of Antiquaries in London and the National Academy of Sciences in Washington, and held honorary degrees from several foreign universities.

While still a young man, he often accompanied Émile Cartailhac (1845–1921), the doyen of prehistory, who had previously denied the antiquity of cave art. Breuil was at the cave of La Mouthe in 1902, when Cartailhec accepted it with his famous "Mea culpa d'un sceptique". He had seen the painted caves of Les Combarelles and Font-de-Gaume, when they were discovered in 1901, and he went to Altamira in 1902. He was also involved in the discovery of Tuc d'Audoubert in 1912 and Les TroisFrères in 1916. His own main contributions were his skilled and laborious copying of the art, its stylistic analysis and interpretation, and its publication in numerous magnificent books. In 1940, it was he who first assessed the Lascaux paintings, but towards the end of his life, he denied the authenticity of those found at Rouffignac in 1956. His bibliography exceeds 793 items (Lantier, 1957).

Pei Wenzhong (1904–1982)

After graduating in geology from Peking University in 1927, Pei had a long and distinguished career as an archaeologist and paleo-anthropologist, including cave excavations of paleolithic remains in many parts of China. Best known and most significant, was his work at the cave of Zhoukoudian (then spelled Choukoutien), 47 km southwest of Beijing. In 1927, a single tooth from there had been recognized by the Canadian, Davidson Black of Beijing, as coming from a previously unknown hominid called Peking Man, *Sinanthropus pekinensis* at that time and now *Homo erectus pekinensis*. Pei joined the excavation there in 1928, and in the very next year he discovered the first complete skull of Peking Man. It was a predecessor of both Neanderthal and modern man, dated to the middle Pleistocene period. It postdates Java Man and is considered to be more advanced than the other early hominids, with a range of cranial capacity overlapping that of modern man. The discovery of the skull was followed, under Pei's direction, by stone tools, charred wood, and animal bones, some of which were burnt. The Abbé Breuil visited the site in 1931 and from 1935 to 1937, Pei studied under him in Paris, where he gained his doctorate.

ARCHAEOLOGY OF CAVES: HISTORY

Archaeology was born during the first half of the 19th century through the systematic excavation of deposits found in the caves of Europe. Those excavations were undertaken by inquisitive intellectuals, geologists, and antiquarians, who were delving into the history of the world and especially of humankind. They established a past for humanity by providing great time depth and previously undocumented variation over human history. In the New World, archaeology in caves helped resolve questions about the tenure of Native Americans, establishing the complexity of their cultures and contributing to our knowledge about agriculture in the prehistoric Americas. Cave archaeology has thus been a fundamental part of scientific understandings of human origins and development, and dramatically changed our view of our world and ourselves.

The birth of archaeology was from the mouths of caves in Western Europe, wrapped up in one of the most momentous intellectual changes in human history: the establishment of human antiquity. Beginning in the late 18th-century Enlightenment, European scholars began to question the biblical account of divine Creation, which according to Bishop Ussher placed the creation of all things, including people, at 6000 years ago. Excavations inside limestone caves and dolines, however, were showing the presence of extinct animals in what we now know were deposits from the last Ice Age. Frenchman Georges Cuvier argued persuasively in 1795 that extinctions had occurred, resulting from catastrophic floods that killed off some species and produced the stony deposits, "diluvium", in which their bones came to rest. He believed that all such events occurred during the 6000-year biblical span, and that humans had nothing to do with extinct animals. Contradictions to Cuvier's view came from caves, in Britain, France, and Belgium.

In 1822, bones were discovered in Paviland Cave in Wales, bringing eminent geologist William Buckland, advocate of the biblical chronology, to the cave. Buckland confirmed the pres ence of extinct animals and uncovered a partial human skeleton surrounded by ivory ornaments and buried in red ochre. The "Red Lady of Paviland" (actually a male, see Britain and Ireland: Archaeological Caves) was of great interest, but Buckland dismissed it as intrusive, denying any association between human and extinct animal remains. A modern radiocarbon age indicates the Paviland hominid is more than 18000 years old. Buckland denied all other associations of humans with antediluvian deposits, because for him, the human species was recent. But in this, he also abandoned equating the biblical Deluge to the diluvium of the geologists. The door was open for events not described in the biblical account.

Excavations in Kent's Cavern (in Torquay, England) by the Rev. John McEnery began in 1825. Over the next four years, McEnery dug beneath a thick travertine floor to find extinct animal bones and stone tools of clear human manufacture. Here was evidence for antediluvian humanity. McEnery recognized this during his excavations but later denied antediluvian status for the Kent's Cavern finds under pressure from Buckland (see Archaeologists entry). In 1842, however, further work at the cave by R.A.C.Austen reaffirmed the association between stone tools and extinct animals, and Austen argued strongly for an antediluvian origin for the deposits and thus for humans in Britain. But with Buckland's great authority, Austen's claims had little effect.

Continental caves became the focus of interest for both human antiquity and cave archaeology. In the mid-1820s Marcel de Serres, Paul Tournal, and Jules de Christol began to develop the science of cave excavation in French sites such as Lunel-Viel, Pondres, Souvignargues, and in caves near Bize. Tournal began to publish on Bize in 1828, when he argued that there was a stratigraphic sequence in the caves including upper levels with human remains, modern animals, and pottery, and lower layers with human remains and extinct animals. Tournal cited Christol's excavations in the Gard, where antediluvian animals such as rhinoceros were found with artefacts, as evidence for a very long sequence of human occupation beginning long before the biblical chronology. For him, the biblical Deluge was a recent historic event in this sequence and unrelated to diluvial evidence. In short, Tournal defined "prehistoric times", although he did not use the term. De Serres concurred based on his work at Fauzan Cave. The French intellectual establishment, led by Cuvier, tried to reject the southern French cave data, but the list of relevant sites was growing too long to ignore.

In Belgium, physician Philippe-Charles Schmerling had begun to explore caves around Liege, finding extinct animal bones, stone tools, and human remains. At Engis in 1832, two human skulls were discovered with the bones of rhinoceros and elephants; one cranium was badly eroded, but the other had a strange shape and bony prominences at the back and over the eyes. It was a Neanderthal, although the definition of that type would have to wait two decades until the type specimen was found at Felderhof Cave in the Neander Valley of Germany. Nevertheless, Schmerling made strong arguments as to the ancient origins of his collections (see Archaeologists entry).

So compelling were the Belgian data that Buckland and Charles Lyell, the eminent geologist who would ultimately synthesize geological and archaeological proofs for the antiquity of the world, were forced to admit the confusion that complex deposition processes in cave sites brought to their position on human antiquity. They pushed archaeologists outside caves to find data they would accept, leading to a series of openair excavations around Amiens and Abbeville in northern France. These digs would finally lead to acceptance of antediluvian human prehistory, but the beginnings of the debate were carried out in caves.

Cave archaeology in the New World has less history than Europe. The first Europeans to penetrate North American woodlands in the late 18th century frequently entered deep caves seeking saltpetre (nitrates) for their gunpowder, leaving their names as incised wall graffiti, and they could not have missed evidence for prehistoric occupation littering the cave floors. But, the invaders' opinion of Native American capabilities was low, and they did not believe that the materials they saw were of native origin.

Yet, American scholars began to investigate the contents of deep caves. At first, as in contemporary Europe, extinct Pleistocene animal bones were of interest. A giant ground sloth (*Megalonyx* sp.) was discovered in a West Virginia cave in the 1790s, causing great interest among the scientists of the day, including Thomas Jefferson. Finds like this showed that extinct animals had populated the New World just as in the Old. In the first part of the 19th century, the brilliant jurist John Haywood catalogued a number of archaeological cave sites in his *Natural and Aboriginal History of Tennessee* (1825), including caves with human effigies sculpted in stone. For Haywood, the aborigines could neither have produced these nor the mounds and earthworks he observed across Tennessee, so he attempted to prove that these must be evidence for lost Hebrew tribes in North America. His view was typical of early American archaeologists generally, despite contradictions from the likes of Thomas Jefferson, whose careful excavations in a mound at Monticello led him to argue a native origin for the varied archaeological features seen on the American landscape.

By the last half of the 19th century, American archaeologists had come to accept the antiquity of Native Americans and their role in producing the archaeological record. Yet this acceptance did not lead to the recognition of the importance of cave sites. In Mesoamerica, however, archaeologists in the 1880s and 1890s began to notice a relation between large Maya settlements such as Copan, Palenque, and Tikal, and caves located nearby or beneath the towns. Caves were clearly used by Maya religious leaders as ceremonial precincts; paintings, burials, and shrines were discovered, reflecting the Maya belief that the underground world was an important source of power and balance for the outer and upper worlds frequented by humans (see America, Central: Archaeological Caves).

There were a few archaeological incursions into North American dark caves (see America, North: Archaeological Caves). In 1875, F.W.Putnam examined the archaeological record of Kentucky's caves, noting their use for human burials and listing an impressive array of artefacts that he recovered in Salts and Mammoth caves, including torch remnants, moccasins, and containers. Also in 1875, local men found the desiccated body of a young boy (misidentified as a female and dubbed "Little Alice") in Salts Cave, igniting the public's imagination and interest in prehistoric cave use. In 1896, W.S.Blatchley excavated a trench in the dark zone of Wyandotte Cave (Indiana) looking for tools used by prehistoric mineral miners; his work was based on archaeological observations made since 1877 by various scholars in that cave, who noted the removal of gypsum and mirabilite from the walls and hammerstones, torches, and containers associated with the mineral removals. Back in Kentucky, Colonel Bennett Young performed the first systematic excavations in Salts Cave, publishing his results in 1910 and detailing a remarkably preserved record including numerous perishable artefacts. Young showed that prehistoric cavers had traversed many miles of dark zone passage in Salts Cave with their simple caving technologies. In 1916, Nels Nelson trenched the "Historic Entrance" to Mammoth Cave, recording a long sequence of occupations there. Another prehistoric cadaver was discovered in Mammoth Cave in 1935. "Lost John" was an adult male who had died when a boulder he was undercutting, presumably in search of cave minerals, collapsed on him.

The largest and most influential cave archaeology project in North America began in Salts and Mammoth caves in 1963 under the direction of Patty Jo Watson. That project entailed large-scale excavations in the vestibule of Salts Cave and the Historic Entrance of Mammoth Cave, archaeological surveys of the inner passageways of both caves, and specialized scientific analysis of various products of fieldwork including numerous human coprolites found scattered about the caves. These studies documented two seminal findings. First, as early as 3000 years ago, Native Americans undertook extensive and dangerous forays into the deep recesses of large caves seeking minerals that had little or no subsistence utility, i.e., their activities were more likely religious or social than purely economic. Second, analysis of human coprolites showed that these people were undergoing a transition to agriculture from a simple hunting/gathering way of life; surprisingly, they were domesticating local plants like sunflower, chenopods, and marsh elder rather than importing plants from Middle America, at that time seen as the source of American agriculture. These discoveries revolutionized American prehistory and have formed the basis of most subsequent work in the Eastern Woodlands.

New discoveries continue to this day. In 1979, a cave was discovered in Tennessee containing prehistoric art in the dark zone. For Charles Faulkner who studied it, the art comprises religious symbols traced into soft mud, giving the cave its name, Mud Glyph Cave. Over the past two decades, nearly 50 such caves have been found in southeastern North America, comprising a prehistoric Native American cave art tradition spanning 4000 years (see Art: Cave Art in the Americas). Caves clearly played a central role in the economic and ceremonial lives of ancient Americans.

Finally, mention must be made of caves in Africa, which, while excavated more recently than elsewhere, have yielded information on the very origins of humanity (see Africa, South: Archaeological Caves). In 1924, Raymond Dart discovered the remains of a young animal that was obviously similar to humans; he named it *Australopithecus*

africanus and argued that it was the earliest known human antecedent, well over 1 million years old. Over the next decades, many similar fossils were discovered in South African caves and dolines, such as Sterkfontein, Swartkrans, and Makapansgat. *Australopithecus* was shown to have great time depth (more than 3 million years) and to comprise several different species. African caves like Klasies River Mouth have also yielded evidence for the origins of modern humans. At Klasies, a sea cave on the southern Cape, and at inland sites like Border Cave, human fossils show that anatomically modern humans evolved in Africa more than 200000 years ago and probably spread from there to colonize much of the Old World, replacing or blending with existing human populations like the Neanderthals in Europe.

Caves around the world have been central in the history of archaeology. Deposits in caves have helped to establish human antiquity, yielded data on the very origins of humanity, and provided information about evolving human cultures across the globe. New information continues to come to light as archaeologists and cavers join forces to examine the deeper recesses of the Earth for evidence of ancient human activities.

ARDÈCHE CAVES, FRANCE: ARCHAEOLOGY

The Ardèche, a region of southeast France around the Rhône valley, contains numerous caves in its limestone massifs, and many of them were decorated during the last Ice Age, often during the Solutrean Period, around 20000 years ago. They continue to be discovered today, usually by speleologists and enthusiasts rather than archaeologists, and a whole series was found by Jean-Marie Chauvet and his companions, culminating in 1994 with the biggest and grandest of all, the cave which now rightly bears his name.

The Ardèche region was among the first in the world where Ice Age cave art was discovered—but unfortunately its age and its significance were not realized for a long

time. In 1870, local archaeologist Jules Ollier de Marichard wrote in his excavation notebook that he had seen "signs of the zodiac" engraved in a deep gallery of the cave of Ebbou, and in 1873 he added that he had seen animal silhouettes sketched on the walls. But Ebbou had to wait until 1946 before its art was rediscovered. In 1879, de Marichard wrote a letter to the eminent French prehistorian Emile Cartailhac, stating that some caves in Ardèche had red paintings of "fantastic animals", but he put nothing in print. In 1878, however, a local schoolteacher, Léopold Chiron, did print something: he had noticed the deep engravings in the cave of Chabot (Gard), and not only took photographs and imprints, but also published a note about them, although he could not know their date. He mistakenly thought he could see birds and people among the lines, because the Chabot engravings are difficult to decipher, and its figures, including mammoths, are far from clear. In May 1879, Chiron wrote to the prehistorian Ga briel de Mortillet to tell him of the discovery of a cave with Ice Age flint tools and with engravings on the walls-Chiron had no doubt the drawings were ancient, since they were covered in calcite. But his pioneering observation was ignored. He again called attention to the Chabot engravings at conferences in 1889 and 1893, but still found no support, while in 1890 he also mentioned engravings in the nearby Cave of Le Figuier (Ardèche).

Some of these sites—such as Chabot—proved to contain occupation deposits from only the Solutrean Period. But one site in the region—La Tête-du-Lion—became one of the first well-dated examples of cave art. Its decorated panel features redochre drawings of an aurochs, deer, and ibex, as well as dots. Immediately below it are the remains of a fireplace, clearly used for lighting by the artist at work, with spots of red ochre next to it on the ground. Analysis of these spots showed that they were of exactly the same composition as the drawings on the wall, and so a radiocarbon date of 19700 BC from charcoal in the fireplace provided a solid age for this cave's decoration in the Early Solutrean Period, like much of the other art in this region.

At the end of 1994, Jean-Marie Chauvet, Eliette Brunel Deschamps, and Christian Hillaire discovered the Chauvet Cave, easily the biggest cavern of the entire region, and far bigger than the other decorated cavities known in the Ardèche. It has proved to contain over 420 painted and engraved figures. It also has numerous and varied traces of human and animal visitors—including footprints, and abundant bones of cave bear. One cave bear skull has been purposely placed on a natural, isolated rock, and has inevitably led to speculations about a cave bear cult, although it could easily have been placed there by a child. Bear clawmarks also occur underneath, or in other places, on top of some of the engraved figures on the walls.

The painted figures include some hand prints, as well as panels of large red dots made with paint on the palm of the hand, and a wide range of "signs". Red and black figures tend to be located in different parts of the cave. A number of different animal species—at least 15–are depicted, including not only the usual range (40 horses, 31 bison, 10 aurochs, 20 ibex, 25 deer), but also many rarer species: 66 mammoths, 15 bears, 72 big cats, and 65 rhinos. Many of the rhino figures show a puzzling broad black stripe across the middle of the body. There are also a spotted panther, an owl, a possible human female, and other figures. Overall, mammoths, rhinos, bears, and big cats constitute up to two-thirds of the cave's animal figures.

Some of the animal figures feature a great deal of infill and very subtle shading, where the paint was spread by hand or with a tool to depict relief or the nuances of the animal's coat. Some of the black drawings in the cave are surrounded by lighter areas of wall which seem to have been scraped to produce increased contrast.

Initial assessments of the content and style of Chauvet's art assigned it to around 20000 years ago, so it was a shock when radiocarbon dates from charcoal in several black figures came out at more than 30000 years ago, placing the cave in the Aurignacian Period. Nevertheless, these dates were initially accepted by most specialists as valid, and they may well prove to be correct. However, serious doubts still remain as to whether they are indeed correct, especially since the cave's art contains so many features which have hitherto been associated with much later phases of the Ice Age-bison heads seen from the front; animals in movement, such as an aurochs with splayed legs and a pair of "fighting" rhinos; the "M" mark and shoulder stripes on some horses; a bison drawn with seven or eight legs and multiple outlines, perhaps to indicate movement; many different ways of showing perspective; and so forth. These features, together with the sheer technical sophistication of the depictions, are certainly causing many specialists to wonder if these radiocarbon dates are indeed correct, and further results by different laboratories as well as analyses of possible natural contamination will be needed to establish once and for all whether Chauvet Cave's art is the earliest known cave art in the world or, alternatively, a more conventional-albeit outstanding-set of images.

ART IN CAVES

Although the vast majority of prehistoric rock art occurs in the open air or in shallow rock shelters—for example in South Africa, North and South America, and Australia—there is nevertheless an important body of art (mostly paintings and engravings) lying in total darkness within deep caves in a few parts of the world. The best-known examples, of course, are some of the hundreds of decorated caves from the Ice Age of Eurasia (see Art: Cave Art in Europe), though art from more recent periods of prehistory is also found deep inside European caves—for example, in several caves in northern Norway, from about 3000 years ago—as well as sealed inside the chambers of megalithic monuments.

The phenomenon is by no means uniquely European. A whole series of deep caves in Australia have been found to contain a profusion of finger markings, such as Koonalda Cave, 15000–24000 years old (see Art: Cave Art in Australasia) and engraved motifs, while paintings—mostly hand stencils—also occur in caves in Tasmania, New Guinea, Sulawesi (see figure), Borneo, China, and elsewhere. Easter Island has abundant decoration inside many small caves, in the form of both paintings and rock carvings and engravings. Increasing numbers of decorated deep caves are also being discovered in various parts of the United States (see Art: Cave Art in the Americas), especially in Tennessee and Alabama, the best known being the Mud Glyph

Art in Caves: Classic hand silhouettes in the cave of Ujung Bulo in Sulawesi, Indonesia. (Photo by John Middleton)

Cave of Tennessee which recently had to be blocked up to prevent further damage to its fragile finger-drawings in soft clay. There is a wealth of decorated caves in Cuba and the Dominican Republic, but alas, the decimation of the local people after the arrival of the Europeans has ensured that we know nothing of the meaning of their cave art.

Although some cave art was always known to exist by local people, its discovery by the world of scholarship can be traced back to the second half of the 19th century in Europe, when a few examples of Ice Age cave art were spotted, culminating in the realisation that Altamira Cave (see separate entry) contained paintings from the Ice Age. The first published account of Maya cave painting in the Yucatan (Mexico) dates to 1897, when Edward Thompson, the American consul in that part of the world, found some paintings in the cave of Loltun, as well as some rock carvings; however he accorded them scant importance, merely describing them as curious symbols and grinning skulls.

Because caves appear mysterious and menacing places to us, there has long been a tendency to associate their art with secret, esoteric, exclusive rites redolent of fear and awe. Rock art in the daylight and the open-air seems far less "private". But it would be simplistic to interpret art of the past in relation to these modern impressions. As we know from Australia, for example, open-air sites can be just as imbued with power and taboo as anything underground. Indeed, some of the art in deep caves appears to be "public", being easily visible in large, readily accessible chambers. However, a great deal of it is undeniably private, in small niches, or chambers only accessible through a long journey or after negotiating difficult physical obstacles necessitating climbs, crawls, or tight squeezes. There are cases—like the famous Ice Age clay bison of Le Tuc d'Audoubert in the French Pyrenees—where the very act of making the journey and of producing the images seems to have been what mattered; the artist(s) never returned to visit their work.

Why was art placed in such inaccessible locations? Deep caves are strange environments, bereft not only of light but also of sounds—except perhaps for dripping water or, at times, bats. One experiences utter blackness, total silence, a loss of sense of direction, a change of temperature, and a frequent sense of claustrophobia. To enter a deep cave is to leave the everyday world and cross a boundary into the unknown—a supernatural world. It is easy to imagine that caves therefore symbolized transitions in human life and could be used for rituals linked with those transitions, especially puberty rites. Or perhaps it was felt that by entering this world one could better commune with or summon up the supernatural forces which dwelt there, and hence the images were made to reach and compel those forces. Cave decoration certainly requires strong motivation, since it involves negotiating such obstacles and taking both equipment and lighting into the site.

As in the Caribbean, we have no ethnographic information from Australia on the use of deep caves—indeed they seem to have been avoided by Australian Aborigines in historical times. But we can gain some insights into potential motivations by studying the deep caves which were decorated by the Maya of Central America (see Art: Cave Art in the Americas). Since theirs was not a prehistoric culture, and since some of their cave decoration consisted of their glyphs (which were their writing), we can both read the texts and learn from Maya ethnohistory what they were doing in caves. It is certainly clear that, for the Maya, it was the act of production that counted, not the durability of the art. "Hidden" or private images are sometimes found in especially awkward or even dangerous locations. Their use of caves involved altars and "chapels", and water was a focus of the rituals here. Caves were considered dangerous and chaotic places, contrasting starkly with the domestic community, and they were visited to make contact with gods and spirits in some way. Sanctity was proportional to spatial remoteness and this factor would certainly help to explain the decorated "sanctuaries" in remote corners of many prehistoric caves: for example, the Tuc d'Audoubert's clay bison are located at the very furthest point of a 900 m long cave, in a chamber reached only after an often uncomfortable and difficult journey. In Maya terms, therefore, these bison were left in a sacred location, unsullied through their utter remoteness from daily human life. The realm of total darkness and silence was the greatest contrast imaginable to the everyday human world.

ART IN CAVES: HISTORY

The history of the study of rock art in deep caves is widely regarded as having commenced with the discovery of the paleolithic art in Altamira, Spain, in 1879 (see Altamira entry). However, ever since the earliest artists created their works others will have viewed them and undoubtedly drawn inspiration for their own subsequent works. For instance, Neolithic art, Roman art, and later inscriptions in the vicinity of paleolithic cave art all suggest that the art was viewed at these various times. Even much of the famous cave art of Lascaux (in the Périgord, Dordogne see colour plate section) is probably not from the Pleistocene, but may have been created in the Holocene, in response to earlier art. In 1458, Pope Calixtus III decreed that the religious ceremonies

held in "the Spanish cave with the horse pictures" had to cease. Although it is unknown which site he referred to, it was almost certainly a site of paleolithic art. This decree also implies the use of the ancient rock art in religious practices in late medieval times. By the 19th century, however, all knowledge of this rock art seems to have been lost, much to the detriment of its rediscoverer.

The life of Don Marcelino Santiago Tomás Sanz de Sautuola (1831–88) was destroyed through his discovery of paleolithic art in Altamira. The archaeological establishment judged the cave art to be a crude joke or a hoax, and considered its discoverer to be either a charlatan or a dupe. De Sautuola produced immaculate publications in 1880 and 1882, trying in vain to secure acceptance of his find, but most of his opponents refused to even inspect the site (de Sautuola, 1880). He died prematurely six years later, a broken and bitter man, in the full knowledge that he had made one of the greatest discoveries in the history of archaeology.

Léopold Chiron had already found engravings deep in the French cave of Chabot in 1878, and in 1890 found more in another site, Figuier. In 1883, Francois Daleau excavated engravings on a wall in Pair-non-Pair that had been covered by Ice Age sediments. However, de Sautuola's treatment by the discipline deterred others from publicizing such new finds. In 1895, a bison engraving was discovered in the French cave of La Mouthe. Emile Rivière, who had seen the Altamira paintings, then found more rock art in La Mouthe, and four years later a paleolithic lamp. Thus the evidence in favour of paleolithic rock art mounted, but full acceptance by the archaeological establishment did not occur until the end of the century.

At that time, a young Catholic priest had begun to develop a great fascination for the subject of European cave art. Abbé Henri Breuil was to dominate the field for the next six decades, and a great deal of our knowledge of the paleolithic rock art traditions is attributable to his unparalleled life work (Breuil, 1952, and see Archaeologists entry). His reign was followed by that of André Leroi-Gourhan (1968), after whose death Jean Clottes became the key scholar of paleolithic cave art. Throughout the 20th century, a stylistic sequence for the art was refined and honed by successive scholars. Its bases were the stylistic genres perceived by the leading researchers, which were often constructs of a very tenuous nature (see also Art in Caves). Although significant changes were made to this stylistic sequence from time to time, it remained unchanged in its essential evolutionary basis. A distinctive development from the most simple and primitive to the most complex and ornate remained its most fundamental tenet until 1995, when it was refuted by Bednarik (1995). This was the result of new discoveries, most especially that of Chauvet Cave in France, whose dating by Clottes et al. (1995) demonstrated that the most sophisticated paleolithic cave art was also the earliest. During the 1990s, the introduction of direct dating of European cave art and the demise of stylistic dating, instances of fakes, and rejections of scientific dating results prompted various controversies, culminating in 1995 in what Michel Lorblanchet later described in La Recherche as an earthquake in paleolithic rock art research.

Cave art is not, however, limited to Europe; it is found in all continents except Antarctica. A second tradition of Ice Age cave art occurs along the southern coast of Australia. The first site discovered was Koonalda Cave, presented by Alexander Gallus (1968). The scientific investigation and the recognition as a specific tradition of Australian rock art only began with the discovery of the Mount Gambier corpus in 1980 (Bednarik, 1990). The first sites located there, Malangine and Koongine Caves, were subjected to direct dating of the rock art by Robert Bednarik in 1980. This was in fact the introduction of scientific dating of any form of rock art, whereas it took another ten years for direct dating techniques to be adopted by French cave art specialists. In contrast to the Franco-Cantabrian cave art chronology, the Australian cultural sequence has not given rise to controversy. This is because it has not been developed through stylistic constructs of individual archaeologists, but through scientific data obtained from substances physically related to the art, and through the identification of specific behavioural traces. In Australia, the Parietal Markings Project is responsible for the discovery of about 90% of all known sites, including all 40 cave sites at Mount Gambier (see also Art: Cave Art in Australia).

Another region noted for its cave art includes parts of Central America and the Caribbean islands (see Art: Cave Art in the Americas). Specific clusters of sites occur in Cuba, Hispaniola (two specific concentrations) and in the general area of Belize, Guatemala, and the Yucatan Peninsula. The cave art of the last-mentioned region is attributed to the Maya and some 22 sites are currently known. This region has been studied especially by Andrea Stone (1995). The dozen or so sites in the Dominican Republic have been presented by Fernando Morban Laucer (1978). There are also minor numbers of cave art sites located on several other Caribbean islands. All cave art of this region is assumed to be substantially less than 2000 years old.

Finally, a remarkable series of rock art sites has been located in several caves in the Kentucky—Alabama region of North America. They are popularly known as "mud glyph caves", but the rock art, which is thought to be fairly recent, seems to occur on moonmilk rather than mud. This series, discovered since 1980, has been presented by Charles Faulkner (1986).

ART SHOWING CAVES

From the earliest of times, man's imagination has been captured by the mysterious underground. It was much later that artists began to create images of caves, and preserve them for us to view today. The early artists largely ignored the question of science as they concentrated on the mystery, fear, and magic of caves. This entry will briefly review the chronology of artwork inspired by caves, from the ancient Greeks to the present day. It will review some of the individual artists who have made an impact on the development of technique and show how people have seen caves through time.

The first caves in art were crude, pictorial descriptions of caves. They would generally and often inaccurately show a passage or cavern as one room and there would be small icons showing bones, mystical characters, and demons. Caves were fearful places. The oldest surviving remnant of a cave illustration is a map of a decorated cave made in the time of Assyrian King Salmanassar III c. 852 BC. Its survival over such a long period is because it was made in bronze relief (see Figure 1 in Caves in History: The Eastern Mediterranean).

The ancient Greeks regarded springs as sacred and viewed caves as homes to nymphs and deities. It was here that philoso

Art Showing Caves: Blue Grotto in Capri. Painting by Y.Gianni. With permission from the owner, Carolina Shrewsbury. (reproduced in colour section as Figure 20)

phers would retreat for contemplation and inspiration. They, in turn, suggested to architects that they build grottos or artificial caves around springs, which would be adorned with shells and crystals to emulate the natural structure of decorated passages in the deeper parts of caves. Basins, like gour pools, would catch and hold the sacred springs and water would be directed though lion-headed waterspouts carved out of tufa.

Later, the Romans used grotto or fountain constructions to decorate theatres or stage sets, to give a more rustic appearance emphasizing the atmosphere of a landscape or scene. These structures, called "nymphaea", were often copied and used as fountained courtyards in large public buildings. Smaller grotto structures kept their more traditional form in private gardens as the sites for small shrines.

The excavations in the 15th and 16th centuries of ancient Roman sites in Italy, such as the Domus Aurea (Golden House) of Nero in Rome, led to a revival of interest in using cave themes in architectural artwork. The High Renaissance Classicism of Raphael and his contemporaries (early 16th century), which was the prevailing style at the time of the initial excavations, was eventually (*c*. 1530–90) succeeded by Mannerism, a style that emphasized the tension between nature and art. Cave imagery was a frequent Mannerist device. They distinguished the styles of man-made grotto between the "architectural grotto" and the "natural grotto". The former retained its old manner of shell, tufa, stone, and moss, finished with small pools and sculptures. The "natural grotto" became more elaborate and took the natural form to extremes of fantasy. Stalactites would hang in

profusion and the walls would be covered in a mosaic of coloured pebbles, shells, and pieces of coral. Then came the Mannerist "ruined grotto". These gave the impression of threatening to collapse upon entering. The innards were a concoction of threedimensional images with seas of strange mythical creatures, with swaths and garlands of exotic blossoms in arbors and wrapped around columns. Mirrors often represented water. Examples of these extravagant temples of the underground can be seen in Grotta Grande designed by Bernardo Buontalenti in Florence c. 1583–85, Grotta Pavese in Genoa c. 1594, and Schloss Hellbrunn in Salzberg c. 1615 by Santino Solari. Fredrich Sutris designed a typical grotto wall, in 1581–86, at the Grottenhof Residenz in Munich, which was very much influenced by the Italian Mannerists.

Later came the introduction of the "automata", a mechanical device that artificially pumped water around a course. The automata was used about 2000 years ago as a prop in Dionysian plays, and was reinvented as a representation of the subterranean forces of nature and man's power to control them. The fact that the automata were powered by water made the artificial grotto the ideal place for them. The only fully functional automata that has been preserved is at the Hellbrunn water garden in Salzberg, Austria. The religious and mystical approach to the decorated grotto was largely confined to central Europe. German royalty, in particular, held a deep fascination for the mystery and magic of the subterranean world.

Progression of the inspiration behind caves in art throughout history is superbly witnessed by representations of the Blue Grotto (Grotta Azzura) on the island of Capri. It has been used within ancient Roman mosaics and mimicked in the architecture of the man-made grottos of famous Italian, French, and German palaces. The cave itself was once adorned with statues and items from Roman worship, which marked it as probably a Nymphaeum. It is indeed a mysterious and wonderful place made famous by the blue and aquamarine light that is reflected from the crystal-clear waters. For centuries after the Romans had been there, the cave seemed forgotten. In 1826 the German painter, August Kopisch, was taken in a small fishing boat to the cave after locals had enthused over the "marvelously blue grotto". From then on, the rediscovered secret of Capri became a popular haunt for painters, poets, and writers. It became fashionable in the 19th century for many wealthy Europeans to do a "Grande Tour", and to acquire a memento or souvenir at each port of call. This would often be a small painting, usually a watercolour of a known landmark of the area—in the case of Capri it would be the Blue Grotto. King Ludwig II of Bavaria was very much inspired and influenced by the Blue Grotto in Capri. Twice, he sent one of his architects to Capri to study the cave. He had the Venus Grotto built for him at the Schloss Linderhof. It is a kitschy, extravagant fantasia of something between the Blue Grotto and the Venushöhle in Horselberg from Richard Wagner's Tannhauser. A large painting depicting a scene adorns an artificial stage, fronted by a large well-lit lake with a boat fashioned into a shell upon which the eccentric King would recline, as a live orchestra played his favourite pieces of music from a hidden pit. Built in 1876-67, it had the first coloured spotlighting used in stage sets. Its grandiosity brought the fashion for artificial grottoes to a close.

During the 1670s and 1680s, Baron Johann Valvasor (see Speleologists) visited Adelsberg Cave, the first European show cave now known as Postojnska Jama in Slovenia. He documented the whole cave with maps and sketches. His formations are shown as the typical view of the cave, full of terrifying creatures from the underworld. His cave dimensions were quite unreliable. Almost a century later, Joseph Nagel (see Speleologists) invited several artists to help illustrate his own volumes on the cave. Sebastian Rosenstingel and Carlo Beduzzi were regular "expedition artists" just as we have photographers and film makers today, depicting the explorer showing royalty and scholars the great chasms.

In the 1790s, a hunter found what was later to become known as Mammoth Cave in Kentucky, United States. This was to become as famous as the Adelsberg cave in Europe. Stephen Bishop, a slave who worked as a guide at the cave, explored most of the system at a time when deep cave exploration was in its infancy. Bishop's work can be seen as a detailed and accurate map of the cave, which he drew freehand by pencil as a document for a guidebook produced by his owner, Doctor John Crogan, who owned the cave at that time.

In the 18th century, in the wake of the garden grottoes and the beginnings of world travel, art inspired by caves was adopted by the classical artist of the day. Walking in the footsteps of August Kopisch, they branched out to incorporate new wonders of earthly magnitude and nature's still power, often portrayed in the magnificent painting of light and towering mountains within the Roccoo movement. One of these artists was a German, Caspar David Friedrich (1774–1840), who painted caves in religious scenes. Though rarely seen, as this type of art has had difficulty as an understood and recognized subject compared to his landscapes, they convey a powerful imagery of reflected light within a dark, mysterious world.

One of the early artists of caves in this Romantic era was Caspar Wolf, a Swiss artist and draughtsman born in 1735 who moved into the French landscape movement and took up a keen interest in mountains and the forces of nature. Many of his works feature the movement of water and it was probably curiosity about the sources (springs) that led him to the many cave areas in Germany and Switzerland. Several of his cave works are on permanent view in the Museum in Aargau, Switzerland, his most famous being of Beatushöhle, a major cave system of the middle alpine regions of Switzerland. He is one of the first known artists to have taken his materials into the cave to produce his own oil and pencil sketches from nature. He was also the first documented artist to understand the geological nature of his subject that, besides the retaining of the Rococo instability, is portrayed clearly in his work.

William Westall arrived in North Craven in 1817 when Weathercote and Jordas (now Yordas) caves were the most frequented show caves. Seven of twelve of his engravings of the area were of caves. The opinion is that Westall made the finest drawings of caves in Britain at that time. He wrote of the entrance of Jordas, "The peculiar character of this view is derived from the great masses of rock that hang from the roof, apparently loose which, combined with the deep gloom of the interior, usually occasion some degree of terror on the first visit to the cave." A few days after working there, a torrent of water from a burst underground stream caused a rock fall and the cave entrance was made considerably smaller.

Over the rest of the 19th century, various artists started to go further into caves to penetrate a deeper realm of huge darkness. Mostly they would retreat to the confines of their warm studios, leaving the cave explorer to regale terrifying experiences of his treacherous expeditions. Alois Schaffenrath, in the mid-19th century, spent much of his time working in Adelsberg Cave as it was being opened up for public show-cave access. His work is significant because he clearly shows how he lit the cave for his sketches, by strategically placing torches in much the same way as artists still do today. It was amongst the explorers of caves at this time that mapping the underground accurately and writing in journals with illustration became more of a priority than impressing a general public with the skills of artistic technique. From the second half of the 19th century into the first decades of the 20th century, there are countless records of descents and well-lit tours underground. Unfortunately, there is little record of who these artists were, but their beautiful, detailed studies can be found in journals, newspapers, and books of this period all over the world. The artwork of the French artist, Lucien Rudaux, who accompanied the travels of Edouard Alfred Martel was however well documented, and can be seen on the web. His magnificent artwork includes *Bramabiau*, 1888, *Padrirac*, 1889, and *Aven Armand*, 1897, all painted in France.

From the end of the 19th century, art played a massive role in bringing awareness of the natural wonder of the underground to general public notice. In the United States, there was significant growth in the discovery of show caves. As speleologists strove for new income during the depression of the 1930s, chasms opened in abundance for any wandering traveller's curiosity. Posters and huge billboards dotted Central America with wonderful displays of an exaggerated, colourful underground. Bowling Green in Kentucky, the home of Mammoth Cave, in particular, has a very long history of artists up to the present day who have been inspired by the variety of formation and passage within Mammoth Cave.

In 1839, photography was born, though it was not for many years that the camera was successfully used underground (see Photographing Caves). This was a new form of art and very much the preference when recording scientific discoveries. Painting found a challenger who could outdo the need for realism in many fields of scientific research. As photography took over the mantle as the leading medium, the oil painters and water-colourists of the day lost their vogue, as far as the needs of reproducing underground images for books, papers, and other media went. Painting caves and taking a sketch book on speleological expeditions and surveys became a private domain. Within the caving ranks, artists worked independently of one another, creating countless cartoons, picture cards, magazine covers, and, if found out, were asked to reproduce photographs.

The American artist John Agnew and the Canadian artist Linda Heslop are among the most well-known and most-reproduced artists of speleology in the world today, with work in a variety of caving books and journals. But they are not the only ones by far. The speleoartist is beginning to attract larger audiences and there are specialized groups that cave specifically to light caves and sketch, often unconsciously working out the nature of geological faults before they know much about speleology! Exhibitions are popular and artist institutions include the St Lukas Gilde (Austria), the International Society of Speleological Art, and the international group SpeleoArt. Although photography has not lost its position as the challenging medium for the engineer and scientist, it cannot overcome the challenge of human talent held in the hands of an artist. That is: to put the metaphor into an image of a cave.

A comment about the future for an art that is firmly entrenched in the speleological world concludes this brief history of caves in art. As well as the great scientific and environmental importance of the karstic environment, there are strong arguments that it should be preserved because of its aesthetic qualities. One of the roles of the artist is to make such natural beauty visible to those who either cannot see it or can see it only poorly. Caves are storybooks of time that nature has created, and another task for artists is to educate a public who are better developed to understand a metaphorical approach rather than a purely scientific one.

ART: CAVE ART IN AUSTRALASIA

Since cave rock art is restricted almost exclusively to limestone karsts, its distribution in Australia is determined by the occurrence of such landforms. While research on Australasian islands has yielded only limited results, four karst areas have been successfully surveyed for cave art on the Australian mainland. These are the Perth region, the Nullarbor, Buchan, and Mt Gambier, the only one to have been surveyed comprehensively, where about 40 sites are currently known. (The map in the Australia

entry shows the location of these four regions.) Mt Gambier is also the only Australasian region that has yielded evidence of a lengthy cultural sequence of rock art traditions occurring in darkness, as well as dating information from both archaeological floor deposits and the rock art itself. With the exception of a single site on the Nullarbor Plain, Koonalda Cave, it is also the only cave art region in this part of the world that has had a significant impact on archaeological theories. Australian cave art comprises a major Pleistocene component, which is entirely nonfigurative and whose motif range matches that of middle paleolithic art traditions of the Old World.

On the Nullarbor Plain the occurrence of cave art has been confirmed in five sites, although further discoveries are still likely. In most cases this art occurs in the form of rock paintings, especially red-ochre hand stencils. Koonalda Cave represents that area's only major known instance of engravings and finger flutings (Gallus, 1968), which form the rock art corpus in three other cave art regions: near Perth, where three sites are presently known (as well as one cave painting site); at Buchan, with only one site; and the large body of cave petroglyphs between Portland and Mt Gambier (Bednarik, 1990). It needs to be appreciated that within the massive rock art corpus of Australia—the largest in the world (several hundred thousand sites)—the continent's cave art still represents only a minuscule fraction of one per cent.

The Mt Gambier region shows a sequence of several distinctive marking traditions. These are often separated chronologically by evidence of geomorphological events, such as tectonic adjustments, roof falls, subsidences, inundations, speleo-weathering or animal scratch marks (including megafaunal marks), and sometimes physically by layers of calcite speleothem (Bednarik, 1998). Finger flutings, made by drawing fingers over a soft, moonmilk-covered surface, seem to represent the earliest tradition (Bednarik, 1986). The traces of another distinctive behaviour occurring early in the sequence are large concentrations of impact marks, often in the form of deeply pounded holes forming discrete wall panels. These deep pits may be as much as 20 cm deep, and individual tool marks remain frequently recognizable in them. They are thought to be the most extreme form of the ubiquitous cup marks (cupules) occurring widely above ground and on much harder rock, including quartzite and granite, in similar large groups. Such cup marks occur in their hundreds of thousands in the continent's north, where they are generally recognized as representing the earliest surviving rock art.

A very different subsequent tradition has been named the Karake style, after the Mt Gambier cave where it was first recognized. It consists of a variety of geometrical motifs, usually deeply pounded and abraded into cave walls, with groove depths of up to 40 mm (Aslin, Bednarik & Bednarik, 1985). Circles are particularly prominent, sometimes forming groups of a few dozen, occasionally with internal vertical parallel lines, lozenge patterns or central pits. Other motifs include simple linear designs resembling bird or kangaroo tracks, but it is not at all certain that this is what they were intended to depict. Such designs grade into arrangements that are defined as CLMs (convergent lines motifs, in which several lines are bunched together, converging at one end but not necessarily touching). Occasional other motif types are zigzag or wavy lines, arcuate designs, and parallel lines. Again, some characteristic features of the tradition can be recognized in the pre-figurative petroglyphs above ground. A distinctive arrangement of several circles at an open granite site has been dated to about 27000 years (Bednarik, 2001), and the art of one of the Karake sites, Malangine Cave near Mt Gambier, has been shown to be in

excess of 28000 years old, through uranium—thorium dating of a covering layer of reprecipitated calcite (Bednarik, 1999). Thus, dates obtained from this cave art tradition match dating of similar rock art at open sites.

Art: Cave Art in Australasia: Cave petroglyphs in Paroong Cave, Mt Gambier. (Photo by Robert Bednarik)

The more recent cave petroglyphs at Mt Gambier consist of shallow abraded engravings of Holocene age, but it must be emphasized that some of the finger flutings, too, appear to be of that period. Another form of cave markings, frequent near Mt Gambier and Perth, consists of apparently unstructured assemblages of tool marks made either with limestone clasts or with chert tools. These are sometimes exceptionally well preserved. Only one of the Mt Gambier sites presents minor pigmented rock art, fully exposed to daylight. Similarly, there is much painted rock art in shelters and cave entrances in a further limestone area, the Chillagoe region of north Queensland, but this is not cave art in the sense that it does not occur in darkness.

Five of the sites of cave petroglyphs along the southern coast have been subjected to archaeological excavations: Orchestra Shell, Koonalda, Koongine, Malangine, and New Guinea 2 Caves. Although some of these yielded Pleistocene occupation evidence, for
none of these cases has a satisfactory nexus been established between sedimentary dates and the rock art. At six of the cave petroglyph sites, subterranean chert or chalcedony mining traces are quite prominent, and it is possible that the mining activities coincided chronologically with some of the rock art production. This is the major corpus of Pleistocene underground mining evidence in the world (Bednarik, 1995).

In Tasmania, three caves with minor rock painting are known, but the direct dating evidence obtained from two motifs, reportedly from blood residues, remains controversial. Cave art also occurs in Papua New Guinea, including small examples of finger fluting in two deep caves, Kalate Egeanda and an unpublished site (Ballard, 1992). Although rock art occurs widely on the islands of Australasia, there are no further cases known of true cave art, even though much of this art does occur in limestone regions. Examples are the shelter paintings of Vanuatu, or the numerous limestone painting sites of New Zealand, none of which occurs more than four metres from the dripline.

ART: CAVE ART IN EUROPE

Many caves in Europe, as elsewhere, have been frequented since the Ice Age and throughout history by new occupants, by shepherds, by the curious or adventurous. In some areas, such as the Basque Country, superstitions and religious traditions associated with caves are probably extremely ancient, perhaps even extending back to the Ice Age. Although art of the Neolithic and Bronze Age is found on the walls of many caves in Europe, from France and Italy to Norway, and some markings from Roman and even medieval times occur in a few, the vast majority of known cave art in Europe is attributable to the last Ice Age, dating from about 35 000 to 10 000 years ago.

While one or two scholars noticed art on cave walls in the 1860s and 1870s, nobody realised its significance or its possible age until the discovery of the paintings of Altamira Cave (see separate entry) in northern Spain. Because of the initial doubts about that cave's authenticity, it was more than 20 years later, in 1902, that the discovery of art in France's Vézère caves (see separate entry) led to the existence and authenticity of Ice Age cave art being finally accepted.

Numerous examples were then found during the first years of the 20th century, but major sites continued to be discovered (e.g. Lascaux in 1940), and indeed one or two are still found every year in France or Spain. Currently about 300 decorated caves and rock shelters of the period are known in Eurasia—unfortunately we do not know if these comprise the majority of the original total, or just a tiny sample.

The known sites vary enormously in size and in numbers of images—some contain a single image, others have many hundreds. The art is found primarily on cave walls, although some ceilings were decorated—most famously that of Altamira—and in a very few caves in the French Pyrenees, drawings have been found in the clay floor. Since most caves have had their floors destroyed by subsequent visitors, we have probably lost untold quantities of floor-art, while abundant images in caves have been covered over by calcite deposits or lost to erosion through being located close to or inside the entrances.

Ice Age cave art comprises a very wide range of techniques. The simplest was fingermarkings on clay or the soft mondmilch (moonmilk) layer on walls. By far the commonest technique in parietal art is engraving, which was done with any sharp flint tool. Bas-relief sculpture was only done in rock shelters or cave mouths, but work in clay-on present evidence limited to the French Pyrenees-ranges from bas-relief to haut-relief (the two famous clay bison of le Tuc d'Audoubert), and even fully threedimensional figures, such as the clay bear in the cave of Montespan. Where pigments were concerned, two colours were used overwhelmingly-red (which is always iron oxide, red ochre, haematite), and black (which is usually charcoal, though manganese dioxide sometimes occurs). The paints were applied with the finger, or with some kind of tool-though none has survived. Some lumps of pigments are in the form of "crayons" with usewear, but most painting was certainly done with liquid paints, applied with a brush or a pad. In certain cases, particularly hand stencils, the paint was spat from the mouth, or sprayed by blowing through a tube. A great deal of cave art seems to have been done in intense episodes of artistic activity by a small number of highly skilled people indeed, in some cases such as Covalanas in Spain, it is virtually certain that a single person was responsible for every figure in the cave.

The subject matter of cave art comprises primarily animal figures—almost all adults drawn in profile, with no groundlines or landscapes, and very few recognisable scenes. Only a limited array of species was depicted—this is not an Ice Age bestiary. They are dominated by horse and bovids (bison and aurochs); deer, ibex, and mammoths are secondary, while carnivores and rhinos are rare, except in Chauvet Cave. Occasionally one species is overwhelmingly dominant, such as the mammoth in Rouffignac Cave.

Humans or "humanoids" (anthropomorphs) occur far more rarely, which constitutes one of the enigmas of cave art—since the artists were clearly capable of drawing them when they wished (there are numerous examples in portable art objects), then their scarcity in cave art may be explained by their depiction being taboo for some reason or, perhaps more probably, simply irrelevant to what the artists were trying to do. The final category of cave art is the range of apparently "abstract" or "non-figurative" motifs, known as "signs". While the simpler signs, such as dots and lines, are inevitably ubiquitous, the more complex ones are highly localized in space and time and have been interpreted as some kind of ethnic marker.

Some cave art was "public", on open view, but much is hidden or inaccessible, which points to a religious motivation for at least some of it. Much appears linked to a complex mythology, and no single explanation can possibly suffice for the phenomenon. Interpretations have varied over the years: at first, the art was assumed to have no particular meaning, it was "art for art's sake" produced by hunters with time on their hands. Subsequently, "sympathetic magic" became the dominant theory—it was assumed that the pictures were symbolically killed (hunting magic) or made to encourage the animals' reproduction (fertility magic). Unfortunately, there are no hunting scenes or copulation scenes among the many thousands of images, very few animals are marked with possible missiles or wounds, and on the whole the artists were not drawing the species which formed the basis of their diet.

In the mid-20th century, attention shifted to developing more complex (and probably more accurate) interpretations, and it was decided to focus on the art itself—by quantifying each category of image, and treating cave art not as a random accumulation of individual pictures, but as a carefully laid-out composition within each cave (an idea developed primarily by the French prehistorian André Leroi-Gourhan).

A more recent approach has been the study of the acoustic properties of decorated caves and rock shelters, an intriguing and long-neglected factor which tries to revive something that one might imagine gone for ever: the sound dimension which accompanied whatever rituals may have been carried out in such sites. Echoes are common in and around decorated rock shelters all over the world, as is the equally mysterious and impressive phenomenon of cavities which focus and project sound, while several decorated caves contain "lithophones"—stalactites which bear percussion marks and sometimes even painted marks.

Overall, since Ice Age art spans such a huge area of Europe—from Portugal to the Urals—and such a huge timespan, and such a tremendous range of techniques and styles, it is obvious that no single explanation can ever suffice for the phenomenon. Each of the many interpretations already put forward probably contains some truth, while there are doubtless many more which have not yet been imagined.

ART: CAVE ART IN THE AMERICAS

Some 300–400 cave art sites are known in the Western Hemisphere, although few of them have been adequately investigated. Numerically, this corpus rivals the European Paleolithic; however, New World cave art presents a more fragmented picture, occurring in a wider range of cultural and geological settings, including sandstone and basalt fissures in addition to deep limestone caves. The present overview encompasses all of these environments if researchers consider them to be caves. Cave art is found in North, Central, and South America, and the Caribbean Islands, which possess the largest concentration in the hemisphere. Cave art sites utilized by hunter-gatherers over 3000 years ago are known in the Americas; however, many sites are associated with sedentary agriculturalists, such as the protohistoric Aztecs of Mexico, the Pueblos of the American Southwest, the Mississippian cultures of the Southeast, and the Taínos of the Caribbean. The most deeply sequestered art is linked with the pilgrimage activities and elaborate ceremonialism of village-dwelling, farming populations who believed that caves were sacred places where spirits could be contacted.

Issues surrounding cave art studies in the Western Hemisphere parallel those of the parent field of rock art research. One of its primary concerns is the relationship between rock art and the earliest human populations—research aided by new techniques for directly dating pictographs and coatings on petro glyphs, the most reliable being ¹⁴C AMS analysis of pigments. Cave art in the New World does not approach the antiquity of European or Australian examples. The oldest New World examples occur in South America, in modest sandstone caves, typically 10–20 m deep (see the South American chapters in Strecker & Bahn, 1999, and Whitley, 2001). Several caves with Late Pleistocene paintings have been discovered in Brazil, where the Caverna da Pedra Pintada revealed datable pigment splashes with a minimum age of 9000 BC. In Argentina, the oldest cave art, assigned to the Toldense culture (9000 BC), features negative hand prints and paintings of guanacos. Hand prints in the Cueva de las Manos in

Patagonia have been dated to 7300 BC. Small caves are also associated with the art of Early Holocene hunter-gatherers in the high Andes in southern Peru and Chile. However, none of the early sites reported in South America have dark zone art. The earliest New World dark zone art is found in the southeastern United States (Tennessee and Kentucky) and dates between 1600 and 1000 BC. These Archaic sites contain both "mud-glyph" art (see below) and incised petroglyphs (Simek *et al.*, 1998).

In the western United States, cave art typically occurs in basalt formations. Some 517 painted motifs, mostly circles and zigzags dating between 1000 AD and the historic period, have been documented in lava tubes in the Modoc Plateau of Califor-nia (Whitley, Loubser & Hann, 2003). Pictographs have also been discovered in one lava tube in Oregon. Owl Cave in Washington houses paintings in an 18 m diagonal basalt fissure (Keyser *et al.*, 1998). In the western United States, cave art is generally given a shamanic interpretation. Other cave art sites are widely dispersed in the west (Montana, Colorado, and Wyoming).

Caves with pictographs, including four with dark zone art, are scattered across the American Southwest (Greer & Greer, 1999). The Mogollon site of Feather Cave, New Mexico (1000 AD) is unique in the Americas in having dark zone art associated with undisturbed perishable materials (Ellis & Hammack, 1968). An isolated chamber (Arrow Grotto) has preserved miniature bows and arrows, wooden bowls, and prayer sticks. Arrows were also found lying under a stencilled hand, and feathers were set into wall crevices surrounding groups of pictographs.

A few cave art sites are found in the American Midwest. Five have been reported in Missouri (Greer & Greer, 1999). One has dark zone pictographs dating to the Mississippian period. The newly discovered Tainter Cave in southwestern Wisconsin has the only dark zone cave art known in the Upper Midwest. Charcoal pictographs dating to 900 AD occur at 70 m in a sandstone tunnel. One portrays a hunter shooting a pregnant deer with a bow and arrow.

Mud-glyph cave art—designs incised into mud-covered embankments and walls—has been known in the southeastern United States since 1979. Five of seven investigated sites date to the Mississippian period (1000–1600 AD) and have Southern Cult imagery, such as the trilobed arrow and weeping eye; however, Archaic sites with related art suggest a more ancient origin for the mud-glyph tradition (Simek *et al.*, 1998). Other caves in the region have incised petroglyphs and mud-drawn pictographs, while Mammoth Cave and Salts Cave have charcoal pictographs drawn with burnt cane torches. With roughly 20 decorated limestone caves, the southeastern United States has the largest number of dark zone cave art sites in North America.

Mesoamerica is another important repository of New World cave art. Greer & Greer (1998) note sites in San Luis Potosí, Mexico. Closer to Mexico City, a 12.5 m lava tube houses an Aztec-style painting. Two cave art sites are associated with the Middle Formative (900–400 BC) Olmec culture (see summary in Stone, 1995). Their large naturalistic paintings are the oldest stylistically datable cave art in Mesoamerica. They are also the most deeply sequestered: at Juxtlahuaca, Guerrero paintings lie 1000 m from the entrance. The greatest concentration of Mesoamerican cave art occurs in the heavily karstified Maya Lowlands, where some 50 sites are known. Strecker did extensive work on cave petroglyphs in Yucatan. Painted sites are summarized in Stone (1995), and new cave art continues to be discovered. Classic period cave painting (300–900 AD) produced

by Maya elites has shed light on the role of caves in archaic states (Figure 1). In Naj Tunich, Guatemala, hieroglyphic inscriptions reveal the politicized nature of elite cave shrines. A more rustic form of Maya cave art is anthropomorphically carved speleothems, also found in Caribbean caves. Evidence suggests that the Maya viewed these "stalagmite idols" as gods (Brady, 1999). Central America south of the Maya area has revealed few cave art sites, although two with pictographs were recently discovered in Honduras (Brady *et al.*, 2000).

Art: Cave Art in the Americas:

Figure 1. Black line painting of a deity ball-player next to the steps of a ball-court. Painting 22 cm high, date *c*. 700 AD. Drawing 21, Naj Tunich, Guatemala. (Photo by Chip and Jennifer Clark)

Ironically, the region with the greatest concentration of cave art, the Caribbean Islands of Cuba, Puerto Rico, Hispaniola (Dominican Republic), and Jamaica, has the least accessible literature for an English-speaking readership. All indications are that hundreds of cave art sites have been located in the Greater Antilles, although they have not been scientifically investigated. They are associated with the protohistoric Taíno and earlier groups. The Cuban archipelago boasts 130 sites (Nuñez, 1985) with cave art spanning several thousand years of Pre-Columbian occupation. Although petroglyphs do occur, the art is dominated by thickly drawn pictographs of geometrics, animals, and frontal figures and faces (Figure 2). Dubelaar *et al.* (1999) have published a guide to Puerto Rican rock art, mentioning dozens of cave art sites found largely in the island's mountainous interior. While dark zone art in limestone caves has major expressions in most regions of the Americas, little has been found in South America. Decorated limestone caves are known in the Chapada Diamantina, Bahia, and the state of Minas Gerais, Brazil; however, pictographs and petroglyphs occur principally in lighted areas near entrances, for instance, in the Lapa da Sol near Iraquara, Bahia (see also Figure 3).

The wealth of cave art found in the Americas offers unique insights into the ritual utilization of the landscape and symbolic systems of populations running the entire gamut of social complexity. Increasing archaeological and public interest in rock art

Art: Cave Art in the Americas: Figure 2. Red paintings of large, thickly drawn symbols; grouping at right, roughly 1.2 m high. Cueva Pichardo, Cuba. (Photo by Reinaldo Morales Jr.)

Art: Cave Art in the Americas: Figure 3. A wall of paintings 10m high in an alcove at the upstream end of the Gruta do Janelão in the Peracu National Park, Minas Gerais state, in Brazil. (Photo by Tony Waltham) promises a bright future for our understanding of this rich expression of indigenous American art.

ASIA, CENTRAL

This region covers deep interior parts of Eurasia within Kazakhstan, Turkmenistan, Uzbekistan, Tajikistan, and Kyrgyzstan (see map in Russia entry). Most of the region lies within the internal catchment basins of the Caspian and Aral Seas and Lake Balkhash. The relief ranges from lowlands of the eastern Caspian (-132m) to the high uplands of the Pamir, and some of the highest mountain peaks of the Tien Shan. Because of its interior continental position and isolation from the summer monsoons, arid or ultraarid climates are characteristic for most of the region. Annual precipitation is commonly within 100–300 mm, but is below 100 mm in many places in lowlands and mountains. Stony, clayey, and sandy deserts on lowlands and uplands are the most common landscapes in Central Asia.

Although soluble rocks crop out through large parts of the region, in both plains and mountains, the dry climate results in generally poor contemporary development of limestone karst. Typical doline-dominated karst landscapes on limestones are found in only a few places in the mountains where local conditions create higher precipitation, as on the Kyrktau Plateau in the Zeravshansky range (see Figure 1). However, caves develop in some mountain areas even below seemingly non-karstic, barren, and fissured surfaces (e.g. in the Bajsuntau region of Tien Shan). It is likely that this cave development is maintained mainly by condensation recharge from the epikarstic zone. A specific "Central Asiatic" arid type of epikarst can be distinguished, characterized by scarcity of dolines and by the presence of the densely fissured near-surface zone, mantles of limestone clasts (the result of physical weathering), and collapse shaft entrances. Another feature of the region is the many hypogenic

Asia, Central: Figure 1. Doline on the Kyrktau Plateau in the Zeravshansky range. (Photo by John Gunn)

caves produced by hydrothermal and sulfuric acid speleogenesis. Opened by surface denudation, small relict caves of this type are abundant throughout the mountains of Tien Shan, Pamir, and Kopetdag. Some large caves are also known, both relict and active (e.g. Syjkyrdu Cave in Pamir, Karljuksky and the Fergansky caves in Tien Shan, Bakharden Cave in Kopetdag). Low precipitation is enough to develop pronounced karst in gypsum and salt wherever these lithologies are at or close to the surface. There are many spectacular evaporite karsts in the region, and it is the aridity that allows karst landscapes to survive on evaporites.

Based on geological structure, Central Asia can be subdivided into several large regions (Grozdetsky, 1981): (1) the Turansky Plain; (2) Caledonian and Hercynian mountains of the Tien Shan; (3) the plains and low mountains of Central Kazakhstan; and (4) the alpine mountains of the Kopetdag range and Pamir.

The Turansky Plain has a Paleozoic folded basement mantled with Mesozoic and Cenozoic cover containing carbonates and evaporites. It is a vast desert region that extends between the Caspian Sea, the Tien Shan and Central Kazakhstan, the Ural Mountains, and the Kopetdag range. The Hercynian carbonate structures of the basement locally crop out in the cores of anticlines (e.g. Mangyshlak) or as low mountain ranges. Most of the Turansky Plain is occupied by the large sand deserts of Karakum, Kysylkum, and Mujunkum. Prominent is the Ustjurt tableland that rises above lowlands between the Caspian and the Aral Seas. The plateau is composed of Neogene limestones and underlying gypsum, and is bordered with distinct denudational cliffs. Karst features include large closed depressions, solution dolines, collapse dolines with vertical walls, and many small caves. The longest cave is Sarykamyshskaya (200 m long) and the deepest shaft is Bolojuk (120 m). Adjacent to Ustjurt on the southwest is the

Karabogazgol Gulf, where a contemporary deposition of evaporites occurs; it is connected to the Caspian Sea by a channel 4 km long. In the eastern part of the Turansky plain gypsum and limestone karst is reported in the Betpak-Dala desert and the Chujsky region (in Carboniferous gypsum).

The Tien Shan is a block folded system that originated during the Caledonian and Hercynian orogenies and regenerated during the Alpine cycle. The ranges of Tien Shan stretch east to west for almost 3000 km through Uzbekistan, Tajikistan, Kyrgyzstan, Kazakhstan, and northern China, and are up to 400 km wide. The highest peaks exceed 7000 m. The Caledonian northern Tien Shan includes ranges north and east of the Fergansky range and the Talaso-Fergansky fault. The Hercynian southern Tien Shan has two series of ranges separated by the Fergansky depression; the Karatau, Ugamsky, Pskemsky, Chatkalsky, and Kuraminsky ranges lie to the north of the depression, while the

Asia, Central: Figure 2. The splendid limestone escarpment of the Bajsuntau ridge, with a number of cave systems truncated in its scarp face. (Photo by Andy Eavis)

Alajsky, Turkestansky, Zeravshansky, Gissarsky, Bajsuntau, and Kugitangtau ranges lie to the south. Thick and extensive Paleozoic carbonates are widespread in the Tien Shan. Mesozoic and Cenozoic sediments mainly fill depressions but locally form ridges folded and uplifted during the Alpine regeneration (e.g. in the Bajsuntau and Kugitangtau ranges). Ice caves are found in mountain glaciers of the northern Tien Shan (Mikhalev, 1989). Karst is better studied in the southern Tien Shan. In the ranges to the north of the Fergansky depression, notable karst landscapes and caves are reported from the Ugamsky and Pskemsky ranges. Among many vertical shafts, the Zajdmana Cave (length 830 m/depth 506 m) and Uluchurskaja Cave (1500 m/ 280 m) are the largest. Many limestone massifs lie within the ranges south and southwest of the Fergansky depression, but doline landscapes and active caves are found only in a few localities. Instead, there are a great many small hydrothermal caves. Some larger caves of this type are found along the southern edge of the Fergansky depression, including Kun-Ee-Gout (a 3000 m long, 3-D system of integrated karst cavities and ancient lead-silver mine workings), the 1480 m long Pobednaja Cave, and the 220 m deep Fersman's Cave in Tjuja-Mujun. A spectacular karst is associated with the Neogene salt and gypsum caprocks in the Kysyl Dzhar Mountains; it is densely pitted with dolines, and swallow holes, and numerous caves are reported but not documented.

The most renowned karst of the southern Tien Shan is the Kyrktau plateau, at the western end of the Zeravshansky range at 2100–2400 m. Its classical karst landscapes (Figure 1) include great karren fields, numerous dolines and many vadose shafts in Silurian limestones and dolostones (Klimchouk *et al.*, 1981). During the 1970s, over 100 shafts were explored there including the Kievskaja Cave, 990 m deep and then the deepest cave in Asia.

The Gissarsky includes the Bajsuntau, Chul' Bair, and Kugitangtau ranges, with extensive carbonate and gypsum formations of Jurassic, Cretaceous, and Paleogene ages folded during the Alpine orogeny. There are several remarkable areas of gypsum karst with densely packed dolines, blind valleys, and many caves. These include the Yakkabag Mountains (on Gissarsky), Mingchukur and Kukhisurkh (on the Bajsuntau) with the Kjaptarkhana Cave over 1000 m long, and Khodzharustam (on the Kugitangtau) with many 20–60 m deep shafts (Gvozdetsky, 1981).

The limestone escarpments of Bajsuntau and Chul' Bair reach more than 3000 m high. Their many important caves include Bojbulok (14270 m/1415 m, currently the deepest cave in Asia) and the Festiva'naja-Ledopadnaja system (13000 m/625 m) (Bernabei & De Vivo, 1992). On the southwestern edge of the Kugitangtau range, in Turkmenistan, the Karljuksky area is renowned for its highly mineralized caves ramifying in three dimensions, which originated by sulfuric acid dissolution. These include the Cupp-Coutunn Cave System (see separate entry), Khashim-Ojuk Cave (6400 m/170 m), and Geofizicheskaya Cave (4300 m/100 m; see photograph in Speleogenesis: Deep-Seated and Confined Settings). In the nearby lower Gaurdaksky range a large tectonically controlled cave of the same name is another example of sulfuric acid speleogenesis. It begins in Jurassic gypsum but extends horizontally for 11010 m in underlying limestones.

Central Kazakhstan lies between the Western Siberian platform, the Ural Mountains, the Altai-Sayan folded belt (see Siberia entry), and the northern Tien Shan. Low hills and plains areas are broken by wide valleys and extensive depressions. Most of the region is occupied by dry steppes with salt lakes in the northern part, and by deserts to the west and south of Lake Balkhash.

The area is composed of Caledonian and Hercynian folded Precambrian and Paleozoic rocks, with carbonates, some heavily metamorphosed in the latter. Surface karst features are rare, though features of karst hydrology include intermittent streams, springs, and small karst lakes in the eastern parts. There are many paleokarstic features, attributed to

the Cretaceous and late Oligocene, including dolines and large depressions filled with clays and bauxites. Large deposits of bauxites and phosphorites, associated with the upper Devonian and Carboniferous limestones, are of karst origin. These beds are often heavily karstified at depth, with porosities reaching 26–28% and high yields of karst water. Deep-seated cavities are encountered in mines in

Asia, Central: Figure 3. An abandoned trunk passage in the Festival'naya cave system in the Bajsuntau escarpment. (Photo by Andy Eavis)

many bauxite and iron ore deposits. In sulfide ore deposits in the eastern parts, some large cavities were formed due to sulfuric acid dissolution.

The Pamir Mountains, situated mainly within Tajikistan, are essentially of Alpine origin. The central and southern parts of the Pamir belong to the same orogenic belt as the adjacent mega-ranges of the Hindu Kush, Karakorum, and Kun-Lun. The eastern Pamir is a high upland with a very arid climate, with the floors of valleys and depressions at 3600–4000 m and mountains rising to 6000 m. The western Pamir is a series of jagged ranges that rise for 1500–3500 m above the bottoms of deep valleys at altitudes of 1500–2500 m. The highest peaks of the Pamir, in the central and northern ranges, rise to over 7000 m.

Current knowledge of karst and caves is limited to a few areas within the Pamir Upland, particularly in its northern part. Limestones of Silurian, Devonian, Carboniferous, and Triassic ages have extensive outcrops, but contemporary karst development is negligible due to the very arid climate. Cave-riddled, mogote-like, rocky hills near Rangkul' Lake are regarded as paleokarst (Gvozdetsky, 1981). The most notable karst site is the Syjkyrdu (Rangkulskaya) Cave, in Triassic limestones at 4600 m above sea level to the south of the lake. The cave, of presumably hydrothermal origin, is a complex 3-D system with 2050 m of passages mapped so far within a vertical range of 268 m. It contains remnants of a "fossil" underground glacier, "cave loess" sediments, and archaeological artefacts.

Gypsum karst with closely packed doline fields is known at many high altitude sites in the Petra Pervogo and Zaalajsky ranges. Gypsum caves in the Petra Pervogo range include one 400 m long, climbing 126 m above the entrance level.

Spectacular salt karst is formed on the Khodja-Mumyn and Khodja-Sartis salt domes, near Kuljab in the Tadhiksky depression. The domes rise up to 900 m above the surrounding plain and support a great variety of karstic features including dolines, deep collapses and shafts, various karren forms, pinnacles, and giant salt "mushrooms" capped with residual boulders of gypsum (Dzens-Litovsky, 1966). The many caves in the Khodja-Mumyn dome include Dnepropetrovskaya (2500 m/100 m), Komsomol'skaya (1800 m/100 m), Soljenoye Chjudo (870 m/60 m), and Vershinnaja (338 m/120 m).

ASIA, NORTHEAST

Eastern Asia has the world's most extensive karst landscapes, largely in the provinces of Guangxi and Guizhou in southern China (see separate China entry). There are also many other significant karst regions within China, but the adjacent lands of Tibet, Mongolia, Korea, and Taiwan all have only minimal karst, while there is little more in Japan. Similarly there is little significant karst in Siberia, though there is a profusion of karst in adjacent countries to the south (see Asia, Southeast entry). Climates in the region vary from wet sub-tropical in southern China to cold, dry continental in Mongolia. This does have a major influence on karst morphologies, but the areas with less favourable climates broadly coincide with those with less limestone, thus enhancing the regional differences.

Mongolia has scattered outcrops of limestone beneath its grassland steppes and barren mountains. Many fragments of relict cave have been found, none longer than 500 m, but

no active caves are known. Modern karst processes above and below ground appear to be on minimal scales in the cold, dry climate.

Korea has two belts of broken outcrops of strongly folded Lower Paleozoic limestones across its mountainous terrain. The smaller belt, in South Korea, contains a number of short caves, of which a high proportion are very well decorated with calcite and have been developed as tourist sites. Its deepest cave, Namgamduk, is a shaft system reaching 181m. There are some areas of doline karst, but most of the outcrop appears as steep wooded slopes with incomplete underground drainage. Little is recorded about North Korea and there are no known regions of conspicu ous karst landforms, though a number of decorated caves have been developed for tourist access. All the longest caves in Korea are lava tubes in Cheju Island (see separate entry), off the coast of South Korea.

Japan has over 1500 km² of karst on small, disconnected outcrops of limestone scattered across this plate boundary terrain of fold mountains and active volcanoes. Karst occurs on all four main islands, but the most significant sites are on Honshu. In the north, the Iwate karst has a number of long caves including Akka-Do with over 8 km of mapped passages. On the west coast, the Niigata karst contains the country's deepest caves with Byakuren-Do (422 m deep) and three others over 300 m deep. The single most important karst is on the Permo-Carboniferous limestone of the Akiyoshi Plateau (see separate entry), near the southwestern tip of Honshu. Uplifted reef limestones are widespread on Okinawa and the Ryukyu Islands, where there are areas of doline karst, numerous caves including Gyokusan-Do with over 5 km of passages, and marine platforms of fretted limestone. There are lava tubes in various of the basaltic volcanoes, with caves over 2 km long on the island of Fukue.

Taiwan has little limestone and little karst. In the eastern flank of the core mountains, the Taroko Gorge has its most deeply incised section through a belt of marbles, but it is a fluvial feature characterized by surface flow on steep slopes. Springs in its floor carry only a small proportion of drainage from the marble outcrops.

TONY WALTHAM

Asia, Northeast: Generalized map of the carbonate outcrops of northeast Asia. These areas are much larger than the areas with significant karst and include areas of dolomitic limestone. Locations of many key karst sites in southern China are marked on the enlarged map in the China entry.

ASIA, NORTHEAST: HISTORY

The countries covered in this entry are China, Tibet, Japan, Korea, Mongolia, and Taiwan. The Chinese and Tibetans have been exploring and using caves for shelter and religion for thousands of years. Reference to karst in China is found frequently in early Chinese literature and is depicted in their art, particularly of the towers of Guilin, while caves featuring Buddhist art have been tourist attractions since ancient times. Studies of Japanese karst have a substantial history in the 20th century and those in Korea less so, while in Mongolia and Taiwan caves seem to have remained unnoticed until comparatively recently.

China

As befits the country of such an ancient civilization, much was known about Chinese karst and caves from very early times up to the mid-17th century. Then there was a long interval before the next phase of karst research in China began after World War II with international links and exchange programmes. The archaeological excavation in the 1920s of "Peking Man" from the cave at Zhoukoudian is described in the entry China: Archaeological Caves.

It is said (Sweeting, 1995, p.33) that caves in north China were described in a book written before 221 BC. More definite, because the texts are known today, are descriptions of speleothems and their use in powdered form as medicine from the 4th century BC to the 16th century AD. Their efficacy in this respect was very real, for people with a calcium-deficient diet benefit enormously from them, just as modern Chinese benefit from drinking crushed Pleistocene "dragon's teeth" to alleviate heart conditions. The pharmaceutical use of speleothems led to their being studied themselves, in the same way that European medicine led to physic gardens and the study of botany (Shaw, 1992).

Ko Hung, in the *Pao Phu Tzu* of about 300 AD, described two objects which are clearly stalagmites. In the Shao-Shih Mountain, "there is a stone pillar standing more than a hundred feet from the entrance to the caves, having on top of it a stone looking like an upturned lid, ten feet high" (quoted from *Science and Civilization in China* by Needham, 1959; vol.3, p.606). Drips, he says, fall into this from the cave roof above. Again: "The shih-kuei chih (stone cassia mushroom) grows in the caves of holy mountains. It resembles the kuei tree (cinnamon), but it is really a stone. It is more than one foot in height, and about one foot in diameter. It is bright and shining. Its taste is sharp, it has branches and twigs" (quoted from translation by Eugene Feifel, in *Monumenta Serica*, 11:7). In 1175 AD Fang Chengda wrote that "Milky water drips continuously in the cave, with the process of condensation taking place simultaneously. [Each stalactite] hollow in its centre is just like a goose feather...and the milky bed as white as snow is formed by the condensation of stone solution" (quoted from *A Brief Introduction to China's Research in Karst*, Yuan Daoxian, 1981, p.3).

A Chinese drawing (Figure 1) of speleothems was included in the *Pên Tshao Kang Mu* (The Great Pharmacopoeia) of Lin Shih-Chen in 1596. The earliest known reference to speleothems being used medicinally is their inclusion among the *materia medica* in the early Chinese pharmacopoeias. These include the *Chi Ni Tzu* which dates from the 4th century BC and the *Shen Nung Pên Tshao Ching* (Pharmacopeia of the Heavenly

Husbandman) about the 1st century BC. A silver box containing fragments of medicinal stalactite dating from the 8th century AD was unearthed in 1970 at a Tang site in Shensi province. In about 300 AD, Ko Hung's stone mushrooms in caves were thought to provide a recipe for long life, either by drinking the water from them or from the material itself, pounded and eaten. The continuing importance of these substances is shown by their being

Asia, Northeast: History: Figure 1. Speleothems in Li Shih-Chen's book of 1596.

Asia, Northeast: History: Figure 2. Xu Xiake.

discussed, with their various uses, in the later mineralogical books such as Tu Wan's Yün Lin Shih Phu (Cloud Forest Lapidary) of 1130 and Chou Chhü-Fei's Lin Wai Tai Ta of 1178. In 1596 Li Shih Chen's Great Pharmacopoeia listed under different names seven kinds of stalactites and stalagmites, separating them not only by coarseness and shape, but also by their being different parts of the speleothems, such as the "root part". At about this time a printed reference of 1541 records a cave fish, now called *Sinocyclocheilus hyalinus*, being found in the Alu Caves of Yunnan (see Biospeleologists entry).

All the above are but interesting details compared with the comprehensive work of Xu Xiake, the assumed name of Xu Hongzu (1587–1641) (Figure 2). He is rightly regarded as the father of Chinese speleology and would perhaps have been the father of world speleology, coming as he did even before Kircher and Valvasor, if his writings had been more widely known to his successors. His book, which was written over a period up to 1640, was the first to describe karst landforms systematically. The original manuscript is in the National Library of China in Beijing, and it was first printed (in Chinese) in 1776. The book is a diary recording his travels around China, undertaken on foot and usually

alone over a period of more than 30 years. Between 1637 and 1640 he was in the karst of south and southwest China, spending 976 days there in all. The karst features described include most of the karst landforms that we recognize today, such as karren, dolines, uvalas, poljes, natural bridges, dry valleys, disappearing rivers, tower karst, blind valleys, water swallets, cave deposits, and caves themselves. His descriptions of these karst features are detailed and basically accurate. Some modern special terms in karst studies in China, such as fenglin or peak forest, originated from Xu Xiake's descriptions.

In Guangxi province alone, Xu Xiake explored more than 160 named caves and tens of caves without names. Many of these caves had never previously been explored. When he explored them, he measured their size, depth, and other dimensions by pacing or by visual estimation. He also collected samples of cave deposits. His descriptions included the distribution, structure, and relationships of the caves; the shape, size, and the direction of cave passages; direction, size, and shape of cave entrances; the shape, size, and colour of cave deposits; flow of water; and explanations of the formations of deposits. Thus, of a big column hanging from the roof: "this is the result of solution and precipitation of rock". Ting (1921) said that Xu Xiake's diary "read more like a 20th-century surveyor's field book than the diary of a 17th-century traveller". A modern assessment of Xu Xiake's work (Hu, 1991), from which much of this summary is drawn, gives a route map of his travels in the karst. A statue of him now stands outside the Institute of Karst Geology in Guilin.

There followed several centuries in which no significant work on karst took place in China. Some studies began again in the 1930s and 1940s and then, after the People's Republic of China was formed in 1949, Europeans from the Eastern bloc were encouraged to visit the tower karst of Guilin where the Karst Institute was to be founded in 1976. In the 1970s and 1980s other Europeans were also welcomed and Sweeting (1995) describes her own and other collaborations. There was Paul Williams's work with the Chinese Academy of Sciences in 1976, followed by a Franco-Chinese hydrological project, and Anglo-Chinese and Chinese-American projects. Of particular note is the China Caves Project, an informal collaboration between British cavers and scientists from the Institute of Karst Geology in Guilin. The project commenced in 1982 (Waltham, 1986), and is ongoing. There have been over 15 expeditions to China and many exchange visits. More recently a most productive liaison has developed since 1995 between the governments of China and Slovenia with exchange visits and joint work by the Karst Research Institute in Postojna, the Yunnan Institute of Geography, and the Institute of Geology at the Chinese Academy of Sciences in Beijing (Chen Xiaoping et al., 1998). Work by the Chinese themselves has developed considerably and all these collaborative projects ensure that they are fully aware of the techniques and traditions of research elsewhere.

Japan

The earliest description of a Japanese cave seems to be the report on Akiyoshi Cave published in 1904 in Japanese (Torii, 1957–59). More widely known in the West is the slightly later account by an English resident, the schoolmaster George Edward Gauntlett (1868–1956) who visited it in 1907. The cave had already been known for a long time but it was difficult to access. Gauntlett (1909) published a plan and offered to pay for some of the passages to be enlarged and a boat to be provided to encourage visitors. A set of

picture postcards was issued at the same time. Gauntlett also reported seven other caves nearby, including a vertical one which he planned to explore. A stream sinking 10 km to the northeast was said to have been traced to the main cave by throwing young rice stalks into the water.

Systematic exploration of Japanese caves was first undertaken by the geologist Denzo Sato from 1920–25 (Torii, 1957–59). Professor Ohhashi had investigated a cave at Akita in 1915 and some in Okinawa were explored by Awatsu in 1920. Biospeleological research was started in 1927 by Professor Masuzo Uémo, later the President of the Speleological Society of Japan. There was more work in the 1930s: Torii collected at 62 sites between 1936 and 1939 and Dr Verhoeff published on the subject from 1939–43. Relatively little was done on prehistoric cave remains but Ice Age humans were found in several caves in 1938, and the discovery of human bones of Pleistocene age was published in 1950. Japanese biospeleologists also worked in Korea with their colleagues there, notably in 1966 (see below). Several other expeditions abroad took place in later years including to Korea in 1976, to the Philippines in 1982 and 1983, and to Taiwan from 1996.

The Speleological Society of Japan was founded in 1975 and started to publish its *Journal*, which still continues, in the next year. The Japan Caving Association was formed in 1959 and its *Japan Caving* commenced in 1969.

Korea

The 1500 m long Dongryong-gul cave in North Korea is said to have been known since the 7th or 8th century (Shikama, 1948) and to have been used as a refuge in the Russo-Japanese and Japanese-Chinese wars. The same cave was surveyed in 1929. Cave fauna was collected there and elsewhere around 1939 and biospeleology has driven much of the subsequent cave research in Korea. In 1966 a joint Korean-Japanese expedition in South Korea explored 21 limestone caves and two lava caves, surveying some of them, and collecting fauna from them and from 49 wells. More biological work followed.

The Korean Caving Association was founded in 1966 and by 1975 had become the Korean Association for Conservation of Caverns which afterwards surveyed those caves designated as national monuments. A cave survey team in the National Science Museum listed 92 caves in 1974, with location, and published references, and the cave Exploration Club of Dongguk University, formed in 1970, reported 66 species from more than 150 caves. The Speleological Society of Korea was formed in 1973 and published a journal from 1975. Its members worked closely with their Japanese counterparts who visited Korea again in 1976 (Lee, 1989).

Mongolia

The karst of Mongolia was almost unrecognized until the 1990s, though the Czech ethnographer Pavel Poucha had noticed a cave near the Russian border in 1956. A Czechled international expedition in 1994 published a map showing widespread patches of karst throughout the country, especially in the extreme north near Chövsgöl nuur. They surveyed several caves up to 300 m long, remarked on the presence of permafrost and noted a cave in pseudokarst in western Mongolia (Holúbek, 1995). Three British visits from 1994 to 1996 investigated caves in the west of the country (including one with paleolithic-style wall paintings of animals), and the Gobi desert.

Tibet

In 1715 two Jesuit priests, Desideri and Freyre, visited the Padmasambhava cave at Chiu Gompa monastery in Ngari province (Gebauer *et al.*, 1995, p.224). The Tibetan karst has also been studied by the Chinese since 1951 (Sweeting, 1995, p.39, pp.212–19), and Loubière (1987) reported a 100 m long cave 15 km north of Lhasa that contained water as well as religious paintings. In the 1980s and 1990s Sweeting and Zhang Dian recorded caves between 4000 m and 5000 m above sea level in northern Tibet, in the Dingri area on the slopes of the Himalayas, and near Lhasa. All were 100 m or less in length and all were dry, having been formed when the water table was much higher. Evidence from the caves suggests a tropical Tertiary period, a warm and wet early and middle Pleistocene phase from which most of the dated speleothems came, followed by the present cold and arid climate from the late Pleistocene.

Taiwan

Less is known about caves and karst in Taiwan than in any other part of northeast Asia. There is reef limestone in the south of the island and Hsu (1975) mentioned three caves there, indicating that they had been little studied. The Japanese started serious investigations in that Taroko Gorge limestone area in 1996.

ASIA, SOUTHEAST

Karst is a widespread and important phenomenon in mainland Southeast Asia. The countries of Myanmar, Thailand, Laos, Vietnam, Cambodia, and mainland Malaysia all contain significant limestone karst areas, which cover around 215000 km², or 10% of the region. Large areas of sandstone and buried evaporite karst are also present. The karst occurs mostly on carbonate rocks older than Jurassic, with the Permian and Carboniferous being the most important, located primarily on structural highs in association with Paleozoic and Mesozoic formations.

Cambodia has limited karst areas. Tower karst dominates the south near Kampot and Tuk Meas. More extensive areas are in the northwest near Pailin, Battambang, and Sisophon, with some around Stung Treng. Laos has the larger part of the extensive Khammouan karst (see separate entry, Khammouan). Other extensive karst is found at Vangvieng, Kasi, Luang Prabang, the Nam Ou valley, and Viengsai. Mainland Malaysia has scattered small karst areas in the central part in Perak, Kelantan, and Pahang States, and near Kuala Lumpur. In the northwest, Perlis State and Langkawi Islands have larger areas of karst. Myanmar has large karst areas on the 500 km wide Shan Plateau, with more at Mogok, near Hpa-an/Mawlamyine and in the Myeik archipelago. In Thailand, the 12000 km² "Western Karst Complex" lies near the Myanmar border. Other large karst areas are at Phangnga, Krabi, Saraburi, Mae Hong Son, Chiang Dao and the Loei/Chum Phae area. In Vietnam, the largest karst areas include the continuation of the Khammouan from Laos and many areas in the north at Lang Son/Cao Bang, Ha Giang, Song Da/Son La and Ha Long Bay (see separate entry, Ha Long Bay).

Climatic Conditions and Vegetation

The region has a tropical to sub-tropical monsoon climate, with strong seasonality. Rainfall usually arrives from May to October (southwest monsoon) and more locally from November to January (northeast monsoon). Total rainfall is around 2500 mm a^{-1} at low to moderate elevations, increasing to more than 5000 mm on the mountain sides exposed towards the southwest. Average annual temperature at low elevations varies from 28°C in the south to 25°C in the north, and to 21°C at altitudes of 1000 m. High temperatures, strongly seasonal rainfall, and high evapotranspiration lead to long periods when there is autogenic recharge to the karst aquifer. Southeast Asia has been subject to moderate fluctuations in climate during Quaternary glacial episodes. The effect of such periods was reduced rainfall and temperature, with only limited impact on karst processes. During some interglacials, it was warmer and wetter than the present.

Vegetation type and density is very variable on the karst. In equatorial areas, rain forest may be present and quite dense. In unspoilt areas of Laos, forest has a lower density, and it is better developed on shaly limestones. In more arid areas, such as Kanchanaburi, Thailand, the vegetation is more xerophytic and deciduous. The native vegetation has been heavily destroyed in many areas by human activities.

Tectonic History

Morphogenetic evolution of the karst is the result of a complex tectonic history. Notwithstanding many uncertainties, three main periods may be considered. The oldest carbonates, with a real importance, are Ordovician. They are partly metamorphosed and outcrop discontinuously in the mountains from northwestern Thailand to mainland Malaysia. Silurian carbonates are found in Vietnam. Devonian carbonates are found mainly on the Shan Plateau, Myanmar, and in northern Vietnam. Carboniferous carbonates are well developed in the Khammouan karst of Laos and Vietnam. Permian carbonates occur

Asia, Southeast: Figure 1. The main karst regions of continental Southeast Asia.

widely throughout Southeast Asia. In Thailand, they are composed of massive limestone. On the Shan Plateau, Myanmar, they are in the thick Devonian to Triassic sequence that is pervasively dolomitized carbonate.

The Indosinian orogeny occurred in the middle Triassic. This significant compression, uplift, and erosion episode affected much of Southeast Asia, bringing many carbonates into subaerial positions, resulting in a prolonged karstification episode. Upper Triassic half-grabens, formed via tectonic relaxation, were filled in part by lacustrine limestone. Occasional Liassic limestones, up to 50 m thick, are interbedded with thick continental formations.

Regional uplift began around 65 million years ago. Combined with the effects of the young Himalayan orogeny and the opening of the South China Sea, it led to large-scale erosion. For example, some 3250 m has been eroded from the central Khorat Plateau in northeast Thailand. As carbonates of various ages became exposed, karst evolution began in earnest. Indosinian karst landforms have often been exhumed and rejuvenated and play a significant role in the evolution of the Cenozoic karst. This long-lasting uplift generated a relative deepening in base level, leading to extensive planation surfaces, large and deep poljes, tower karst, and fengcong karst.

Paleokarsts and Cave Fills

Paleokarsts have formed mainly during the Indosinian and the Cenozoic erosion episodes. The stratigraphic gap of the Indosinian period reaches a maximum of 60 million years in Central Laos, though effective erosion time may only have lasted 20–35 million years. Paleokarst landforms of the Permo-Carboniferous limestones include karstified surfaces (southern Thailand), valleys and low rolling hills (north central Thailand and central Laos), and tower karst (same regions plus northwest Cambodia and Ha Long Bay). Karst breccias, with a reddish, calcareous silty matrix, are common and have been dissected by later caves and quarries. Paleokarst fills were subsequently buried and underwent diagenesis to the same degree as the host carbonate.

The offshore Nang Nuan oil field, in the Gulf of Thailand, appears to produce from caves in Permian to Jurassic limestones buried beneath thick Cenozoic sediments. In Myanmar, the Yadana gas field, also offshore, is located in the karstified, though highly porous, upper part of an upper Oligocene to lower Miocene isolated carbonate platform.

The current erosion episode has generated more paleokarsts that are moderately lithified, as in Cambodia. Pleistocene paleokarst fills and associated faunas have been described from Thailand and Myanmar (vertebrates at Mogok). Partial cave fills, many with prehistoric remains, have been found throughout the region, notably at Tham Hang and Tham Pha Loi, in northern Laos, and in Cambodia.

Surface Morphology

Southeast Asia contains some of the most spectacular surface karsts in the world, with a wide variety of tropical karst landforms. Lithological differences determine variations in morphology. Thinly bedded, argillaceous, and partly metamorphosed Ordovician limestones in Thailand and Malaysia, and Liassic limestones in Thailand and Laos, show a massive morphology with moderately steep slopes and few holokarst features. Massively bedded Permo-Carboniferous limestones, though sometimes partly dolomitic, evolve into holokarsts. The advanced diagenesis, fracturing, and purity of these

limestones produces sharp-edged and spectacular landforms. Their salient feature is the existence of karst massifs, with very steep slopes or cliffs rising from karst plains, which merge with the subdued topography of other rocks. Karst plains result from planation at the rainy season water-table level. Lateral dissolution forms notches, resulting in cliff collapse and increased slope angles. In Ratchaburi, Hpa-an, and Kampot, a raised paleosea level probably generated some planation through wave erosion and mixing corrosion.

Positive landforms consist of fengcong, towers, and pinnacles, some of which are highly developed (e.g. the tsingy morphology of the Khammouan karst). Negative features include poljes, uvalas, dolines, and large shafts, giving access to underground streams (e.g. near Kanchanaburi). Major canyons often cut through karst terrains, for example, those of northwest Vietnam and the parallel Salween and Mae Khlong Rivers of Myanmar and Thailand, respectively. Karren are very well developed and excellent examples of most forms can be seen on virtually any bare rock surface. Travertine waterfalls are common features and the huge falls near Pyin-Oo-Lwin, Myanmar, are a good example.

Caves

In holokarst areas, caves are extremely numerous and often large. The Phong Nha system in Vietnam, is to date 44.5 km long, but it is made up of separate caves. The longest known caves of the Southeast Asian countries are: Laos—Nam Non Cave, 22.1 km; Vietnam—Hang Khe Ry, 18.9 km; Thailand—Tham Phra Wang Daeng, 13.1 km; mainland Malaysia—Tempurung Cave, 4.8 km; Myanmar—Mundewa Cave, 1.8 km; and Cambodia—Roung Dei Ho/Roung Thom Ken system, 1.8 km. The largest cave entrance is Tham En in Khammouan, 215m wide and 30 m high. Large chambers include: 260×240 m in Tham En, and 210×155 m in Tham Koun Dôn, both in Laos. Tham Toutche, near Kanchanaburi, has a chamber $200 \times 180 \times 50$ m, entered via a passage 100×35 m and 300 m long. The largest subterranean river flows through the 6.5 km long, 40×40 m main passage of the Xé Bang Fai Cave, at an average 68 m³s⁻¹. The deepest cave is Cong Nuoc in Vietnam (600 m deep). Tham Phi Seau in Laos gently rises up to +315 m.

Caves are predominantly subhorizontal. Multilevel systems, containing fine examples of phreatic and vadose morphologies, have been found. Caves in mountainous areas often show complex evolutionary histories, notably Tham Chiang Dao in northern Thailand. Vertical systems are not so common, though some deep pits do exist. Speleothems of all kinds are frequent and sometimes spectacular, such as the 60 m high column in Tham Sao Hin, Kanchanaburi, a 2 m wide shield in Tham Nam Thieng, Khammouan, and cave pearls to more than 20 cm in size in the latter cave.

High atmospheric CO_2 levels are encountered in some caves, with up to 8% being measured in Tham Kubio, northeast Thailand. High CO_2 is particularly prevalent in caves of western and northern Thailand and near Taunggyi, Myanmar. The possibility of a deep-seated CO_2 source is likely, as there are numerous thermal springs in the region and other geological indications. A biogenic source is more likely in Phangnga area, southern Thailand.

Partly Drowned Karst

Several coastal karst areas have been inundated by the sea, due to tectonic subsidence (from mainly extensional deformation) and/or rising eustatic sea level. The best examples are the islands found along the coast of the Andaman Sea from the Myeik Archipelago to Phangnga Bay, the Langkawi Islands, the Ang Thong Islands in the Gulf of Thailand, and Ha Long Bay, Vietnam. Karst morphology, prior to inundation, was mature to very mature. Ang Thong consists of relatively massive hills, though tower karst is most common in other locations. Only towers and hills protrude from the sea with the karst plain, the area between them being fully submerged. The towers may form groups that start inland and extend out into the sea.

A prominent solution notch often marks present-day sea level. Locally, another notch occurs at 4–6 m above, representing a former high sea-level stand. Caves may pierce the towers as inland stream caves, as tidal range caves (some opening in the notches) and completely submerged caves, with the best examples in the Andaman Sea and Ha Long Bay. Another interesting feature is the "hong", located within many of the islands. It is a partly drowned chamber, with the top often partly opened to the sky, usually accessible via boats through a cave at low tide. "Hong lakes" are large dolines, with marine to brackish lakes, surrounded by sub-vertical cliffs, and can reach more than 300 m in diameter. Good examples are found in Phangnga Bay, Langkawi, Ang Thong, and Ha Long Bay.

Most of the caves and "hongs" undoubtedly formed prior to invasion by the sea. However, karstification, due to mixing corrosion at mainly rainy-season haloclines, is a powerful process. It modifies inherited morphologies and creates new ones, such as the many tidal range caves and notches seen in the area. Terrigenous sediments, supplied by rivers, form overall prograding tide-dominated coastal deposits that progressively cover the karst until eventual burial. The tower karst of Mawlamyine, Myanmar, is undergoing this process. In such areas, a sheet of freshwater may cover the area over long periods during the rainy season.

Dolomite Karst

Dolomite fluviokarst covers large parts of the Shan Plateau, Myanmar. The low competence of the rock produces smooth, rounded landforms, including cupola-shaped hills with low angle slopes and rounded valleys. Cliffs are found mostly along the main valleys that progressively deepen into canyons and reach the plateau edge. Travertine dams and flowstones are common along the streams. The deep gorge at Gogteik is the most famous and has travertine caves. Cave formation processes are depressed in dolomite. Explored caves have relatively small cross sections. The most significant are Mundewa Cave near Taunggyi (1.8 km) and Peik Kyin Myaung Cave near Pyin-Oo-Lwin, both with streams.

Mineral-Bearing Karst

Limestones and interbedded silici-clastic rocks at Mogok, Myanmar, have undergone high regional metamorphism and intrusion by acid igneous dykes. Rubies, sapphires, spinels and other high-quality gemstones have crystallized in the limestone. Karstification produced a characteristic mountainous landscape with barren lands and crypto-lapies. A large proportion of the area has a thick soil cover. Some dolines are present, sometimes very impressive. Many caves are found, mostly with small passages. Gemstones are concentrated in cave fills, in colluvium trapped between the rockhead pinnacles and in valleys. Hydrothermal ore-bearing veins are present in some karst areas. Cassiterite (tin ore), eroded from nearby granites, occurs as karst placer deposits in peninsula Malaysia. The tin-bearing alluvium is exploited from depressions in the karst surface and from cave fills. Saltpetre is extracted from certain caves in Myanmar, Laos, and Vietnam.

Sandstone Karst

Karst features and caves are known in the thick Mesozoic sandstones of the Khorat Plateau, northeast Thailand. Surface karst is often relatively bare and the landforms are somewhat different to those of the carbonates. The sandstones tend to suffer more disintegration than solution, with sharp-edged features being rare. In planar areas, with low to moderate dip, the surface drainage converges into dip-directed, incised channels. A few of these end in blind valleys, where the stream sinks underground as at Tham Patiharn. Runiform landscapes and pinnacles occur where a duricrust or a conglomeratic bed has selectively protected from erosion. Dolines are rare. Caves rarely exceed 100 m in length. The exception is Tham Patiharn at 784 m long, with a boulder choke at the end. The upper and lower level passages in this seasonal stream cave are similar to limestone caves and show large sections. A few siliceous speleothems are present. Many of the small caves are outlets whose formation was comparable to that of soil pipes.

Human Use of Caves and Karst

Caves and karst in Southeast Asia have been widely used by Man since prehistoric times (see separate entries, Asia, Southeast: Archaeological Caves; Burials in Caves). Buddhism is the dominant religion in the region and makes use of many caves as hermit retreats, underground temples, and places of worship. It has been estimated that Buddhism utilizes several hundred caves in Thailand alone (see Religious Sites). Some very famous Buddhist caves are Pindaya Cave, Shan Plateau, containing more than 8000 Buddha images, the Pak Ou Caves near Luang Prabang, Laos, Tham Khao Luang in Thailand and the Marble Caves in Vietnam. The Batu Caves in Malaysia (Figure 2) are used for worship by followers of Hinduism. Animism related to caves still exists in Laos, Myanmar, and northern Thailand.

Caves have long been used as hiding places for people and valuables. Villagers once hid in caves in Kanchanaburi to evade Burmese warriors. Caves in Laos were used by soldiers as moving

Asia, Southeast: Figure 2. The main chamber of the Temple Cave in the Batu cave system in Malaya, with the concrete floor in readiness for frequent religious festivals. (Photo by Paul Wycherley)

bases during World War II. Caves were used as shelters during the Vietnam War in Vietnam and Laos, especially along the Ho Chi Minh trail. In the Viengsai area, they were converted into factories, schools, administrative centres, hospitals and dormitories, etc. Phatet Lao political leaders lived in natural and reshaped caves in Viengsai for around ten years. Caves on the seashore, which have an open entrance at low tide, have provided pirates with hideouts in the Andaman Sea. The 7.5 km long Nam Hin Boun underground river in Khammouan has been used as a throughfare for more than a century and is traversed by boats ferrying both passengers and goods. Caves such as the 1.2 km long main way in Tham Heup, Khammouan, are used by people walking to reach their remote villages in Laos and Vietnam.

Natural resources gathered from caves include gemstones, tin ore, guano, saltpetre, water for drinking and agriculture, and food in the form of fish, bats, swifts and swift nests. Karst quarrying is a massive industry. Offshore Nang Nuan oil field, in the Gulf of Thailand, and Yadana gas field, in the Andaman Sea, are in karstified limestone.

ASIA, SOUTHEAST ISLANDS

With a total area of about 230000 km², the islands of Southeast Asia contain some of the most varied karst regions in the world (Gillieson & Spate, 1997). Many are of high relief, with spectacular arrays of tower and cone karst, several of which have now been added to the World Heritage List in recognition of their special geomorphology and biology. They are scattered throughout the islands of the Malaysian archipelago as well as the adjoining fringe of the Asian mainland. Karst is found in Borneo, the Philippines, Indonesia, and the island of New Guinea (Figure 1). The tectonic setting of the Southeast Asian region is complex, due to the interactions between the Philippine, Pacific, Australian, and Eurasian plates. An older, stable region comprising the Asian mainland, peninsular Indo-China and Borneo abuts a younger unstable region associated with widespread neotectonism coupled with island-arc volcanism. The most extensive limestones in Borneo are the massive shallow-water Eocene to early Miocene rocks in northern Sarawak, including the

karst of Gunung Mulu. Smaller carbonate outcrops of Cretaceous age are found in northern Kalimantan and Sabah, with younger Miocene uplifted reef limestones along the northwest coast. The Sunda and Banda volcanic arcs form the underlying structure for the karst of Indonesia. The karst is discontinuous, and is formed on Mesozoic and Tertiary limestones, with the largest continuous area in Gunung Sewu. In contrast, the karst of Sulawesi is formed on Tertiary limestone in the central and southwestern parts of the island. The Philippines contain a complex array of karst landscapes formed on rocks ranging from Cretaceous to Tertiary in age, and also widespread Quaternary raised reefs.

Three genetic types of tower karst can be identified in the region:

- 1. Residual hills protruding from a peneplaned carbonate surface covered by a veneer of alluvium. This is a very common karst style throughout Southeast Asia, where alluvial deposition has occurred adjacent to the limestone. Examples include the tower karst of south Sulawesi, Indonesia (McDonald, 1976).
- 2. Residual hills emerging from carbonate inliers in a planed surface cut mainly across non-carbonate rocks. This style is more common where older Paleozoic limestones occur as strike belts in volcanic or other sedimentary rock types. Examples include the karst of the Emia and Mendi valleys, Southern Highlands, Papua New Guinea.
- 3. Isolated carbonate towers rising from steeply sloping pedestal bases of varying lithologies, e.g. the steep mountain karst of East Timor.

Cone karst is widespread throughout insular Southeast Asia and finds its best expression in the Gunung Sewu karst of Java and the Bohol karst of the Philippines. Here polygonal depressions with residual hills entirely cover the limestone plateau surfaces. The depressions are frequently drained by bedrock shafts, which are partially or totally blocked by soils and debris from vegetation. Many show alignment of the karst depressions along major lineaments, and there may be cone asymmetry due to the underlying geological structure. In many parts of southeast Asia these depressions are partially infilled with soils derived from volcanic ash deposits.

Pinnacle karst is a spectacular small-scale landform found principally in the humid tropics and subtropics, with the bestknown examples coming from Gunung Api, Mulu, and Mount Kaijende, New Guinea. Typically the pinnacles are razor-edged limestone blades, closely packed, which can attain heights of thirty to fifty metres. The intervening depressions frequently contain thin organic soils, dense root mats, and deep fissures. Hundreds of pinnacles may be found in an area of a few hectares.

The Maros karst area of southern Sulawesi, Indonesia, has attracted a number of French caving expeditions. Here spectacular tower karst of dominantly Tertiary age occurs in a wide belt, with gorges, springs, and some natural arches. The karst has been dissected by marginal rivers, and the tower bases have a large number of cliff-foot caves and through caves. In addition, relict passages and overhangs occur at varying levels on the towers and are used as burial sites by the Torajan people.

Asia, Southeast Islands: Figure 1. The main karst areas of Island Southeast Asia (details are not shown on the mainland).

Gunung Mulu National Park in Sarawak, Borneo (see Mulu Sarawak), is world famous with large caves that have been systematically explored since the first expedition in 1978. The karst of the Gunung Sewu area of southern Java has been studied extensively since the 1930s and presents the classic cone karst developed on Miocene limestones.

The Puerto Princesa Subterranean River National Park is situated on the northwestern coast of Palawan, Philippines, and formed part of the land bridge between Borneo and Luzon during glacial epochs. The limestone is of middle Miocene age and is quarried locally as marble. The karst landscape includes extensive limestone towers and polygonal karst, as well as a large polje at Culiatan. The towers attain altitudes of 600 to 1000 m, where their tops have extensive spitzkarren and rough sharp pinnacles termed "assegai karst" (Longman & Brownlee, 1980), while the flanks show deep solution runnels. The limestone massif is drained by the St Paul's Underground River (Figure 2). This strike-oriented main passage is essentially horizontal and navigable by boat for more than 6 km making it probably the world's longest tidally influenced river cave (Hayllar, 1981). The present limit of exploration is a sump that is relatively close to a major stream-sink. Given that the entire catchment is within the reserve, this site offers significant potential for ongoing studies of tropical karst landform processes, as well as interactions between terrestrial and marine processes on a limestone coast. In 1999 the National Park was inscribed on the World Heritage List.

The island of Bohol in the south-central Philippines is world famous for a distinctive karst known as the "chocolate hills". The limestone covers an area of about 600 km². This landscape is characterized by smooth, cone-shaped isolated hills of limestone, which have elongated interfluvial ridges. Three sets of summit elevations have been discerned, while the individual form of the mogotes reflects the structural geology of the area. The karst depressions are usually elongated, and are sometimes closed. These narrow valleys open into flat valleys which resemble poljes. Individual karst landforms include extensive

caves, stream-sinks and springs, and tufa dams on the watercourses. Over 50% of the karst landscape is flat and supports irrigated agriculture, principally rice. Steeper slopes are terraced and may be planted with rice or support plantations. There has been a profound decline of about 40% in the outflow of springs in the karst over the last 20 years. This is not explained by climatic change and instead shifts in land use and resource allocation seem to be implicated.

The large island of New Guinea contains karst areas occupying around 15% of the land area and extending from sea level to nearly 4000 m. There is a great diversity of karst types in this tectonically active landscape, where present uplift rates are 2-3 mm annually. The major rivers of the central cordillera of New Guinea cut through the karsts, and there are extensive alluviated karst plateaux, one of which has an area of 15000 km² in the Kikori-Kutubu area of the Southern Highlands. On the large islands of New Britain and New Ireland there are extensive poly

Asia, Southeast Islands: Figure 2. Outline map of the karst at Saint Paul, on Palawan Island, the Philippines, where the river cave reaches from the sink east of Cullatan out to Saint Paul Bay (after map by D.Balazs).

gonal and doline karsts—the Nakanai area contains New Guinea's deepest cave, Muruk, which is over 1100 m deep. This karst system drains to large springs at sea level on the nearby coast. Karst areas are of local importance for water supplies and for their soil resources. More recently, considerable gas and some oil reserves have been found in the

Southern Highlands karst belt, and there are plans to pipe the gas across the Torres Strait to Australia.

The combination of rugged relief, karst terrain, and high rainfall makes the limestone ranges of western Papua New Guinea some of the least populated and least-visited areas on Earth. These karsts lie on the southern flank of the central ranges and are bounded by huge scarps up to 700 m high. The maximum recorded annual rainfall is 11000 mm at the Ok Tedi mine site on Mt Fubilan. With a topographic relief of around 700–800 m, a sequence of pure Miocene limestones up to 1500 m thick, and rainfall in excess of 5000 mm over much of the area, high rates of karst denudation and cave development can be expected. The related Mamo Kananda and Atea Kananda caves (Gillieson, 1985) underly the Muller Range and achieve a total length of 50 km and a depth of 525 m. The caves contain large river passages, flood-prone phreatic mazes, and abandoned upper canyons. Further west in the Victor Emanuel Range the huge passages of Selminum Tem extend for 25 km and drain to springs below the escarpment (Figure 3).

The western half of the island of New Guinea contains extensive karst areas ranging from sea level to 5000 m at Puntjak Jaya (Carstenz Pyramid). The escarpment to the south of the glaciated alpine karst descends nearly 4000 m to the coastal plains, and is now part of the Lorenz National Park. This area has some of most spectacular alpine karren fields, giant dolines, and cliffs in the world, and its caves are still relatively unexplored. The huge Baliem Valley near Wamena drains into a very large cave, partially explored, which flash floods with overnight rises of 30 to 5 m (Figure 4). Other caves in the Baliem are used as burial sites by the Dani people. To the east the Star Mountains massif on the border of West Papua and Papua New Guinea contains glaciated karst with large dolines and some caves. Extensive Quaternary raised reefs in West Papua, Ambon, and Waigeo are unstudied by karst scientists and unexplored by speleologists. On Waigeo there are areas of karst with large karst springs and

cave entrances visible from the air, extending into the sea to form an archipelago of circular islands, drowned cones with sealevel notches.

ASIA, SOUTHEAST: ARCHAEOLOGICAL CAVES

Archaeological research in Southeast Asian caves was started in the late 19th century, by colonial officials in Indonesia, Malaysia, and Vietnam. Their investigations and subsequent research shows that caves have been used as temporary shelters and burial places by humans over the past 40000 years and serve as post-depositional containers for their stone, bone and shell tools, food remains and other material residues. The remains of these small bands of hunters and gatherers, probably of Melanesoid, or at least non-Mongoloid type, are usually called the Hoabinhian Culture, from the region in northern Vietnam, where they were first recognized early in the 20th century. Fossilized remains of extinct hominid species have also been found in a few limestone fissure deposits in Vietnam and Thailand. Many caves also contain evidence for the non-anthropogenic climatic and environmental changes from the late Pleistocene into the mid-Recent period.

During the Iron Age (c.500 BC-AD 200) and later, many caves in western Thailand and East Malaysia were used to place hollowed log coffins, or large pottery jars for secondary burial, as in coastal regions of Indonesia and the Philippines. Others contain prehistoric rock paintings and engravings and from the mid-first millennium AD. Buddhist images, shrines, and inscriptions were created in caves in Burma, Thailand, and central Vietnam (see Asia, Southeast, and Religious Sites).

Thailand

Cave research started later in Thailand than in neighbouring Malaysia, but over 100 caves of archaeological significance have been found. However, only one flexed Hoabinhian burial is so far known from a cave (Sai Yok) in Thailand, in contrast to the many found in Malaysia, Vietnam, and Indonesia. The bestknown archaeological cave in the country is Spirit Cave (Tham Pi) in Mae Hong Son province in the northwest. Excavated in the 1960s and 1970s, Spirit Cave has produced evidence of a range of plant foods eaten by the cave occupants, from about 12000 to 7500 years BP. In the late 2nd millennium BC, later peoples left their pottery and stone adzes as evidence of their brief visits—Spirit Cave, as well as other caves in the area such as Tham Lod, contains wooden coffins dated to about 2200–1200 years BP.

Caves at Ban Kao and Tham Khao Thalu in Kanchanaburi Province, have also yielded a large amount of prehistoric finds, including log coffins. Limestone caves and scarps along the Thai—Burmese border, in the Petchabuan Range of Central Thailand, and overlooking the Mekong River in Nakorn Sawan Province, all contain galleries of rock paintings, making Thailand an important area for prehistoric art.

Human occupation at Lang Rong Rien cave, in Krabi Province of Peninsular Thailand, has been dated from *c*. 40000 BP, making this one of the oldest inhabited sites in Southeast Asia and an important location for studying the long-term human occupation of the region. Further south, in Satun Province, recent exploration by Thai archaeologists shows that this also has many caves with significant archaeological deposits. In 1999, a discovery of possible *Homo erectus* skull fragments, at a fissure deposit in Lampang province, northern Thailand, may extend human use of caves in Southeast Asia to over 500000 BP. If confirmed, the find would be the first evidence for the existence of *H. erectus* in Asia outside China, Vietnam, and Indonesia.

Vietnam

The numerous caves and rock shelters in the limestones of Hoa Binh, Than Hoa, and Bacson Provinces, long ago attracted the attention of French geologists, such as Madeleine Colani and Henri Mansuy, and their research, and that of later Vietnamese researchers, has produced the earliest and richest sequences of human occupation in Southeast Asia. At Lang Cuom Cave, Colani uncovered a deposit of about 100 skulls in 1927, with very few post-cranial bones—perhaps the remains of headhunting or ancestor cults. Other caves contain flexed inhumations sprinkled with red or yellow ochre. Vietnamese archaeologists date the Hoabinhian and Bacson Cultures to between *c*. 12000 and 7000 years ago and refer to them as "Early Neolithic" but it seems that no evidence for food production has been identified. Some *H. erectus* teeth, found in Tham Khuyen and Lang Trang fissure deposits, were dated between 480 ka and 148 ka.

The drowned karst towers of Ha Long Bay (see separate entry) contain caves that preserve the remains of human occupation from over 15000 years ago, when the sea level was much lower and the towers stood in a forested plain drained by fast flowing rivers. Some islands (e.g. Hon Vung Ba Cua) also contain red ochre rock paintings—the first so far known in Vietnam.

Malaysia

In the 1880s, cave excavations on Peninsular Malaysia were pioneered by scientists with interests in geology. There are many caves with archaeologically important remains, especially Gua Cha in Kelantan, which has been relatively preserved from commercial destruction through its isolation. Gua Cha contains a Hoabinhian occupation and burial with clear evidence of the replacement of Hoabinhian culture by intrusive Neolithic, probably Mongoloid settlers, who brought a more settled agricultural way of life, made pottery, polished stone tools, and buried their dead laid out in individual burial pits with many grave goods.

The Lenggong Valley in Perak contains Peninsular Malaysia's only Palaeolithic site, a karst area with some 40 small caves, many of which have archaeological remains. An open-air 75000 year-old stone tool workshop was found at Kota Tampan, which is thought to have been abandoned, following heavy ash falls from a volcanic eruption in Sumatra. At Gua Gunung Runtuh, excavated in 1990, the oldest complete skeleton in Malaysia, dated to *c*. 11000 years ago, was found together with stone tools and food remains; this is popularly known as "Perak Man". Other caves in the area contained stone tools, bones, pottery, and jewellery, dating over the last 10000 years. The oldest rock paintings in Malaysia are about 2000 years old at Gua Tambun, on an exposed cliff in Perak.

In Sarawak, East Malaysia, the Niah Cave complex is internationally known from the pioneering research of Tom Harrisson and is now a major tourist attraction, both on account of the enormous caverns with their daring birds' nest collectors, and

Asia Southeast: Archaeological Caves: Wall art in the Painted Cave of the Niah cave group in the Subis Hills of Sarawak. (Photo by Tony Waltham) the 40000 year old sequence of human occupation. The earliest evidence for human presence in Malaysia was a skull dated to *c*. 38000 years, found in the Great Cave at Niah. Harrisson's excavations revealed late Pleistocene chopping tools and flakes, and Neolithic edge-ground axes, bone points, adzes, pottery, shell jewellery, mats, nets, boats, then iron tools, ceramics, and glass beads dating to the Iron Age. Tom and Barbara Harrisson excavated 166 burials–39 of them Mesolithic, the rest Neolithic. The site is being re-excavated by a joint Malaysian-British team to determine the accuracy of Harrisson's work, to obtain a more refined chronology and recover evidence for environmental changes made possible by recent archaeological scientific methods. The Painted Cave at Niah has paintings roughly 1200 years old, depicting boats and people practising their funerary rites (see photo). A number of carved wooden coffin "death ships" were found in 1958 on the floor below the paintings.

In Sabah, caves at Baturong were inhabited from 17000 years ago, when the site became accessible after a lake, which had been formed by volcanic deposits blocking the nearby river, dried up. Later human occupation dated to about 3000–2500 years BP and later still from the first millennium AD, has also been excavated by Bellwood and others in the Madai Caves near the eastern coast of Sabah. Wooden coffins, dating to the 14th century, have also been found in many Sabah caves.

Indonesia

Limestone caves with archaeological remains, ancient burials, and rock paintings are numerous in Indonesia, from Sumatra to Moluku and West Papua, but relatively few have been well excavated and reported, except in South Sulawesi and Timor. The site of Guwa Lawa, in east-central Java, was recognized to be rich in sub-fossil fauna, and human burials and occupational debris, following work there by van Es and van Stein Callenfels in the 1920–30s, but only sketchy reports were published. Recently a joint Indonesian-French project has restarted cave research in central Java, with very promising results. Flexed burials of Hoabinhian affinity are known from caves in Java, including Guwa Lawa and, as in Vietnam and Malaysia, on the basis of large molars, rugged skulls and lack of mongoloid characters, have been labelled "Melanesoid".

In the Maros karst region of South Sulawesi, some 40 km inland from the provincial capital of Makassar, deposits at a rock shelter named Leang Burung 2, have been dated by Glover to between c. 31000–20000 BP, and similar dates have been obtained from another such site near Pangkajene. At Ulu Leang 1, a cliff foot cave in the Lealeang Valley, with a rich sequence of occupation with freshwater and marine molluscs, stone and bone tools, and plant remains, was also excavated by Glover and dated from c. 10000–2500 BP. Many other caves in the region contain similar materials, as well as red ochre hand stencils and paintings of animals, such as the *Babirusa*—an endemic wild suid. Higher level caves, such as Ulu Lleang 2, contain jar burials of a late prehistoric Iron Age. Caves, sometimes artificially enlarged as rock-cut tombs, in the Toraja Highlands of Central Sulawesi, have long been used for burial and are now popular tourist attractions.

The remote island of Timor in eastern Indonesia, is also rich in limestone caves with human occupation deposits. Research started there with the work of Bühler and Willems in the 1930s, was continued from Australia by Glover in the 1960s and very recently archaeologists from Australia, led by Spriggs and O'Oonnor, have resumed work in East Timor, finding evidence for occupation at Lene Hara Cave at the eastern tip of the island dated to *c*. 31000 BP. Other important archaeological cave deposits have been excavated at Uai Bobo 1 and 2 (from 13000 BP), at Lie Siri (from 9000 BP) and at Nikiniki in western Timor.

The Philippines

Limestone caves with archaeological remains are found in many parts of the Philippines, especially in the Cagayan Valley of northern Luzon and in Palawan Island, where a National Museum team, headed by the late Robert Fox, excavated a skull, teeth, and jaw at Tabon Cave in 1962, originally dated to *c*. 22000 BP, but now re-dated to *c*. 16000 BP. The cave, at an altitude of 33 m, is one of more than 30 in the outcrop, once 30 km from the sea. After people abandoned Tabon, Guri Cave became an important shelter between *c*. 5000 and 2000 years ago. Flake stone tools, bones of wild pig and deer, were found and marine shells show the sea had reached its present level by that time. Other stone age sites include Laurente and Rebel Caves, near Penablanca in the Cagayan Valley of northern Luzon, inhabited about 16000 years BP, and at Ayub Cave at Maitum, Cotabatu Province, Mindanao Island, containing spectacular anthropomorphic burial jars representing individual persons buried there nearly two thousand years ago.

ASIA, SOUTHEAST: BIOSPELEOLOGY

Southeast Asia is not a homogeneous biogeographical area. Situated at the contact between several tectonic plates, its paleogeographical history is probably the most complex and the least known among the large land masses of the world (Whitmore, 1987). Limestone rocks of various geological ages and extent are present up to the highest altitudes (Sulawesi: Mt Mekongga, 2800 m), representing all the classical karst types, from coral limestone to immense plateaux and cone karsts. An important feature controlling the diversification of cave fauna' is habitat fragmentation. Southeast Asian karsts are extremely fragmented. Thousands of limestone outcrops exist inland in Java, Sumatra, Sulawesi, and Peninsular Malaysia. Climate is another influential factor for subterranean biodiversity. The region is mostly under an hyperhumid tropical climate, which is thought to hamper the evolutionary shift towards obligate subterranean life, but some parts of the region (in Laos, central and eastern Thailand, and parts of Java, Sulawesi, and Eastern Maluku) experience a relatively dry or seasonal climate.

The biospeleology of Southeast Asia has a long history. As long ago as 1888, the Italian zoologist Leonardo Fea made important zoological collections in Burma (presentday Myanmar) caves near Moulmein (present-day Mawlamyine). Eugene Simon, the French arachnologist, collected and described the first cave species of the Philippines in 1892. In 1899, the Skeat expedition collected cave animals in southern Thailand. The Batu Caves in Peninsular Malaysia were sampled and studied in great detail by several biologists, from Ridley in 1898 to Mc-Clure in 1967. Very few cave-adapted species were found in these caves and it is probably the main reason why tropical caves were thought to have a low troglobitic richness, an idea which lingered until the work of Frank Howarth (summarized in Howarth, 1983). It was only in the 1980s that troglobitic and troglomorphic cave species began to be discovered in large numbers, first in Mulu caves of Sarawak (Chapman, 1984), then in Thailand and southern Sulawesi (Deharveng & Leclerc, 1989). There is now evidence that limestone caves in all Southeast Asia regions host rich troglobitic and stygobitic fauna (Deharveng & Bedos, 2000). However, overall knowledge of the subterranean fauna of Southeast Asia remains poor and uneven, and there are few well-documented sites (Figure 1). No biological information is available for the large limestone ranges of Kalimantan or Timor, and even in Java, only 3 karstic regions out of a total of 60 have been reasonably sampled for their subterranean fauna. There are also many taxonomic gaps, especially for microarthropods. For example, fewer stygobitic copepods are known from subterranean habitats in the whole of Southeast Asia (Juberthie & Decu, 2001: five species), than from Afghanistan alone (seven species). Furthermore, habitats have been unevenly sampled. Cave troglobites and stygobites are the focus of collecting, while anchialine and interstitial habitats, and to a lesser degree guano, are rarely sampled. Finally, virtually nothing is known about the biology and ecology of cave species in the region, making the ecological status of many of them disputable. In spite of these considerable gaps, some general traits of the subterranean fauna of the region are taking form following the important discoveries of the last two decades.

Despite its complex paleogeographical history, the subterranean fauna of Southeast Asia is surprisingly homogeneous at the level of the highest taxa. Compared to temperate regions, and as in other tropical areas, Arachnida tend to outnumber insects in diversity within terrestrial habitats, while decapods and isopods tend to outnumber amphipods in aquatic habitats. Differences with other tropical cave fauna are marked by the presence

Asia, Southeast: Biospeleology: Figure 1. Locations of the main caves and karst areas in Southeast Asia that have been surveyed for subterrarean fauna.

of several characteristic zoological groups, all of which are functionally important in the ecosystem. Some of these taxa may extend into the Indian subcontinent or Australia, and some may be lacking in Southeast Asia margins (Maluku islands in Indonesia, or northern Vietnam), but most are present in all the documented areas of the region. They are: (1) the swiftlets of the genus *Collocalia*, guano producers at the same level as bats; (2) the bat-eating snake *Elaphe taeniura* and its related forms; (3) the large rhaphidophorid crickets of the Rhaphidophorini tribe, an oriental group, which form the basis of invertebrate food webs in all caves of the region; (4) the giant Arthropods

(crickets, sparassid spiders, amblypygids, centipedes), which haunt energy-rich habitats of lowland caves; (5) the cambalopsid millipedes, which live in dense populations at the surface of guano piles; and (6) the Nocticolidae, a cockroach family rich in troglomorphic species and present in many caves of the region.

The characteristic faunal elements listed above represent a small part of the subterranean fauna of Southeast Asia in terms of biodiversity. According to the most recent works (Juberthie & Decu, 2001), about 150 obligate subterranean species have been described in Southeast Asia, and many more are listed as undescribed morphospecies, or as species of uncertain ecological status. The number of non-obligate but regular subterranean species (mainly guanobites) is probably also very high. Most taxa of this cave fauna are narrowly endemic, many being known only from a single karstic unit or a single cave. Among the troglobitic species, a number of species belong to monospecific genera, and several are highly troglomorphic. Compared to epigean fauna, these rare taxa and their remarkable adaptive features give an exceptional biological value to the subterranean fauna of the region, in spite of its low species richness.

The origin of subterranean fauna may be approached at different levels. At a broad scale, it has been possible to relate in a few cases the distribution of taxa to major paleoor biogeographical features. The eastern part of Southeast Asia is the transition zone between Australian and Asian fauna, indicated by Wallace's and related lines (Whitmore, 1981). This major biogeographical limit is reflected in part by the regional subterranean fauna. Several generic or supragenic taxa are not known east of Java, for example Cyphoderopsis (Collembola) or carinate cambalopsid millipedes. However, no subterranean taxon of the Australian region has its western limit near Wallace's line. At Batu Lubang in Halmahera, the easternmost documented cave site of Southeast Asia, the known troglobites do not exhibit any particular relationship with Australian fauna. From Thailand to Maluku, the bulk of the subterranean fauna is clearly constituted of lineages from the Oriental Region, eventually extending to Australia such as Nocticolidae cockroaches. The Kra Isthmus in southern Thailand is a second important chorological limit, clearly marked in the flora. It is also significant for some cave fauna: within their Southeast Asian range, the Collembola Cyphoderopsis (troglobitic paronellids) and Willemia nadchatrami (a guanobitic hypogastrurid) are only present south of the isthmus, while Troglopedetes is only known north of the isthmus in Asia. Another important faunal change occurs in continental Southeast Asia from west to east, best illustrated by the distribution of cave entomobryioid Collembola, where Troglopedetes of western Thailand gives way to a troglomorphic line of Coecobrya in eastern Thailand, then to Lepidonella in Vietnam. This pattern is in agreement with the existence of an Indochina block independent from other parts of Southeast Asia until about 30 Ma years ago, based on recent plate tectonic reconstitutions (Whitmore, 1987). However, the relevance of these limits and the broad scale paleogeographical reconstructions to the whole cave fauna is not supported by several taxa, and chorological data are too loose to derive any interpretation for most groups.

The majority of the obligate subterranean species and guanobites belong to groups which are well represented in epigean habitats of the region, such as Collembola, spiders, or crabs. A few taxa do not have epigean relatives anywhere in the world, but are diversified in subterranean habitats of Southeast Asia, such as *Stenasellus* isopods or bogidiellid amphipods among stygobites. Relictual subterranean taxa, i.e. without known

relatives in the regional epigean fauna, but with epigean relatives elsewhere in the world, were thought until recently to be absent from tropical caves (Chapman, 1986). They might be actually present in Southeast Asia, as suggested by recent discoveries of isolated mono- or oligo-specific genera, like the Opilioacari *Siamacarus* of Thailand, or the Coleoptera *Mateuellus* of Sulawesi and *Laosapliaenops* of Laos.

Beside these remarkable taxa, endemic species swarms have been discovered in increasing number among the subterranean fauna of Southeast Asia. They are composed of closely related and geographically isolated species, which fit more or less the fragmentation pattern of subterranean habitats. For instance, at least four different species of the stygobitic genus *Stenasellus* (Isopoda) have been recognized in the fragmented limestone habitats of Gunung Seribu (West Sumatra). Swarms of this kind are to be expected among many obligate subterranean lineages of Southeast Asia, as suggested by taxonomic studies on ochyroceratid spiders (Deeleman-Reinhold, 1995), or paronellid Collembola (Deharveng & Gers, 1993).

As a rule, troglobitic and freshwater stygobitic assemblages are exclusively constituted of narrow endemic species. Patterns are different in guano and anchialine subterranean communities, where widespread forms (such as tineid moths for guano, or the shrimp *Parhippolite uveae* for anchialine habitats) co-occur with species of more limited distribution.

The high level of endemism and the high taxonomic differentiation of Southeast Asia subterranean fauna can be explained by the high fragmentation of the habitat and by the selective constraints imposed by the underground ecological conditions (see Subterranean Habitats), which makes the adaptive shift from epigean to subterranean life particularly demanding (Gibert & Deharveng, 2002). To cope with these conditions, obligate cave species have developed remarkable morphological and biological adaptations in temperate regions, which were long considered to be rare in the tropics. It is not actually the case. Biological adaptations have never been investigated, but highly troglomorphic species have been discovered since the 1980s in Southeast Asia. Troglomorphic taxa exhibit a regression of pigment and eyes, a loss of wings (in Pterygota), and an elongation of appendages (in Arthropoda) compared to their epigean relatives. They are found in most subterranean lineages and in all areas of Southeast Asia, but they seem to be more frequent and often more modified in seasonal tropics like Laos or southern Sulawesi (see Salukkan Kallang, Indonesia: Biospeleology).

Guanobites do not usually differ morphologically from epigean species. This morphological contrast with highly modified troglobites living in the same ecosystem illustrates how various

Asia, Southeast: Biospeleology: Figure 2. Generalized terrestrial food webs in Southeast Asia caves, excluding parasitic taxa (after Deharveng & Bedos, 2000, modified).

the subterranean habitats and their associated evolutionary constraints can be. Almost all subterranean habitats have been encountered in Southeast Asia: freshwater interstitial, oligotrophic freshwater, anchialine habitats, and energy-poor to extremely energy-rich terrestrial habitats. However, the MSS (Mesovoid Shallow Substratum) or Superficial Underground Compartment has not been recorded, though a variant may exist associated with volcanic boulders. Each of these habitats has its own faunal assemblage. Guano accumulations, produced by bats or swiftlets, are conspicuous and pungently smelling features in many Southeast Asia caves. They host giant arthropod assemblages in the region, and very dense populations of meso- and micro-arthropods, according to the generalized food web summarized on Figure 2 (Deharveng & Bedos, 2000). In contrast to assemblages of guano and other energy-rich habitats (flood debris, root mats), troglobitic and stygobitic communities are restricted to oligotrophic habitats. Troglobites are mainly found foraging around micropatches of food resources scattered in an overall azoic environment, mostly disseminated faeces of swiftlets, bats, or rhaphidophorid crickets (Figure 2). They never colonize guano accumulations. Stygobitic species are found in small endogeneous inlets, phreatic waters, percolating waters, and more rarely in exogeneous streams which have been filtered through fine boulders. They are absent in large sink-resurgence systems, where epigean fauna are often abundant. In principle, Amphipods feed on particulate or dissolved organic matter, and Isopods are predaceous, but some species are able to shift from predaceous to saprophagous, others are omnivorous, and the feeding habits of most Southeast Asia stygobites (from fish to aquatic beetles) are so poorly documented that it is impossible to summarize their trophic relationships.

With its high proportion of endemics, phylogenetically isolated lineages and highly evolved taxa, the subterranean fauna of Southeast Asia represents a unique and fragile biological heritage. Quarrying with its many collateral and irreversible damages, water pollution, deforestation, and over-frequentation of caves are currently taking a heavy toll on karstic ecosystems of the region. Guano caves appear particularly vulnerable, because of the sensitivity of bats and swiftlets to disturbance. Traditional swallow nest exploitation has so far permitted preservation of a significant part of this biodiversity, but the prospects are more uncertain for other kinds of subterranean habitats. In spite of the increasing concern of public opinion in Southeast Asia, this biological heritage is at risk in many karstic areas (Vermeulen & Whitten, 1999).

ASIA, SOUTHEAST: HISTORY

Although there are few indigenous speleologists and no regional journal or serial publications, Southeast Asian caves witness great cultural, religious, and natural heritage, their human use dating back perhaps 50000 years. This review documents use and exploration of caves. About 10–15% of the region is karst (less in Malaysia and Cambodia), often in remote locations. Nevertheless karst has an immense significance for sustainable agriculture, water quality, tourism, and biodiversity conservation in the region.

Accessible, published knowledge of caves must be separated from the indisputable antiquity and continuity of their cultural importance. Although caves preserve the evidence better than open spaces, early hominids clearly occupied and exploited the region's karstlands (see entry on Asia, Southeast: Archaeological Caves). Protohistoric cave artefacts evidence ethnic and cultural flux and well-developed trading networks extending to India and beyond; some peninsular sites suggest early links with Indian Brahmano-Buddhist culture. Across the north, many caves contain wooden coffins (Kiernan, Spies & Dunkley, 1988), inadequately studied but tentatively dated at 0–1000 AD. Tin has been mined from karst areas in Perak (Malaysia) for 1500 years. The Chinese visited caves in Malaya, Borneo, and elsewhere during the Ming Dynasty (1368–1634 AD), trading birds' nests, an industry still flourishing in southern Thailand and forming a significant tourist attraction in Phangnga Bay.

Many caves have been renowned as religious sites for more than a millennium. About 1345 AD Li Thai, King of Sukhothai described the veneration of caves and their integration into the Buddhist community. Thailand alone hosts perhaps 200 Buddhist caves, mostly in tower karst, many preserving examples of stylistic changes in iconography extending perhaps 1300 years. The darker recesses are frequently meditation sites and occasionally, as in Tham Tab Tao near Chiang Mai, icons nearly a kilometre inside evidence early exploration by monks. Pindaya Cave in Burma contains perhaps 10 000 images, while the best-known cave in Laos, Tham Thing near Luang Prabang, may once have housed 37000.

Speleological Investigations

Early European accounts described littoral caves and others close to the coast, or along routes of travellers and explorers such as Henri Mouhot. Rugged topography, civil unrest, and limited support infrastructure inhibited exploration and indigenous research until relatively recently, with most early work undertaken by colonial officers and expatriates, especially in Malaysia, Indonesia, Vietnam, and Burma (see, for example, Annandale, Brown & Gravely, 1913). In 1924 Sawicki wrote the first modern account of karst in Thailand. Later, occasional peripatetic scientists and speleologists such as Denes Balazs (1968; 1976) in Indonesia and Philippines and Heinrich Kusch in Thailand greatly advanced understanding of the region's potential. However, the era of organized expeditions awaited relatively cheap travel in the 1970s, and Mansfield's (1985) valuable historical survey, though timely, was published when half the region's countries were still inaccessible to travellers.

Much karst lies far from urban areas, in rugged, remote and sparsely populated pockets of some of the world's poorest countries. Many expeditions seeking grand adventure instead encountered unpredictable logistics and capricious officialdom, experiencing the truism that it is better to travel hopefully than to arrive. Multiskilled interdisciplinary teams cooperating with local groups usually achieved most, with British, Australian, Italian, and French expeditions predominating. Some British expeditions (especially those studying Mulu) attracted significant sponsorship, while Australians have been self-funded. Continuity of study has been rare, notable exceptions being Limbert's Vietnam expeditions and the Australian and French (Association Pyrénéenne de Spéléologie) projects in Thailand and Indonesia. Small, self-funded foreign expeditions visit Peninsular Malaysia annually.

Malaysia and Thailand are well documented; local groups explore caves, commercial caving adventure trips are available, and Dean Smart spent several productive years as Thailand's cave specialist. Successive, focused Australian and French expeditions surveyed some of the longest caves in the region and awakened indigenous awareness of karst heritage. The Siam Society's Journal occasionally publishes research on Thailand's caves, especially archaeological sites. However a reasonably continuous tradition of indigenous study has emerged only in Malaysia, led until recently by expatriates, culminating in major compendiums (Bullock, 1965; Price, 2001). The entry on Mulu, Sarawak describes the remarkable outcomes of work there.

Elsewhere exploration generally remains at reconnaissance level, confounded by political, military, insurgent, and logistical difficulties. Laos and Vietnam were inaccessible until 1990. In Laos, several groups explored Vang Vieng, while Claude Mouret's 11 expeditions prospected the vast Khammouane Karst and other regions, including the impressive Nam Hin Boun, pro viding a solid foundation for further studies. Burma is severely restricted, graphically highlighted in the only significant speleological account (Dunkley *et al.*, 1989). Small French expeditions have since returned but vast areas remain completely unvisited. Cambodia is still speleological *terra incognita*.

Vietnam encourages foreign expeditions on a joint venture, multiskilled basis, primarily where a local benefit exists, especially tourist potential. Among others, Howard Limbert's six expeditions since 1990, mostly with Hanoi University, concentrated on underground river systems in the rugged central and northern border ranges contiguous with karst in Laos and China, such as Hang Khe Rhy, Hang Over, Hang Phong Nha, Nguom Sap, and Nguom Lung Sam.

After Balazs, little was published about Indonesia and Philippines, and comprehensive reviews are needed to facilitate further work. In Indonesia, Dr Robbie Ko coordinates cave studies. Large river caves in the Gunung Sewu karst of southern Java proved irresistible to several foreign groups, and others roamed Timor, Sumba, Seram, Sumatra, Sulawesi, and Halmahera. A dozen frustrating forays into Irian Jaya barely sampled its tantalising prospects despite massive limestone in high relief, karst rising to nearly 5000 m on Jaya Peak (Carstensz Pyramid), and possibly the world's largest stream sink (Baliem River).

The Philippines Mountaineering Federation encompasses indigenous cave exploration, hosting joint ventures in Luzon, the Visayas, Mindanao, and Samar. The magnificent, 21 km long St Paul's Cave on Palawan was mapped by several groups, and the extraordinary

karst of Coron Island was explored (Piccini & Rossi, 1994). On Bohol, caves were investigated for their hydrological significance for agriculture.

Greater political stability, development pressures, and increasing local interest throughout Southeast Asia combine to improve the prospect both of further spectacular discoveries and of more intensive, focused research.

ASIA, SOUTHWEST

The dry lands of southwest Asia, colloquially known as the Near and Middle East, include a belt of eroded fold mountains, reaching from Turkey to Afghanistan, along with the Arabian Peninsula to their immediate south. They are distinguished by desert and semi-desert terrains, where summer temperatures normally exceed 40°C, while winters frequently drop below freezing, except on the coastal strips. Annual rainfalls in the interior are typically 200 mm or less, rising to around 1000 mm on the coastal mountains of the Mediterranean, notably in Lebanon and much of Turkey, and to about 500 mm on the mountains of Yemen and southern Oman, which are caught by the edge of the Indian Ocean monsoons.

Southwest Asia has large tracts of Mesozoic and Tertiary limestones, together with chalk, dolomite, and gypsum, all inherited from Tethyan deposition. Many were folded within the AlpineHimalayan orogenic belt, while others have been left little deformed on rigid basement blocks. Karst development is greatly restrained by the modern dry climate, so that potentially cavernous rocks extend across large areas and over high ranges of altitude, with few or no known caves of any significant size. Throughout the region, the Pleistocene was marked by pluvial stages, when fluvial and karstic processes were active. Some relict karst features and scattered remnants of cave passages and sediments survive from those times.

The caves and karst of the region are best reviewed by country, in sequence roughly from west to east.

Turkey (see separate entry) has more known caves than the rest of the region put together. Much of the Taurus Mountains are limestone karst and the region also contains the great travertine deposits of Pamukkale (see separate entry), while the gypsum karst of central Turkey is of major importance.

Syria provides a complete contrast, with minimal visible signs of karst. However, beneath its largely empty deserts there are four major karstic aquifers. The Jurassic limestones that form its western mountains are a minor extension of the karst in Lebanon, but there has been little investigation of any caves on the high land. The vauclusian rising of Fijeh has a mean outflow of $7.5 \text{ m}^3 \text{ s}^{-1}$, and supplies much of the water for Damascus. It lies below an anticlinal ridge of Cretaceous limestone, and has been dived to a depth of 77 m. Further east, the same limestones have minimal signs of karst on their low desert ridges, where they yielded the excellent building stone for Palmyra. Tertiary limestones in the southeast form the large dry Chami Plateau, with its cap of thick calcrete. They also contain the Rasel-Ain springs, at the head of the Khabour River, which have a total mean flow of 38 m³s⁻¹; they lie close to the Turkish border, with most of their catchment in Turkey. The water rises from the buried aquifer along faults through overlying Miocene clay, and emerges from collapse depressions in covering alluvium (Burdon &

Safadi, 1963). Karstic conduits within Miocene gypsum of the Fars Series account for underground drainage of some large basins in the northeastern desert, where Cater Magara has 7300 m of passages.

Lebanon has a major karst region on the Jurassic Kesrouane Limestone of the Jebel Liban, west of the Beqa'a Valley. The spectacular mountains have many deep caves. Faouar Dara has a large, clean streamway descending 22 shafts to a depth of 622 m. Qattine Azar, 548 m deep, has 2 km of large stream passage, reached by a shaft of 182 m. The water from both these caves resurges close to the sea, at Fawar Antelias, 18 km from and 1540 m below Faouar Dara. The coastal foothills contain a number of large river caves, including the spectacular Jeita (see separate entry). The Mediterranean coast of Lebanon is notable for its major submarine resurgences in Mesozoic and Tertiary karstic aquifers (Ghannam, Ayoub & Acra, 1998). Springs beneath 45 m of water, in Chekka Bay, may yield 60 m³ s⁻¹ from fissures in the Cretaceous Sannine Limestone, fed in part from the deeper Jurassic limestone.

Israel has the rolling karst hills of soft Cretaceous and Tertiary limestone and chalk in the Judean desert. The Dead Sea scrolls were found in small fissure caves in the scarp face at Qumran, and the Mount Carmel caves (see separate entry) are of archaeological importance but there are few significant known caves of length or depth. Much more significant for earth scientists is the salt karst of Mount Sedom (see separate entry).

Jordan has even less karst east of the Dead Sea. Cretaceous limestones have some collapse dolines and calcrete crusts on the hills north and south of Kerak, while the spectacular tufa cascades of Hammamat Ma'in are fed by radon-rich, geothermal waters that circulate through limestones at depth.

Iraq has no karst in its central Mesopotamian lowlands. Inthe northwest, the Sulevani Plain has dolines, some short caves and underground drainage in the Miocene Fars gypsum that forms a continuation of the karst plain in Syria. The northeast encompasses a small sector of the Zagros limestone belt of Iran, where stream-sinks, caves and springs have been reported in the Mosul region and Shanidar Cave (see separate entry) is an important archaeological site.

Saudi Arabia has a basement of granite and Paleozoic sandstone, exposed in the west, that has subsided beneath the Tethyan carbonates and mudrocks forming the petroleumrich belt along the Persian Gulf. Karstic dissolution has contributed to the permeability of some of the buried reservoir rocks. Fossil groundwater is also being "mined" from non-renewable limestone aquifers, for irrigation in parts of the eastern interior. The main outcrops of the Jurassic to Eocene carbonates and sulfates are on the escarpments northwest and south of Riyadh, and also those nearer the Gulf coast. Of the many large collapse dolines, Ain Hit is the best known, 88 m deep to its water surface and dived into a series of flooded chambers; these lie in limestone, though the entrance descends through Jurassic anhydrite. Further north, the Cave of the Falling Star is a shaft, 100 m deep, that bells out into a large chamber. Over the border, in Kuwait, dissolution of the Eocene Dammam Limestone has caused some deep collapses in thick cover sediments.

Yemen has the same limestones, better exposed in parts of its mountainous terrain. The Jurassic Amran Limestone around San'a has various hot springs, and also caves reported to yield steam clouds from hydrothermal waters, but these await investigation. Tertiary limestones form the plateaus either side of Wadi Hadramaut (in the east of the country), but details of the karst are little known. The island of Socotra has limestone

mountains, where Hoq Cave has 3000 m of mapped passages and Giniba Cave has a chamber 200 m long and 150 m wide beneath the Deksam Plateau.

Oman has its Dhofar karst in the far south on the same Tertiary limestones as those over the border in Yemen, but this area has a wetter climate that frequently shrouds the Qara karst plateau in fog. It is distinguished by some large collapse dolines, of which Tawi Atayr is 130 m across and 210 m deep. Quanaf Cave has a large passage 1500 m long, descending 223 m to a long lake, unexplored because of bad air. Hatat Lohum is a smaller shaft system, reaching 207 m in depth. Banks of travertine hundreds of metres high cascade into Wadi Durbat, but their tree cover indicates a level of activity that has declined in the modern climate. In northern Oman, the Selma Plateau (see separate entry), southeast of Muscat, has the deepest and finest caves of the Middle East, also in Tertiary limestone. Southwest of Muscat, Jabal Akhdar is the higher escarpment on a massive breached anticline of Mesozoic Wasia Limestone. Its surface is bare limestone fretted by microkarren and dry wadis, while its caves include Kahf Hoti (see figure), a fine through system 5 km long and 262 m deep (Waltham, Brown & Middleton, 1985). Percolation water entering Hoti is at 32° C, while its many lakes are cooled to 21° C, by evaporation into the through wind. Many of Oman's northern caves (and some in Abu Dhabi) are distinguished by large masses of banded flowstone that are cut through by narrow stream trenches. The flowstone is a relict of karstification in pluvial stages of the Pleistocenewhich were synchronous with interglacial stages of the higher latitudes (Burns et al., 2001), and not with the glacial stages, as had previously been assumed.

Abu Dhabi is the only one of the United Arab Emirates that has significant known karst. Jebel Hafeet is an isolated anticline of Eocene limestone that crosses the border into Oman. It has no surface karst features larger than microkarren, but it has a handful of caves (none with more than 500 m of passages). Bulbous phreatic tunnels perched 800 m above the modern water table may have been formed by hydrothermal dissolution and may predate part of the late Tertiary tectonic uplift. Kahf Hamam is a singularly unpleasant cave, with a temperature of 33°C and 100% humidity. There are also mature dissolutional foot caves carved into both the limestone and the veneer of old, cemented, bahada debris. Further north, hills of Mesozoic limestone in Ras al Khaimah contain some small relict caves, but little is known of any karst on the limestone's furthest outcrops on the Musandam peninsula.

Iran (see separate entry) has extensive tracts of limestone in the Zagros Mountains. There are few caves, but Ghar Parau reaches 751 m deep, and Ghar Alisadr has over 11 km of mapped passages.

ASIAGO PLATEAU, ITALY

The Asiago Plateau, also called the plateau of 7 'Comuni', is the largest mountain group in the Venetian Pre-Alps and one of the main caving regions in Italy. The plateau area covers c. 600 km² and is c. 25 km long (north—south) and up to 30 km wide, being delimited by large and steep scarps (Figure 1). The range in elevation is from a few hundred metres to an altitude of 2300 m.

The dolomite of the late Triassic (Dolomia principale), which constitutes the basement of the plateau, was deposited in a platform environment and ranges over a thickness of 1000 m. The overlying limestones, mostly of Jurassic and Cretaceous age and ranging over slightly less than 1000 m in thickness, were deposited in three main environments: lagoon, platform, and basin. The Calcari grigi formation of the lower Jurassic is an expression of a lagoon environment and is characterized by lignite and clay bands. Rosso Ammonitico, of the middle and upper Jurassic, is a condensed unit rich in iron oxides and ammonites. Biancone, of the lower and middle Cretaceous, is a chalk-type limestone, rich in clay, especially in its middle and upper parts. Scaglia Rossa, of the upper Cretaceous, is found outcropping only in small areas of the plateau. Paleogene basaltic lavas and tuffs are locally interbedded with the limestones. An early speleogenesis inside the carbonate sequence is probably linked with Paleogene vulcanism.

Asiago Plateau, Italy: Figure 1. Map of the karst geosystem of the Asiago plateau.

The mountain group constitutes the upper part of a tectonic wedge produced in the framework of the alpine orogenesis. The wedge is delimited on the southern margin by the thrust of Bassano-Valdobbiadene and on the northern margin by the backthrust of Val di Sella. The southern part of the extruded wedge is bent to form an asymmetrical anticline, the central part a syncline, and the northern part another asymmetrical anticline.

In accordance with these tectonic structures, three main geomorphological subunits are recognizable: the southern plateau, corresponding to the top of the southern anticline; a central basin corresponding to the central syncline; and a northern and upper plateau corresponding to the northern anticline (Sauro, 1995; Mietto & Sauro, 2000).

The southern plateau is characterized by a network of dry valleys, with wide floors and steep slopes. This fluviokarstic network evolved within the Jurassic limestones through the fluvial network, which developed in the overlying rock units during uplift. The central basin presents a dense network of V-shaped dry valleys, which mostly developed under periglacial conditions. The ridges between the valleys are covered by thick eluvial and colluvial mantles, mostly composed of soil and loess-like sediments, clay, and weathered chert fragments. The northern plateau is characterized by both karst and glacial forms, such as glacio-karstic closed depressions and limestone pavements.

The evolution of the morphostructure was marked by the gradual arrangement of the tectonic structure and by the accom panying erosional events. The old karst drainage system fed large karst springs at the foot of the northern scarp of the plateau. Two large cave systems (Bigonda and G.B. Trener caves, at an altitude of c. 350 m), that developed in epiphreatic conditions just below the old water table and now hang 150 m above the Valsugana (upper Brenta Valley) valley floor, have been mapped for over 30 km. During exceptional flood conditions, such as the November 1966 flood, these caves behave like overflow outlets.

The present-day spring caves are in the Valle del Brenta at the foot of the eastern scarp of the plateau (Oliero and Ponte Subiolo spring-caves, at an altitude of *c*. 150 m). The average discharge of the three main springs is estimated to be *c*. 15 m s⁻¹ (Meneghel *et al.*, 1986). Divers have explored more than 5 km of the underwater caves. The underground piracy, with the development of new springs, and of relative underground network, is a consequence of the deepening of the lower Brenta Valley, through fluvial and glacial erosion during the middle and upper Pleistocene.

The more than 2300 explored caves are mostly vertical in development (Mietto & Sauro, 2000). The best known are listed in the Table. It is possible to distinguish some main types of cave, and in particular:

- 1. alpine-type shaft systems, consisting of successions of vertical shafts separated by narrow passages, especially frequent in the northern plateau;
- 2. old swallowing systems, consisting in large underground meandering gorges connected by vertical shafts, especially frequent in the southern plateau;
- 3. cave systems with intermediate characters between the two previous types;
- 4. simple shafts and chambers, relicts of old systems cut by the erosional surfaces;
- 5. simple small shafts resulting from inception-type speleogenesis, mostly in the epikarstic zone at the transition between rock layers with different hydraulic conductivity, in particular inside or near the Rosso Ammonitico rock unit (Klimchouk *et al.*, 1997); 6. epiphreatic spring caves developed mostly just below the water table;
- 7. old epiphreatic caves, now active only during exceptional floods.

The different types of caves are an expression of the evolution of the various geomorphological environments of the karst mountain group. In particular, the large swallowing systems probably began to develop as swallow holes inside the old network of fluvial valleys, afterwards being dried by the development of the karst network. Some of these systems have been reactivated during the cold phases of the Pleistocene, swallowing the melting water of the local glaciers, as documented by the filling deposits (e.g., Giacominerloch). The alpine-type shaft systems have developed gradually during the denudation and the uplifting of the plateau. The bottom of the Abisso di Malga

Fossetta is not far from a branch of the old epiphreatic cave of Bigonda. In many caves of the upper plateau, there are ice deposits, also with considerable volumes (Busellato & Gruppo Grotte Schio, 1991).

Asiago Plateau, Italy: Some of the best-known karst caves in the Sette Comuni Plateau (for types, see text).

Perched aquifers are stored, both in till deposits, and in the densely fractured chalktype limestones. The water circulates very fast through the main cave passages of the karstic aquifer.

Asiago Plateau, Italy: Figure 2.

Domed ice roof of a large chamber in Buso della Neve di Zingarella. The ice block, seen from below, shows its layered structure. A speleologist is descending on a rope (from Busellato *et al.*, 1991, with the permission of the authors). A tracing experiment between an active swallow hole and the main springs revealed an average speed of about 400 m h^{-1} over a distance of about 10 km and a difference in elevation of 1000 m (Gennari *et al.*, 1989). The response of the springs to the input of heavy precipitation may be only a few hours (Celi & Sauro, 1995).

During the cold phases of the Pleistocene, a plateau glacier developed in the northern part of the mountain group, and at the last glacial maximum, the extent of the local glacier was c. 270 km². Some glacial tongues reached the central basin, which was an important glacial outlet. After deglaciation, the plateau was rich in creeks, lakes, and springs, but during the Holocene, the reopening of karst swallow holes caused a progressive "desertification" of the plateau (Sauro, 2001). The Gelpack creek, which crosses the central basin and which discharges its waters in many shallow holes, is a relict of the glacial outlet.

During the holiday periods, the central basin becomes like a small town, attaining a population of 100000. In connection with the urbanization, a flourishing quarrying industry has developed. There is also an integrated system of industries producing modern cattle-breeding farms and related installations for dairy production. Over the last 30 years the average quarried limestone exceeds the limestone eroded naturally by karst solution by about three times (about 1000 tons/day as opposed to 300 tons/day) (Meneghel *et al.*, 1986).

The increase in water consumption has required the recycling of deep karstic water from the main springs which, after use, is returned as wastewater that is polluted with organic substances, chemical compounds, etc. This recycling accounts for a quantity that is of the order of 0.5% of total precipitation. Although the various forms of impact are severe, the quality of the karst water is still relatively good. Some specimens of *Proteus anguinus* (cave salamander), introduced into the local aquifer from the Carso di Trieste during the mid-19th century, have reproduced and have continued to survive. The impact of urbanization has certainly been mitigated by the presence, in the central basin, of the chalk-type limestone and by the thick alluvial cover. The mostly deserted upper plateau is a much more vulnerable environment, but here human impact is now relatively scarce.

ATAPUERCA CAVES, SPAIN: ARCHAEOLOGY

The Sierra de Atapuerca, located 15 km east of Burgos in northern Spain, is the world's largest known repository of fossil humans from the Middle Pleistocene period, between one million and 127000 years ago. Archaeologists have been working here since 1976, but have barely scratched the surface of this extraordinary set of sites.

At the turn of the 20th century, a stone-quarrying company cut a great railway trench, or "trinchera", through the southwestern part of the sierra, providing a first glimpse of a host of sediment-filled limestone caves which, it is now known, were occupied by early humans as well as by carnivores and bats. Most of them had filled up with sediments and the detritus of collapsed roofs and entrances. At one site known as the Galeria, archaeologists have been excavating since the 1980s in a hard breccia containing pebble tools and flakes of quartz, quartzite, and flint, as well as Acheulian hand axes and cleavers. Uranium/ thorium dating has attributed stalagmitic deposits at the top of the Galeria to about 125000 years ago. From estimates of the rate at which sediments accumulated in the cave, it has been calculated that the first human presence in the levels

below occurred around 350000 years ago, with sporadic occupation up to 200000 or 150000 years ago. A fragment of a human parietal (skull) bone, about 250000 years old, was found here in close proximity to a hand axe.

The nearby Gran Dolina, another collapsed limestone cave, contains sediments some 20 m deep spanning a period from more than one million to about 120000 years ago, the bottom half belonging to the Lower Pleistocene (before 780000 BP) and the top half to the Middle Pleistocene. Primitive stone tools were first found in layer TD4, known to be more than 700000 years old. Since 1994, primitive, blue-stained human teeth as well as bone fragments from at least six individuals have been recovered from a higher level, TD6, together with numerous stone tools including hammer-stones, flakes and cores made from quartzite river pebbles and flints, but no hand axes or cleavers. This layer is 0.6 m below a level dated by paleomagnetism to 780000 years ago, so the human bones must be between 800000 and a million years old, perhaps the oldest in Europe. They have been ascribed to a new species, *Homo antecessor*, thought to be ancestral to modern humans. Cutmarks on some of the human bones have been interpreted as evidence for canni balism. The tools from TD4, located below TD6, are clearly at least a million years old.

A few hundred metres from the Trinchera is an enormous cave, the Cueva Mayor, with a red painting of a horsehead near the entrance which was long supposed to be from the Ice Age, though it is now thought to be modern. At the back of the cave, an arduous 500 m from the entrance, is the famous Sima de los Huesos (Pit of the Bones) where investigation was triggered in 1976 by the discovery of a human jaw more than 200000 years old. It was found in sediments which, for centuries, had been yielding cave bear remains. A side chamber contains cave bear dens and claw marks gouged in pockets of clay, looking as fresh as if they had been done yesterday. The whole cave is marked with graffiti, the oldest from 1561. Local people have been coming here for hundreds of years to obtain bear bones and teeth—according to a tradition, every young man of the region must present his fiancée with a bear tooth from the Cueva Mayor as a sign of his provess.

In 1976 Spanish paleontologist Trinidad Torres came here to collect sediment containing bear bones. It was this sediment that yielded the human jaw that eventually inspired the current investigations. Excavations began in 1983, and showed that beneath the thousands of cave bear bones there were rich deposits of human remains. Some time after the pit was no longer used by humans, hibernating bears began to fall into it. So far, the pit has yielded more human bones of the period—more than 200000 years ago—than all other sites combined. Even small phalanges and other hand and foot bones are unearthed, while sieving of the sediments recovers the tiny bones of the inner ear.

The pit has revolutionized knowledge of *Homo heidelbergensis*, a transitional species between *Homo erectus* and Neanderthals. Although only 2–3% of the pit's deposits have so far been examined by the slow, painstaking excavation work, almost 2000 bones have been found from at least 33 individuals, and perhaps as many as 50. All parts of the skeleton are present, and males and females are equally represented, with most individuals being adolescents or young adults. It seems that, over several generations, bodies were carried into the cave and tossed into the shaft in a form of crude mortuary ritual—essentially the earliest known burials in the world. The absence of herbivore bones and stone tools indicates that this was not an occupation site, and the lack of carnivore damage suggests that the bones were not left there by animals.

These bones represent about 90% of all pre-Neanderthal bones ever found in Europe. The people seem to have been robust; their teeth are very worn from chewing plants, but there are no cavities from dental disease, and overall the bones show few signs of illness or trauma. The remains include three remarkably well-preserved skulls found in 1992, with large Neanderthal-like brow-ridges and projecting faces, and a complete pelvis has also been recovered.

Another site in the Trinchera, the Sima del Elefante (Pit of the Elephant), where work began recently, has yielded a few tools of *c*. 200000 years old, and it seems to be connected to the Cueva Mayor hundreds of metres away, which means that in this site alone there remain millions of cubic metres of unexplored Pleistocene sediments. This fact, together with the other caves and shelters in the sierra which have not yet been excavated, ensures that Atapuerca will remain a site of world importance for decades to come.

AUSTRALIA

A relative paucity of karst in Australia is partly attributable to the great age of the ancient shield of which much of the continent is comprised, which predates most of the life forms from which biogenic carbonates are derived. The shield is also sufficiently old that ample time has elapsed for such limestone as was deposited to have been eroded away (Jennings, 1983). Nevertheless, many aspects of Australian karst make it of great scientific interest. Karst and caves have developed in carbonate formations that range in age from Pleistocene to Precambrian, and the 200000 km² Nullarbor Plain area is one of the larger karst areas on Earth (see Nullarbor Karst). Australia is also the only continent

to lack the Tertiary orogenic belts that are elsewhere rich in caves, but the resulting history of tectonic stability has enabled the survival of some very ancient karst phenomena. The Wombeyan karst in New South Wales and Eugenana karst, Tasmania, have been exposed since the Devonian, and karst features older than the Permian have been reported from several other karsts.

Great climatic variation across the continent contributes to Australia's considerable karst geodiversity (Figure 1). Australia is the driest continent apart from Antarctica and this, coupled with the low relative relief and hence lower potential hydraulic head, has inhibited karst evolution. Thus, in the Tertiary limestones of the vast Nullarbor, only 300 caves and 1400 dolines have been recorded while in contrast, highly evolved karst occurs in similar rocks in wetter southeastern South Australia. Karsts in the humid Eastern Highlands are the most highly evolved despite sedimentary environments in the Tasman mobile zone having been only marginally suitable for carbonate deposition. Most of these karsts are small and surrounded by non-carbonate rocks, aggressive runoff from which rapidly attacks and erodes the limestone.

Climate change has also been of great consequence to karst evolution. Although the evidence is ambiguous, the principal caves beneath the Nullarbor may have formed under previously wetter conditions. There is less ambiguity in the Eastern Highlands and Tasmania, where many karsts bear a legacy of previously cooler conditions. Continental Australia and Tasmania are now entirely deglaciated, and while late Cainozoic glaciation of mainland Australia involved only a few small cirque glaciers distant from any karst, ice caps and valley and cirque glaciers previously covered c. 7000 km² of Tasmania. Oligocene glacial sediments in the Forth Valley, immediately upstream from the Lorinna karst, imply that the present broad topography was already established, again highlighting the relative antiquity of even these most alpine of Australian karsts.

A reduction in forest biomass during cooler and drier episodes in the late Cainozoic allowed periglacial slope instability to extend to low altitudes in Tasmania, mantling many karsts with allogenic regolith. At Junee-Florentine, cave streams were displaced by colluvial and alluvial sediments causing temporary reversion to surface drainage (Goede, 1973). Periglacial effects have also been recorded from Yarrangobilly, New South Wales and elsewhere in the southeastern highlands of mainland Australia.

Some Australian karsts

The youngest carbonates in which karst has formed are dune limestones (<700 ka old) in coastal southwestern Western Australia, on the Eyre Peninsula and Kangaroo Island in South Australia, southern Victoria and scattered localities on the Bass Strait islands and western Tasmania. Syngenetic karst (see separate entry) has developed in these poorly consolidated aeolianites. Solution pipes typically connect the surface to caves at the water table. Easter Cave, southwestern Western Australia, contains >7.5 km of passages, and nearby Strongs Cave contains straw stalactites to 9.8 m in length.

The arid—semi arid Nullarbor karst contains some very large caverns such as those of Koonalda, Abrakurrie, and Webubbie

Australia: Figure 1. Location of principal karst areas and caves in Australia.

caves but the longest, Old Homestead Cave (~28 km), is a maze of relatively small passages. The karst province of southeastern South Australia, formed in Oligocene limestones, includes a World Heritage-listed Tertiary mammalian fossil site at Victoria Fossil Cave, Naracoorte (see Australia: Archaeological and Paleontological Caves). Karst formed in Miocene limestone also occurs in the Murray Valley, South Australia.

Notwithstanding the general absence of Tertiary orogenic influences in Australia, karst in the arid Cape Range, Western Australia, has formed in four emerged post-Miocene marine terraces, the caves containing a well-developed invertebrate fauna with strong Gondwanan affinities (see entry Cape Range, Australia: Biospeleology). Karst also occurs on Australia's external Territory of tropical Christmas Island, on the boundary between the Indo-Australian and Caroline plates. The carbonates here comprise raised coralline shore platforms that fringe a core of Oligocene—Miocene reef limestones overlying volcanic rocks. To date, only minor karren have been recorded from poorly known Miocene—Oligocene limestone in the remote sub-Antarctic Australian Territory of Heard Island in the southern Indian Ocean.

Limestones of Permian age host karsts at Kempsey in New South Wales. Relatively widespread but impure Permian limestones in Tasmania are known to contain small caves only at Gray and on the coast at Maria Island. Caves formed in Carboniferous limestone at Texas, Queensland, were inundated by an artificial reservoir constructed to provide water for the local tobacco industry.

The tropical, semi-arid Limestone Ranges of the Kimberley region, Western Australia comprise an exhumed Devonian barrier reef system with a relief of *c*. 80 m. The limestone has been dissected to form an alluviated labyrinth karst. Other important karsts formed in Devonian limestone occur in Queensland at Mt Etna, previously the scene of a long-running conflict over limestone quarrying, and at Broken River. Karst in rocks of this age also occurs in New South Wales at Wee Jasper, Timor, and Wellington, the latter an important megafaunal fossil site, and in Victoria at Buchan where incision probably resulted from tectonic uplift (Webb *et al.*, 1992). Other small karsts formed in Devonian limestone include the Lake Sydney glaciokarst in Tasmania, where stream-sinks buried by glacial sediment during the most recent glaciation are presently being exhumed as underground drainage is re-established.

The Chillagoe tower karst, northern Queensland, is formed in Silurian limestone (see Chillagoe and Mitchell-Palmer Karsts). More than 150 karst towers up to 100 m high also occur further north in the seasonally arid Mitchell-Palmer karst, characterized by very rugged karren and containing caves of considerable biological interest. Silurian limestones also host some of the most significant karsts in New South Wales, at Jenolan, Yarrangobilly, Cooleman Plain, Wombeyan, Bungonia, Colong, Bendithera, and Wyanbene. About 45 km of passages have been surveyed within the Jenolan tourist caves complex, which lies within the Greater Blue Mountains World Heritage Area (Kiernan, 1988).

A greater proportion of carbonate rocks accumulated in those parts of the sedimentary basins that were to become Tasmania. Rainfall totals and effectiveness are greater in Tasmania than over most of Australia and it is here that Australia's deepest caves are located, near the retreating margins of caprocks that have protected the carbonates, thus permitting retention of relatively high local relief. Current information suggests the deepest is Niggly Cave (375 m) in the Junee-Florentine area, but Anne-A-Kananda (373 m) at Mt Anne, and the 12 km long Ice Tube-Growling Swallet system (360 m), also at Junee-Florentine, are also within the range of potential survey error.

The most highly evolved of the *c*. 300 Tasmanian karsts are formed in Ordovician limestones. The most intensively studied are at Mole Creek, Junee-Florentine, and at Ida Bay where >23 km of locally massive passages have been mapped to date in Exit Cave, one of numerous karsts within the Western Tasmanian Wilderness World Heritage Area (Figures 2–4) and the scene of another conflict over limestone quarrying. Recognition of a rich Pleistocene human occupation site in Kutikina Cave (formerly Fraser Cave) in the Franklin River Valley played a major role in establishment of this World Heritage Area and the defeat of proposals for hydro-electric reservoirs that would have inundated many riverine karsts. A number of additional cave occupation sites have since been discovered in southwestern Tasmania, including Pleistocene art at Ballawinnie Cave in the Maxwell Valley and Wargata Mina in the Cracroft Valley. The altitude of some caves at Precipitous Bluff on Tasmania's south coast is broadly coincident with emerged coastfacing terraces of probable Tertiary age, making these caves potentially significant for

studies of neotectonic uplift around the Tasmanian coast. Several Tasmanian karsts are of biological significance. Karsts at Abercrombie and Walli, New South Wales, are also formed in Ordovician carbonates.

Extensive karstification has occurred in Cambrian carbonates in the Barkly Tableland of the Northern Territory and northern Queensland. Water table caves in low karst towers of possible Cretaceous age occur in the Katherine area. The Bullita Cave system, Gregory National Park, is Australia's longest surveyed cave, comprising a 65 km long maze with many daylight holes. A Miocene vertebrate fossil locality in the Riversleigh karst has World Heritage status. Hydrothermal waters are present in some of these karsts and particularly extensive tufa accumulations occur at Lawn Hill. Caves in the low relief Camooweal karst descend 60–70 m to a water table that may rise 20 m after storms. In the Flinders and Mt Lofty Ranges, South Australia, cave development in Cambrian carbonates has been inhibited by aridity.

A complex of caves formed in Precambrian dolomite at Hastings includes one of Tasmania's more important tourist attractions (Newdegate Cave). The greatest topographic relief attained by carbonate rocks anywhere in Australia is ~600 m, at the important Mt Anne glaciokarst in southwestern Tasmania (Figure 2). Surface karst landforms, warm springs, and small caves in the Tarkine area, northwestern Tasmania, are formed in extensive magnesite deposits and hence are rare on a world scale. Karst has also formed in Precambrian carbonates at Coorow, Western Australia and in the Flinders Ranges, South Australia.

Some karst features have also formed in non-carbonate rocks. Dissolution of silica in relatively insoluble rocks has produced some large caves, including stream caves, in Upper Proterozoic quartz sandstones. They include Whalemouth Cave, North Kimberley, Western Australia, and others in Arnhem Land, Northern Territory, and adjacent parts of northern Queensland. Runiform relief is well developed in the Ruined City, Arnhem Land. Notwithstanding a lack of subsurface drainage, the sandstone ridges and towers of the Bungle Bungle Range, Western Australia, have also been interpreted as karstic because dissolution of the quartz cement in the sandstone has been fundamental to tower evolution. Other caves have developed in the Triassic Hawkesbury sandstone of the Sydney Basin and rockshelters in sandstone are widespread. Formation of a cave by dissolution of autometasomatic alteration products in dolerite has been reported from Wayatinah, Tasmania and caves in basalt at Coolah, New South Wales, also appear to have formed by dissolution of a zeolite zone. Little evaporite karst is known apart from a few small gypsum caves in the Wolf Creek meteorite crater, Western Australia.

Turning to non-karst caves, some impressive pits appear to be the result of subjacent karst collapse, including the 100 m deep Big Hole, formed in Devonian sandstones and shales near Braidwood, New South Wales. A system of lava tubes extends for c. 100 km from the Undara Volcano, North Queensland, which erupted 23 km³ of lava c. 0.19 million years ago. The longest single cave has been explored for about 1 km (Atkinson, 1990). Numerous lava tube caves are also present in the Pliocene to Holocene lava flows of western Victoria, on sub-Antarctic Heard Island, and elsewhere. The stability and climate of the Australian continent has favoured development of extensive areas of duricrust formed over weak, decomposed material that is susceptible to erosion by piping. Despite considerable potential for caves there has been negligible investigation of these duricrusts. The most extensive caves may have formed beneath ferricretes. The greater hydraulic gradient in the weathering profile at breakaways and jump-ups facilitates mass removal, but percolines more distant from scarps suggest prior preparation may be involved. Some raised sea caves are of considerable scientific interest, including important archaeological sites at Rocky Cape, northwestern Tasmania, and on Hunter Island, Bass Strait. Iron Monarch Cave, King Island, is a raised sea cave formed in noncarbonate rocks but contains many speleothems formed of carbonate leached from overlying dune sands.

AUSTRALIA: ARCHAEOLOGICAL AND PALEONTOLOGICAL CAVES

In 1831, a small party of Europeans, less than 50 years in Australia, climbed into a doline (Breccia Cave) in the Wellington Valley, on the western slopes of the ranges northwest of Sydney. George Ranken fixed his rope to a projection that gave way, revealing that it was in fact a gigantic bird femur. From the red cave earths, Ranken and explorer Major Thomas Mitchell collected specimens of extinct marsupial and avian megafauna, and dispatched them to scientists in Edinburgh and London (Rich, van Tets & Knight, 1985). So was born vertebrate paleontology in Australia.

The oldest and most diverse cave fossils in Australia are at Riversleigh, northern Queensland (Archer, Hand & Godthelp, 1991). From the late Miocene on, caves developed in the OligoMiocene and Cambrian limestones. Some fossils are contemporary
with the deposition of the younger limestones, but others accumulated in pit-fall caves and fissures or as the prey remains of carnivorous bats. In the mid-Tertiary Riversleigh was rich lowland rainforest, with the most diverse faunal assemblages of any known from the Australian continent, containing at least 68 mammal species in 27 families as well as birds, reptiles, amphibians, fish, molluscs, and insects. As the continent drifted north, the climate became drier and the rich rainforest faunas all but disappeared. Today, the ancient cave deposits are found as surface outcrops on low, dry, and dusty hills. Riversleigh, protected within Lawn Hill National Park, is part of the Australian Fossil Mammal Sites World Heritage Area, recognized in 1994.

Fossils have been found in Australia in all kinds of caves and everywhere caves occur. In deep, wet caves in older limestones in the Great Dividing Range, along the east coast of Australia, they tend to be disarticulated jumbles of broken bones in red cave earths, sometimes consolidated into hard breccias. Much of the fossil deposits at Wellington Caves fall into this category, although the remaining caves here are old and inactive.

Caves in the younger Tertiary and Quaternary limestones and calcarenites along the southern coasts of Australia tend to be large, horizontal tunnels, where sediment, containing the remains of passing wildlife captured by dolines, has built up huge talus piles. At Naracoorte Caves, South Australia, the tunnel floors are strewn with skulls and skeletons of Late Quaternary giant extinct marsupials (Wells, Moriarty & Williams, 1984). The Naracoorte Caves Conservation Area (300 ha) is also part of the Australian Mammal Fossil Sites World Heritage Area.

Fossil deposits derived from predators occur in all types of caves. Owls roosted in entrances to deep caves, or crevices and fissures on limestone cliff faces, and marsupial carnivores, especially the Tasmanian devil, Sarcophilus, once widespread on mainland Australia, made their dens not only in limestone caves, but also in lava tunnels, common in the volcanic plains of western Victoria. Most known predator deposits are late Pleistocene or Holocene in age, but Riversleigh preserves much older accumulations made by carnivorous ghost bats (Megadermatidae), whose prey included fish, frogs, lizards, birds, and small mammals including other bats. These caves with younger predatorderived faunal assemblages provide much information about local faunas before the impact of Europeans. They also commonly contain archaeological material. Karst areas with important archaeological sites include the southwest of Australia, including the Nullarbor Plain, the southeast highlands, Tasmania, and also New Guinea, which like Tasmania, lies on the Australian continental plate and was connected by dry land at times of glacial low sea levels. The term "cave" tends to be used indiscriminately by Australian archaeologists for both karst and nonkarst caves and rock shelters. Many famous archaeological "caves", in Arnhem Land in Northern Territory, the Carnarvon Ranges in Queensland (Kenniff Cave), the Grampians in Victoria, and on the New South Wales coast, around Sydney, occur in sandstone ranges or sea caves. Flood (1999) is a useful introduction to the wide range of archaeological caves and shelters in Australia.

There are ethnographic accounts of Aboriginal fear of dark caves, but there is much archaeological evidence of dark zone penetration. About 24000 BP, just before the height of the last glaciation, Aboriginal people climbed down 20 m cliffs into the huge Koonalda doline on the Nullarbor Plain, the karst plateau edging the Great Australian Bight. They moved into the high dark tunnels of the cave, and by torchlight, quarried flint and marked abstract patterns in the soft cave walls.

In southwestern Tasmania, caves such as Kutikina, with rich faunal assemblages, preserve evidence of human settlement of periglacial uplands between at least 30000 and 12000 BP. After an early phase, most were unoccupied during the height of the Last Glacial Maximum, then intensively used as hunting camps during the time of ameliorating climate, 17000–13000 BP. The deposits are dominated by the bones of wallabies (*Macropus rufogriseus*) and wombats, but are also noted for artefacts made from "Darwin glass", from the Mt Darwin meteorite crater. Most sites were no longer used after 13000 BP, probably due to the reduction of the preferred open habitat of the game species as forests expanded (Porch & Allen, 1995).

Many of these important cave sites lie within the Tasmanian Wilderness, inscribed on the World Heritage List in 1989. In 1995 Kutikina, Ballawinne, and Wargata Mina were returned to Tasmanian Aboriginal community ownership, the first time Aborigines had been given both tide and sole management of land in a World Heritage Area. Wargata Mina contains the most southern cave art in Australia; hand stencils there, with human blood protein as a constituent of the red pigment, date to 11000 BP (*Loy et al.*, 1990).

A review of Aboriginal use of karst caves in southeastern Australia by Spate (1997) identified about 30 localities used as occupation or art sites, and for the disposition of the dead, dating back as far as 23000 years. The area with the richest record, Cooleman Caves, in the alpine Kosciuszko National Park, has perhaps the harshest climate.

Many archaeological cave sites have extant faunal remains of mixed provenance, and also extinct megafauna, though doubts remain whether any demonstrate Aboriginal predation on the latter. In Cloggs Cave, in southeast Victoria, stone artefacts occur in an owl pellet deposit, with rare bones of the extinct kangaroo Sthenurus; Seton Rockshelter, Kangaroo Island, South Australia, has quartz artefacts, rare Sthenurus teeth, but mainly bone fragments typical of Sarcophilus. These sites have similar dates, 17-16000 BP, associated with the Sthenurus levels. Aboriginal people regularly, if sporadically, lived in Devils Lair, in far southwest Western Australia, from 33000 to 6000 BP. Bone points occur at 22000 BP, and bone beads at 13000 BP. The remains of wallabies and other animals in Devils Lair were hunted by both humans and Sarcophilus, and lower layers contain extinct marsupial megafauna. Nombe, a karst rock shelter in the New Guinea highlands, has a similar antiquity and contents: wallables and possums hunted by the occupants, as well as the occasional bones of extinct megafauna (Mountain, 1993). Sarcophilus apparently never reached New Guinea, so the highly distinctive chewed fragments of its prey are missing from this site. A pattern emerges: extinct Pleistocene species occur in lower units, overlaid by rich, and often mixed, archaeological and predator accumulations of bone, but no firm evidence of human predation of the megafauna.

Finally, New Guinea also has the highest and most unusual karst archaeological site, Mapala Rockshelter, at 4000 m, set beneath a limestone block perched by retreating ice across lateral moraines near the Carstenz Glacier in the Indonesian west of the island. Again, this is a hunting camp, containing wallaby and possum bones, dating back more than 4000 BP, but used in living memory by the Damal people (Hope & Hope, 1976).

AUSTRALIA: BIOSPELEOLOGY

In the late 19th century scientists recognized that Australian caves contained terrestrial and aquatic species that belonged to ancient and relict groups of value to studies in evolution. Widespread studies of Australian cave life did not commence until the 1970s and there have still been few systematic surveys of cave or groundwater (aquifer) faunas. While a few detailed studies have been conducted of hypogean ecology, environment, and evolution, much of the known fauna remains undescribed. The composition of Australian cave fauna is influenced by past connections with the supercontinents Pangaea and Gondwana, and by it having formed part of the eastern seaboard of the Tethys Ocean during the Cretaceous. Above all, it is shaped by the onset of aridity, following the separation of Australia from Antarctica about 45 million years ago, which displaced wellwatered, cool temperate, and subtropical forests, as Australia drifted northwards. Aridity appears to have played a prominent role in isolating cave species now far from the humid ecosystems of their ancestors.

Australia, which covers 7.7 million km^2 and is of generally low relief, contains extensive shield regions that have remained above sea level since the Paleozoic and so support numerous relictual lineages of freshwater stygobites. Over 500 discrete areas of carbonate rocks occur in Australia (see map in Australia entry). The caves and karst support terrestrial, fresh and saltwater, and anchialine ecosystems. Hamilton-Smith and Eberhard (2000) presented a regional classification of the subterranean fauna based on recognized bioclimatic zones. These include tropical climates in the north, a large subtropical dry province occupying the centre and the western seaboard, a transitional zone with winter rain along southwestern coasts, and a warm temperate/tropical transition zone largely covering the Eastern Highlands.

Until recently, the subterranean fauna of Australia—with the exception of that in Tasmania which has had a more humid climatic history than the mainland with periods of Cainozoic glaciation—was perceived as being much less diverse than those from the well-studied caves of Europe and North America. This coincidence in Tasmania of glaciation with speciose troglobite communities was consistent with the Northern Hemisphere model in which glaciation was perceived as the driving factor in troglobite evolution. However, recently this perception has been overturned, especially by discoveries within the tropics and the arid parts of the continent. Notably diverse cave faunas occur in Tasmania, Jenolan Caves (New South Wales), Far North Queensland (Chillagoe karst and Undara lava tube), and Cape Range and Barrow Island (see Cape Range, Australia: Biospeleology). Areas where strongly cave-adapted species are sparse include the aeolian limestones of the southwestern coasts and the extensive Nullarbor karst (especially stygofauna).

The island state of Tasmania, with 300 discrete karst areas, exhibits a higher proportion of troglobites than found on the mainland in New South Wales, with 200 discrete karst areas, having 34 and 17 troglobitic genera respectively, distributed among a comparable number of families. However, by comparison, some tropical caves are species rich (Malipatil & Howarth, 1990) and the arid tropical Cape Range and Barrow Island karst in Western Australia supports 51 obligate subterranean genera in 42 families (32 troglobite and 19 stygobite genera). In the tropics, numerous cave-adapted planthoppers (Homoptera: Fulgoroidea) occur in which the adults retain the underground root-feeding behaviour common amongst the nymphs. These co-occur with epigean species and provide a graded series of morphological change associated with adaptation to cave life. Different species display all grades of cave adaptation from almost no modification from surface relatives to the loss of eyes and pigment and strongly reduced wings (Hoch & Howarth, 1989).

Amphipods, a major component of world cave faunas, were long considered sparse in Australian inland waters, and thought especially to abhor the tropics. Recent work has uncovered a diversity of amphipods in the arid zone and in the tropics, represented by a number of families considered to belong to both marine and freshwater lineages. The distribution of the latter, along with other ancient freshwater crustacea, coincides closely with areas not covered by marine incursions during the Cretaceous (Bradbury, 1999).

In southwestern Australia, root mats forming in shallow streams of caves in aeolian limestone support a diverse aquatic community, largely lacking overt modification to cave life (Jasinska *et al.*, 1996). Whether these mats also support a terrestrial component, such as seen in the tropical planthoppers, is unrecorded.

Many species are restricted to single karst areas, especially in the impounded karsts of eastern Australia (Thurgate *et al.*, 2001), but even within a given karst area there is often no interbreeding between populations of troglobites in adjacent caves (Humphreys & Adams, 2001). Unexpected small-scale endemicity also occurs in the stygofauna inhabiting groundwater calcretes of arid Australia. These are limestone masses deposited

from groundwater flow into the alluvium filling ancient paleochannels. They form where the baselevel of the groundwater approaches the surface and are found upstream of the saltlakes (playas) that occur at intervals along the length of the paleochannels. For example, most of the 49 known species of stygal diving beetles (Dytiscidae) are restricted to a single calcrete body (Watts &: Humphreys, 2000). Molecular data suggest that sepa-

rate dytiscid lineages invaded groundwater in the middle Miocene with the onset of general aridity (Cooper *et al.*, 2002), but other calcretes appear to support much more ancient faunas with Gondwanan affinities (Poore &; Humphreys, 1998), or contain rich assemblages of amphipods.

Owing to sparse research in Australia, meaningful comparison with the diversity of subterranean faunas of other continents is premature. Certain areas, such as Chillagoe, Undara, Jenolan, and Cape Range, contain rich troglobite faunas by world standards. But there are extensive karst areas, such as the Barkley Tableland, the Nullarbor and the syngenetic karst in aeolian dunes of the southwestern coasts, that apparently contain low to very low diversity of strongly cave-adapted species. These factors, combined with the generally low proportion of carbonate landscape in the fragments of Gondwana, suggest that the overall diversity in Australia may not be high by world standards, but the case remains open.

Biospeleology has resulted in the discovery in Australia of a number of higher taxonomic groups (e.g. Class Remipedia; Orders Thermosbaenacea, Misophrioida and

Spelaeogriphacea), and of important evolutionary linkages between phreatoicidean isopods (see figure) from Africa, Australia, and New Zealand (Wilson & Keable, 1999). A number of troglobitic and stygobitic species and several cave communities are specifically protected under fauna legislation, part of an Australian ethos of cave and cave fauna protection that is projected strongly internationally (Watson *et al.*, 1997).

AUSTRALIA: HISTORY

The first verified report of limestone in Australia was of abundant quantities of stratified limestone in the vicinity of the Tamar Estuary in northern Tasmania, in a report to Governor King by Colonel William Patterson in October 1804 (Lane, 1975). The first such report on mainland Australia was made in Governor Macquarie's dispatch to Earl Bathurst of 30 June 1815, which recorded the discovery of limestone by G.W.Evans at Limestone Creek, a tributary of the Belubula River, west of what was to become the town of Bathurst in New South Wales (Carne & Jones, 1919: pp.6–8). The Bathurst district also provided the first record of a European entering an Australian cave, when, on 8 November 1821, William Lawson, one of the trio credited with the crossing of the Blue Mountains, explored Limekilns Cave. Lawson recorded in his journal (Lawson, 1821):

Camped at the Limestone Hills, here government has a kiln built for burning of lime for the use of the settlement which proves to be the very best quality. Here is a curious cave through a solid rock of limestone. Its entrance is very narrow. At nine o'clock at night I took four men with three candles and proceeded into it about one hundred yards. At the end is a fine pool of clear water. In many places for several yards together I was obliged to creep on my hands and knees. The inside of the cave is very curious and well worth seeing. I got some fine specimens. Came out at one o'clock in the morning.

While it is likely that caves were discovered at Bungonia in New South Wales by early settlers around 1820, the earliest written report was by botanist and explorer Alan Cunningham, who noted in his diary on 27 April 1824 that, passing through limestone country, "we found the land exceedingly cavernous. Orifices four feet in diameter connected with capacious subterraneous Excavations, appeared in every part of the Forestland, of whom some presented yawning fissures of apparently great depth" (Cunningham, 1824). The report went on to describe a visit to what is now known as Drum Cave (B13), though they were stopped by a pit of "unfathomed depth"—later surveyed at 43 m.

The earliest-known illustrations of Australian caves were three watercolours executed in 1826 by a professional painter, Augustus Earle, of "Mosman's Cave, Wellington Valley, NS Wales". These pre-dated by two years the publication of the first written report on the Wellington Caves by Hamilton Hume, a member of Sturt's 1828 expedition (Hamilton-Smith, 1997). The paleontological value of the caves at Wellington was realized about 1830 and became well known following the publication of Major Mitchell's journals in 1838 (Mitchell, 1838). These include a plan of the caves, which was the first accurate cave plan to be published in Australia (Figure 1).

Australia's earliest-known cave map was prepared by surveyor Henry Hellyer in August 1827, but this was not to scale and was not published until 1990 (Figure 2) The cave, at Rocky Cape on the north coast of Tasmania, is in quartzite and was noted by Hellyer as being 10 feet (3 m) wide at the entrance and 80 feet (24 m) deep. The cave became known as Rocky Cape North Cave and yielded important information on the Aboriginal inhabitants of the area over the previous 8000 years (Middleton, 1990).

The first published plans of Australian caves accompanied Capt. John Henderson's record of his observations in New South Wales (Figure 3) (Henderson 1832). Although relatively crude and not to scale, the two sketches are identifiably of Tunnel Cave (BN25–28) at Borenore and Breccia Cave (or Bone Cave No. 3) at Wellington.

Caves were easier to find in Western Australia. In March 1827, two years prior to European settlement, Capt. James Stirling noted that the "heads" at the mouth of the Swan River were composed of limestone which, "subject to the action of the surge, is worn into Caverns". Exploring inland in the vicinity of Cape Naturaliste, Stirling noted "compact limestone, sections of which were seen 200 feet in depth" and "under the limestone cliffs, many magnificent Caverns; some of these are remarkable for their extent and some for the beautiful stalactites and incrustations which they contain" (Stirling, 1827).

While the Jenolan Caves (formerly Binda or Fish River Caves) in the Blue Mountains of eastern New South Wales would have been known to the Gundungura people for millennia, their discovery by Europeans is shrouded in mystery. A widely accepted story is that they were found by James Whalan in 1838 while searching for a cattle thief named McKeown. Unfortunately there is no contemporary record of this event, or any reliable record of McKeown, although the first published name of the caves, in 1856, was "McKeon's Caves" (Havard, 1934). Certainly, James's brother, Charles Whalan, who had the closest farm to the caves, conducted the first tourist parties to them in the 1840s and 1850s. Jeremiah Wilson, an immigrant from Enniskillen, Ireland, settled in the district in 1843 and began exploring the caves in 1855. John Lucas, the member of the Legislative Assembly for the area, visited the caves in 1861 and, as a result of his representations, a reserve was declared over the "Fish River Caves" on 2 October 1866– the first Australian cave reserve. Wilson was appointed the first caretaker on 12 January 1867. Originally, visitors to the caves camped in the Grand

Arch, but Wilson constructed the first accommodation house in 1880 (Dunkley, 1986). The outstanding cave surveyor of the late 19th and early 20th centuries in Australia was Oliver Trickett (1847–1934). As an employee of the New South Wales Department of Mines, he began surveying caves in 1896 and continued till his retirement in 1919. Although originally employed as a survey draughtsman, he was given responsibility for the management of all of the colony's caves and he supervised much of the work which went into opening caves to the public at Jenolan, Wombeyan, Wellington, Yarrangobilly, and Abercrombie. He produced numerous maps, photographs, detailed reports, models, and informative guidebooks (Middleton, 1991).

In South Australia the Narracoorte Caves (formerly Mosquito Plains Caves), on the traditional lands of the Boandik people, were first entered by Europeans in 1845 when Benjamin Sanders recovered some of his sheep from what became known as Blanche Cave, where they had been driven by the Aborigines. A reserve was placed over the cave in the late 1870s, but the first ranger was not appointed until 1885. William Reddan was in charge of the cave from 1886 and discovered others; he resigned in 1916 (Lewis, 1977).

The speleological significance of Australia's largest area of outcropping limestone, the Nullarbor Plain, appears not to have

been recognized until Professor Tate went looking for artesian water for grazing cattle (Tate, 1879). The first expeditions specifically to study the caves of the region were conducted by Capt. J.Maitland Thomson between 1930 and 1960 (Dunkley, 1967).

The first recording of karst caves in Tasmania resulted from an excursion by the Lieutenant-Governor, George Arthur, and his party, in January 1829 to inspect land being applied for by the Van Diemens Land Company in the island's northwest. The Assistant Government Surveyor, Thomas Scott, recorded in his diary for 15 January 1829 that, beyond "Moleside" (now Mole Creek) the party "visited a remarkable cavern in the limestone rock". A more detailed account of the cave visit was given in the *Hobart Town Courier* on 28 February 1829 (Clarke, 1999); the cave had obviously been found earlier

by local settlers. Concern about vandalism in caves near Mole Creek dates to at least 1873 and arose over the alleged removal of "a cartload of cave formations". By April 1879 the Tasmanian Government had moved to reserve 300 acres around the "new caves" near Sassafras Creek and a further 100 acres around the "old caves" (Oakdens, Wet, or Caveside Caves). In 1881 Henry Judd and a party of four discovered a cave in the Cracroft Valley in southern Tasmania and reported on the 400 yards of passage explored (Kiernan, 1978). Judds Cavern was found to contain Aboriginal hand stencils in 1987, and subsequently became known as Wargata Mina; with Kutikina and Ballawinie caves it was returned to Aboriginal ownership by an Act of the Tasmanian Parliament on 6 December 1995.

Stewart Ryrie recorded his visit to a cave at "Buckan" (Buchan), Victoria, on 7 April 1840; he "descended into one of them a considerable depth but saw nothing remarkable" (Ryrie, 1840). In 1889, James Stirling recorded and mapped caves at Buchan (Stirling, 1889; Hamilton-Smith, 1986). The government took control of 279 acres of land in 1900 and this subsequently became part of the Buchan Caves Reserve. Buchan Caves were opened to the public in 1907 (Kahrau, 1972).

In 1882 caves were first recorded in the Rockhampton area, central Queensland, by John Olsen, a Norwegian immigrant. These were opened to the public in 1884 and remain a local tourist attraction (Caffyn, 1970).

AVES (BIRDS)

Birds in karst landscapes can be grouped into three rather indistinct categories: casuals, birds which visit and utilize both karst and non-karst areas; usuals, which regularly favour karstlands as feeding or nesting sites; and habituals, which are restricted or closely tied to karst habitats. Studies dedicated to contemporary birds in karstlands are in their infancy, so this account, which focuses particularly on tropical species, should be regarded as preliminary. For a brief account of fossilized bird remains in cave sediments and what they reveal about paleoenvironments, see Bramwell (1976).

The casuals are the most numerous species in karstlands but their utilization of specifically karstic resources has not been studied in detail. Vegetative structure, food sources, and nesting sites are no less important to the casuals than the other categories

and in some respects they may be related to the karst substrate. Cliff-nesting species, for example, will utilize karst and nonkarst cliffs without necessary regard to lithology but with due regard to cliff morphology. Barn Owls (*Tyto alba*), Cliff Swallows (*Petrochelidon pyrrhonata*), and flycatchers such as the Eastern Phoebe (*Sayornis phoebe*) of North America sometimes nest or roost in cave entrances, but certainly not exclusively.

On the basis of available studies it is difficult to differentiate between the casuals and the usuals, which include species that forage or nest regularly in karst landscapes, although they may also spend time in adjacent non-karst areas. A study of birds recorded in the karst terrain of Belize (Day, 1989) indicates that over 300 of Belize's approximately 550 bird species have been recorded in the karst, with at least 250 of these occurring on a regular basis. In this context, karstlands may be more significant avian habitats than has been realized previously.

The habituals have received the greatest attention, although they are the least numerous of the three categories. They may be subdivided into two types: those that inhabit exclusively terrestrial karst landscapes, and those that are associated with caves.

The surface dwellers include more than a dozen species that occur almost exclusively in limestone vegetation or in intimate association with limestone rocks and cliffs. In southern Mexico, for example, Sumichrast's Wren (*Hylorchilus sumichrasti*) and Nava's Wren (*Hylorchilus navai*) inhabit karst forests especially near limestone outcrops (BirdLife International, 2000; Stattersfield *et al*, 1998). Likewise, the Cuban Solitaire (*Myadestes elisabeth*) nests exclusively on steep limestone cliffs in moist montane forest (BirdLife International, 2000; Garrido & Kirkconnell, 2000). In Southeast Asia three species of babbler, the Limestone Wren Babbler (*Napothera crispifrons*), the Streaked Wren Bab bler (*Napothera brevicaudata*), and the Sooty Babbler (*Stachyris herberti*) similarly are found in evergreen forest with limestone outcrops (MacKinnon & Phillipps, 2000; Robson, 2000; Bird-Life International, 2000; Stattersfield *et al.*, 1998). The Greater Melampitta (*Melampitta gigantean*) roosts in forested dolines in Irian Jaya (Stattersfield *et al.*, 1998) and the Giant White-eye (*Megazosterops palauensis*) occurs in limestone forests and thickets on Palau (BirdLife International, 2000; Stattersfield *et al.*, 1998).

Birds habitually associated with caves may be regarded as habitual trogloxenes, using caves temporarily for shelter from weather, safe nesting, and raising young but completing their life cycles at the surface. Most use the entrance habitat of caves as nesting sites, feeding in adjacent surface landscapes, although often venturing deep into caves beyond the threshold or twilight zone. The vast majority of cave-dwelling birds are insectivorous, with the notable exception of the South American guácharo or oilbird (*Steatornis caripensis*) which feeds on fruit (de Schauensee and Phelps, 1978).

The most numerous cave-nesting birds are the tropical swiftlets (*Collocalia*, and perhaps *Hydrochous* and *Aerodramus* spp.), whose colonies are particularly associated with Southeast Asia, New Guinea, and the South Pacific islands. (Swiflet taxonomy is a vexed issue; the reader is referred to the discussion by Chantler & Driessens, 1995, who consider all swiftlets as belonging to the genus *Collocalia*.) There are some 25 species of cave-nesting swiftlets including the Edible-nest Swiftlet (*Collocalia fuciphaga;* Chantler & Driessens, 1995), whose saliva-based nests provide the essential ingredient of bird's-nest soup. At least five species of swifts (*Chaetura* and *Apus* spp) also nest in caves, although not exclusively, as do the Red-rumped and Cave Swallow (*Hirundo daurica* and

Petrochelidon fulva). The Red-rumped swallow is found in Europe, Africa, temperate and southeast Asia, in the Greater and Lesser Sundas, and in the Philippines (Jeyarajasingam & Pearson, 1999). The Cave Swallow is found from southern North America to southern Mexico and the West Indies (Terres, 1980). The Grey-necked Rockfowl (*Picathartes oreas*) of West Africa also nests colonially in caves (BirdLife International, 2000; Stattersfield *et al.*, 1998), and the Angolan Cavechat (*Xenocopsychus ansorgei*) can also be regarded as a trogloxene because it forages and sometimes nests in cave entrances (BirdLife International, 2000).

Perhaps the most fascinating cave-nesting bird is the neotropical guácharo or oilbird (Steatornis caripensis). Colonies of this cave-nesting nocturnal frugivore, whose Spanish name may be translated as "one who cries and laments" (Jackson, 1982), occur in South America northward from Bolivia to Venezuela, Guyana, and Trinidad (Thomas, 1999). The colony in Venezuela's Guácharo Cave has been estimated at 19000 birds (Jackson, 1982). Introduced to European science by Alexander von Humboldt after a visit to Venezuela in 1799, the oilbird is so-called in English because native Americans used oil from the bodies of chicks for cooking and illumination. Like the swiftlets, the guácharo navigates in caves by echolocation, emitting highpitched tongue clicks. Echolocation, the use in navigation of reflected sound as part of vocalizations, is known among birds only in cave-nesting swiftlets and the oilbird (Gill, 1995). Among swiftlets, some species in the genus Collocalia are particularly well adapted to nesting in the interior of caves. Those species that do so are possessed of the ability to echolocate, which they use as an aid to navigation within the darkness of cave nesting sites. The echolocation abilities of swiftlets are not "ultrasound" sonar, as is typical of bats. Instead these are low-frequency sounds, brief "clicks" at 2-10 kHz frequencies, and about 1 millisecond in duration (Medway & Pye, 1977). The oilbird (Steatornis caripensis) uses clicks of a longer duration (15-20 milliseconds) and of a wider frequency range (1-15 kHz) (Konishi & Knudsen, 1979).

BAMBUÍ KARST, BRAZIL

The carbonate rocks of the Bambuí Group represent by far the largest area (c. 105000 km²) of carbonate karst in Brazil, corresponding to over half of all karst areas in the country (see map in America, South). The Bambuí Group comprises a sequence of pelitic and carbonate marine sediments of Precambrian age. Of the six formations that make up the group, two form karst scenery. The Sete Lagoas Formation lies over the basal glaciogenic Jequitaí Formation, and is characterized by light-grey limestone and dolomite with some clay/silt intercalations. It is overlain by the pelitic Serra de Santa Helena Formation, followed by the Lagoa do Jacaré Formation, another carbonate unit that comprises darker oolitic and pisolitic limestone, again showing some interspersed pelitic lenses. Their thickness can reach a few hundred metres, although rarely more than 200 m lies above the water table. Most of the Bambuí karst lies over the São Francisco Craton, a tectonic unit stabilized in the Precambrian. Thus, the carbonate sequences are mostly undeformed, except where they lie close to the border of the craton.

Well-developed karst terrains occur both in the Sete Lagoas and Lagoa do Jacaré Formations, both with highly seasonal climate (dry winter, wet summer) with precipitation levels ranging between 1000 and 2000 mm a^{-1} . The landscape is usually subdued, with low-gradient rivers and savannah-like vegetation. Much of the Bambuí karst is a covered karst, marked by soil generated by the weathering of pelitic upper units. The karst scenery shows most of the typical karst landforms (Figure 1), and due to the large area of carbonate there is significant variability between sites. Over 2000 caves are known in the Bambuí karst, which is a very small number considering the still great speleological potential of the region.

Within the Bambuí karst, many sites present major karst development and significant caves, such as the Arcos/Pains, Lagoa Santa, Cordisburgo, Montes Claros, Peruaçu (all in Minas Gerais State), São Desidério, Serra do Ramalho (Bahia State), Mambaí and São Domingos (Goiás State). Among these, Lagoa Santa, Peruaçu, Serra do Ramalho and São Domingos deserve special mention due to the outstanding nature of their karst and caves. The Lagoa Santa area is the birthplace of Brazilian speleology and arguably the best-studied karst area in the country, with over 500 known caves. The known caves are mostly short (less than 10 are over 1 km in length) and display extensive sedimentation and paragenetic features, including very rich fossiliferous deposits studied since the 19th century. A complex underground hydrology, including lakes at the base of limestone

Bambuí Karst, Brazil: Figure 1. Razor-sharp ridges of rillenkarren score the bare surfaces between clumps of cactus and thorn bush in typical terrain on the Bambuí limestones. (Photo by Tony Waltham)

cliffs, characterizes this karst. Urbanization is rapidly encroaching, and groundwater pollution, induced doline development, soil erosion, limestone quarrying, and cave vandalism are among the serious environmental problems facing the Lagoa Santa karst.

The Peruaçu area has been ranked among the most scenic karst areas in the world. Its highlight is the outstanding Gruta do Janelão, a 4.7-km long cave that contains a major river passage up to 100 m wide and high (Figure 2). Collapse of the roof has created a series of scenic skylights that allow the entry of natural light and growth of tropical vegetation within the cave, creating an exceptionally beautiful underground landscape (Figure 3). Massive speleothems occur throughout the passage. The Gruta do Janelão is the last cave excavated by the allogenic Peruaçu River. The other three caves upstream

are also of large dimensions, although shorter and devoid of the beautiful light effects. The 150 m deep collapse, Peruaçu Canyon, between the caves, and several dry and very well-decorated caves now truncated from the underground drainage (many representing major archaeological sites) complete the landscape, a magnificent fluvio

karst scenery that deservedly has recently been granted National Park status.

The elevated limestone plateau known as Serra do Ramalho is another notable karst area. Recent exploration has revealed a series of major caves with long meandering passages. Among the caves, there are seven over 3 km long, although ongoing exploration will undoubtedly reveal many more. Most caves experience very high flood events. On the edges of the karst many significant caves occur, such as the 16 km long Gruta do Padre, where paleomagnetic dating of clastic sediments has allowed determination of fluvial incision rates of 25–34 m Ma⁻¹.

The limestone in the São Domingos area outcrops as an elongated ridge parallel to the major scarps of Cretaceous sandstone. Some large rivers (with discharges up to 5 m³ s⁻¹) pour off the sandstone and sink into the ridge, creating a series of outstanding cave systems, with six caves presently over 5 km in length. The caves are characterized by large river passages with equally large and very well-decorated upper levels. Underground confluences are common in the area, and thus few large springs occur in the distal side of the ridge. The core of the São Domingos karst is now protected by the Terra Ronca State Park.

As a whole the Bambuí karst presents a varied karst scenery that spans 10 degrees of latitude. It has significant scientific potential, since several paleontological and archaeological sites are commonly associated with the caves. Furthermore, a number of medium-sized cities depend on groundwater from the Bambuí karst aquifer. Environmental pressure is increasing in the area, although recently a few conservation units have been created to protect the karst resources.

BAUXITE DEPOSITS IN KARST

Karst bauxites are formed as terrestrial sediments accumulated on carbonate rocks in karstic depressions and weathered under humid tropical and subtropical conditions. In the past they were thought to be derived from residual deposits, but they are now believed to originate from volcanic ash and tephra that is transported into karstic depressions by various agents: water, wind, and gravity. Karstic depressions tend to trap material from the surrounding areas (Bárdossy, 1989), and if there is extensive deep weathering of

feldspar-bearing ash, for example, the feldspars will be desilicified, leaving behind deposits—bauxites—rich in aluminium. At the same time, karstification will affect the underlying limestones, and weathering residues from these will be added to the bauxite.

Karst bauxites are clay-like, earthy, non-crystalline, usually reddish deposits found in karstic depressions (karren, dolines, and poljes). The dominant mineral is boehmite (α -Al₂O₃·H₂O) with a low percentage of gibbsite (α -Al₂O₃·H₂O) and diaspore (β -Al₂O₃·H₂O). The fabric of bauxite deposits may be pelletal, pisoidal, ooidal, conglomeratic, arenitic, spheroidal, or micro-debris. Karst bauxites from both vadose (oxidizing) and phreatic (reducing) diagenetic environments have been identified (D'Argenio & Mindszenty, 1995). There are seven main karst bauxite belts worldwide, in North America, the Caribbean, the Mediterranean, from Iran to the Himalayas, from the Urals to Siberia, East Asia, and on the margins of the Pacific Ocean (see Figure). In 1998 the world production of bauxite was 125 million tonnes, including both laterite and karst bauxites. Of this, nearly 25% was made up of karst bauxites. The main karst bauxite producing countries are Jamaica, China, Kazakhstan, Hungary, and Greece (see Table). In 2001, bauxite output was expected to increase in Jamaica (with an output of 15300 thousand tonnes per year) and China (with an output of 2709 thousand tonnes per year).

The largest reserves of karst bauxite are found in Jamaica, where 9.3% of the world's economic reserves are located. The bauxites are found in Cockpit Country infilling 10–30 m deep dolines. Lenticular surface deposits 5–15 m thick cover the limestone plateau. The basement rock is a Middle Eocene-Lower Miocene shelf/slope limestone (Comer, 1974). These bauxites contain c. 46–47% of A1₂O₃. Total Jamaican reserves amount to some 2000 million tonnes. Mining began in 1952, with the production of 0.5 million tonnes. In the mid-1980s output increased to more than 12 million tonnes annually. At the end of the 1980s output fell below 10 million tonnes, but in the 1990s increased to more 10 million tonnes. The economy of Jamaica depends heavily on exporting alumina and bauxite. The alumina output is 3 million tonnes per year, with five of the mines being open-cast. Mines are currently being operated in Clarendon, Dry Harbour, Ewarton, Kirkvine, and St Elizabeth. The following mines are not producing at the moment: Lydford, St Catherine, St Elizabeth—JBI, and Trelawny (with a combined total of 470 million tonnes of reserves).

The karst bauxites of Hungary occur in the form of lenticular, stratiform, graben, and deep doline deposits in the karst regions of the Trans-Danubian mountain range (the dolines are 10-30 m in diameter and 30-60 m deep). The bauxites contain *c*. 48-55% of $A1_2O_3$. Two Cretaceous horizons have been identified within dolines formed on karstified Triassic limestone and dolomite surfaces, and an Eocene horizon on an Upper Cretaceous karst surface. The bauxites occur mostly below the karst water table. The extraction of subsurface lenticular bauxite beds is carried out by strip-mining. Bauxite production commenced in the Bakony Mountains in 1926. In the 1980s the annual bauxite production reached 3 million tonnes. In order to prevent a fall in the karst water table, the mines of Gánt and Iszkaszentgyörgy were closed down during the bauxite crisis of the 1980s. Economic reserves were estimated at 31.3 million tonnes in 1995, while the production in Hungary was 0.935 million tonnes in 1999, and increased to 1.046 million tonnes in 2000. Out of the total economic reserves, some 4.6 million tonnes occur in operating mines and 17.4 million tonnes are located in explored

but unexploited areas. The annual output of Hungarian bauxite mines is 1.5 million tonnes. The operating mines are at Halimba, Fenyőfő, Óbarok, Iharkút, and Németbánya.

Karst bauxites are known to exist in New Guinea, but there is no specific information available about them. Bauxite formation began in the Pleistocene and continues up to the present day. The deposits accumulated in dolines on polygonal karsts. Bauxites and bauxite-like deposits have been described from New Ireland, Sorgeri, Bereina, and Cape Nelson (Hughes, 1990). In Oceania, further occurrences are known from the Philippines, the Solomon Islands, and the Loyalty Islands.

More than 95% of the bauxite extracted worldwide is used in alumina production. Three tonnes of bauxite are needed to produce one tonne of alumina, and two tonnes of alumina are required to produce one tonne of aluminium. The remainder is used by the abrasive, refractory, and chemical industries. During the refining of one tonne of aluminium, 1.2 to 4 tonnes of highly alkaline red mud residue are generated. There are various techniques available to process this mud. One involves mixing it with sandy soil to increase its acidity and increase nutrient retention capacity. If it is mixed with desiccated compost it has a beneficial impact on wetland vegetation and can contribute to the conservation of wetlands. Red mud mixed with gypsum can be used as a filter in sewage treatment systems. After intensive drying, cajunite, an excellent adsorbent, is produced, which is used to remove wet pollutants. Other important uses of red mud are as a substitute for clays in brick and tile manufacturing, in the ceramic industry, for foundations in road construction, or as a filler in PVC and rubber production.

Reclaiming land damaged by bauxite mining is a major environmental task. On former arable lands, revegetation is very slow, so it is more feasible to plant trees on the site or use the land for grazing. Air pollution from the dust produced during the extraction and transport of bauxite can also be a major problem. In areas that have been strip-mined, hazardous waste is often disposed of thoughtlessly, and harmful substances leach very rapidly into the karst system. Legal protection has to be ensured for these areas. During mining, karst water is pumped out and this can lead to the lowering of the karst water table and the drying out of karst caves, lakes, and springs. The first bauxite mine reclamation survey was launched in 1991, by the International Primary Aluminium Institute. The latest report of the survey was published in 2000. It shows that some 70% of former mining areas have been returned to native forest, 17% to agriculture and pasture, and 10% is being used for industrial purposes, urban development, or commercial forest plantations. Useful and educational geological trails have also been created in abandoned bauxite mines.

BEAR ROCK KARST, CANADA

Interstratal solution breccias are common and widespread in the geological record (see Solution Breccias). However it is rare to find them widely exposed at the surface, resistant and displaying large secondary karst landforms developed upon them. One example is the karst in the Bear Rock Formation, which is of Lower and Middle Devonian age and extends >50000 km² in subcrop under the Mackenzie Valley and Mackenzie and Franklin Mountains in the Northwest Territories of Canada. In its central area (64–66°N, 125–130°W) it rests unconformably on 500 m or more of thick to massively bedded dolostones overlying >100 m of salt and redbeds, and is overlain by resistant limestones (Hume Formation) succeeded by thick siltstone, shale, and clay deposits of Mesozoic age.

Where it has been cored during oil exploration deep beneath the valley, the intact Formation consists of a regular sequence of dolomite and anhydrite beds (a typical supratidal or "sabkha" facies) totalling 250–300 m in thickness and becoming disturbed (brecciated) towards the top (Meijer Drees, 1993). In outcrop on the flanks of the mountains east and west of the valley, it is always found as a solution mega-breccia, reduced to ~200 m or less in thickness beneath the Hume Formation and thinning to zero upslope (Figure 1). Brecciation and cementation are complete to the base of the Formation, which is now composed of resistant cliff-forming pack breccias and regressive float breccias, both of dolomite and dedolomite clasts cemented by secondary calcite and occasional gypsum. A particularly resistant pack breccia of several metres thickness, that has developed along the surface (the Landry Member), is attributed to near-surface evaporative effects, i.e. exceptionally deep case-hardening. Evidently, both brecciation and cementation have been caused by circulation of meteoric groundwaters, commencing in the mid-Tertiary and continuing to the present.

The outcrops of the Bear Rock Formation range in altitude from 100 to 1000 m above sea level. Mean annual temperatures are -7 to -10° C (January mean about -28° C), supporting a zone of continuous permafrost calculated to be approximately 50 m in depth. Mean annual precipitation ranges 350–450 mm: most falls as snow but heavy rainstorms may occur in summer. The region was covered by the margin of the Laurentide Icesheet during the last (Wisconsinan) glaciation; the ice was comparatively thin and sluggish, depositing very little till in the mountains.

Bear Rock Karst: A dolomite and dedolomite solution breccia created by preferential dissolution of gypsum in the Bear Rock Formation at Bear Rock near Fort Norman, Northwest Territories, Canada. The section is ~15 m in height. (Photo by Derek Ford) All outcrops display karst landforms. The principal types are:

- 1. dolines (sinkholes) and compound dolines of solutional and/or collapse origin, tens to hundreds of metres in length or diameter;
- 2. blind valleys where allogenic streams flow into the karst and sink;
- 3. greater solutional troughs along the edge of the Bear Rock Formation or following faults within it, many containing seasonal or permanent lakes;
- 4. small poljes of tectonic origin or created by glacial moraine dams; polje floors are up to 5 km² in area and have catchments as great as 90 km².

There are also small caves formed by seepage and frost action in cliffs ("frost pockets") and stream caves blocked by detritus or ice.

Periglacial processes attack all features, partially filling them with talus or solifluction lobes. Where the karst development is most intensive, however, (in the Canyon Ranges of the Mackenzie Mountains), the dominant appearance is of a "dissolution drape landscape" that is unlike any the writer has seen elsewhere. It is suspected that the Landry Member thickened and was stable under pre-Ice Age conditions. Either glacier margin meltwaters or groundwater leaks through the permafrost via unfrozen taliks then broke it up into the slabs, that are now seen tipping down into new karstic depressions in the weaker breccia beneath.

Field studies covering three melt seasons established that, despite the presence of nominally continuous permafrost, there is effective groundwater circulation through the outcrops and to depths exceeding 500 m. Recharge is chiefly via allogenic waters able to maintain conduit inflow along the upstream margins, or through ponds of meltwater that build up in the sinkholes until pressure ruptures the ground ice and permits rapid drainage. These latter taliks are of distinctive karstic origin (Ford & Williams, 1989, Figure 10.13). There is also some supra-permafrost flow to shallow springs and seepages in cliff faces. Discharge is via seasonal and some perennial springs: most are located at the lowest topographic positions, indicating that the groundwater systems are mature despite effects of the recent glaciation and modern permafrost.

Early in the melt season the spring waters have a $CaSO_4$ ionic composition representing the dominance of shallow (permafrost active zone) meltwaters. In midseason the larger springs change to an MgSO4 composition with water temperatures as high as 4°C, indicating the discharge of deeper waters that are accomplishing dedolomitization. The few perennial springs (which create winter "icings") have a significant NaCl component. Modelling suggests that there are three-component groundwater circulation systems involving the Bear Rock Formation, the underlying dolostones and the salt, and which are extending the brecciation process today. Analysis of oxygen isotope patterns in precipitation, sinking streams and springs indicates that mean residence times of the MgSO4 waters are 40–90 days, suggesting flow rates of ~20–60 m d⁻¹ through the breccia.

BELGIUM: ARCHAEOLOGICAL CAVES

The valleys of the Meuse River and its tributaries are mainly eroded in limestone. Many natural shelters, in the form of sometimes quite deep caves, can be found within this karstic system. The entrances to the caves were occupied continuously by humans, from the Paleolithic to modern times. In contrast, the deeper parts of the caves and galleries only served as occasional refuges during troubled periods (e.g. protohistory, the Roman era). There is abundant archaeological evidence of occupation, with the principal sites including La Naulette, Chaleux, Trou Da Somme, Furfooz, Trou Magrite, Bois Laiterie (Ardenne Meuse Valley), Grottes de Goyet (Samson River), Grotte du Docteur, Trou Sandron (Mehaigne River), Trou Al'Wesse (Hoyoux River), Fond-de-Forêt, and Grotte Walou (Vesdre River) (see map). Here, three of the more important sites (Spy, Engis, and Scladina) are presented in more detail.

Numerous Belgian caves have been excavated since the early 19th century, when the discipline of prehistory was first developed. The first Neanderthal was discovered near Liège at the site of Engis, in 1830, by Philippe-Charles Schmerling (see Archaeologists). The general palaeolithic sequence, established by Edouard Dupont on the basis of key sites in the province of Namur (Trou Magrite, Grottes des Goyet, among others), remains valid for Western Europe. Subsequently, the famed Neanderthal burials of Spy Cave were discovered in 1886 by Marcel De Puydt and Max Lohest, and were studied by Julien Fraipont. This pioneering research utilized methods from several disciplines: geology, stratigraphy, and paleontology. Nowadays the methods used are more strictly archaeological.

Spy Cave

The rocky overhang above the entrance of Spy Cave has provided the original name of the site—"Betche al'Rotche" ("beaked rock" in Walloon). The interior of the cave was initially excavated without any proper methodology, but the terrace was subsequently excavated by a multidisciplinary team from Liège (1885–86). A substantial and important stratigraphic sequence was recognized. Near the middle of the terrace, two Neanderthal skeletons were discovered. Because the skeletons were nearly complete, they were probably buried intentionally. They are associated stratigraphically with a late phase of the Middle Paleo

Belgium: Archaeological Caves:

Grotte du Docteur, 10. Trou Sandron, 11. Trou al'Wesse (Modave), 12. Goyet, 13. Marche-les-Dames, 14. Trou Da Somme, 15. Bois Laiterie, 16. Presle, 17. Montaigle, 18. Couvin.

lithic (Charentian or Eastern European Micoquian). Other Mousterian levels, as well as a probable Acheulean level containing bifaces (shaped tools used as hand axes), form the lower part of the sequence. Upper Paleolithic strata are found above the burials. A thick layer called "red" by the excavators (resulting from iron oxide) contained a large number of Aurignacian artefacts, including numerous ivory pendants. Several dispersed artefacts, probably intermediate between the Mousterian and the Aurignacian, include foliate points corresponding with the beginning of the Upper Paleolithic in Northern Europe. A

Gravettian level with tanged points and unifacial points ("points a face plane") overlies the Aurignacian level, and this industry is also found across the north European plain (comparable with open-air sites such as the Maisières-Canal, near Mons). The sequence continues with a sterile loess corresponding to the cold phase of the Second Pleniglacial, during which there is no evidence of human occupation in Northern Europe. Finally, traces of human occupation during the Late Upper Paleolithic are found above the loess layer.

Engis Caves

This is a series of four or five shelters and small caves opening at the summit of a limestone cliff near Engis in the province of Liège. Some of them have been destroyed as a result of the extension of alum-extraction quarries, but others have yielded archaeological material, primarily of Mousterian and Gravettian age. The research here was begun in the 1820s by Philippe Charles Schmerling, a professor at the University of Liège, before the discipline of prehistory was established. Schmerling discovered the remains of two humans, of which only the skulls remain today. One is a Neanderthal child—the first Neanderthal discovered (although not recognized as such until after the eponymous discovery in 1866 in the Neander valley in Germany). The second is now known to be of Mesolithic age, based on a date recently obtained. Schmerling thus established the antiquity of humankind, based on the association of human remains and paleolithic tools with extinct fauna, long before the discovery of Neanderthals and before Darwin's theory of evolution was published.

Scladina Cave

Discovered in the 1970s in the village of Sclayn (province of Namur), Scladina has been the focus of systematic research by a team directed by the University of Liège. It is the main and upper cave of a long network of galleries, opening at different points in the valley. The cave was completely filled in at the time of discovery and the sediments form a long sequence several metres thick. At the base, as yet not fully investigated, the deposits correspond to oxygen isotope stage 6. The deposits excavated to date belong principally to the last interglacial (stage 5) and to the beginning of the following glacial (stage 4). The main human occupation occurred during the first temperate oscillation, around 130000 years ago (stage 5e?), characterized by a Levallois Mousterian lithic industry and a subsistence economy oriented toward the exploitation of the chamois. Another interglacial stratum, more recent (around 117000 years ago) yielded the dispersed remains of a Neanderthal child, including the maxilla, the mandible, isolated teeth, and other postcranial remains. Excavation is ongoing in these levels. Near the middle of the glacial deposits (around 38000 years old), another Mousterian industrythe Charentian—is present. Finally, late paleolithic traces, as well as disturbed Neolithic burials, were found at the top of the deposits.

BELIZE RIVER CAVES

A small, little-known, and somewhat eccentric country, Belize is a pocket of Creole, Mayan, and British heritage, surrounded by countries of predominantly Spanish origin. Located along the northeast coast of Central America, it measures only 300 km from its southern rainforests to the savannahs of its northern border with Mexico. From the nation's eastern Caribbean coast, site of the world's second longest barrier reef, Belizeans look 100 km westward to their border with Guatemala, which in 1991 relinquished its claim that Belize was a Guatemalan state. Despite its small size, Belize has world-class caves, including some of the world's largest chambers and passages, perhaps one of the greatest concentrations of archaeologically significant caves (see America, Central: Archaeological Caves), and a diverse subterranean fauna that is still largely unstudied (see America, Central and the Carribbean Islands: Biospeleology). The country's rich speleological potential has been explored with increasing frequency since 1970, with much of the work focused on its amazing river caves.

Five main karst areas occur in the southern half of Belize, formed mainly in Cretaceous limestones (Veni, 1996). Southern Belize is dominated by the Maya Mountains, igneous and metamorphic rocks, reaching a maximum elevation of 1122 m at Victoria Peak and receiving over 3000 mm of annual rainfall. The size and locations of Belize's river caves are directly related to the Maya Mountains. Most of the country's large caves have been formed by large volumes of water flowing off the highlands onto the limestones of four of the five main karst regions. Equally important is that the water is chemically undersaturated with calcite. As a result, the water rapidly dissolves the limestone to form vast underground passages and chambers. In general, the caves are best preserved close to, but not next to, the highlands. Both at their contact with the non-karstic highland rocks and furthest away from the highlands, the limestones tend to become thinner, allowing less space for caves. Many caves are truncated by collapse.

The largest caves in Belize tend to be long stream passages, or former stream passages, with relatively little depth. Much of the vertical extent occurs in steep doline entrances, within the larger spaces of the passages, and down the gradient of the long passages. In the Boundary Fault Karst Area of central Belize, the development of multiple levels of passages by underground streams, carving new passages at lower elevations, is especially important in creating deeper caves. The Table lists some of the country's longest caves.

Among the country's most notable caves are the Chiquibul and Caves Branch cave systems. The Chiquibul is located in the Vaca Plateau karst area in west-central Belize. It was formed by the downcutting of the Chiquibul River flowing west off the Maya Mountains and includes a series of large, perennially active, seasonally active, and hydrologically inactive galleries. The main passages are more than 50 m wide by 30 m high and connect to the Belize Chamber. This unusually wide section of passage is one of the largest chambers in the world, at about 250 m long by 200 m wide and at least 50 m high. Three main caves make up the cave network, the longest of which is the linked Cebada Cave and Actun Tunkul. Prior to their connec

Belize River Caves: Longest caves of Belize.

tion they had been the two longest caves in the Chiquibul Cave System, and they are now the longest cave in Central America (Miller, 2000). The entire hydrologically linked network is 60 km long and crosses into Guatemala, where the underground Chiquibul River reappears at the base of a 200 m wide by 80 m high cave entrance.

Like the Chiquibul, the Caves Branch is a system of hydrologically connected caves some of which have not yet been physically connected by exploration. Petroglyph-St. Herman's Cave System is the longest single cave of this system with a surveyed length of 17 km. It is fed by Actun Chek and Actun Lubul Ha, which capture water from a 64 km² non-karst drainage area that flows north off the Maya Mountains. Caves Branch Cave is the downstream segment of the system and is truncated by several large dolines that have collapsed into its large passages.

Eco-tourism and adventure tours dramatically increased in Belize during the 1990s. Trips are regularly scheduled for Belize's river caves like Caves Branch, Blue Creek Cave, Barton Creek Cave, and a few even into the remote Chiquibul. The large size of the passages makes access relatively easy for non-cavers, and floating in inflatable automobile tire tubes in pleasant 25°C temperature streams is a welcome respite from the tropical heat and humidity on the surface. Archaeological material within the caves lends to the mystery and appeal of the tours but raises concerns about the possibility of

inadvertently spurring some to seek out and loot artefacts from these and other caves. However, positive impacts that occur through education include tourist money that supports conservation and research, and proactive management of a few caves by some tour operators. The longterm impacts of these tours on Belize's caves and cultural heritage remain to be determined.

BIODIVERSITY IN HYPOGEAN WATERS

Biodiversity in hypogean waters (both cave and interstitial) may be considered as the absolute number of all species inhabiting hypogean waters; the number of stygobitic (i.e. obligate hypogean aquatic) species; or the relationship of either of these numbers to surface fauna richness. At a global scale, biodiversity can be associated with specific biogeographical, hydrographical, or political units, or an area with an arbitrarily defined size and shape. It may also be measured as the number of higher taxa (e.g. orders or classes), rather than species. Biodiversity will be considered here according to a combination of these criteria. Due to the wide variety of methods available for computing species richness, and also because in different areas either the epigean or the hypogean fauna may be inadequately studied, comparisons are difficult.

Overall Biodiversity

The number of stygobitic species was estimated to be over 1000, or *c*. 8% of all freshwater metazoan species in Europe, according to data in *Limnofauna europaea* (Illies, 1978), but their true number is probably close to 3000 (Sket, 1999b). This is because proportionately more karst is present in Europe, and its interstitial waters are comparatively well investigated (Marmonier *et al.*, 1993). Since stygophile and stygoxene species have often not been reported as such, their numbers cannot be easily estimated. While over 50% of species in surface fresh waters are insects (either as larval or all stages), insects are poorly represented in hypogean waters. By contrast, 38% of European freshwater Crustacea species are stygobitic. Some of the subgroups are highly

stygobitic (Isopoda and Amphipoda at 50% and Bathynellacea at 100%). Approximately 60% of all described stygobitic freshwater species in Europe are Crustacea, and half of these are Malacostraca. In North America, where the Entomostraca have been poorly studied and interstitial waters are not well explored, the Malacostraca represent 76% of the Crustacea (according to data in Peck, 1998) and worldwide in anchialine habitats they represent *c*. 60% of the entire stygobitic fauna. Therefore, Crustacea, and the Malacostraca for which more exact and more recent data are available, are a particularly good model group for demonstrating the diversity of regional stygobitic faunas.

Biodiversity of the Malacostraca

Marine, continental, and hypogean waters are each inhabited by 10 or 11 of the 15 orders of Crustacea. There are approximately the same number of families containing stygobitic species as freshwater species. Three orders are limited to hypogean waters, and a fourth occurs in the deep sea as well as underground. Recently, Sket (1999a) estimated the number of described stygobitic Malacostraca species as 2130, while the estimated number of all described malacostracan taxa was close to 20000. Thus, if the estimates are correct, some 10% of all malacostracan species are stygobites.

Hot Spots

The diversity of hypogean fauna is spatially very variable (see Table). Among regions of roughly the same area, the wider Dinaric (or west Balkan) region has nearly 400 species and subspecies (according to data in Botosaneanu, 1986), which is by far the richest biodiversity worldwide (see Dinaric Karst: Biospeleology). The biodiversity of the hypogean waters of Slovenia, which forms a small part of the Dinaric region, is as high as in some areas ten times larger. The Dinaric region is followed by the east Balkan, Pyrenean-Aquitanian, and Rhodano-Lotharingian regions, all of which are positioned along the belt where most European centres of high overall biodiversity occur. Some taxonomic groups may be even more concentrated—around 40% of all known stygobitic species of Gastropoda (Mollusca) inhabit the Dinaric region.

Regions outside Europe with similar total numbers of stygobites are much larger in size, and mainly occur within the northern warm temperate belt. Stygobitic faunas in tropical regions are generally less diverse, although their paucity is not as striking as the relative scarcity of terrestrial troglobitic faunas in the tropics. In all comparisons, it should be borne in mind that only in Europe have interstitial fresh waters been moderately well explored; this is not the case even in North America, let alone in tropical countries.

High numbers of regional stygobitic species are also mirrored in rich local faunas. Of the 20 richest caves—in which 20 or more specialized hypogean species have been recorded (Culver & Sket, 2000)—there are 11 with 20 or more stygobites. Among the richest are the Postojna-Planina Cave System (49 stygobites), the Vjetrenica Cave in Bosnia-Herzegovina (40 stygobites), and the anchialine Walsingham Cave System in Bermuda (up to 37 stygobites). These three caves, each with their own encyclopedia entry, differ in interesting ways. Postojna—Planina Cave System has a rich assortment of non-stygobites in addition to the usual stygobites, as do the Walsingham Caves. By contrast, the aquatic fauna of Vjetrenica Cave is almost exclusively stygobitic. Why are there so many crustacea? Although the difficult environmental conditions, restricted accessibility, and relative ecological homogeneity of the hypogean realm severely limit the potential numbers of stygobitic species in general and also intrinsically exclude some groups (like the Insecta), some other groups may locally be over-represented when compared with epigean habitats. This is particularly the case with malacostracan groups.

Since the under-representation of Insecta underground could possibly be explained by their higher energetic demands, the successful invasion and diversification of the Crustacea may be explained by a number of circumstances. First, the absence of insects has left a number of potential niches. Second, high speciation rates can be achieved by spatial partitioning within a region that has a high degree of spatial isolation. Third, the geographical co-occurrence of a number of species is possible if there is specialization to different ecological niches. Fourth, temperatures in hypogean habitats are stable, and the absence of low winter temperatures allows the survival of species that entered the area in warmer times. Finally, a turbulent geological history may have influenced high speciation rates locally.

High numbers of hypogean species for some groups are compensated for by their restriction to smaller areas. As many as 78% of the stygobitic taxa in the Dinaric region are endemic to that region (153400 km^2) and 37-67% of the taxa may be endemic to one of its subregions, measuring only $3500-51000 \text{ km}^2$ in area. According to data from Illies (1978), 50 stygobitic and only six epigean species of Copepoda: Cyclopoida were limited to one of his regions in Europe (which are 150000-

Biodiversity in Hypogean Waters: Numbers of stygobitic taxa (species and subspecies) in the

regions with the highest diversity, according to data in Botosaneanu, 1986 (from Sket, 1999b). Marine interstitial taxa (labelled as "Q" or "Q, P") excluded. A: regions of highest diversity in Europe; B: richest regions outside Europe; C: subregions of the wider Dinaric region (first line in category A).

	Name or region	Number of stygobitic taxa	Approximate area (km ²)

	Serbia (west)	15 (6)	33800
	Montenegro and Kosovo	55 (36)	24500

350000 km² in area), while only two stygobitic and 45 epigean species were distributed throughout six or more such regions. A number of stygobitic species were known from one locality only.

Species may also be heterogeneously distributed within a cave system, according to their ecological needs, a fact neatly illustrated by the example of Vjetrenica (Sket, 1999a). It has been shown that the number of species in a cave system depends to a great degree on the region, but is positively correlated with the richness of food resources and with the size of the caves (Culver and Sket, 2000). The existence of hundreds of mostly stygobitic *Niphargus* species and subspecies in Europe is possible through their extreme diversity of size and shape of all body parts (indicating a variety of ecological niches) as well as their highly restricted ranges.

BIODIVERSITY IN TERRESTRIAL CAVE HABITATS

The subterranean fauna is a mixture of forms with different origins and life histories, characterized by convergent features—adaptations to life in permanent darkness and high humidity. For geographical, geological, ecological, or historical reasons there are regions or even individual caves in the world that shelter an unusually high number of troglobitic species. These biodiversity hot spots include the Lanquedoc aquifers in France and the Edwards Aquifer in Texas, and in terrestrial cave habitats the Dinaric karst in Slovenia, Movile Cave in Romania, and Mammoth Cave in Kentucky (the latter four have separate encyclopedia entries). Most cave animals are invertebrates, dominated by arthropod groups such as Arachnida and Insecta (see Table) but there are also some troglophilic vertebrates. This entry discusses biodiversity in caves by taxonomic group.

The Isopoda are mostly aquatic but include terrestrial cave species belonging to the Suborder Oniscidea (see Crustacea: Isopoda Oniscidea). Sometimes these species do not differ greatly from their epigean relatives, but some are characterized by classic adaptations to life in darkness.

The Arachnida (see separate entries) are very diverse, and have successfully colonized many ecological zones, including caves. Cave scorpions have been recorded only from

Mexico, Ecuador, and Sarawak. The smaller Pseudoscorpiones lack the poisonous tail spine of the scorpions. Subterranean species are

Coleoptera	300000 species	2000 troglobitic species	69% Atlantic-Mediterranean regions

present in most families, with some genera being completely restricted to caves. The Araneae (spiders), one of the most abundant groups of land animals, are also common in caves. Some of their morphological adaptations are less reported from other groups: troglobitic spiders have more mechanical receptors than the troglophiles, and relative length of the appendages is directly correlated with the degree of adaptation. The Opiliones, or harvestmen, possess a pair of defensive glands that produce noxious secretions. They are present on every continent and in every terrestrial environment. Some representatives are good biogeographical indicators. The Ricinulei is a small order with species living in caves and tropical leaf litter. Members of this order have been described from American caves, with some populations being relatively well represented (more than 10000 individuals). Twenty-five troglobitic Schizomida species live on guano or plant debris, and rarely under rocks. Their distribution is limited to the tropics. The Amblypygi (whip spiders) contains some 40 troglophilic and troglobitic species, found in Central and South America, Africa, and southern Asia. Of the 20 species of Palpigradi (miniature whip scorpions), several cave species are known from the Mediterranean region. The Acari are frequent in caves: mites are associated with guano or live on soils, organic matter or in rock cracks, while ticks are parasitic on bats.

The four classes of Myriapoda (see separate entry) are abundant mostly in Europe and temperate regions of North America. Chilopoda (centipedes) have soft bodies with many unfused trunk segments, each one with a pair of legs; the first pair is modified to form large poisonous fangs. Some of the epigean species have troglomorphic features, but data about their adaptations are generally scarce. Diplopoda (millipedes) have two pair of legs on each segment, a calcified cuticle, and no fangs. All three suborders of this class have species living in caves, some of them with more body segments. The only troglobitic Pauropoda have been reported from Japan. The Symphyla, a very old group, include small, eyeless, and depigmented representatives. It has two cave species, both of which are found in Postojna Cave (Slovenia).

The insects (see separate entries) include all arthropods with three pairs of legs and three body segments. Collembola, the oldest group of insects, have occupied all the terrestrial biotopes, especially soils. For example, in the Palearctic and Mediterranean zones alone there are 240 troglobitic species. These species are K-strategists (i.e. their reproduction is regulated to maintain small numbers of offspring, in view of the population capacity limit, K, of the habitat) and many studies have been made of their physiology and behaviour. A pair of posterior cerci or feeler-like appendages characterizes the Diplura, which are pre-adapted for life in darkness. Two families have cave species distributed mostly in the Palearctic region. Pre-adapted representatives of Thysanura have two caudal filaments. Ten cave species are known with representatives on each continent. In the Dermaptera (earwigs), the cerci form heavily sclerotized posterior forceps. Species of two Dermaptera families are found in caves, but only two species, from lava tubes, display strong adaptations. Cave cockroaches belonging to the Blattodea are largely distributed throughout the tropics, both in karst and in lava tube caves. The species have various adaptive features. The Psocoptera (psocids, booklice), a small group with few subterranean species, is distributed mostly in the Mediterranean region. The representatives of the Homoptera (plant bugs) have piercing/sucking mouthparts forming a beak. All cavernicole species belong to groups where the immature stages live close to the soil or in the soil, and they are found in tropical areas and some temperate regions. Hypogean individuals communicate by low-frequency signals transmitted as vibrations through the substratum. Trichoptera (caddisflies), together with Lepidoptera (butterflies and moths) and Diptera (flies), are components of the cave-wall community-most species are subtroglophilic, troglophilic, and guanophilic. Some flies are troglobitic, with more or less obvious adaptations. Out of the Orthoptera group, the crickets and some tettigonids will colonize caves. Some crickets are true troglobites, but others use caves only as shelters. Cave tettigonids are troglophilic, ubiquitous components of the cave-wall community, which display troglomorphic features. Hypogean species of Notoptera are described from the western United States, South Korea, and west Japan. The ectoparasitic fleas from the Order Siphonaptera are associated exclusively with bats or other cave mammals, and have no notable adaptations. Another common component of the cave-wall community is the Hymenoptera (wasps, bees), including troglophilic, subtroglophilic, and trogloxenic species. The Coleoptera (beetles) is the best-represented underground group, with almost 2000 species distributed worldwide; they are frequent in the temperate regions.

Troglobitic vertebrate species are not nearly as numerous as the invertebrates, although the faeces and guano of these vertebrates may, in some caves, represent the only source of food for underground communities. Amphibians (frogs, toads, and salamanders) are usually trogloxenes in entrance habitats, however eight truly troglobitic species are known, seven of them from North America. (*Proteus*, the only troglobitic vertebrate in Europe, is described elsewhere in this Encyclopedia.) Aves (birds; see separate entry) include six troglophilic species. Mammalia (mammals) include

troglophilic or trogloxenic species from different groups (marsupials, rats and other rodents, insectivores, pigs, okapi, felines, etc.) and Chiroptera (bats; see separate entry). The diversity of cave vertebrates may have been greater in cave refugia during climatic fluctuations; for example, the recently extinct cave bear during the Pleistocene. At least 93 fossil vertebrate species have been identified in Pleistocene sediments at Victoria Cave, Naracoorte, Australia (see Australia: Archaeological and Paleontological Caves). OANA MOLDOVAN

BIOFILMS

Microorganisms are individually very tiny, but early in the history of life on Earth they invented the biofilm: a wonderful method of protecting themselves and extending their influence on the environment. A biofilm is a coating on rock or other surfaces composed of microorganisms, extracellular slime and other materials that the organisms produce, and particles (sediments, organics, or minerals) that are trapped by or precipitated within the film. Caves often contain biofilms on many of their surfaces, formed both subaqueously and subaerially (under both wet and relatively dry conditions). The variety of biofilms in caves can be quite spectacular even to the naked eye (Figure 1). Closer inspection reveals the intimate associations between cells, slime, and particles (Figure 2).

Biofilms are ubiquitous in nature. Examples include the plaque that grows on teeth and algae that grow on the inside of fish tanks. Films can be very thin and invisible to the naked eye or very thick and even geologically significant. Biofilms are probably common because they provide a large number of advantages for the bacteria, fungi, cyanobacteria, and algae that live in them. Protection from desiccation and ultraviolet radiation are major advantages for biofilm organisms that live in surface habitats, but even in the dark and usually humid environments of caves, the biofilm serves many functions. It can provide protection from chemicals and ions that might be harmful to the organisms and serves as a kind of "pantry" for storing potential nutrients and growth factors, allowing organisms to concentrate materials that may be sparse in the larger environment (e.g. Costerton *et al.*, 1994). Protection from extremes of pH (relative degrees of acidity or alkalinity) can allow biofilm organisms to live in conditions that they could not tolerate without their protecting blanket of film. In some cases, the biofilm can retain concentrations of antimicrobial or inhibitory substances that organisms produce to help protect themselves from other microbial competition for resources and from predation by higher organisms such as protists and small invertebrates.

Biofilms in caves are found in many different guises. At least anecdotally, they seem to be unusually diverse compared to those found on the surface (e.g. Boston *et al.*, 2001; Melim *et al.*, 2001). Strings, loops, thick mats, filamentous fabrics, thin slippery coatings, dense encrustations, highly mineralized Fe/Mn deposits, chalky crusts, gelatinous rinds, iron-rich slimes, manganese fluff, and some moonmilks found in caves may all qualify as biofilms by the definition cited above. The specific chemistry, geology, ecology, and microclimatology of a cave helps to dictate the exact details of a biofilm structure (Stoodley *et al.*, 1999), however, the tendency to form these films is widespread.

The nutrient base available to a biofilm is a dominant factor controlling its overall abundance. While most caves probably receive small amounts of organic materials that form the basis of the ecology of a film or mat, the role of organisms that rely for their life energies on inorganic substances (known as chemolithoautotrophs) remains unclear. However, in caves with significant inorganic sources of energy (e.g. reduced sulfur, iron, or manganese) the chemolithoautotrophic contribution to the system may predominate (Kinkle &: Kane, 2000; Boston *et al.*, 2001).

Besides trapping particles within the film or mat, biofilms can also strongly affect the nature and rate of dissolution and mineralization processes in the underlying rocky substrate. Bio-films can concentrate substances that chemically attack their substrata, increasing the rate of dissolution compared to analogous abiotic processes. They can also promote the formation of elec

Biofilms: Figure 1. Biofilms occur in many forms from thin, invisible layers to thick, colourful spongy mats. Upper left: actinomycete bacteria form a

beautiful pink biofilm in a Hawaiian lava tube cave. trochemical corrosion cells (known as tubercles) created by acid-producing sulfideoxidizing organisms. Of similar importance is the process of *in situ* precipitation of minerals within mats and films. Calcite precipitation of unique crystal morphologies have been documented (Folk & Chafetz, 2000) and manganese mineral precipitation of unique crystals has also been reported (Spilde *et al.*, 2002). The resulting mineral particles, if they prove to be solely biogenic, may provide an important tool for investigation of fossil biofilms and preserved microbial mats as well as elucidating living biofilm formation mechanisms.

Biofilms can form in water under rapidly running conditions and on the humid surfaces in caves with no running water (Northup *et al.*, 2000). This plasticity in the ability to exploit many different habitat types, fundamental cave geochemistries, and hydrological conditions make biofilms and mats a highly significant feature of subterranean ecosystems. Furthermore, because calcium ions seem to play an important role in adhesion of cells to surfaces, carbonate caves are in a unique position to chemically encourage biofilm formation. Unusual properties of calcium ions encourage interactions with protein and polysaccharide adhesin molecules at the cell surface. Calcium helps to neutralize the electrically active double layer between cell and substrate, thus promoting adhesion.

The term "microbial mat" simply refers to a biofilm that has achieved a thickness and size easily visible to the human eye. A mat type common in daily experience is a thick layer of algae, mud, and associated slimey substances that grow around the margins of

water bodies. A more elaborate microbial mat type is known as a "stromatolite", that is, a layered structure created by microbial growth at the surface covered by episodic deposits of sediments followed by further growth of the organisms to entomb those particles. In contrast to their vast abundance on early Earth as shown in the geological record, stromatolites are now rare on the Earth's surface and restricted to a few protected lagoonal environments. Without weather and often without a significant population of higher organisms, caves can provide thick microbial mats with a protected environment in which to grow, precipitate minerals within their structure, and potentially fossilize into cave stromatolites that show the banded structure in cross section of their surface counterparts (Melim *et al.*, 2001).

Biofilms are such an effective means of promoting the survival and growth of microorganisms that it has been suggested that they are actually primary units of evolutionary selection rather than the organisms that they contain (Caldwell & Costerton, 1996). The co-evolution and metabolic dependence of biofilm organisms upon one another is quite striking. This may explain why it is often difficult or impossible to grow biofilm organisms in isolation, especially those from caves. The diversity and importance of biofilms and mats in caves makes their study one of the cutting edge research topics of modern microbial biospeleology.

BIOKARSTIFICATION

Biokarst refers to karst landforms, usually small in scale, produced mainly by organic action. Biokarstification is an umbrella term for the organic processes involved in the creation of such landforms. These processes can be divided into two main types, organic contributions to weathering and erosion, and biological aids to reprecipitation, or deposition of calcium carbonate. Biokarstifying processes have been suggested as being important in landform production in a whole range of environments, including karren on Mediterranean limestone surfaces (Fiol, Fornos & Gines, 1996), caves (as found, for example, in Lechuguilla Cave, New Mexico by Cunningham *et al.*, 1995) and coastal limestones (e.g. around many Mediterranean coasts as reported by Schneider & Torunski, 1983 and Schneider & Le CampionAlsumard, 1999). Most biokarstification activity appears to result from the action of a suite of micro-organisms and lower plants, including cyanobacteria, fungi, algae, and lichens, often in mixed biofilm communities. Higher plants may also be involved, largely through root activity, as may animals, for example through the biocorrosive action of urine, or the boring and grazing activity of a suite of coastal molluscs.

In terms of erosional manifestations of biokarstification, the major processes involved are biochemical contributions to carbonate dissolution, biochemical and biophysical processes of boring and grazing, and the biophysical weathering activity of lichens. Many organisms are known to secrete substances which are capable of enhancing limestone dissolution, including organic acids and carbon dioxide. In many cases, it has proved difficult to determine the exact mechanism by which organisms (especially micro-organisms) encourage dissolution, but the pitting of underlying limestones associated with many micro-organism communities (as shown, for example, in the Negev Desert environment, by Danin & Garty, 1983) illustrates that it does occur. Roots can also bore by chemical and physical means, but their role in biokarstification has been much less well studied in recent years.

A whole host of grazing and boring molluscs and other organisms commonly inhabit the intertidal zone of limestone coasts and cause considerable biochemical and biophysical erosion, through the action of chemical secretions and the rasping of teeth and claws. For example, a recent study has illustrated the role played by limpets in weathering and eroding chalk shore platforms in east Sussex, southern England, through both excavation of hollows (homescars) and also ingestion of chalk during grazing on algae on the surface (Andrews & Williams, 2000). Experimental observations here suggest that limpets are responsible for about 12% of the downwearing in areas they inhabit. In most places, combinations of organisms act together, with complex spatial and temporal dynamics, and it can be hard to quantify the overall effect. Some quantitative studies of individual processes and their net action have been made for a range of tropical, Mediterranean and temperate coastal environments (see, for example, the work of Trudgill, 1976, from Aldabra Atoll, and Trudgill, 1987, from the Burren coast, Co. Clare) as reviewed by Spencer (1988).

An important biophysical weathering role has been identified for several lichen species as a response to wetting and drying. Lichens can absorb a huge amount of water, and swell to many times their original size. Drying produces a concomitant shrinkage, and repeated wetting and drying can exert enough force to pluck away fragments of limestone. Moses and Smith (1993) carried out an experimental study on this lichen role, and suggested that it may play an important role in the enlargement of kamenitzas on temperate limestone pavements. Although many studies have isolated individual biokarstic processes, and even quantified the role of individual organisms, it has so far proved difficult to quantify the overall biological contribution in relation to other earth surface processes, such as dissolution.

Depositional forms of biokarst, such as tufas and some speleothem and travertines, also exist. In these cases, organisms play a range of roles in aiding deposition of calcium carbonate and other minerals. Organisms may directly precipitate minerals as part of their life processes, and they can also play indirect roles through altering the chemical microenvironment to favour precipitation of minerals out of solution, and finally they can provide a site (or nucleus) for precipitation. Pentecost (1981) has discussed the various roles that cyanobacteria and algae play in tufa deposition. In essence, organisms can be either active or passive contributors to tufa deposition. Active roles include the direct precipitation of calcium carbonate or alterations of the nearby chemical environment, for example through removal of CO₂. Passive contributions to tufa deposition include the provision of suitable substrates for deposition and nucleation of calcite. Several studies have been made of the balance of processes influencing tufa deposition, for example by Viles and Pentecost (1999), who illustrate the roles of a range of cyanobacteria, algae, and higher plants in the fast build-up of tufa barrages in a small karst stream in South Wales. In most cases, a mixed community of organisms contributes to the formation of depositional biokarst landforms in a whole suite of ways, and it can be very difficult to untangle individual roles.

Although much work on biokarstification has focused on small-scale organisms and their role in the production of small-scale landforms, most karst landscapes have an important, and neglected, biokarstic component, in the form of plant and soil effects. Plants and soils, including associated micro-organisms, play a huge role in dissolution in many karst environments, with plants taking up calcium and magnesium directly and contributing to the production of acidic soils.

BIOLOGY OF CAVES

The biology of subterranean habitats (known as speleobiology, biospeleology, cave biology, or subterranean biology) is a research field incorporating all aspects of biological study of the biota from subterranean habitats and/or the study of subterranean habitats themselves. Speleobiology is not a coherent scientific discipline with its own methodology, rather it is a research field that relies upon the techniques and concepts of different biological disciplines (hence the term speleobiology), as well as from physical speleology (hence the traditional name biospeleology). Caving techniques have always been vitally important in providing biological samples during field investigations. However, caving or speleological knowledge is not a prerequisite for all speleobiological studies.

History

The first published account of specialized cave species was in 1541 when a Chinese author mentioned "hyaline fish living in the caves" in Yunnan (see Biospeleologists). These were described as *Synocyclocheilus diaphanus* in 1994. In 1689, Valvasor documented that a spring near Vrhnika in today's Slovenia brought animals from underground, which the locals proclaimed as dragon's young. The same creature was described as *Proteus anguinus* by J.Laurenti in 1768, also from an epigean or surface habitat. It was first described from caves by Jeršinovič von Loewengreif in 1797. In 1772, G.A.Scopoli wrote about fungi in old mine galleries, the first study of underground plants.

The serious search for cave animals began in the period 1830–45 with the first description of a cave beetle, drobnovratnik or slenderneck, *Leptodirus hochenwartii*, by L.Čeč in Postojna cave, Slovenia. After describing the species in 1832, F.Schmidt issued a large reward of 25 forints for the next specimen. Discoveries in the Slovenian karst continued with additional beetles and cave snails. In 1840, Močulski (Motschoulsky) reported cave beetles in the Caucasus, and soon after this the cave fish *Amblyopsis spelaeus* and a number of invertebrates were recorded in the United States by T.Tellkampf and colleagues.

The period 1845–1950 was characterized by the discovery of rich faunistic communities and surveys in several European countries, North and Central America, and New Zealand. Beside taxonomy and faunistic studies, some ecological data and the details of the structure of reduced organs in subterranean organisms was documented, and important theories regarding cave animals began to appear. One of the most important early biospeleologists was the Danish zoologist J.C.Schiödte, who investigated and published records regarding Slovenian cave fauna in the 1840s and 1850s and also made the first attempt at a general ecological classification of cave fauna. J.R.Schiner added a faunistics chapter to Schmidl's (1854) early speleological monograph concerning the same area. He criticized Schiödte's classification system and introduced the nomenclature ("Troglophilen, Troglobien"), which is essentially still in use today.

Additional important early biological contributions were made by Delarouzee in 1857 on cave beetles in Pyrenean caves; Bilimek in 1867 on cave fauna from Mexico, Chilton in 1882 on hypogean animals from New Zealand, and Apfelbeck who initiated systematic cave faunistic investigations in Bosnia and Herzegovina during the late 1880s. In 1871 Packard, a prominent neoLamarckian, wrote a monograph regarding the cave fauna of Mammoth Cave, Kentucky. In 1888, Jurinac published a doctoral thesis devoted to a local (Croatian) cave fauna, while D.Šoštarić investigated the fauna of local wells. The great monograph by O.Hamann, *Europaeische Hoehlenfauna* (1896) cited 400 references on speleobiological subjects. The first century of speleobiology was concluded with the foundation of the first underground biological laboratory, in the Paris catacombs, by A.Vire in 1897.

During the 1920s and 1930s, A.Remane discovered and recorded the existence of interstitial fauna in marine sands of the Nordsee and Ostsee and S.Karaman discovered and recorded the existence of interstitial fauna in fresh waters of Macedonia. Since this pioneering work, interstitial habitats and some other non-karstic hypogean habitats have been included in the research field of speleobiology.

The first half of the 20th century was marked by a number of great monographs, by Vire (1900), Eigenmann (1909), Spandl (1926), Stammer (1932), and Dudich (1932). The Romanian biologist E.G.Racovita (Racovitza, 1907) wrote his "Essai sur les problèmes biospéologiques", thus promoting the name for this research field, which had initially been proposed by Vire in 1904. He also initiated, accompanied mainly by his French colleagues R.Jeannel and P.A.Chappuis, systematic faunistic and taxonomic investigations named "Biospeologica". This resulted in the publication of over 80 monographs and papers between 1907 and 1962. One of the most important results of this period was a great synthetic, but not analytical, list of the world cave fauna (Wolf, 1934–38).

Following World War II an underground laboratory was established at Moulis, France, in 1954. The investigations in Moulis were enormously influential and initiated research in several biological areas and regions. Subsequently major advances have been made in experimental ethology, experimental genetics, population genetics, ecological genetics, physiology, molecular phylogenetics, and biogeography of subterranean organisms. Several comprehensive monographs on cave fauna and subterranean biology in general have been published, including those by Vandel (1965), Barr (1968), Ginet & Decou (1977), Camacho (1992) and Wilkens, Culver & Humphreys (2000). Monographs on specific themes include Gibert, Danielopol & Stanford (1994, mainly interstitial water); Riedl (1966, marine caves); Chapelle (1993, microbial life); Thines (1969, hypogean fishes); and Culver (1982, evolution and ecological genetics). In *Stygofauna Mundi* (Botosaneanu, 1986) there is a list of all stygobitic (i.e. aquatic) species with basic data on their distribution and ecology. The *Encyclopaedia Biospeologica* (Juberthie & Decou, 1994–2001) presents comprehensive reviews of taxonomic groups represented in subterranean habitats as well as the hypogean faunas of a number of countries.

The remainder of this entry reviews the contributions of some branches of biology and speleology, commencing with cladistics and cladistic techniques. These have remained controversial since their inception, but they have had some impact on studies of systematics and evolutionary histories of subterranean taxa. Among the first successful uses of cladistics to delineate the evolutionary history of subterranean species was that of Notenboom (1988) on the amphipod genus *Pseudoniphargus*. Notenboom used morphological characters to construct the cladogram, and molecular characters (especially mtDNA sequences). These have subsequently been extensively used on the spider genus *Nesticus* (e.g., Hedin 1997) and on the amphipod genus *Bactrurus* (Koenemann & Holsinger, 2001).

Subterranean fauna are distributed in all tropical and temperate regions, even close to northern glaciers. The diverity of fauna is richest in Mediterranean Europe, particularly in the Dinaric karst. In the tropics, this fauna is comparatively poor, particularly in terrestrial habitats. From the European Balkan Peninsula, more than 660 aquatic and more than 970 terrestrial obligate subterranean species have been recorded. In North America, whose interstitial fauna is poorly studied, 425 aquatic and 930 obligate terrestrial cave species (of which 350 are Coleoptera) are known; the very optimistic prediction is that over 6000 hypogean taxa exist (see America, North: Biospeleology). In Europe around 2000 stygobitic taxa have been recorded, about 8% of the aquatic fauna, and this may rise to around 3000 in total. The richest aquatic group is Crustacea, and beetles (Coleoptera) are the richest terrestrial group. Except for beetles, insects are poorly represented relative to their abundance in epigean habitats. Recent advances in data acquisition and in digital mapping capabilities are leading to rapid increases in geographic analysis of distribution patterns.

Historical biogeographic investigations have been mainly devoted to the mechanisms and causes of subterranean colonization (see Colonization entry). Historically, caves were mainly presented as refugia of passively imported ancient elements, but it is increasingly stressed that "modern" invasive species actively penetrate and colonize hypogean habitats. Active colonization appears to be the most reasonable explanation, since any species will colonize subterranean habitats it is in contact with if it is able to survive and reproduce there. Some species may be isolated underground, but no species will successfully survive and reproduce when forced underground if its gene pool does not contain suitable genes (alleles). There have been attempts to estimate the age of cave populations by degree of eye reduction (see Adaptation: Eyes), as well as by the degree of heterozygosity and by molecular clock hypotheses for DNA sequence data. However, the former is invalid if the reducing mutations are not neutral and the latter may be wrong if a cave population is not the result of a single invasion wave. The results have been widely disparate estimates of the age of different groups and it is not possible at present to distinguish between real differences in age and the errors in the estimates themselves.

The process of cave-related evolution was historically often explained by "Lamarckian" or "neoLamarckian" processes. However, it has been shown that even the slightest "troglomorphisms", like partial skin depigmentation, are often genetically fixed, although discussion about the reasons for regressive evolution (e.g. development of depigmentation and eye reduction) still continues (see Evolution of Hypogean Fauna). The number of authors advocating selection (by economizing on resource use) is similar to the number advocating mutation pressure (reductive mutations being selectively neutral underground). A consensus exists about the selective-and adaptive-advantage of constructive troglomorphisms. The genetic and morphogenetic mechanisms of some reductions are gradually being clarified (e.g. Yamamoto & Jeffery, 2000). This demonstrates the possibility of some slight phenotypic influences of darkness on the visual/neural systems of subterranean organisms (Cooper et al., 2001). Some authors even predict reduction of some genetic mechanisms (of mismatch repair: Langecker, 2000). The degree of adaptation and specialization in relation to the subterranean environment enables us to classify the species (or races) occurring in subterranean habitats. Some very elaborate systems have been developed but they are mostly useless since (1) for a great number of species we can only speculate about their presence/absence on the surface and (2) the latter may depend on local abiotic and biotic conditions (Sket, 1986). Schiner's system as modified by Holsinger & Culver (1988) and combined with the data about troglomorphism appears to be the best employable solution (see also Organisms: Classification entry).

The genetic structure of cave populations has been a topic of interest for decades, particularly because of the potential role of genetic drift in cave organisms. Among the earliest work on this problem was that of Kosswig on genetic polymorphism in *Asellus aquaticus*. Extensive genetic analysis of polymorphisms of soluble enzymes revealed that levels of genetic variation in invertebrate populations were not generally reduced related to surface populations. However, in vertebrates, genetic variability was often low, indicating small population size and an enhanced role for genetic drift. Sbordoni *et al.* (2000) also reported that populations could be differentiated on the scale of a few hundreds of metres.

Physiological investigations have been mainly directed to the measurement of metabolic rate (see also Adaptation: Physiology). It has been found that subterranean species generally have lower metabolic rates than epigean taxa, although there are exceptions. Low metabolic rate allows some cave animals to withstand extremely disoxic or poisonous conditions (Sket, 1986). However, we do not currently know if subterranean organisms can reproduce successfully in these environments. A physiological connection between restricted feeding and longevity has been proven (e.g. Tatar & Rand, 2002) and further studies will probably show whether there is any evolutionary connection between "starvation physiology" and the long lives of cave animals.

Regarding the sensory physiology and ethology of subterranean organisms, reactions to light have been thoroughly investigated. The sensitivity of some eyeless animals to light has been known for some time, but an interesting recent discovery suggests the "blindness" of some animals with well-developed eyes (Cooper *et al.*, 2001). Sensitivity and reactions to other stimuli has not been given enough attention. Some ethological mechanisms, like circadian rhythms and agressive behaviour are the subject of reduction in troglobites while a seasonal periodicity may be observed more often (Lamprecht & Weber, 1992). There have also been changes observed in some feeding behaviour patterns of cave fish while differences in the sexual behaviour unre lated to the cave environment (Juberthie-Jupeau, 1988) may have played a role in speciation.

Most research on the population ecology of cave animals has been concerned with modifications of life history traits that occurred as a result of adaptation to the cave environment. While some r-strategic traits, like progenesis, occur in some interstitial habitats (Coineau, 2000), the stable cave environment facilitated inhabitants a K life strategy with slower ontogeny, neoteny, low offspring numbers, and a long life span (Culver, 1982). This makes troglobites particularly weak competitors with epigean species in relatively food-rich habitats (e.g. if the subterranean habitat is slightly polluted; Sket, 1977), even if a cave species is not physiologically bound to the climatic characters of the subterranean environment. In contrast, cave species are good competitors in the food-poor environment of caves, and competition often involves predation because competitors are also potential food.

Karst hydrogeology is important to speleobiology because of the constraints it imposes on the distribution and movement of cave organisms. A more explicit connection was made by the French biologist Rouch (1986) who pioneered the concept of the karst basin as an ecosystem. Hydrogeology also plays a key role in anchialine habitats (see separate entry).

The search for chemoautotrophic organisms in caves has been the focal point of cave microbiological studies. Early workers, especially Caumartin (1963), were able to isolate

chemoautotrophic bacteria from caves. More recent work has emphasized their importance in ecosystem energetics. Relying on a battery of stable isotope and biochemical tests, Sarbu, Kane & Kinkle (1996) were able to demonstrate convincingly that Movile Cave in Romania was a rare case of a chemoautotrophically based subterranean ecosystem (see Movile Cave and Microorganisms in Caves entries). Microbes also figure prominently in the many processes of deposition of minerals in caves (see Microbial Processes in Caves).

Finally, the need to conserve and protect subterranean animals has grown increasingly important. Protection of bats has attracted the most attention (Stebbings, 1988) because of the vulnerability of hibernating and maternity colonies to destruction. Protection of other species is of increasing concern because of the growth of problems of groundwater contamination and development (Sket, 1999; see also Conservation: Cave Biota).

BIOSPELEOLOGISTS

This entry provides short biographical sketches of researchers, now deceased, who were known for either "firsts" in biospeleological discoveries or for their influence on biospeleological ideas. The order is chronological, according to the time in which they made their major contribution to speleology.

In 1537, the Italian poet and scholar Giovanni Giorgio (GianGiorgio) Trissino (1478– 1550) recorded what must have been a form of cave amphipod (probably *Niphargus*) from a cave in northern Italy. He also wrote detailed accounts of Italian caves. However, it is thought that the first printed report of a cave organism was by Yi-Jing Jie, who described an eyeless hyaline fish from the Alu caves of Yunnan in China in 1541. This species, *Sinocyclocheilus hyalinus*, was not scientifically described until 1994. The French engineer and mathematician Jacques Besson (c. 1530–73) reported little eels (*petites anguilles*) in a cave stream somewhere in Europe in 1569. However, he did not give a locality, and neither did he describe the fish as blind or depigmented (Romero & Lomax, 2000).

Athanasius Kircher (1602–80), a German-born Jesuit polymath, wrote *Mundus Subterraneus* in 1665, probably the first printed work on earth science to include speleology. There he enumerated numerous cave organisms, including mythical beasts such as dragons, although none of the animals that he mentioned displayed the typical features associated with troglomorphic animals: blindness and depigmentation. (Romero, 2000). In 1674, the English naturalist Martin Lister (1639–1712) published the earliest reference to underground fungi.

The Slovenian historian and naturalist Janez Vajkard [Johann Weichard] Valvasor (1641–93) published the first systematic study of caves in a particular area, and explained the mystery of disappearing karst lakes by a system of underground rivers and reservoirs (see also Speleologists). In his 1689 book *The Glory of the Duchy of Carniola*, Baron Valvasor described the discovery of the blind cave salamander *Proteus anguinus* at a karst spring near Vrhnika. This was the first troglobite to be scientifically described and named, by the Viennese zoologist Josephi Nicolai Laurenti in 1768.

In 1748, Marc-René Marquis de Montalembert (1714–1800), a French aristocrat, reported a blind, subterranean fish in a spring at Gabard, Angoumois, near one of his estates in southwestern France in 1748. However, no drawings or specimens were preserved and his description remains unconfirmed (Romero, 1999a).

The first study of underground plants was published in 1772 by the Italian naturalist Giovanni Antonio Scopoli (1723–88) (Scopoli also sent specimens of *Proteus anguinus* to other researchers in Europe, and it was one of these specimens that Laurenti examined). Green plants in the mines of Freiburg that had not fully developed due to lack of light were described in 1793 by the German naturalist and geographer Alexander von Humboldt (1769–1859). In 1799 he visited Guácharo Cave in Venezuela, and described the nocturnal oilbird, *Steatornis caripensis*, flocks of which emerge from the cave at night. In 1805 he published a description of a freshwater species of catfish ejected from an underground volcano in Quito, Ecuador, although this discovery remains unsubstantiated (Romero & Paulson, 2001).

Karl Franz Anton von Schreibers (1775–1852) performed the first detailed anatomical studies of *Proteus anguinus*, on one of Scopoli's specimens stored in the Vienna Natural History Museum. He also bred *Proteus* in artificial underground caves.

In 1842, August Otto Theodor Tellkampf (1812–83), a German physician who emigrated to America, visited Mammoth Cave, and later described several species of invertebrates from the cave fauna. He also contributed detailed descriptions of the northern cavefish *Amblyopsis spelaea* and concluded that its eyes and those of blind cave crayfishes had become rudimentary from lack of use (Romero, 2002)

Jean Louis Rodolphe Agassiz (1807–73), a Swiss anatomist who emigrated to the United States and served as Director of the Harvard Museum of Comparative Zoology from 1859 to 1873, in 1847 proposed a plan to raise individuals of *A. spelaea* under different light conditions, to study the influence of illumination on its eyes and pigmentation. A creationist, he thought only of the effects of the environment on development, not of the environment influencing evolution. He never carried out the experiments, but several of his students also showed a great deal of interest in cave fauna, and later developed his ideas (Romero, 2002).

The Danish naturalist Jørgen Matthias Christian Schiödte (1815–84) was particularly interested in the correlations between anatomical characteristics and the biological conditions under which organisms live. Schiödte's 1849 work: *Specimen faunæ subterraneae* provided the first classification of cave animals: shade animals, twilight animals, animals in the dark zone, and animals living on stalactites.

Jeffries Wyman (1814–74), the first curator of the Peabody Museum of Yale University, studied *A. spelaea* in great detail. Although it lacked eyes, Wyman found that it had well-developed optic lobes. He proposed in 1854 that this imperfection of the eyes "might be owing to a want of stimulus through a series of generations" and that the organ of vision, however imperfect, "is more like the eyes of other vertebrates". For him, *A. spelaea* was an excellent subject for the study of evolution (Romero, 2001).

In 1854, Ignaz Rudolph Schiner (1813–73) classified cave organisms according to their degree of dependence on the underground environment: troglobites, troglophiles, and "occasional cavernicoles" (trogloxenes). This classification was later modified by Emil Racovitza, and is commonly used today.

Charles Darwin (1809–82) believed that cave fauna supported his theory of evolution. He noted that cave fauna were more closely related to the fauna of the surrounding regions than elsewhere. He first considered the mechanisms of both natural selection and disuse to explain troglomorphic features, i.e. enlargement of some sensory systems and appendages in the former and blindness and depigmentation in the latter. To him this suggested a "contest…between selection enlarging and disuse alone reducing these organs" (Darwin, *On the Origin of the Species by Means of Natural Selection*, 1859). However, by the third edition of his book in 1861 he relegated the importance of natural selection, eliminating his speculation about a "contest" between selection and disuse.

Alpheus Hyatt (1838–1902), a student of Agassiz, visited Mammoth Cave in 1859, and collected cave fauna. He used the specimens to demonstrate that here were animals whose phylogenetic lineage had become "old" (Romero, 2001).

In 1864, the American paleontologist and evolutionist Edward Drinker Cope (1840– 97) described what he thought to be a new species and genus of troglomorphic fish, *Gronias nigrilabris*, from Pennsylvania, without presenting any evidence that such a fish had been captured in the hypogean environment (Romero, 1999b; Romero & Romero, 1999). Cope introduced the idea that evolution was directed by trends, and that when an organism travelled too far down an adaptively specialized path, as in adaptation to living in caves, it could not reverse this process. He also described the life cycles of the cave fauna of Wyandotte Cave, Indiana.

In 1871, Alpheus Spring Packard Jr (1839–1905), another former student of Agassiz, examined Mammoth Cave specimens,

Biospeleologists: Athanasius Kircher (top left); Emil G.Racovitza (top right); René Gabriel Jeannel (bottom left); Albert Vandel (bottom right).

and the fauna, particularly the fish, convinced him of their usefulness as a demonstration of Lamarckian evolution. He thought that cave fauna had a very recent origin and that the loss of certain organs was compensated for by the hypertrophy of others.

Frederic Ward Putnam (1839–1915), another of Agassiz's students, visited Mammoth Cave in 1871, and in 1874 collected a large number of specimens. He criticized Cope's interpretation that *A. spelaea* was able to survive in those waters because of its "projecting under jaw and upward direction of the mouth [which] renders it easy for the fish to feed at the surface of the water", and presented numerous examples that contradicted Cope's assertions. He viewed the amblyopsids as former marine and saltwater estuary fishes that were slowly trapped in that geographical area. He also described a new species of amblyopsid, *Chologaster agassizi*.

Edward Ray Lankester (1847–1929), a British neo-Darwinist, proposed that blindness among cave animals was due to a special type of natural selection. In an 1893 article in *Nature*, he suggested that some animals are, by chance, born with defective eyes. Occasionally a few animals—some with normal eyes and some with defective eyes—fall or are swept into caves. In each generation, those that have good eyes are able to see the light and escape, and eventually only those that are blind remain in the cave. He also believed that one can find organisms degenerating ontogenetically and phylogenetically. In his 1880 book *Degeneration: A Chapter in Darwinism* he defined "degeneration" as "a loss of organization making the descendant far simpler or lower in structure than its ancestor".

Carl H.Eigenmann (1863–1927) was a German-born ichthyologist who studied and worked in the United States. Much of his work between 1887 and 1909 was devoted to understanding how visual structures were lost in cave vertebrates. He described two new species of cave fish: *Amblyopsis rosae* from Missouri, and *Trogloglanis pattersoni* from the artesian waters of San Antonio, Texas. He published more than 40 papers, abstracts, and books on cave fauna—his *Cave Vertebrates of North America* (1909) being the most important. Originally a neo-Lamarckian, Eigenmann thought that the reduction or disappearance of organs among cave animals was a case of convergent evolution. He pointed out that a lack of pigmentation had to be understood as the combination of genetically fixed and epigenetically (environmentally influenced) determined characters (Romero, 1986b). He believed that cave faunas were not the result of "accidents", but rather the product of active colonization.

In 1896, Armand Viré (1869–1951), a French scientist and cave explorer attached to the Museum National d'Histoire Naturelle, set up the world's first underground laboratory, which operated until 1914 in the catacombs of the Botanical Garden in Paris. He published several articles on European cave fauna, based on his visits to caves.

Emil G.Racovitza (Racovița) (1868–1947) was a Romanian zoologist who worked in France until returning home in 1920. His *Éssai sur les problèmes biospéleologiques* (1907) is considered to mark the birth of biospeleology as an independent science. He initiated an extensive international research programme called "Biospeologica" (primarily intending to document and collect cave fauna). In 1920 he founded the world's first Speleological Institute in Cluj, Romania. He explored 1200 caves in Europe and Africa, collected about 50000 specimens of cave animals, and published 66 papers on subterranean fauna. For Racovitza, an anti-neo-Darwinist, all cave organisms were

"preadapted" to the cave environment where "the function creates the organ." (Motas, 1962).

The French entomologist René Gabriel Jeannel (1879–1965) studied subterranean beetles mostly from Europe and Africa. With Racovitza he founded the journal *Biospéleologica* in 1907, became deputy manager of the Speleological Institute in Cluj, and in 1926 published *Faune cavernicole de la France*.

Charles Marcus Breder Jr (1897–1983), the director of the New York Aquarium, led the renaissance of the study of cave fishes by *using Astyanax fasciatus* as his prime subject of research. He emphasized behavioural, physiological, genetic, and ecological approaches (Romero, 1984; Romero, 1986a; Romero, 2001). Many of Breder's contributions are still cited, and several of his associates and students have studied this cave fish. Breder was the dominant figure in hypogean fish research in the 1940s and 1950s.

Curt Kosswig (1903–82), a German scientist who spent many years in exile in Turkey, used the results of his own Mendelian studies to explain the "rudimentation" or loss of structures among cave animals. He founded the cave fish team at the Zoological Museum and Zoological Institute at the University of Hamburg.

Albert Vandel (1894–1980) founded the Laboratoire souterrain de Moulis in 1948. In his highly influential book on cave biology (*Biospéologie: La Biologie des Animaux Cavernicoles*, 1964) he proposed that the evolution of cavernicoles was neither neo-Lamarckian nor neo-Darwinism, but which he called "organicist". According to him, all phyletic lines pass through several successive stages: creation; expansion and diversification; and finally specialization and senescence. The last stage of this cycle was "regressive or gerontocratic" evolution. He considered cavernicoles to be good examples of regressive evolution. However, his ideas lack empirical support.

BLUE HOLES OF THE BAHAMAS

Blue holes are karst features from the Bahama islands which have been documented for over 100 years. The Bahamas comprise an archipelago consisting of 29 large islands and 661 small islands (called "cays"), extending from near the Florida peninsula southeastwards for 1400 km to Hispaniola. Blue holes are water-filled vertical openings in the carbonate rock of the islands, which exhibit complex morphologies, ecologies, and water chemistries (Figure 1). Their deep-blue colour is a result of a water depth greater than 10m. Blue holes are the composite result of carbonate deposition and dissolution cycles, which have been controlled by glacial sea-level fluctuations. As a result, blue holes are polygenetic in origin, forming by three possible mechanisms:

- 1. Glacial melting and sea-level rise can form blue holes by drowning dolines and shafts developed in the vadose zone during sea-level lowstands (Figure 2A);
- 2. Deep dissolution voids are produced in the phreatic zone of carbonate platforms (Figure 2B). Exploratory drilling has encountered large voids at depths of 21 to 4082 m; the deepest of these voids was large enough to accept 2430 m of broken drill pipe. These voids can collapse towards the surface to create a blue hole—a process called progradational collapse (Mylroie *et al.*, 1995) or aston collapse (Palmer, 1986);
- 3. The Bahama islands are steep-walled platforms, and there is abundant evidence of fracture along the margins of these platforms. These fractures form parallel to the

coast, commonly in an "*en echelon*" fashion, to create graben-like features (Figure 2C). Where these fractures are open to the surface, it is possible to enter the extensive and deep blue-hole systems (Palmer, 1986).

Blue holes have been widely studied by cave divers over the last 30 years, initially by George Benjamin (1970). They have provided information regarding karst processes, global climatic change, marine ecology, and carbonate geochemistry. The term "blue hole" has been used in a variety of ways, but they are best defined as: "subsurface voids that are developed in carbonate banks and islands; are open to the Earth's surface; contain tidallyinfluenced waters of fresh, marine, or mixed chemistry; extend below sea-level for a majority of their depth; and may provide access to submerged cave passages." (Mylroie *et al.* 1995, p.225).

Blue Holes of Bahamas: Figure 1. Watling's Blue Hole, San Salvador Island, Bahamas. (Photo by John Mylroie)

Blue holes are found in two settings: ocean holes open directly into the present marine environment and contain marine water, usually with tidal flow; inland blue holes (Figure 1) are isolated by the present-day topography from marine conditions, and open directly on to the land surface or into an isolated pond or lake, and contain tidally influenced water of a variety of chemistries, from fresh to marine. The most common alternative use of the term "blue hole" is to describe large and deep karst springs.

Blue holes are widely distributed in the Bahamas. While the largest and best-known blue holes are found on North Andros,

Blue Holes of Bahamas: Figure 2. Dolines and vadose shafts produced during sea-level lowstands are drowned by sea-level rise to produce blue holes (A). Phreatic voids produced deep in the platform, possibly within the freshwater lens during sea-level lowstands, form blue holes when the collapse reaches the surface, and sea-level rises (B). Fracture of the steep bank margins of the Bahamas creates voids that become blue holes (C).

South Andros, and Grand Bahama islands in the northwestern Bahamas, blue holes are found on islands all the way to Great Inagua Island at the southeastern end of the archipelago. In the northwestern Bahamas, blue holes with depths in the 100–125 m range are common, and it was thought that their depth was limited by the position of the lowest glacial sea-level lowstand, which was 125 m below present sea-level. However, exploratory wells commonly intersect voids below that depth, and Dean's Blue Hole on Long Island in the southeastern Bahamas was found to be over 200 m deep, ending in a large chamber. Blue holes commonly lead into major horizontal cave systems, such as Lucayan Caverns (9184 m long) on Grand Bahama Island, and Conch Blue Hole (1153 m long) on North Andros Island.

Blue holes are most often thought of in terms of the Bahamas, but similar features are found worldwide. The cenotes of the Yucatan region of Mexico are very similar (see Yucatan Phreas, Mexico), as they are also water-filled shafts that commonly lead to extensive cave systems underwater. Cenotes with many features similar to blue holes are also found in the Mount Gambier region of southern Australia, well away from the coast. Florida's extensive karst contains many sinks and holes that lead into water in a manner analogous to blue holes, and southern Africa has deep, flooded shafts (Farr, 1991). However, the Bahamian blue holes appear to be unique in that they have strong currents that oscillate with the tide. The currents can be so strong that even the fittest scuba diver can be overcome. The reversing flow of blue holes has been viewed as an aspect of subplatform water flow in the carbonate banks of the Bahamas; flow in some blue holes does not reverse, but is a continuous discharge (Whitaker & Smart, 1997). The reversing flow of blue holes does not appear to be a factor in their formation, but rather an effect of their forming under other conditions and being inherited as pathways for tidal and groundwater flow patterns.

The reversing flow of ocean blue holes creates an important biological environment. The ebb and flow brings nutrients and prey into the blue holes, which support a variety of organic life, and the rock walls of the blue holes are an important hardground for organisms that need to attach themselves to a solid substrate in order to survive. Deeper in the blue holes, there are a number of cave-adapted organisms, such as *Lucifuga*

speleotes, the blind Bahamian cave fish. More significantly, a new class of Crustacea, Remipedia, was discovered in the Bahamian blue holes in the late 1970s (Yager, 1981). Inland blue holes commonly have fresh water overlying marine water, to produce a halocline. The collection of organic material at this horizon creates a food source exploited by a variety of organisms. Excess accumulation of organics can lead to anoxic conditions, and the development of an ecology based on chemosynthesis by reducing bacteria.

BOA VISTA, TOCA, BRAZIL

Toca da Boa Vista is the longest cave in the Southern Hemisphere—a maze of dry passages over 100 km long that seems to extend interminably beneath the semi-arid terrain of northeastern Brazil. The cave appears to represent a rare (and by far the longest) example of a cave generated by sulfuric acid produced within dolomite through the oxidation of sulfide. Toca da Boa Vista contains also significant fossil remains and calcite deposits that have yielded important paleoenvironmental information.

Toca da Boa Vista is located close to the village of Laje dos Negros (municipality of Campo Formoso) in the dry lands of northern Bahia State (located on Figure 1 of the America, South entry). Mean rainfall is about 480 mm a^{-1} , with consider able interannual variability. The cave is contained within dolomites of the Salitre Formation, Una Group. This Precambrian carbonate sequence (see America, South) extends over much of the northern half of the state of Bahia, generating major karst features around Andaraí, Iraquara, and in the Jacaré River valley. However, the better-developed underground karst occurs near Laje dos Negros, where the two longest caves in Brazil are located close by. Toca da Boa Vista has 102 km of mapped passages (as at January 2003), while Toca da Barriguda is 28.7 km long (see figure). They are separated by a mere 700 m, and undoubtedly share a common genetic history, although some morphological differences exist between them, such as the large rooms of Toca

Boa Vista, Toca, Brazil: Outline map of Toca da Boa Vista and Toca da Barriguda, drawn in true relationship to each other. Survey by Grupo Bambuí de Pesquisas Espeleológicas.

da Barriguda. A connection between these two major caves is likely in the future, and would result in a mega-system among the top 10 longest caves of the world.

Toca da Boa Vista is a two-dimensional and roughly horizontal maze that undulates in profile, reaching a maximum depth of 60 m below the surface. Although the cave plan is strongly suggestive of joint control, most passages do not appear to follow any joint at ceiling level, and neither can an initiation horizon or conspicuous bedding plane be observed in the walls. However, the cave floor is almost always obscured by breakdown or sedimentation. The cave shows abrupt variations of cross-section along its passages and lacks vadose features and common fluvial forms such as scallops or meanders. Cupolas, sharp bedrock projections, and cuspate marks abound, and the walls (and

speleothems) are heavily corroded by condensation corrosion (see Condensation Corrosion), yielding dolomitic sand. The caves show no relationship to the surface, which is basically flat ground without noticeable karst features. Wall-rock dissolutional phreatic features can be followed up to the cave entrances, showing that the cave passages used to extend above the present surface elevation, having been truncated by denudational lowering.

Toca da Boa Vista shares many of the features of deep-seated hypogenic caves of sulfuric acid origin (see entries on Carlsbad and Lechuguilla Caverns; Speleogenesis: Deep Seated and Confined Settings), although it lacks massive gypsum deposition and a three-dimensional pattern. The local geology does not favour a deep-seated origin because the carbonates were deposited on a craton stabilized in the Precambrian, and no deep sources of acidity (such as hydrocarbon deposits or volcanic emissions) are known to occur. However, the carbonate sequence of the Una Group is known to host massive deposits of sulfide. The oxidation of pyrite beds within the dolomite is a possible source of acidity. Because the pyrite would be oxidized by groundwater, it should not be directly observed in cave walls. Gypsum deposits, due to their high solubility, would be easily removed by later phreatic water flow. Hydrochemical analysis of the Una Group aquifer demonstrates that there is a correlation between groundwater sulfate and bedrock Ca and Mg, indicating that sulfate is being produced by bedrock-water reactions. The lack of sulfate beds within the carbonate suggests that sulfide oxidation is the most likely mechanism for sulfate generation in the area.

Large-scale speleogenesis through metal sulfide oxidation has not been recognized elsewhere in the world. The two-dimensional, mostly horizontal nature of the cave conforms with stratabound deposits of sulfide described in other areas of the Una Group. Such "shallow" hypogenic speleogenesis exhibits a stronger lithological control than either deep-seated or epigenic caves, because the source of the acidity lies within specific carbonate units. Sharp morphological changes are likely to reflect heterogeneities in the distribution of the sulfide.

While the ages of Toca da Boa Vista and Toca da Barriguda exceed the limit of the Useries method, minimum ages for the caves have been obtained through two magnetically reversed fine-grained sediment deposits. It is highly likely that these two sediments represent distinct reversal episodes, yielding a minimum age of 1.07 million years, although it is very probable that the caves started forming earlier in the Tertiary.

Subaqueous speleothem deposition is widespread in certain areas, representing a wellmarked former lake level about 13m above the present water table. Uranium-series ages of shelfstone and subaqueous coralloids, together with dating of surface travertines, have allowed the recognition of a wetter period from the last glacial maximum to the beginning of the Holocene (Auler & Smart, 2001). Remarkably complete and very wellpreserved fossil remains have been located in the areas close to the entrances. Some of these fossils represent the first complete skeletons of certain Pleistocene extinct species, such as an extinct cave dog (*Protocyon troglodytes*), a small bear (*Arctotherium brasiliense*), and a large monkey (*Protopithecus brasiliensis*) (Hartwig & Cartelle, 1996). A complete skeleton of a new species of large monkey (*Caipora bambuiorum*) has also been found among the subaqueous deposits of the cave (Cartelle & Hartwig, 1996). The age of the fossils has been constrained through ²³⁰Th/²³⁴U dating of calcite layers associated with the bones. The interval of deposition spans much of the last glacial period, but also includes a few older deposits.

The cave does not face any immediate threat, due to its isolated location and difficult access. Its high internal temperature (around 28°C) and the intricate nature of the passages, do not favour commercialization. No special measures have been taken to preserve this outstanding speleological site.

BOOKS ON CAVING

Historical introduction

It is difficult to state the exact number of caving books printed worldwide each year but it ranges between 100 and 200, representing less than one tenth of the annual page output of caving journals (see separate entry). However, their history is far longer, beginning over 2000 years ago. Most of the early references to caves are very short sentences contained in books dedicated to completely different topics (from medicine to poetry, from philosophy to science). Thus, the first known publication completely dedicated to caves was a four-page pamphlet printed in 1535 by Berthold Buchner concerning the exploration of Breitenwinner Höhle in Germany: the single copy still existing is conserved in the State Library of Ulm. In 1665 A.Kircher printed the first edition of *Mundus Subterraneous*, which is generally accepted as the first scientific book on caves and karst (Figure 1). A few years later J.W.Valvasor published the four volumes of his *Die Ehre des Herzogthums Crain* (1689), in which his explorations of several caves in the Karst region are described and the blind cave salamander *Proteus anguinus* is first recorded as a "baby dragon".

Up to the first half of the 19th century only a few hundred speleological books were printed. Many were just reports of cav

Books on Caving: Figure 1. Title page of *Mundus Subterraneous* (Kircher, 3rd edition, 1678).

ing explorations but some dealt with hydrogeology and speleogenesis (Vallisnieri, 1715), cave morphology (Cappelleri, 1757), cave mineralogy (Zimmermann, 1788), or biology (Configliachi, 1819).

At the end of the 18th and at the beginning of the 19th century tourist guides to famous caves, often enriched by beautiful engravings, became rather popular books: the first general book on the show caves of the world (Lang, 1801) reports on famous caves from Germany, Belgium, England, Portugal, and Greece.

The birth of modern speleology should date from the publication of *Die Grotten und Höhlen von Adelsberg, Lueg, Planina und Laas* (Schmidl, 1854), the first speleological treatise dealing with different caving topics from biology to mineralogy, and from cave exploration to mapping. Later, in 1882, *Celebrated American Caverns* (Hovey, 1882) became the first important caving book printed outside Europe. The caver who most improved caving literature was E.A.Martel, who almost single-handedly brought speleology to the attention of the wider public. In his lifetime he printed over 700 articles and over 20 books on caving topics (see Chabert & Courval, 1971), the most famous being *Les Abîmes* (1894) (Figure 2) and *Nouveau traité des eaux souterraines* (1921). Thanks to Martel's activities, from the end of the 19th century several books on caves and speleology began to be printed worldwide. The Austrian G.Kyrle also contributed with outstanding papers: in particular his *Grundriss der Theoretischen Speläologie* (1923) should be mentioned here.

Present situation

Nowadays caving books are printed in all five continents. Their subjects include the different scientific fields involved in the underground world, novels and humorous books, technical manuals, show cave guides, cave inventories, and general or local histories of caving activity. Over 60% of published caving books describe explorations, either in the home area or overseas. Of the former, one of the first was the account by Lawrence & Brucker (1955) of the exploration of Floyd Collins Crystal Cave and this was notable as it was produced by a major US publisher. Similarly, *Ghar Parau* (Judson, 1973), one of the first books to tell the story of an overseas expedition, was produced by a major publisher and printed in both Britain and the United States. In contrast, most exploration reports are printed by a single caving club or association. Despite the high quality and general interest of many of these publications, they are not easily accessible outside the country or even the region in which they were printed. Exceptions are represented by a few books such as *Lechuguilla: Jewel of the Underground(Taylor, 1991) and Río La Venta: Treasure of Chiapas* (Badino *et al., 1999*).

Books on Caving: Figure 2. Cover page of *Les Abîmes* (Martel, 1894).

Although a few details on the techniques of cave exploration were printed in the first half of the 20th century (Boegan & Bertarelli, 1926), the extremely fast development in exploration techniques experienced from 1960 to 1980 provided an incentive for the production of several technical manuals, the most well known being *Techniques de la spéléologie alpine* (Marbach *et al.*, 1973), which was printed in four different editions from 1973 to 2000 and *On Rope* (Padgett & Smith, 1996).

A popular category of caving books amongst both cavers and non-caving scientists is represented by the general treatises on speleology, which give an overview on the different scientific fields related to caving. The first such book was *La Spéléologie* (Martel, 1900) and practically every country in the world, where speleology exists, has its own manual. Milestones in this field are still *British Caving* (Cullingford, 1953) and *The Science of Speleology* (Ford & Cullingford, 1976).

Some 3–5% of cave books are inventories, although most of these only have a regional distribution. Exceptions are those that give a general worldwide overview such as the *Atlas of the Great Caves of the World* (Courbon *et al.*, 1989). Show cave guides, which represent about 20% of the caving books, normally have high print runs (up to 20000) but never have a really wide circulation among cavers, being always confined to the tourist audience.

In the last 20 years or so, a growing category of caving book has been the monograph dealing with research in a specific field of scientific speleology. These books normally have a diffuse circulation owing to their being of interest to both specialized researchers and cavers. It is impossible to cite even a small fraction of these monographs, though those surely worthy of mention include *Paleokarst* (James & Choquette, 1988), *Speleogenesis* (Klimchouk *et al.*, 2000), and the *Encyclopaedia Biospeologica* (Juberthie & Decu, 1994). Probably the most successful monograph with worldwide distribution was *Cave Minerals* (Hill, 1976) and the later *Cave Minerals of the World* (Hill & Forti, 1997).

In contrast to research monographs, there have been a small number of books by experienced cavers that are aimed at the general public and which try to give an impression of caves and cavers. Early examples were Casteret's *Dix ans sous terre* and *Au fond des gouffres* published in English as *Ten Years Under the Earth* (Casteret, 1938). *Depths of the Earth* (Halliday, 1966) sold widely in the United States and elsewhere while *Radiant Darkness* (Bögli & Franke, 1965) and *The World of Caves* (Waltham, 1976) were notable for extensive use of large, spectacular, colour photographs. Closer to the Casteret tradition and introducing the general public to the sport of cave diving, was *The Great Caving Adventure* (Farr, 1984). Finally, brief mention must be made of the small group of publishers that specialize in caving books. These include Speleo Projects in Switzerland, Zephyrus Press (United States) which reprinted, or printed English editions of, many famous caving books, and Cave Books (United States), a division of the Cave Research Foundation which publishers a wide range of material from expedition reports to fiction. Many national caving bodies such as the NSS and BCRA also have their own publishing branches.

How to get information

Cave books published prior to 1900 are extremely rare and often expensive, so they are hard to find. One of the largest collections of old caving books is in the F.Anelli Cave Documentation Centre, Bologna (Italy), where over 1250 publications from 1590 to the first years of 1900 are available for direct consultation. Relevant bibliographic information may be extracted from *History of Cave Science* (Shaw, 1992) and A *Guide to Speleological Literature of the English Language 1794–1996* (Northup *et al.*, 1998).

It remains the case that only a few caving books have a true international audience, most being of national or local interest. Thus most books are printed in runs of under 2000. Moreover only a few professional booksellers in Europe and North America specialize in cave and karst books. Hence many new caving books and particularly those of mainly local interest, are distributed through caving clubs and societies, which advertise them through their bulletins.

The best source of information for both caving books and caving journals is the Bibliographic Bulletin of the International Union of Speleology: *Speleological Abstracts*, printed annually by the Swiss Speleological Society and available also on the internet at www.isska.cm/bbs. In the case of old and/or out of print books it is possible to refer to the local UIS *Documentation Centres* (see Caving Journals entry for the list of their addresses) to obtain the required xerox.

BRITAIN AND IRELAND: ARCHAEOLOGICAL AND PALEONTOLOGICAL CAVES

The British Isles contain several regions of karst landscape with abundant caves (Figures 1 and 2; see also Figure 1 in Europe, North), while sea caves are also widespread, particularly on the western and northern seaboards of Britain. Archaeological and paleontological remains are frequently found in these caves, but in most instances the finds are fragmentary and they often lack a secure stratigraphic provenance. The remains of Pleistocene animals are fairly common, but there are very few human skeletons that date to earlier than the Holocene, and there are no known examples of paleolithic art on the walls of caves in the British Isles. The archaeological record in British and Irish caves is therefore impoverished compared with comparable sites in continental Europe; nevertheless the discoveries made in British caves in the first half of the 19th century were highly significant to the development of knowledge and ideas concerning human antiquity and in demonstrating that early humans were present in Britian at the same time as extinct Ice Age animals.

Scotland

The Creag nan Uamh caves are formerly phreatic systems developed in Cambro-Ordovician dolomitic limestone in the Allt nan Uamh Valley, 5 km south of Inchnadamph in Sutherland, northwest Scotland. The caves were covered by the Late Devensian ice sheet and the cave sediments—gravels and cave earthsare predominantly derived from glacial materials. Archaeological excavations at the caves in the 1920s revealed many naturally shed reindeer antlers, which were presumed to have been cached in the caves by paleolithic hunter-gatherers (Lawson, 1981). Subsequent radiocarbon dating has shown that the antlers were deposited in at least three separate episodes during the last (Devensian) glaciation, and, together with the absence of evidence for the contemporary presence of humans, the faunal remains are now thought to have accumulated by natural agencies. After the end of the last ice age the caves were used as burial chambers by neolithic and bronze age people.

A series of caves and rock shelters containing archaeological material are located at a present-day altitude of 10 m around the former shoreline of Oban Bay, in Argyll on the northwest coast of Scotland. These former sea caves were uplifted during isostatic rebound of the Scottish coastline after the last glacial maximum, and the cave entrances were then utilized by Mesolithic hunter-gatherers between about 8000 and 4000 BC. Some of the caves were later used as burial sites during the Neolithic, Bronze Age, and Iron Age periods (Saville & Hallen, 1994).

Wales

Comprehensive reviews of the cave archaeology of Wales can be found in Ford (1989), and only two of the most important sites are mentioned here. Pontnewydd Cave is located near Denbigh, about 10 km from the north coast of Wales. The cave was excavated by Stephen Aldhouse-Green in the 1970s and 1980s (Green, 1984). The site is distinguished archaeologically by its abundance of stone tools of Lower Paleolithic type, together with waste flakes from their manufacture. Accompanying fauna show that the cave was occupied by early humans during an interglacial period about 230000 years ago (Oxygen Isotope Stage 7). Fragmentary bones and teeth of several human individuals have been excavated from debris-flow deposits in the cave, but radiocarbon dating has shown that at least some of these human remains are derived from disturbed Holocene burials.

Paviland Cave, also known as Goat's Hole Cave, is located on the Gower Peninsula on the south coast of Wales. The cave is the richest early Upper Paleolithic site in the British Isles, and has produced the region's only ceremonial burial from the Ice Age, radiocarbon dated to 26 ka. The burial was discovered in 1823 by William Buckland, who thought that the ochre-covered skeleton was that of a Roman prostitute, hence it is colloquially known as the "Red Lady of Paviland". Subsequent study has shown the skeleton to be that of a young adult male whose grave had been furnished with carved ivory bracelets and wands and perforated seashells. Further excavations in the cave during the 20th century recovered thousands of stone tools and more bone and ivory artefacts, and a recent programme of radiocarbon dating has shown that the cave was occupied episodically throughout the Upper Paleolithic, from about 30000 to 12000 years ago (Aldhouse-Green, 2000).

England

In Britain, the caves of South Devon, developed mainly in coastal outcrops of the Devonian Limestone, were among the first such sites to be subject to scientific investigation. Kent's Cavern in Torquay (known earlier as Kent's Hole) was first excavated in the 1820s by the Reverend John McEnery (see Archaeologists). McEnery's controversial claim of finding stone tools that were contemporaneous with the bones of extinct animals was rejected by the eminent geologist William Buckland, who regarded the stone artefacts as intrusive. However, careful excavations by the Torquay Natural History Society, directed by William Pengelly in 1846 and continued in the 1860s, corroborated the work of McEnery through meticulous recording of the stratigraphic levels where the bones and artefacts were found. Brixham Cave, on the Devon coast 8 km

south of Kent's Cavern, was also excavated by Pengelly in 1846 and provided additional proof of the antiquity of human activity in Devon.

Most of the faunal remains and artefacts from Kent's Cavern are of Last Glacial and Holocene age, but elements of a much earlier fauna, including cave bear, sabretoothed cat and the pine vole *Pitimys gregaloides* indicate that some deposits are of Hoxnian or earlier age (Oxygen Isotope Stage 10 or earlier). Lower Paleolithic hand axes have also been recovered from the lowest stratigraphic unit in the cave, confirming the great antiquity of the sequence of deposits in this cave. Cave-infill deposits of similar age have been investigated at Westbury Quarry in Somerset. The cave was exposed by quarrying of the Carboniferous Limestone in 1969, revealing a layered sequence of sands, gravels and limestone breccias, and conglomerates. Most of the faunal remains were found in the upper calcareous deposits, and the bones are predominantly of large carnivores and rodents, with the latter deriving from owl pellets (Andrews, 1990). Through comparison with other dated paleontological sites in Britain, the Westbury fauna is thought to date to about 500000 years ago. The presence of flint artefacts and cut-marked animal bones indicate the presence of early humans at Westbury at this time.

Several other caves on the Carboniferous Limestone outcrop of the Mendip Hills have produced human remains and artefacts, although these mostly date from the late Upper Paleolithic and Holocene. In Cheddar Gorge, Gough's Cave and Sun Hole both contained Upper Paleolithic burials dating to about 14000 years ago. The human bones from Gough's Cave exhibited cutmarks, showing that the bodies had been defleshed, using stone tools, before they were buried. The nearby caves of Wookey Hole, 10 km to the southeast of Cheddar, include the paleontological sites of Hyaena Den (explored by William Boyd Dawkins in the 1850s), Badger Hole, and Rhinoceros Hole.

Creswell Crags, located on the county boundary between Nottinghamshire and Derbyshire, comprises a natural gorge and cave system within the narrow linear outcrop of Permian age Magnesian Limestone. Archaeological interest in the caves at Creswell Crags began in the 1870s, when Pin Hole, Church Hole, Robin Hood's Cave and Mother Grundy's Parlour were excavated by the Reverend J.Magins Mello (a local antiquary) and Thomas Heath (the curator of Derby Museum), who were provided with specialist advice by William Boyd Dawkins and Professor George Busk of the Royal College of Surgeons. Excavations continued at the caves in the 20th century, and the caves are now managed as an educational resource by the Creswell Heritage Trust.

The Creswell Caves have yielded important cultural and environmental remains dating from the Middle and Upper Paleolithic (approximately 100000 to 10000 years ago). Mousterian (Middle Paleolithic) and early Upper Paleolithic flint tools have been found in the caves, and Creswell Crags is the type site for the Creswellian Industry, a distinctive suite of late Upper Paleolithic ("late glacial") stone tool types that is found throughout northwest Europe. Robin Hood's Cave produced one of the very few genuine examples of ice age art found in Britain, an animal rib engraved with a drawing of a horse's head. This artefact, together with an engraved drawing of a human figure on another rib fragment from Pin Hole, have their closest affinities with portable engraved art found at late Upper Paleolithic sites in northern France and Belgium.

Victoria Cave, near Settle in North Yorkshire, is another site that was systematically explored during the second half of the 19th century. The cave was discovered by Joseph Jackson, an amateur collector, who brought the site to the attention of the Society of Antiquaries of London. Subsequent investigations were conducted in 1870 and 1878 by the Settle Caves Exploration Committee, working under the auspices of the British Association for the Advancement of Science and advised by a scientific panel that included some of the most distinguished geologists and archaeologists of the day. The excavation and recording methods employed at Victoria Cave were based on the innovative principles pioneered by William Pengelly at Kent's Cavern, and included the early use of photography to monitor the progress of the work. The excavations revealed a preglacial bone-bearing deposit sealed by nearly five metres of later sediments, and Victoria Cave is best known today as a paleontological site dating from the Ipswichian Period of the last interglacial, approximately 130000 years ago.

Ireland

Ireland's caves (Figure 2), like those in Britain, were intensively investigated in the late 19th and early 20th centuries, and much of the evidence for the colonization of Ireland by animal species from continental Europe has come from faunal remains recovered from caves. A large programme of radiocarbon dating of animal and human bones from Irish caves has recently been completed, clarifying the depositional history of many of the cave sites (Woodman *et al.*, 1997). In County Waterford the caves of Ballynamintra, Kilgreany, and Shandon have all produced Upper Pleistocene fauna, together with younger Holocene deposits, which at Kilgreany and Ballynamintra contained evidence of prehistoric human activity, including burials. In County Cork, Castlepook Cave and Foley Cave both contained Pleistocene fauna, with more recent Holocene fauna in the uppermost deposits. The Edenvale and Newhall/Barntick group of caves in County Clare has produced vast amounts of animal bone that was deposited in the late glacial and Holocene periods, and archaeological material is also present in these cave systems.

Natural caves and fissures in Ireland were used as burial chambers during the Neolithic Period—a similar practice to that observed in Britain (Chamberlain, 1996). Three separate examples of such burials have been discovered in County Limerick in caves and rock fissures at Annagh, Cahirguillamore, and Killuragh. Unlike the situation in Britain, caves continued to be used as burial sites in the early historical period (even after Ireland was Christianized) and there are also examples of medieval occupation debris, including charcoal, pottery, metalwork, and bone artefacts at several cave sites in Ireland.

BRITAIN AND IRELAND: BIOSPELEOLOGY

A relatively small number of hypogean taxa have been recorded in Britain and Ireland, compared to mainland Europe. The low number of troglobitic and stygobitic fauna recorded in subterranean habitats largely reflects the glacial history and post-glacial colonization of taxa. Despite some enthusiastic collection and recording of organisms from caves during the early and mid-20th century, little systematic biospeleological research has been undertaken in Britain and Ireland. Recent research has indicated that new discoveries are still to be made and that this largely neglected area of research may provide valuable information regarding the colonization of troglobitic/stygobitic taxa. However, a number of sites and populations of subterranean organisms are under threat

from human disturbance, and the need for active management and conservation of this important biological resource has only recently been recognized (Wood & Gunn, 2000).

A total of 46 troglobitic/stygobitic taxa have been recorded from Britain and Ireland (12 terrestrial and 15 aquatic, plus a further 19 interstitial forms). Collection of fauna from caves in Britain and Ireland began in the mid-19th century, although the primary period of active collection and recording was under the direction of the Biological Recorder of the Cave Research Group, Mary Hazelton, between 1930 and the late 1970s. Records for Great Britain were published in 15 parts, between 1938 and 1978, with a compilation of records for Ireland being published in a separate volume. Additional cavernicolous data has been summarized for specific limestone regions, e.g., northern England, Mendip, Peak District, and Wales. There are no stygobitic fish or amphibians in Britain and Ireland, although some populations of stygophilic fish may exist (Proudlove, 1982), and bat colonies have been recorded within a number of caves.

While the cave fauna of Britain and Ireland is relatively well known, the groundwater fauna of the large chalk aquifers, and hyporheic fauna associated with riverine gravels, has been poorly studied. It is likely that important discoveries will be made in these areas, particularly with regard to microcrustacea such as copepods and cladocera. The majority of freshwater organisms found in British and Irish caves are accidental occupants (e.g., larvae of Ephemeroptera, Plecoptera, and Trichoptera washed into caves), although some are stygophilic. The freshwater amphipod *Gammarus pulex* is often abundant in caves, and some populations are certainly stygophilic, displaying incipient troglomorphic characters such as reduced body pigmentation. Other taxa, such as the diving beetle, *Hydroporus ferrugineus* (Dytiscidae), are clearly stygophilic as adults, although the larvae have only been recorded in subterranean waters and may be stygobitic.

The majority of the freshwater stygophilic taxa in Britain and Ireland are Crustacea, although relatively little is known regarding subterranean Ostracoda, Cladocera, Copepoda, and other meiofaunal groups. The distribution of freshwater stygobitic taxa is strongly associated with the occurrence of carbonate rocks (see map), with numerous records from springs, wells, riverine gravels, and other groundwater dominated habitats. The most diverse hypogean group is the Amphipoda with six taxa in the genera *Niphargus* (five in Britain and two in Ireland) and *Crangonyx subterraneus* being recorded to date, with the most recent discovery (*Niphargus wexfordensis*) being made in 1980.

The biogeographic distribution of most cave-dwelling organisms generally reflects that of carbonate rocks and Pleistocene glacial episodes. However, two species, *Niphargus aquilex* and *Antrobathynella stammeri*, have been recorded some distance north of the last glacial maxima in England, as well as *Antrobathynella stammeri* from Scotland. Other taxa have also colonized areas that have been glaciated, such as *Proasellus cavaticus* and *Niphargus fontanus* (South Wales), *N. kochianus kochianus* (Norfolk and Cambridgeshire), and *N. kochianus irlandicus* (central Ireland).

The terrestrial fauna of British and Irish caves, and other subterranean habitats such as mines, is dominated by accidental and troglophilic organisms. In the threshold region, spiders of the genus *Meta* are common, as are two species of trogloxene moths (*Scolyopteryx libatrix* and *Triphosa dubitata*), which hibernate in the winter. The most important members of the terrestrial communities in the dark zone are Collembola, which act as consuming detritivores, and mites which are predators. More than 70 species of

Collembola have been recorded but only 15 are common, with the most frequently recorded being *Tomocerus minor*. Over 40 species of mites have been recorded, of which six are probably troglobites. Other common inhabitants are the isopod *Androniscus dentiger*, the mycetphilid fly *Speolepta leptogaster*, and the beetle *Trechus micros*.

The lack of research on British and Irish cave fauna, and the perceived paucity of aquatic and terrestrial fauna in caves, is reflected in the fact that none of the species currently have any

Britain and Ireland: Biospeleology: Map of Britain and Ireland indicating the distribution of selected freshwater hypogean taxa (*Antrobathynella stammeri, Crangonyx subterraneus, Niphargus aquilex, Niphargus* fontanus, Niphargus glenniei, Niphargus kochianus kochianus, Niphargus kochianus irlandicus and Proasellus cavaticus). The grey areas are outcrops of rock sequences that contain some limestone units and are therefore more extensive than the actual limestone outcrops or the areas of karst landforms.

form of statutory protection. Around 75% of cave passage in Great Britain lie within Sites of Special Scientific Interest, and 11 caves are recognized for their importance for hibernating bats, but none of the citations mention any cavernicolous fauna.

There is a long history of anthropogenic disturbance of subterranean ecosystems in Britain and Ireland, with clear evidence of bacterial contamination at some sites. Quarrying, changes in agricultural practices, waste disposal and groundwater abstrac tions all pose serious threats to the fauna of subterranean ecosystems. Many of the potential impacts to the communities that occupy British and Irish caves have been identified, including those associated with show-cave development and recreational caving (Gunn *et al.*, 2000).

Britain and Ireland have few obligate subterranean taxa and are biodiversity "coldspots" compared to many other karst areas. However, there are numerous troglophilic and stygophilic taxa and much has yet to be learned from the detailed study of the ecology and physiology of subterranean organisms. All obligate subterranean taxa were troglophilic in their evolutionary past, and the paths to obligation and troglomorphy may be revealed through the study of these organisms.

BRITAIN AND IRELAND: HISTORY

The earliest explorers of British caves in historical times were undoubtedly lead miners, who encountered natural "opens" in the course of their search for ore. A notable example is the exploration of Pen Park Hole in Gloucestershire, leading to the first survey of a natural cave ever to be published (Shaw, 1992, pp.14–15). Another early scientific reference to British caves is the account of a descent of Elden (*sic*) Hole, Derbyshire, by John Lloyd in the 1772 *Philosophical Transactions of the Royal Society*. Subsequently, early geologists, such as Adam Sedgwick (1785–1873) and Sir Roderick Murchison (1792–1871) came along. They were trying to form the big picture from the complex structures and strata that constitute the British Islands. They found caves with bones buried in silt, and thus the diluvial theory of a universal flood, which supported biblical teachings, persisted for a while. William Buckland (1784–1856) was its principal proponent, with findings in Kirkdale Cave in Northern England, after which he wrote *Reliquiae Diluvianiae* (Relics of the Flood) in 1823. He soon realized the errors of his thinking and came to appreciate the reality that caves simply sat there in the landscape "catching" things that went past and were in fact "museums"

Britain and Ireland: History: Survey of Pen Park Hole Gloucestershire, by Captain Grenville Collins, September 1682. First published in *Philosophical Transactions of the Royal Society*, 143, 1683.

of a changing surface topography. Although there was some exploration for its own sake and for tourism, cave sedimentology developed as the main interest in caves throughout the 19th century, with paleontology and archaeology being the principal themes. Édouard Martel (1859–1938) visited, and extended several of the best-known British and Irish caves in 1895, and this provided impetus for exploration, first in England and then in Ireland. The Yorkshire Ramblers' Club (YRC), founded in 1892, was thus activated by Martel's successful descent of Gaping Gill Main Shaft (110 m) and made a second descent the following year. It continued with the exploration of most of the open shafts of the Three Peaks area of the Northern Pennines each year, until war broke out in 1914. Harold Brodrick (1875–1946) led the YRC to follow in Martel's footsteps with explorations in County Fermanagh, from 1907. They started with the Boho block, Noon's Hole, Arch Cave (Ooboraghan) and Pollanafrin, and then moved south to the Marble Arch area in 1908. E.A.Baker, and members of the YRC, started to examine the County Clare limestone area in 1911, but it was the University of Bristol Speleological Society that made major discoveries from 1948 to 1970 (Tratman, 1969). Jack Coleman (1914– 71) was at the forefront of Irish cave exploration for many years and wrote what is still the only text on the caves of the whole of Ireland (Coleman, 1965).

Limestone hydrology attracted attention on Mendip, Somerset, with the Wookey Hole resurgence and its sink at Swildons Hole in 1901 (Baker & Balch, 1907). Herbert Balch (1869–1958) formed the Mendip Nature Research Committee in 1908 and they pursued the exploration of Swildons Hole. St Cuthbert's Swallet and Eastwater Cavern also drain to Wookey Hole but connections are not in prospect, there being an intervening deep and tortuous phreas. Wookey was, however, the birthplace of cave diving, with the pioneering activities of Graham Balcombe (1907–2000), Penelope Powell and Jack Sheppard from 1935 (see Diving in Caves entry).

The first comprehensive attempt to coordinate cave science and exploration in Britain came in 1935 when Eli Simpson (1884-1962), Leo Palmer (1891-1962) and other leading academics formed the British Speleological Association (BSA). They had observed the formation of similar bodies across Europe and strongly felt the need for this in Britain. During the war years, the BSA was held together by Eli Simpson (Craven, 2001), but unfortunately there were many personality clashes and although it struggled on as a "national" caving organization with regional groups it never regained its scientific or national credibility. From 1946, the position of a scientific caving society was filled by the Cave Research Group (CRG), which substantially coordinated British cave research through the publication of its Transactions and other scientific publications, together with British Caving. It was founders Aubrey Glennie and Mary Hazelton who jointly did much to foster the study of hypogean fauna in Britain. The CRG was blessed with some extremely competent cave surveyors. Lewis Railton (1907-71) set the benchmark for cave survey and presentation with the Ogof Ffynnon Ddu survey publication (Railton, 1953), and with Arthur Butcher set out a clear and well-defined basis for a range of techniques and presentation standards (see Surveying Caves entry). There was much duplication of effort and the two organizations merged to form the British Cave Research Association (BCRA) in 1973. Trevor Ford edited Transactions of the CRG and then BCRA for 30 years from 1965, for which he was awarded a Certificate of Merit by the National Speleological Society of the United States in 1995 and an OBE (Order of the British Empire) in 1997.

Exploration of the longest and/or deepest cave systems did not come until quite late in the day. Although the Gaping Gill-Clapham Cave System saw considerable attention from the YRC, the Yorkshire Speleological Association (1906–14) and many others from

the early days right through to the present, it has still only been connected by cave divers, with a current total length of 18 km. In the Northern Pennines, it was the Lancaster-Ease Gill System that came to be the most extensive, at 75 km. Exploration did not start until 1946, with the chance discovery of Lancaster Pot by BSA members, who attempted to establish an underground laboratory that was gated and locked. It did not function, but rather led to the fragmentation of the BSA and the formation of many new caving clubs (Eyre, 1989).

The biggest system in the Peak District is now Peak-Speedwell, which came together incrementally from the early efforts of the BSA in the late 1930s up to the present (see Peak District entry). Following the formation of the BCRA in 1973, the one remaining active group of the former BSA became the Technical Projects Group (later Technical Speleo Group, TSG) and it has continued to work on this complex system. With the discovery of "Titan" in 1999, it now boasts the tallest vertical feature in British caving (vertical range 219m).

There is a scattered area of Devonian reef limestones in south Devon. The caves of Higher Kiln Quarry, Buckfastleigh, Reed's Cave-Baker's Pit, have the distinction of being the most extensive in Britain, developed in pre-Carboniferous limestones—over 3 km. Many were rich in mammalian bone deposits; early excavations being carried out by Buckland and Pengelly. The latter was the inspiration for the establishment at Higher Kiln Quarry in 1962, of what is now the William Pengelly Cave Studies Centre (and Trust).

The geographical layout of the South Wales limestones as one layer in a huge depositional basin, where the cave bearing strata have been exposed by transverse fluvial activity at a number of isolated sites, has provided a complicated explorational picture. In the Swansea Valley, the South Wales Caving Club and its precursors worked first at Danyr-Ogof (1936–39) and then Ogof Ffynnon Ddu in the 1946–53 period. Major extensions to both of these systems were made in the 1960–80 period. Exploration of the Mynydd Llangattock area further east began in 1957, with the Agen Allwedd breakthrough. A complex system of as yet unconnected caves gradually came together with discoveries in Ogof Daren Cilau, Eglwys Faen, and Ogof Craig ar Ffynnon. The most recent phase in this region commenced in 1994, with the discovery of Ogof Draenen at the southeastern extremity of the limestone above Blaenafon. Exploration here by many caving clubs is still progressing and the system now exceeds 70 km (see Draenen entry).

In North Wales, there is a substantially concealed area of limestone where most caves are accessible only as a result of dewatering of the aquifers by lead mining activities. The Alyn River Caves were dewatered firstly by the Halkyn Deep Level and then by the Sea Level or Milwr Tunnel, which ceased driving in 1957. Further south, the three cave systems of Dydd Byraf, Llyn Du, and Llyn Parc are fragments of one extensive system first entered by lead miners. The North Wales Caving Club rediscovered these through persistent detective and exploration work throughout the 1970s and 1980s.

There are a number of scattered limestone outcrops across Scotland. Many of these contain relatively small caves, those of Assynt, Sutherland, being the most numerous, extensive and most thoroughly explored, with the Grampian Speleological Group being the chief activist since its formation in 1961.

BURIALS IN CAVES

Caves accessible to humans have been used from the Paleolithic to the present. They provide a variety of burial conditions, such as graves in the ground, body exposure on the floor, coffins exposed in selected places, storage of bones or pieces of bone in jars, and cremation urns. Habits have varied through time, and also according to the particular people, social status of the deceased person, position in the family, age, and cause of death.

In Mousterian times, and perhaps before, *Homo sapiens neandertalensis* buried their dead in caves and rock shelters such as Tabun Cave, Israel, dated to about 180000 years ago. The first discovery of a Neanderthal grave was in 1908 at La Chapelleaux-Saints Cave, Corrèze, France. In La Ferrassie, Dordogne, France, eight bodies were placed into man-made graves, given specific positions and covered with protective flagstones, artefacts, and earth mounds. Clearly, Neanderthal Man was conscious of death and life, as shown by his rituals. In Shanidar Cave, Iraq, the covering was pine branches and flowers (see Shanidar Cave, Iraq: Archaeology), and in Teshik-Tash Cave, Uzbekistan, a boy's body was circled with ibex horns. Archaic *Homo sapiens sapiens* were also given offerings, as in Qafzeh, Palestine, that indicate belief in a life after death. The reality of

Mousterian burials has been questioned by a number of authors, such as Gargett (1999). Though their comments bring an interesting insight into the necessary fossilization processes, deliberate burial could be confirmed in most of the cases.

Dordogne caves have provided evidence of burials for nearly every prehistoric period. Some caves were repeatedly used, as for instance, Rouffignac (Neolithic, Bronze, and Iron Ages), or Déroc Caves (Late Neolithic and Chalcolithic).

Burial habits evolved, from mainly collective exposure on the floor during the Neolithic, with up to a hundred bodies in a single cave; partial (accidental, sometimes ritual) burning of bones; graves in the cave floor (Mousterian, Bronze Age); ash deposits near gallery walls after cremation (appearing during Late Bronze II Age); bone storage after flesh removal (Late Bronze Age); body exposure on wooden platforms, as in La Fontanguillère (Bronze Age) and Foissac Caves (Lot, France, Chalcolithic Age); or apparently little use (during Iron Age before Tene III, perhaps because of widespread cremation). In some caves, body remains lie on flowstones or clayey ground subsequently covered with calcite, for instance Early Iron Age remains at Palabres Cave (Lot, France). Some people occasionally hid themselves in caves, but were smoked in with wood fires at the entrance and so died.

The cave environment and noticeable cave features were taken into consideration, probably in relation to belief or specific interest. Late Bronze Age ashes from cremation in Rouffignac Cave entrance were placed in galleries with Magdalenian wall paintings. Wooden platforms in La Fontanguillère and Foissac Caves were located above a permanent stream, perhaps in relation with a water cult or to signify a route to the realm of the dead. At different periods variable artefacts, pottery, and offerings were placed besides bodies.

Comparable habits existed elsewhere in the world. In Vietnam, for instance, a few caves and rock shelters were possibly used for burial during Lower Neolithic Hoabinhian II-III and three caves, Pho Binh Gia, Khéo-Phay, and Lang Cuom, revealed skulls of people of the Bacsonian culture. In the latter, skulls were rubbed with red ochre; 80 to 100 individuals were present—probably a secondary burial. Children's skulls were used as funeral urns or trophies. Many caves with Upper Neolithic remains are very rich in burial-related attributes.

In Laos, Mesolithic—and perhaps older—human remains were found in Tham Pong. A Lower Neolithic burial was uncovered in that cave (an adult on its back) and in Tham Hang South, where six bodies, including three lying on their back on an ash blanket, were placed parallel to the cave wall. Upper Neolithic burial possibly existed in Tham Hang. Burial in karst fissures of Khammouan karst, sometimes associated with pottery, lasted up to 400 to 300 BC. These burials are similar to some modern burials as in Sagada (see below) and suggest a possible use of coffins. Undated, relatively young coffins are also found in the area.

Hardwood coffins are common in nearly 100 caves of the Mae Hong Son and Kanchanaburi areas of Thailand (200 BC800 AD) (see also Asia, Southeast: Archaeological Caves). Many of these caves have a difficult access and the coffins themselves are stored in inaccessible locations, such as on ridges or ledges, some even being placed horizontally on pole systems. The coffin shapes vary and their length may exceed 2 m. Associated items include glass beads, ceramics, and metal objects.

Caves in the Southeast Asian islands, such as Borneo (Malaysia, Indonesia) and Palawan (Philippines), offer similarities with the mainland and make the link with modern times. Borneo's Niah Cave delivered a 38000 years old *Homo sapiens* skull, tree trunk Neolithic coffins dated 2460±70 years BP, 1000-year-old boat-shaped coffins, together with many other burials. More coffins are found in several areas of Borneo, as in Sabah State, the upper reaches of Mahakam River, and recent ones in Mulu karst (e.g. Cave of the Winds).

Palawan caves in the Tabon area have demonstrated human presence for at least 45000 years, including the Tabon Man (22–24000 years BP) and long time burial habits. In the Early Neolithic, a flexed male body in Duyong Cave was placed face down in a grave, with associated earrings and tools (2680 \pm 250 BC). From *c*. 1500–1000 BC in the Late Neolithic, to the 14th century AD, jars offered primary and secondary burial, though skulls were sometimes buried separately.

Jars, covers, vessels, and other items are sometimes very numerous: there being up to 200 in the single-chambered Tabon Cave (200–500 BC)—with glass beads, as in Thailand, and lime containers, probably for betel chewing; more than 500 such items in Tadyaw Cave, with iron tools of the advanced Metal Age (100 BC to 300 AD); more than 78 in Manunggul Cave, many of Late Neolithic (890–710 BC) and Early Metal Age (190 BC), including pottery covers showing a ship of the dead and one trunk-shaped pottery coffin 73×34 cm large for secondary burial. Bone painting with haematite occurred during the Neolithic and Early Metal Age (from *c*. 1500 to 1000 BC, to *c*. 190 BC) and gradually disappeared before the 13th century AD.

In rare narrow caves, bodies were put into maceration on the ground, probably wrapped in a mat. Skull burial, supine position (primary burial), and bone bundles (up to seven persons) were also observed.

All sites were chosen for their beauty or magnificent scenery. Jars were often placed in the daylight, or sometimes in dark chambers decorated with beautiful stalagmites. Nearly all burial caves in the Tabon area face the sea at various elevations (115 m in a sheer cliff at Manunggul), as do burial caves in the Palawan El Nido area and in southern Luzon. Jars are usually placed along walls, occasionally protected by stones, leaving space for new jars or ritual gatherings (cult-of-the-dead), or in the centre and at the rear of the cave.

Also in Palawan, two bodies and funeral attributes were placed one century ago in a cave of Balagbag Cliffs. In Lungun Cave, a 1.15 m long hardwood log coffin (700–1000 AD) closed with pegs, was placed high above a small stream; iron tools and some pottery were found inside. A beautifully carved, 2.24 m long, wooden boat-coffin was found on a cliff ledge (13th or 14th century).

Wooden coffins are found in several mountain areas of South east Asia, especially in Luzon, Philippines, and Sulawesi, Indonesia. In Kabayan, northern Luzon, more than 20 caves are packed with hollowed tree trunks containing mummies in a foetal position, that are up to 400–500 years old. Bodies were rubbed with a medicinal plant decoction and smoked during long funeral rites. Carved coffins, such as a water buffalo-shaped coffin made of fine wood, were reserved for elite people. Skulls and bones are stored in some caves.

In Sagada, northern Luzon, cave and cliff burial is still occasionally performed. More than 50 sites exist, mainly on the karst fringe close to villages. Coffins are exposed on the cave floor, ledges (high above a cave stream in Matangkib Cave), horizontal poles, or

placed in fissures, because locals believe that the souls of deceased adults are able to move and must be left free to do so. Selecting a future coffin location takes into account kinship, deceased person's quality and social role, and the availability of suitable locations. Infants, children, and women who died in childbirth are buried outside.

Coffins are traditionally made up of hollowed pine logs with a lid, and closed by vine ties or pegs. Occasionally, lids were carved (lizard, a symbol of felicity), pegs as well: they were reserved for highly appreciated persons. Normally no offering is placed in coffins. Bodies are commonly given a foetal position. Recent coffins are often nailed wooden planks and bear bodies laying on their back. A few burial jars have been discovered.

There can be no long time between death and body transfer to the burial site. The rituals to bring the corpses to the caves are by tradition rather strict. No sharp noise must occur during the body transfer to the coffin already placed in the cave, which explains why selected caves or cliffs are not distant from the village. Once all required sacrifices are completed, the deceased person is considered as definitely departed to another world.

In Tanah Torajah, Sulawesi, log coffins are placed in caves (or man-dug underground chambers) after long ceremonies, with numerous sacrifices. Selected caves are located at ground level or at various elevations on karst slopes. Some are accessible by long bamboo ladders used for one burial only. Rituals during coffin carriage to the burial site are less strict than in Sagada and loud noise is common. Coffin shaking and irregular loops are made, so the soul cannot remember the way back to the village. Then the coffin is quickly carried to its final place. The dead has now attained the status of an ancestor and a statue of him is placed near the burial place, facing the realm of the alive. Children cannot access this status and so are usually buried in hollowed trees. Recent to present burial caves are also known in Papua New Guinea, in Lifou Island, and nearby New Caledonia, in Tahiti and Marquesas Islands, Easter Island, and Patagonia (Alakaluf Indians).

In the United States, cave burials have been found for example in western Kentucky. In Salts Cave, the flexed mummy of a 9 year old boy (dated at 10 BC to 30 AD±160 years) was found high upon a ledge, desiccated by the dry, cool atmosphere. In Short Cave, mummies of a baby, an adult sitting in a stone grave with offerings, and a flexed or sitting adolescent, were all dressed with deerskins. In Mammoth Cave, a flexed female body was buried in an oval grave lined with burned grass or fibre matting. Burnt bones were uncovered separately. Short and Salts Caves revealed primary burials of people defleshed for this purpose. Ashes mixed with animal and human bones were found in crevices near the entrance (and also inside Salts Cave). Bones from foetuses to adult individuals were very abundant, with marks of defleshing (questionably burial rituals or cannibalism), and many were partly burnt—probably accidentally. Some ornaments and tools, and many fabrics were present. The remains are likely to belong to several Indian or close populations.

In eastern Kentucky, Ash Cave was used for primary interments of female adults and children; it also contains layers of ashes and vegetal remains with many fabrics. In Tennessee and Missouri, primary and secondary burials have been uncovered in caves. Burnt bones, stone slab graves, and pottery were found in Miller's Cave, Missouri.

Burial caves are known in South and Central America, for instance in Maya areas of Central America. In Brazil, 8–10000 year old remains of the Lagoa Santa Man were found in Sumidouro and other caves in Minas Gerais, and 40000 year old human remains in rock shelters of Piaui State.

Africa also has burial caves, e.g. of Dogon people in Bandiagara Cliffs of southern Mali.

Cave burials exist because favourable natural sites, adequate beliefs, and necessity are present at the same time. It is remarkable that this habit has lasted since Paleolithic times and that similarities are found in different locations and cultures. Although a variety of ritual uses of caves do still occur, burials are gradually disappearing under the pressure of Christianity and westernization of indigenous cultures.

BURREN GLACIOKARST, IRELAND

The Burren plateau of northwest County Clare is the finest example of a karstic terrain in Ireland. The landforms of the Burren have been strongly influenced by glacial and periglacial processes, as well as by purely solutional, karstic processes, and in this respect the landscape resembles that of the Yorkshire Dales karst in England, with extensive areas of limestone pavement.

The Burren is bounded to the west and north by the Atlantic Ocean and Galway Bay, respectively. The southern boundary is where the limestone passes beneath younger shale and sandstone of Namurian age. This corresponds to a line from Corofin to Kilfenora to Lisdoonvarna to the coast at Doolin. The eastern limit of the Burren is the foot of the scarp at an altitude of approximately 60 m, which extends from Corranroo Bay in the north to Kilnaboy in the southeast (Figure 1). The area defined above is some 360 km² in extent and forms a gently inclined plateau at 200–300 m above sea level in the north and 100–150 m above sea level in the south, bounded by steep scarps on all but the southern

flank. Only isolated summit areas exceed an altitude of 300 m and the highest point is the shale-capped Slieve Elva at 344 m. To the west, the three Aran islands are, in many respects, an extension of the main Burren.

The Burren karst is developed in Carboniferous limestones, with some 500 m of limestone succession exposed. Differing characteristics of the limestones are reflected in landforms and in hydrology throughout the Burren. For example, the Maumcaha Unit, 70 m in thickness, with few joints or bedding planes, is overlain by a 140 m thick strongly bedded sequence of limestones (the Aillwee unit), and underlain by a similar sequence, some 150 m thick. The massive unit forms steep, uniform slopes or cliffs, whilst the bedded units form tiers of stepped terraces, particularly on the northern flank of the Burren overlooking Galway Bay

The uppermost stage of the limestone is the Brigantian Slievenaglasha Formation, characterized by more coarse-grained rocks than the main Burren Limestone, and incorporating numerous nodules or sheets of chert between the limestone beds. The chert seems to function in a similar manner to the shale

Burren Glaciokarst: Figure 1. Major depressions and seasonal lakes within the Burren Karst, Ireland.

layers, as an important control on the groundwater movement, and to an extent on landform development. Resting unconformably on the Brigantian limestones, are the Namurian sequence of calcareous shales, phosphatic shales, siltstones, and sandstones. In the western Burren, the Namurian rocks reach northwards to form the uppermost part of the hills of Slieve Elva and Knockauns, while the adjacent hill of Poulacapple is capped with a thin outlier of Namurian shales.

The rocks of the Burren are tilted to the southsouthwest with dips of 1–5 degrees over much of the area, with gentle asymmetric folding along northnortheast southsouthwestern axes, only becoming apparent in the eastern Burren. Two major joint sets, oriented approximately north—south and east—west, occur over the whole area, their relative dominance and spacing varying locally. The slight inclination of the rocks over most of the Burren plateau forms an extensive dip-slope, mainly of Slievenaglasha Limestone, declining gradually in altitude from north to south and contrasting with the steep north-facing scarp slope.

The karst of the Burren has developed as the overlying Namurian strata have been stripped away by fluvial and glacial action, exposing the limestone to solutional erosion. In the past, as now, the contact between the acidic, impermeable Namurian rocks with surface rivers and the limestone, was a zone of intense karstification. Removal of the Namurian strata has extended westwards and southwards and so the oldest karsts are those of the northern and eastern Burren, whilst the youngest are those at the present shale—limestone contact in the Lisdoonvarna—Kilfenora area.

Annual precipitation on the Burren averages approximately 1500 mm, of which 1000–1100 mm becomes recharge. Point recharge via sinking streams is largely confined to the contact between the overlying impermeable Namurian rocks and the limestone in the west and southwest of the Burren. Elsewhere, recharge is diffuse and hence caves are uncommon. Underground drainage is strongly influenced by the geology. Numerous layers of clay, shale, and chert interbedded with the limestones, act as barriers to the vertical percolation of rainwater and encourage sub-lateral flow of water, particularly along bedding partings. The final outlet for the Burren groundwater is via peripheral springs located at hydrological lows, such as the River Fergus valley and the littoral or submarine springs on the Atlantic coast and Galway Bay, or at the contact with the overlying Namurian rocks to the south of the Burren. The springs on the west (Atlantic) coast occur up to 500 m offshore and at depths of up to 15 m below sea level.

Enclosed depressions, the diagnostic landforms of karst regions, are abundant: more than 1500 such features, exceeding 100 m² in floor area, occur on the Burren plateau, together with several hundred smaller hollows. One-third of the depressions exceed 1000 m² in area. The greatest concentration of enclosed depressions is in the central and eastern parts of the plateau, with a smaller clustering between Slieve Elva-Knockauns Hill and the coast. Only one-quarter of the enclosed depressions are circular in form, the remainder being elongate to some extent, with some 15% resembling sections of gorge or trench, rather than conventional dolines. The dominant orientation of the enclosed depressions is parallel or sub-parallel to the direction of ice movement during the last glacial advance (north-south) and glacial erosion may have enlarged many depressions and accentuated their elongation.

Burren Glaciokarst: Figure 2. Terraced limestone pavements on the nearly horizontal limestones of Slieve Carran. (Photo by Tony Waltham)

In the central Burren are two very large enclosed basins, sufficiently large to be described as poljes or large uvalas, with a combined area of c. 16 km², enclosed by the 125 m contour. The Carran depression has an area of 9 km², extends to an average depth of 30 m below the surrounding plateau surface, and contains a stream fed by springs, which sinks at the southern end of the depression. In wet conditions, the swallow hole is unable to cope with the inflow of water and a lake forms in the depression, even though the floor of the basin is more than 70 m above the water table. To the west of the Carran depression, is the slightly smaller enclosed basin of Kilcorney-Meggagh, with a total floor area of 7 km².

Limestone pavements, or decayed pavements with surfaces of loose limestone slabs, cover 20% of the Burren plateau and northern flank (Figures 2 and 3). A further 30% of the plateau surface consists of a mosaic of bare rock and patches of thin rendzina soils. The best pavements develop where the dip of the rocks is low and where this dip corresponds to the slope of the

Burren Glaciokarst. Figure 3. Limestone pavement at Sheshy More. (Photo by John Gunn)

ground surface. Pavements are found on all the limestones of the Burren, but are particularly well developed on the highest beds of the Brigantian, near the contact with the Namurian strata.

Along much of the Burren coastline, and especially on the western Atlantic facing shore, limestone bedrock is exposed on the foreshore. Between high and low tide levels, a distinctive suite of karren, mainly kamenitza, has developed in response to erosion of the limestone, by a combination of biologically driven dissolution and direct erosion by marine organisms (see Coastal Karst).

The great majority of extensive cave systems on the Burren are associated with streams that sink at, or close to, the contact between the limestone and the overlying Namurian shales and sandstones, and are therefore active stream caves. Many of these caves have developed in the north-south joint systems and are oriented north—south down the dip of the strata. Such caves are commonly developed within a single bedding plane for long distances, typically perched above a chert-rich horizon, and occasionally stepping down one bed or more via a vertical drop. The caves are linear or dendritic in plan view. The passage form of these caves typically comprises a wide, low roof section of enlarged bedding plane incised by a narrow trench or canyon that contains the stream. The trench is typically 0.3–3 m wide but may be up to 30 m deep. Passage cross sections are therefore typically T-shaped.

Some of these caves (e.g. Polldubh) are simple, single stream conduits, in which the morphology and dimensions of the cave passage are obviously related to the present day stream and may be of Holocene age. Others have a more complex morphology, with abandoned sections of passage, oxbows, and offset meander belts at different heights above the active stream route, together with calcite and sediment accumulations, for example, the Pollnagollum and Doolin systems. The longest cave known is Pollnagollum, with more than 14 km of passages surveyed. Some three other caves exceed 5 km in length and a further 17 exceed 1 km in length. Vertical development in the caves is limited, with the exception of Poll na gCeim (130 m deep) and Faunarooska Cave (95 m deep)

There are also caves of presumed great age, often in locations wholly disjuncted from the present-day hydrology. Examples of such caves are Vigo Cave and Aillwee Cave. Sediment infills are widespread in these caves, ranging in type from complex bedded sequences of fine sediments (e.g. Pol-an-Ionain and Aillwee Cave) to extensive sand deposits of unknown origin, as in Glencurran Cave. Pol-an-Ionain also contains the largest stalactite in the British Isles (7 m; Self, 1981).

The age of the Burren caves has not been thoroughly investigated, but limited evidence from U-series dating of calcite specimens suggests that the simple stream passage caves may be of Holocene age, whilst the more complex stream caves may originate from at least last interglacial times (120–132000 years ago). Dates from Aillwee Cave suggest an age considerably greater than half a million years.

CALCAREOUS ALPS, AUSTRIA

About one sixth of the surface of Austria is comprised of karstified rocks (see map in Europe, Alpine entry), and some 14000 caves had been surveyed as of 2001. More than 90% of these caves occur within the Northern Calcareous Alps, but there are also notable areas of karst and caves in the Central Alps (e.g. see entry on Spannagel Cave) and in the Southern Calcareous Alps. The great economic significance of these karst terrains is illustrated by the fact that many major cities in Austria are supplied by high-quality karst-derived drinking water. The geological history and evolution of large cave systems in the Eastern Alps of Austria has traditionally been attributed to successive phases of uplift since the Tertiary, subsequently modified by the pervasive Pleistocene glaciations. Recently, Frisch *et al.* (2001) elaborated this model further by combining structural and thermochronological data. According to their model, major cave formation commenced during the Late Miocene under climatic conditions significantly different from the present, and continued throughout the Pliocene and the Quaternary.

The western karst plateaus of the Northern Calcareous Alps, west of the Salzach River, include the massifs of the Leoganger Steinberge, the Steinernes Meer, and the Hagengebirge. In the Leoganger karst, Lamprechtsofen was until 2001 the world's deepest explored cave (-1632 m). It extends from the high plateau down to the Saalach River with a surveyed length of nearly 50 km, and emerges as a water cave where the final part is developed as a show cave. East of the Saalach River, the more extensive plateau of the Steinernes Meer (which translates into English as "rocky sea") contains the Kolkbläser-Monsterhöhlen system with a measured length of 44 km and at least four genetically different passage series. In the Hagengebirge, the major caves are Tantalhöhle (34 km long) and Jägerbrunntroghöhle (30 km long, 1078 m deep). East of the Hagengebirge, the deeply entrenched Salzach River has created a local relief of nearly 1500 m, which is crucial for the latest evolution of the subsurface karst.

Tennengebirge is a major karst plateau, some 20 km southeast of Salzburg. It has more than 700 known caves, including some of the longest in Austria; Eisriesenwelt is one of the largest ice caves in the world, with a surveyed length of about 40 km. The Tennengebirge, like most of the other plateaus of the Calcareous Alps, is composed of thick Upper Triassic Dachstein Limestone, locally with steep dips. As a result of this thickness, in conjunction with successive uplifts and periods of stability, the massif has recorded all of the karstification phases, now laid out as recognizable cave horizons. The evolution of the Tennengebirge is clearly shown in Figure 2 by the morphology of the Cosa-Nostra-Bergerhöhle system (Audra, 1994). Karstification began during the

Oligocene, beneath a cover of gravel deposits, known as Augensteine (1), which were progressively stripped from the Lower Miocene onward. During the Miocene, deep karst conduits developed, thanks to the input of major drainage from the non-karstic alpine ranges, which fed into the tectonically controlled networks (2). These horizontal levels, developed during periods of tectonic stability, have been layered by successive phases of uplift (3). The oldest and highest (~2100 m), still to be found among old Tertiary cones (Kuppen), corresponds to the Ruinenhöhlen (4), cavities which are currently being destroyed by erosion (including Hornhöhle). At altitudes of 1500–1700 m, large labyrinthic networks occur (5), known as the Riesenhöhlen (the giant-cave level, e.g., Eisriesenwelt). Following a major uplift during the Pliocene, torrential runoff from the Central Alps could no longer reach the karst systems of the Northern Calcareous Alps. Subsequently, vertical passages developed as a result of the increase in hydraulic head (6), and their formation accelerated during glaciations under the influence of local ice caps and the Salzach glacier.

The Cosa-Nostra-Bergerhöhle system includes several generations of cave networks. The entrance of the Cosa Nostra Cave is a tubular gallery of Miocene origin containing reworked weathered sediments (7). The remaining parts of the system are of Pliocene and Quaternary origin. The shaft zone, as much as 750 m deep in places (6), is then linked to the Bergerhöhle-Bierloch tubular horizontal network (8). During the Pliocene,

Calcareous Alps, Austria: Figure 1.

Ice-scoured limestone surfaces with massive rinnenkarren on the Rofangebirge, one of the western massifs of the northern Calcareous Alps. (Photo by Tony Waltham)

the valley floor was at an altitude of about 1000 m, and the karst system was fed by sinking streams, transporting Jurassic pebbles into the caves (9). Following the lowering of the water table, the caves became vadose, and the clastic sediments were then overlain

by a first generation of large flowstones bearing a reversed paleomagnetic polarity (i.e., older than 780000 years). During the glacial periods, the deeper parts of the system were episodically flooded up to over 600 m high, and deposition of carbonate-rich varves occurred, dated as younger than 780000 years by their normal paleomagnetism. These varves cover older sediments. The bottom of the network is linked to the 700 m high phreatic zone (10), which corresponds to a structural barrier. During high stage, water pours into the Brunnecker Cave, where the discharge finally emerges at the present 500 m high base level of the Salzach River (11). Brunnecker Cave contains granite pebbles originating from old Salzach glacial deposits, and these are responsible for the canyon and pothole morphology. At present, a second generation of less abundant flowstones (one has a Th/U date of 5200 years BP) is developing in the Bierloch and Brunnecker Caves.

The eastern karst plateaus include the Totes Gebirge (with the largest area of high alpine karst in Austria) and the Dachstein massif (with the highest peak of the Northern Calcareous Alps at 2994 m). The three longest caves in Austria are Hirlatzhöhle (87 km) and Dachstein-Mammuthöhle (58 km) in the Dachstein, and Raucherkarhöhle (79 km) in the Totes Gebirge, and there are many other significant caves such as DÖF-Sonnenleiterschacht (16 km, -1054 m) and Schwarzmooskogeleishöhle Gebirge (54 km, -1030 m). It is notable that the vadose and epiphreatic zones of some of these caves are already reaching the modern base levels and resurgence levels. Nevertheless, the base flow even of the large karst springs in this area is dominated by small joints rather than by cave passages (Pavuza, 1998). Together with the Eisriesenwelt (in the Tennengebirge) the Dachstein-Rieseneishöhle, and to some extent the Dachstein-Mammuthöhle, represent the rare type of perennial ice caves that contain large underground glaciers. The ice of the Dachstein Caves is surprisingly young, as ¹⁴C dates on organic debris from the ice base yielded an ice age of not more than 800 years. This implies that these caves became icefree at least once during the Holocene. Currently a distinct decline of the ice bodies can be observed (Mais & Pavuza, 2000). On the plateau surface, the extensive karren landscapes emerged after the retreat of the last Pleistocene glaciers some 10000 years ago. Ongoing measurements (using limestone tablets) indicate that surface corrosion rates are about 100 mm/10 ka, which correspond well with the heights of the uneroded basements of the limestone pedestals.

CANADA

Karst rocks are widely distributed around the central Precambrian Shield in Canada (Figure 1). In outcrop, there are \sim 500000 km² of limestone and marble, 600000 km² of dolostone, and 80000 km² of evaporite rocks, a total similar to China, where the world's most extensive karstlands are found. Along the southern and western fringes of the shield, these rocks occur as thin, little disturbed sedimentary veneers of Paleozoic age, dominated by shallow marine, lagoonal, and reefal facies, and passing beneath younger sandstones, shales, and clays downdip. To the east and north, deposits are thicker, more varied, generally folded and faulted. The Western Cordillera contains thick sequences of shallow marine, reefal, and lagoonal facies, plus deeper marine rocks on the west coast. These mountain ranges are Cretaceous—Tertiary in age, with some uplift and deformation continuing today.

Modern ecoclimatic conditions on the karst range from coastal rainforest to high alpine and polar deserts. The southern interior has a continental climate, with moderate precipitation and cold winters. Permafrost is widespread in central regions and continuous in the north.

Almost all of Canada has experienced repeated glaciations, including general submergence under Laurentide Continental and Cordilleran ice sheets during the last (Wisconsinan/Weichselian) glaciation. Effects of glaciation have been chiefly destructive or inhibitive—erasing, dissecting, and burying karst landforms, and clogging aquifers and caves with injected detritus. "Outcrop" is something of a misnomer in much of the lowlands, because the karst bedrocks are buried under many metres of glacial till, outwash, etc. and are often hydrologically inert. However, in suitable conditions, glacial deposits may also preserve karst aquifers and enhance their productivity, while the most rapid rates of cave development anywhere probably occur around glacier margins during the melting stages (Ford, 1987).

To the north, permafrost becomes progressively thicker and more continuous, restricting karst by limiting groundwater circulation to the seasonally thawed zone or to leakages (taliks) into sub-permafrost groundwater. There is little modern development along the Arctic mainland coast or in the islands, where "felsenmeere" (tracts of frost-shattered rubble) are predominant. Some limestone karren and epikarst groundwater flow are reported where hydraulic gradients are steep (e.g. Akpatok Island) and a few shallow dolines and sinking streams lie in gypsum and salt exposed in diapirs.

The Canadian Shield

The Shield is chiefly composed of igneous or metamorphic rocks unsuited to karstification, although dolines are reported in a carbonatite (calcium carbonate igneous rock) in Ontario. Thick marbles in the southern shield in Ontario and Quebec contain some postglacial "shortcut" caves through narrow ridges and a few older phreatic relicts. In the Belcher Islands, Hudson Bay, pavements and small dolines occur on some younger Proterozoic limestones that escaped metamorphism.

The St Lawrence and Western Interior Platforms, Hudson Bay Lowlands

These lowlands are remnants of the general cover of Paleozoic carbonate and evaporite rocks deposited over the worn-down shield. Strata dip gently away from the shield, forming wide plains edged by low but steep escarpments facing inwards. The combination of low relief and widespread burial by glacial deposits limits modern karst to narrow zones of higher hydraulic gradient, such as crests of escarpments or river gorges.

Anticosti Island is wholly carbonate, with relief up to an altitude of 300 m, and an exceptionally strong master joint set. Most formations are thin-bedded and shaly, however, restricting development to shallow epikarst. Thicker limestones, in the Salmon River basin, support a holokarst with deep kluftkarren, desiccated string bogs, and spectacular stream-sinks.

There are many local features between Quebec City and the Ottawa Valley; Boischatel, St Casimir, and Bonnechere are notable postglacial stream caves (Beaupre & Caron, 1986). Beneath and alongside the Ottawa River are ~10 km of "textbook" anastomosing bedding plane passages forming today, with fierce currents and accessible only to divers. Limestone terrain between Lake Ontario and Georgian Bay in Ontario is notable for extensive tracts of shallow pavement, with distinctive alvar ecology.

Niagaran dolostones form a ~50 m escarpment extending 900 km from New York State, through Niagara Falls, the Bruce Peninsula, and Manitoulin Island in Ontario, to the Door Peninsula of Wisconsin. Karren pavements are common along the scarp crest, broadening into peninsulas of holokarst between glacial breaches locally. Attractive sea caves and coastal karren are found along the Great Lakes shores and there are short mazes and stream caves elsewhere.

The Hudson Bay Lowlands are a muskeg (peat bog) terrain on glaciomarine sediments burying carbonate rocks. The land

Canada: Figure 1. The outcrop of limestone, dolostone, and sulfate rocks in Canada and the subcrop of the Prairie salt.

is still rebounding vigorously from glacial loading. Karst is seen in small gypsum outcrops and where rivers entrench the rising land. Resistant bioherms (organically derived rock mounds), surrounded by moats of dolines, rise like castles above the muskeg, draining it to the nearest gorge.

In Manitoba, the platform consists of ~400 m of dolostone, minor limestones, and gypsum. The city of Winnipeg rests on a glaciolacustrine clay plain that buries and preserves >400 km² of dolostone pavement, converting it into a productive aquifer. Between Lake Winnipeg and Lake Winnipegosis are tracts of doline karst, some serving as snake hibernacula. Quite exotic is the Lake St Martin impact crater (Jurassic) filled

with lagoonal gypsum, that now hosts many short caves (McRitchie, 1991). There are extensive, shallow pavements north of the lakes.

South of the Great Slave Lake there is an area of 50000 km² underlain by >850 m of carbonates and evaporites. In the south, the Athabasca Tar Sands (the largest known oil deposits) are partly accumulated in paleokarst traps. Further north, Wood Buffalo National Park contains the most extensive gypsum karst in Canada, chiefly suffosion dolines where there is only glacial till on the gypsum, and larger collapse dolines with a thin cover of dolostone. Known caves are few, becoming water-filled or blocked by ice. There are large regional springs (blueholes) with high salt contents (Ford, 1997). West of the park is Pine Point, a remarkable Devonian doline and cavernous paleokarst that trapped important lead/zinc deposits: Quaternary glacial loading rejuvenated some of the dolines.

Beneath much of Alberta and Saskatchewan, the Devonian Prairie Salt is >200 m thick where not thinned by dissolution, >500000 km² in extent, and buried 200–2500 m beneath later carbonate and clastic rocks. The eastern (up-dip, shallow) edge has receded by an average of 130 km westwards, as a consequence of interstratal solution. More than 100 breccia pipes, and larger solution troughs up to 360 km² in area, are known in Saskatchewan and Alberta. Many of these are linked to effects of glacial loading and recession, although the surface expression is very muted (Anderson & Hinds, 1997).

Atlantic Region

The Great Northern Peninsula of Newfoundland has tracts of limestone pavement and well-developed coastal karst despite the fact that sea ice is fast to the shore for four or more months each winter. The Goose Arm karst displays >250 m of relief, conical hills, and large closed depressions in steeply dipping Ordovician limestones and dolostones. It is interpreted as a cone karst, highly modified by glacial erosion and disruption of groundwater flow.

Further south in Newfoundland, Nova Scotia, and New Brunswick, the karst is chiefly of collapse and suffosion dolines in thick, locally deformed, gypsum and anhydrite, buried by glacial deposits. Densities are up to 100 km^2 and the largest individuals are >500 m in diameter. Where the overburden is thin there are patches of "schlottenkarren" (solutional funnels 0.5–1.5 m in diameter, tightly packed together). Caves are short, with much breakdown. In the Gaspe Peninsula, Quebec, narrow bands of steeply dipping limestone display some modern karst drainage and three ancient caves modified by glacial action.

The Western Cordillera

This area comprises the Rocky Mountains of Alberta-British Columbia, coastal and interior ranges, Vancouver Island and the Queen Charlotte Islands in British Columbia, the Mackenzie Mountains and Franklin Mountains in the Northwest Territories, and outlying ranges in Yukon Territory. The majority of Canada's known caves, including all of the longest and deepest, are found in this large region, as well as the most accentuated surface karst features. The southern Rockies and Vancouver Island are the most intensively explored areas.

The southern Rockies extend 950 km from Crows Nest Pass, to Mt Bocock, near Fort St John. Eastern (Front) ranges are composed chiefly of thick Paleozoic carbonates

overthrust on Mesozoic clastic rocks, creating steep narrow cuestas. "Main" ranges are broader, with thick carbonates overlying massive quartzites that contain thin limestones. The mountains are sculpted into classic alpine glacial forms. Some hundreds of cirques and U-shaped valleys display karst drainage. There are major karst depressions overdeepened by glacier scour. The best development occurs on plateaus or benches above deep entrenchments. Pavements, shafts, all types of sinkholes, and relict caves are found, draining to major springs in the valleys (Ford, 1979).

The greatest density of known caves is around Crows Nest Pass, a deep entrenchment that attracts strike-oriented karst drainage from north and south. The topographic Continental Divide (between drainage to the Atlantic and Pacific) is breached by Yorkshire Pot (14 km of passages, 390 m deep) and Gargantua (Figure 2; 6 km long, 290 m deep), two excellent examples of alpine multiphase caves with phreatic loops. Between Banff and Jasper, Castleguard Cave (see separate entry) extends beneath the Columbia Icefield, and is therefore a classic feature of glaciokarst.

The Bow Valley is noted for Banff Hotsprings, a major thermokarst discharge via small caves, and Ratsnest Cave (4 km long, 245 m deep), another multiphase complex with evidence of many episodes of glacial flooding. Near Jasper is the Maligne River, the largest-known sinking river in Canada. Its catchment of 2300 km² drains into a polje, Medicine Lake, where the waters pass underground for 16 km, descending ~400 m to springs aggraded by glacial deposition. Mean discharge is ~13 m³ s⁻¹, maximum >45 m³ s⁻¹. Underground flowtime is as short as 11 hours during floods (Smart, 1988). In the Main Ranges west of Jasper, the Mural Formation is a thinner limestone between quartzites. Where it dips steeply, the deepest Canadian cave, Arctomys, has developed as a staircase of vadose potholes descending to a siphon at a depth of 536 m (Rollins, 2002). Where it is more level, at Small River, there is a model sub-glacier karst.

North of Jasper there is active exploration but few studies. Plateaus near Bastille Mountain, at Moon River, and in the Dezaiko Range, are reported to contain hundreds of dolines, many caves, and resurgences. "Close to the Edge" is a window into a spectacular shaft, 254 m deep. The most northerly discoveries are short caves in a 45 m thick Triassic limestone near Mt Bocock (Rollins, 2002).

The best karst development in the interior of British Columbia occurs in narrow, steeply dipping bands of marble, i.e. "stripe karst". Nakimu Caves (4.5 km long, 270 m deep) and the Mt Tupper system in the Selkirk Mountains are the most spectacular, channelling alpine meltwaters in roaring cascades. Further north, near Prince George, there is Fang Cave, another dynamic river system.

Canada: Figure 2. The ancient phreatic tubes of Gargantua Cave are truncated in the limestone cliffs beside the Ptolemy Meadows in the high Canadian Rockies; the main entrance to the cave is reached by a traverse across the lower snowfield. (Photo by Tony Waltham) The Franklin Mountains and Mackenzie Mountains lie, respectively, east and west of the Mackenzie River, between the latitudes of Great Slave and Great Bear Lakes. They are very extensive and scarcely inhabited. The Franklins and eastern half of the Mackenzies (the "Canyon Ranges") are composed of thick Paleozoic carbonate formations with much gypsum, anhydrite, and salt. The Franklins contain many large dolines, where dolostone and other cover rocks have collapsed into gypsum. Around the west end of Great Bear Lake, van Everdingen (1981) mapped ~1400 dolines, 27 larger compound features, and 63 major springs. This is at the discontinuous—continuous permafrost transition. Dolines diminish in frequency further north.

South Nahanni & Bear Rock Breccia

South Nahanni (see Nahanni entry) is a spectacular karst in the southern Mackenzie Mountains and the Bear Rock Breccia (see Bear Rock Karst entry), 450 km further north, supports another significant karst. Between them are small patches of Nahannitype corridor karst with springs and caves, a moraine-dammed polje, and some large karst depressions and pavements on dolostones.

Yukon Territory

In Yukon Territory relict caves, a sinking river, and several large perennial springs (icings) are known in limestones in the remote Ogilvie Mountains, a region that escaped glaciation (too dry) but has continuous permafrost. The caves are important as refugia and because of massive, relict speleothems attributed to late Tertiary (pre-permafrost) conditions (Lauriol *et al.*, 2001).

Vancouver Island and the Queen Charlottes

This area has the most dynamic modern karst settings in Canada. The principal karst rock is a fine-grained marine limestone up to 800 m in thickness, underlain and overlain by volcanics and partly metamorphosed rocks. It crops out from sea level to an altitude of 2000 m, mostly in steeply dipping, strike-oriented mountain ranges. Intense glacial erosion has suppressed development of large surface karst features, although there are a few big, ice-modified, closed depressions. Some peaks reach the alpine tundra but most limestone slopes are covered by coniferous forests. Precipitation ranges from 1500 mm a^{-1} at sea level up to a possible 5000 mm or more at the summits.

The principal surface karst landforms are abundant karren and small dolines. Hundreds of caves are known, the majority being explored only for short distances because of constrictions, sediment blockages, or siphons. However, five of the ten longest and deepest Canadian caves are on Vancouver Island, including Arch-Treasure Cave (~8 km), and Thanksgiving Cave, 400 m deep. Speleothems are abundant, chiefly of calcite and post-glacial in age. There are mammal and bird remains in entrances and a few instances of low-lying caves being used for interments. Clear-cutting forest practices have substantial impacts in some karst areas, chiefly soil erosion and cave sedimentation (Harding & Ford, 1993).

CANARY ISLANDS: BIOSPELEOLOGY

The Canary Islands support an interesting, highly endemic invertebrate fauna, and are an excellent model for understanding island evolution. The subterranean environment includes a rich fauna that has evolved independently of that occurring on the adjacent African mainland; all species are locally endemic and some belong to unexpected animal groups.

The archipelago is located in the northeast Atlantic between 27°37′ and 29°35'N, and 13°20' and 18°10'W. There are seven main islands aligned from east to west: Lanzarote, Fuerteventura (the nearest to Africa, 110 km), Gran Canaria, Tenerife, La Gomera, La Palma (the most distant, 460 km), and El Hierro. They are all of volcanic origin and were built up from the sea floor. In consequence they have never had subaerial contact either to
each other (except Lanzarote and Fuerteventura) or to the mainland. The eastern islands, Lanzarote and Fuerteventura, are the oldest (15-21 Ma) and the age diminishes towards the western islands, El Hierro being the youngest (<1 Ma). The most probable geological origin is explained by the hotspot theory, where successive volcanic islands form as tectonic plates move over a stationary hotspot in the mantle, though volcanic activity has started again in some of the older, eastern islands, and stopped in some western (La Gomera) each one following independent cycles according to its stage of erosion, which alternately activates and stops volcanic periods (Carracedo *et al.*, 1998).

The climate is subtropical, strongly influenced by the humid northeast trade winds, which combined with the altitude and the northwest dry winds, produce an inversion layer and marked vegetational zones. The eastern islands are lower and much drier, but the central (Tenerife 3714 m) and western islands are high and more humid, especially on their north slopes.

There are volcanic terrains of acidic and basaltic nature, the latter being more extended and suitable for the development of subterranean habitats. The most abundant caves are lava tubes, formed only in pahoehoe basaltic flows, but there are also volcanic pits and a network of voids and cracks, which together with the mesovoid shallow substratum (MSS, or terrestrial interstitial habitat) also form habitats supporting hypogean fauna. Lava tubes usually collapse or become silted within a few hundred thousand years, thus only persisting in relatively young parts of the islands and being almost absent on Gran Canaria and La Gomera where there has hardly been any recent vulcanism. The richest islands in such caves are Tenerife (131 recorded tubes and pits), Lanzarote (30), La Palma (70), and El Hierro (35). The longest cave systems are Cueva del Viento (17.5 km) and Cueva de Felipe Reventón (1.9 km) in Tenerife, Cueva de Don Justo (6.5 km) in El Hierro, and Cueva de los Verdes (6.5 km) in Lanzarote. However, richness of adapted cave fauna does not depend on the extent of the caves, but on their environmental conditions; thus lengthy but dry caves such as Cueva de los Verdes have no terrestrial troglobites at all, while the small Cueva de los Roques (Tenerife) holds 24 troglobitic species, 4 of them endemic to the cave.

Terrestrial troglobites have evolved locally and are exclusive to each island, or even to a part of an island if underground barriers prevent such animals dispersing. The Anaga peninsula of Tenerife developed as an independent island that joined to Tenerife when this grew about 2 Ma ago; many genera are repre sented by different, vicariant troglobitic species in Anaga and in the rest of the island, but never overlap their distribution (Oromí & Martin, 1992). When such barriers do not exist, the same species can be present in distant, apparently isolated caves on the same island, because the network of cracks, and especially the MSS, allow dispersion even in terrains lacking tubes. As a result of this phenomenon, very recent lava tubes like Cueva de Todoque (formed in 1949) in La Palma have already been colonized by troglobites. Even on islands without suitable caves (Gran Canaria and La Gomera) there are fauna adapted to the MSS (Medina & Oromí, 1990).

Lanzarote has abundant lava tubes, but has a dry climate with scarce soil cover making most caves almost sterile, with no adapted terrestrial fauna known so far (Martin, 1989). The situation in Fuerteventura is much the same except for Cueva del Llano, a humid cave where two troglobites occur: the longlegged spider *Spermophorides fuertecavensis*, and the harvestman *Maiorerus randoi*, a unique species of the suborder Laniatores in the

Canaries (see Figure 1). Dry lava tubes are occupied mainly by lavicolous species such as the cricket *Hymenoptila lanzarotensis*. The aquatic fauna, especially that of anchialine habitats which are widespread in Lanzarote, is much richer. Jameo del Agua and Túnel de la Atlántida are remarkable caves for both their large dimensions and their fauna of marine origin, with at least 19 stygobitic species. These include the abundant polychaete worm *Gesiella jameensis* and the anomuran crab *Munidopsis polymorpha*, a tourist attraction in the show-cave of Jameo del Agua. The anchialine waters of Lanzarote harbour the richest assemblage of misophrioid copepods in the world, with at least six endemic species belonging to five different genera, two of them monotypic and one, *Palpophria aestheta*, being the single representative of the family Palpophriidae. Other crustaceans of special interest are *Stygotantulus stocki* (Tantulocarida), *Halosbaena fortunata* (Thermosbaenacea), *Heteromysoides cotti* (Mysidacea), *Spelaeonicippe buchi* (Amphipoda), and the only

Canary Islands: Figure 1. *Maiorerus randoi* (Opiliones: Phalangodidlae), the only species of a relictual, endemic genus with no relatives in the Canary Islands. It is unique to a cave in Fuerteventura island. (Photo by Pedro Oromí)

remipede species known so far from the eastern Atlantic: Speleonectes ondinae.

Tenerife is by far the richest island both in lava tubes and hypogean terrestrial fauna, its species generally being more troglomorphic than in other islands. As many as 64

troglobites are known to date, some with their ancestral epigean equivalent species still living on the surface; this is the case for the millipedes Glomeris sp. and Dolichoiulus spp., the centipedes Lithobius speleovulcanus and Cryptops vulcanicus, the wood louse Venezillo tenerifensis, and the planthopper Tachycixius lavatubus. Others are relict species without extant surface ancestors on the archipelago. For example, the spider genus Canarionesticus (1 sp.); the ground beetles Wolltinerfia (3 spp.), Canarobius (2 spp.), and Spelaeovulcania (1 sp.); and the weevils Oromia (2 spp.) are all endemic genera including only troglobitic species. The range of underground niches together with long timescales and geological features such as underground barriers and other isolating mechanisms have promoted several cases of adaptive radiation: the spider genus Dysdera has seven troglobitic species on the island (most of them being sympatric), and the Loboptera cockroaches include 11 species (mostly allopatric with different degrees of adaptation to the underground; see Figure 2). Tenerife and other western islands are remarkable for the variety and abundance of rove-beetles occurring in subterranean habitats, many of them highly troglomorphic: Alevonota (6 spp.), Ocypus (2 spp.), Domene (see Figure 3; 5 spp.), and Medon (2 spp.). Since lava tubes in the Canary Islands have no permanent water streams or pools, stygobites occupy only phreatic waters and constitute a poor fauna compared to that of terrestrial habitats. In Tenerife 15 hypogean crustaceans have been recorded; among them the copepods Parastenocaris (2 spp.) and the amphipods Pseudoniphargus associatus and Rhipidogammarus mivariae are found in freshwater habitats, and the remaining seven crustaceans occur in brackish underground waters.

The westernmost La Palma and El Hierro are the other islands with abundant hypogean fauna. Possibly due to the islands' younger age their troglobites are less evolved, and very often the genera colonizing the underground are much the same in these two islands but different to those of Tenerife: *Cixius* and *Mee*

Canary Islands: Biospeleology: Figure 2. *Loboptera troglobia* (Blattaria: Blattellidae), the bestadapted cockroach to cave life among

11 cave-dwelling species of this genus in the Canary Islands. (Photo by Pedro Oromí)

noplus (planthoppers), Trechus, Thalassophilus, Licinopsis, and Parazuphium (groundbeetles), Laparocerus and Baezia (weevils). Furthermore, some species belong to higher groups never found in other caves of the Canaries and even of the Palaearctic, such as terrestrial sandhoppers (Amphipoda), earwigs (Dermaptera), or thread-legged bugs (Hemiptera Reduviidae). The terrains are geologically young and the prevailing MSS is of the volcanic type (Oromí, Medina & Tejedor, 1986), which holds an abundant fauna made up of local ambimorph species of Loboptera, Licinopsis, Trechus, and Alevonota. In La Palma most of the 31 recorded troglobites are spread all over the island, except two cockroaches (Loboptera spp.) and four planthoppers (Cixius spp.) which are clearly allopatric, a feature also observed in other islands for these groups of insects. They can be considered as local relicts together with the long-legged bug Collartida tamausu, the planthopper Meenoplus claustrophilus, and the rove-beetles Domene benahoarensis and Alevonota (3 spp.), since no epigean relatives are known on the island. However, other animals like Dysdera ratonensis, Licinopsis angustula, Trechus benahoaritus, and Laparocerus zarazagai have ancestral species on the surface of La Palma. Other nonrelictual species are included in groups which have very few troglobites worldwide: the *earwig Anataelia troglobia* which sometimes occurs in the same cave as its epigean relative *A. lavicola*, and the sandhopper *Palmorchestia hypogaea* belonging to a local genus with another representative living in the forest. Only two aquatic species are known from La Palma, both found in brackish interstitial waters: *Pseudoniphargus multidens* and *P. upicola*.

The hypogean fauna from El Hierro includes 19 troglobites, many of them belonging to genera also represented in La Palma by vicariant species. The cockroach *Loboptera ombriosa* is the most widespread troglobite in the island, showing a cline of morphological adaptations from big, red-brown individuals in the north to smaller yellowish ones in the extreme south. Distributional patterns of other species also indicate differences between the El Golfo area at the northwest covered by humid forests, and the rest of the island with pine forest and drier bushland. Three ambimorph ground beetles of the genus *Licinopsis* are found: *L. picescens* in caves and MSS of El Golfo, and *L. obliterata* and the more adapted *L. schurmanni* in the rest of El Hierro. The most troglomorphic animal on the island is the thread-legged bug *Collartida anophthalma*, a relict belonging to a genus from Central and Eastern Africa with the only troglobites on the Canary Islands. The aquatic fauna is scarce and limited to brackish interstitial waters, where two amphipod crustaceans have been found: *Pseudoniphargus salinus* and *Ingolfiella canariensis*.

The caves on El Hierro are generally well preserved but on La Palma and Tenerife some caves have open, easy access and in these there has been damage to speleothems, graffitti on the walls, and accumulation of rubbish. But probably the worst problem is pollution due to domestic waters poured into some caves, in which the adapted fauna has disappeared and alien opportunistic species invade the subterranean environment.

The only inhabited lava tube on Fuerteventura endures continuous alterations and pressure from politicians to become a show cave, which would be the epitaph for the unique *Maiorerus randoi*. An EU Legal Instrument For the Environment (LIFE) project on conservation of the cave habitat was carried out from 1999–2001, but it only concerned the caves located in public protected areas of three islands (Fuerteventura excluded). A study on the current hypogean fauna compared to that recorded 20 years ago, an inventory of the bat species and populations and their underground roosts, and an accurate analysis of the increasing factors of environmental damage were performed for 50 caves in Tenerife, La Palma, and El Hierro. The final report also included a proposal for a sewage network for the area of Cueva del Viento, as well as every necessary action for better conservation of other deteriorated caves. In spite of the initial interest by the Canary Government on this subject, no signs of continuity are evident and none of the recommended actions have been completed; in the meanwhile, this unique fauna remains threatened.

CAPE RANGE, AUSTRALIA: BIOSPELEOLOGY

Cape Range is the only Tertiary orogenic karst in Australia and supports one of the world's richer subterranean faunas. The fauna occurs in three parts, separate terrestrial faunas in Cape Range proper, on its coastal plain, and a relict fauna, largely of Tethyan origin, occurring in the anchialine groundwater of the coastal plain (see map in Australia entry).

Cape Range is an anticline of Eocene/Miocene marine limestones and forms a peninsula projecting northward into the Indian Ocean on the mid-west coast of Australia. To the west the peninsula is the closest point in Australia to the continental shelf, while to the east it abuts the vast North West Shelf. The peninsula is fringed by a coastal plain and exhibits a series of raised wave-cut terraces to the west. The range rises to an altitude of

330 m and is dissected by gorges which cut through the highly karstic Tulki Limestone into the underlying and marly Mandu Limestone. The gorges thus form a discontinuity in the karst which serve as a barrier to dispersal of the subterranean fauna. In addition the marl retains a groundwater layer at which the caves develop laterally. More than 600 caves are known, mostly vertical solution pipes, with or without collapse, to 100 m depth and similar lateral extent. Five caves within the range reach water and one has extensive development (>6 km) near the water table.

Cape Range lies just within the tropics and experiences an arid climate (mean annual rainfall 284 mm, pan evaporation 3219 mm) in which the episodic rainfall is largely torrential. Consequently, caves may dry continuously for 1–2 years before being rewetted. The vegetation is largely tussock grass (*Triodia*) with areas of *Acacia*, *Eucalyptus*, and *Banksia*.

Although Cape Range is now an arid area, far removed from rainforest, the area has a relict rainforest fauna with both temperate and tropical elements. The diverse subterranean fauna encompasses both terrestrial and aquatic ecosystems and is entirely endemic to the range. It includes at least 30 highly troglomorphic species, among them the most troglomorphic cockroach in the world (*Nocticola flabella*) in which only the mouthparts and genitalia are heavily sclerotized. Characteristic taxa include myriapods (centipedes, millipedes), arachnids (micro-whipscorpions, pseudoscorpions, scorpions, spiders, mites), insects (beetles, cockroaches, crickets, planthoppers, japygids), and crustaceans (slaters). A subfamily of pseudoscorpions (Indohyinae) confined to the circum-Indian Ocean region is represented in the cave fauna (*Hyella*), and there are at least six endemic genera, the micro-whipscorpion *Draculoides*, nemobiline cricket *Ngamarlanguia*, pseudoscorpion *Hyella*, paradoxosomatid millipede *Stygiochiropus*, a japygid dipluran, and a ctenid spider. The only aquatic taxon known from the range is an endemic genus of melitid amphipod (*Norcapensis*).

Allozyme analysis has shown that the southern two-thirds of the range contains three distinct genetic provinces, which are largely separated by areas of deep gorges. Even within these provinces *Stygiochiropus* millipedes mostly do not interbreed even between adjacent caves. Within the northern part of the range a suite of distinct species is recognized.

On the coastal plain and flanks of the range a related but quite distinct troglobitic fauna is present. Access is very limited due to sparse surface openings and much information has been derived from bores drilled for limestone resource assessment. A notable attribute of this fauna is the presence of six troglobitic species in three genera of micro-whipscorpions (Schizomida), a seventh, *Draculoides vinei*, being confined to the caves in range proper.

The coastal plain is fringed with the only continental anchialine system known in the southern hemisphere. These near coastal groundwaters, affected by marine tides, typically exhibit highly stratified physicochemical properties (see Anchialine Habitats entry). The characteristic fauna occurs below a thermohalocline and hydrogen sulfide layers, in conditions low in oxygen and supporting chemoautotrophic energy fixation. It is mostly accessed through traditional and later pastoral wells and recent bores, although several caves access this habitat including Bundera Sinkhole, a site globally notable for its fauna (Humphreys, 1999). The anchialine ecosystem contains the only blind cave fish in Australia, a gudgeon (*Milyeringa*), and a swamp eel (*Ophisternon*). Most of the

remaining taxa are crustaceans and include halocyprid ostracods, harpacticoid, cyclopoid, calanoid, and misophrioid copepods, atyid shrimps (two species of *Stygiocaris*, sympatric in places), cirolanid isopods, remipeds, thermosbaenaceans, melitid, bogidiellid, and hadziid amphipods, and bathynellid syncarids. A number of other higher taxa are represented including turbellaria and polychaetes (Humphreys, 2000a,b).

Cape Range, Australia:

Biospeleology: Some subterranean animals from Cape Range. In rows from top left: 1. The millipede, Stygiochiropus communis; 2. Nocticola flabella, the world's most caveadapted cockroach; 3. Lasionectes exlevi, the only member of the Class Remipedia known from the southern hemisphere; 4. Unnamed blind philosciid isopodp; 5. Bamazomus vespertinus, one of seven species of micro-whipscorpions known from Cape Range; 6. Stygiocaris stylifera, an atyid shrimp inhabiting groundwater of the coastal plain; 7. Glennhuntia glennhunti, a harvestmen endemic to the coastal

plain; 8. *Halosbaena tulki*, the only member of the Order Thermosbaenacea known from the southern hemisphere; 9. *Milyeringa veritas* (Eleotridae), one of two cave fishes sympatric on Cape Range. (Photos by Douglas Elford)

This fauna is notable because its affinities principally lie with the fauna from anchialine caves on either side of the North Atlantic. This relationship is supported by numerous congeneric (*Halosbaena, Haptolana, Lasionectes, Danielopolina, Liagoceradocus, Stygocyclopia, Speleophria*) or closely related species (endemic genus *Bunderia*). These lineages occur on the full "Tethyan track" (Stock, 1993), that is, they occupy that part of the ocean that contained congruent epicontinental seas in the Mesozoic (between 200 and 60 million years ago). These "Tethyan" lineages probably have a long stygal history, i.e. restricted to subterranean realms, following vicariant events resulting from the movement of the tectonic plates during the Mesozoic. This fauna includes the only southern hemisphere representatives of the Class Remipedia, the Orders Thermosbaenacea and Misophrioida, and the genera *Danielopolina* and *Haptolana* (Humphreys, 2000b).

About a quarter of the Cape Range karst province lies within Cape Range National Park. However, many of the most significant sites lie in areas of active resource exploitation or with resource potential under active pursuit. Water is abstracted from karst aquifers to supply Exmouth town and military facilities (airforce and naval communications bases) and the rapid growth of tourism attracted largely by the long Ningaloo fringing reef on the west coast. Nearly 100 km² are under limestone mining or exploration tenements and there is active petroleum exploration. A number of the terrestrial (e.g. *Hyella* sp., *Stygiochiropus* spp.) and aquatic subterranean species (e.g. *Milyeringa veritas, Ophisternon candidum, Lasionectes exleyi*) are listed under threatened species legislation or are recognized as belonging to endangered communities. Amongst the latter are Camerons Cave, within the Exmouth townsite, and Bundera Sinkhole which lies in a bombing range reserve. The World Heritage potential of Cape Range has been noted independently for its karst features and its subterranean fauna.

CARBON DIOXIDE-ENRICHED CAVE AIR

Carbon dioxide (CO₂) is a colourless, odourless gas, which tastes acidic. Most caves have air enriched with carbon dioxide, although in the majority of cases this is only slightly above the average surface atmospheric concentration of 0.04 volume/volume (v/v)%. Carbon dioxide in aqueous solution is a critical component in both the solution and precipitation of speleothems and the solution of limestone. In addition, an elevated level of CO₂ in cave air can be an indicator of pollution in the cave or in its catchment. Thus, it is important to understand how this gas is generated and distributed in caves.

To elucidate the sources of CO_2 and its distribution and movement, both spatially and temporally, within caves, it is necessary to conduct experimental studies. Identification of the CO_2 sources requires measurement of both CO_2 and oxygen (O_2) levels, together with measurement of humidity, temperature, and pressure. Analysis of trace gases, for example hydrogen sulfide and methane, can give additional information as to a CO_2 source. Early methods for the analysis of cave air are reviewed in James (1977). For CO_2 studies in wild caves, Dräger or Gastec gas analysers are recommended, as these instruments are portable, robust, and versatile, enabling O_2 and other gases to be measured in addition to CO_2 . Modern methods of measuring air quality are described in the entry on Tourist Caves: Air Quality. Smith (1996) lists the simple CO_2 tests available to the exploration caver.

There are three distinct types of CO₂ enrichment in cave air (James, 1977):

Type I: The addition of CO₂ to cave air with dilution of other air components

This type of CO_2 enrichment of cave air is common, particularly in caves containing active speleothems. As cave waters precipitate calcite, CO_2 is liberated and can degas from solution into the cave atmosphere. In general, the elevated level of carbon dioxide produced in this manner is low and the associated oxygen depletion is modest. Hence, the atmosphere in well-decorated areas is not hazardous. For example, in Tommy Grahams Cave, Nullarbor Plain, Australia, a chamber between two siphons has a measured CO_2 level of 4.0 v/v%. The CO_2 source is degassing of carbonate water, hence the depletion of O_2 (0.8 v/v%) is barely discernible. In contrast, Hanimec Cave, Slovakia, sometimes has a CO_2 level of 36 v/v%, mainly due to volcanic emis sions, and calculations show that the O_2 depletion would be in the order of 17.5 v/v%.

Type II: The replacement of O₂ by CO₂

This type of CO_2 enrichment is due to respiration by the flora and fauna in caves. A respiratory quotient of one implies that one molecule of O_2 is replaced with one molecule of CO_2 . However, the respiratory quotient varies with the organic material being utilized by the organism and can be as low as 0.7. Type II processes can occur within the cave or in soil above the cave; in the latter instance, CO_2 enters the cave atmosphere by barometric pumping. It is not possible to distinguish these sources from each other.

Type III: Cave air in which there has been depletion of O_2 without an equivalent increase in CO_2

There are many mechanisms leading to Type III cave air, including addition of nitrogen, methane, or hydrogen sulfide to the residual fraction or the removal of O_2 by non-respiratory processes. The table lists caves with Type III CO₂ and possible causes of the Type III atmosphere (James & Dyson, 1981).

Carbon Dioxide-Enriched Cave Air: Caves with Type III CO_2 and possible causes of the Type III atmosphere.

Cave	Cause
Tlamaya Cave, Mexico	Anoxic mud (natural)
Odyssey Cave, Australia	Iron bacteria (natural)
Lower Kane Cave, United States	Oxidation of sulfides (natural)
Kacna Jama, Slovenia	Waste from a paper mill
Sinkhole Plain caves, Kentucky, United States	Domestic and industrial waste

Halbert (1982) recommended the use of Gibbs triangle to categorize CO_2 -enrichment in cave air. The triangle can be generated for dry air or, if temperature and humidity are measured, modified for moist air. It is particularly useful when the CO_2 -enriched cave air is composed of a mixture of types. For example, both natural and anthropogenic Type III processes are often associated with micro-organisms, which at the same time generate Type II CO_2 -enriched cave air. Carbon stable isotope studies can assist in the identification of CO_2 sources and have been used with great success by Klimchouk and

Jablokova (1989), who were able to distinguish between aerobic microbial CO_2 production (Type II) and anaerobic microbial CO_2 production from methane (Type III).

The concentration of carbon dioxide is lowered in the cave atmosphere by three major mechanisms: (1) by diffusion of the gas into air with a lower CO_2 concentration; (2) by advection, that is, air currents carrying and venting it from its source; and (3) by solution in water; CO_2 can be dissolved in dripping or condensation waters until they are saturated with it. In caves with streams, floods or periods of steady rainfall can completely clear the gas.

Carbon dioxide, if sufficiently concentrated, can be a hazard to explorers in caves regardless of rock type. The physiological consequences of the combined effects of increased CO₂ and associated depleted oxygen (O₂) are discussed in James, Pavey & Rogers (1975). It is critical for cavers to be able to detect the presence of hazardous CO₂ levels. A number of papers (Renault, 1972 & 1979; James & Dyson, 1981; Ek & Gewelt, 1985) are available to exploration cavers that assist in predicting in which caves, where in them, and under what conditions hazardous levels of CO₂ may occur. It is pertinent here to dismiss the myth that this heavier-than-air gas sinks to the cave floor and ponds. The mixing of CO₂ with air occurs spontaneously by diffusion. The separation of CO₂ from a gas mixture via the reverse process is not possible under cave conditions. As a general rule, the greatest enrichment of CO₂ will be near to its source.

CARBONATE KARST

The carbonate rocks, limestone and dolostone, are the principal hosts of dissolutional caves and karst landforms. Although significantly less soluble than sulfates and salt, they are much more widespread at the Earth's surface and underground, and usually have greater thickness. Limestone is more important than dolostone because of its greater solubility. On every scale, it hosts greater varieties of karst landforms, cave patterns, and morphology than are found in other rocks.

Limestone is composed of calcium carbonate (CaCO₃), deposited as the minerals aragonite and calcite. Aragonite has an orthorhombic atomic structure, forming crystals with acicular, prismatic, or tabular shapes, with a density of 2.95. Sr^{2+} and

Carbonate Karst: Figure 1.

Composite facies model to illustrate deposition of limestone, early dolostone, and evaporite rocks. This is a generalized, simplified picture. Not all facies will be present in any given transect. Narrow belts range from a few metres to a few kilometres in width, wide belts from hundreds of metres to more than 100 km. Modified from Wilson, 1974. Ba^{2+} are common substitutes for Ca^{2+} atoms in the lattice. Calcite is trigonal, with massive, scalenohedral, or rhombohedral crystals, with a density of 2.71. Mn^{2+} , Fe^{2+} , and Mg^{2+} may substitute for Ca^{2+} . Over geological time spans, aragonite is unstable, with most of it inverting to calcite.

The common environments for limestone deposition range from the deep sea to supratidal mudflats or marshes overwashed by storm waters (Figure 1). Shallow platforms, sheltered lagoons, and open shelves are most common (Scholle, Bebout & Moore, 1983). Limestone forming in such environments is composed of aragonite or calcite marine debris such as shell and skeletal fragments, faecal pellets, and precipitates in algal mats, with interstices partly filled with carbonate mud ("micrite"). Popular petrological classifications by Folk (1962) and Dunham (1962) give textural details. The deposits accumulate in regular layers ("beds") separated by minor discontinuities marking disturbances, such as an influx of clay during a storm. Bedded limestones can range from single beds within sequences of clastic rocks such as sandstones or shales, to continuous carbonate deposits up to five kilometres in thickness. Most karst is developed on and in limestones 10–1000 m in thickness.

Coral reefs and other mounds, such as carbonate sand dunes, make a small but distinctive volumetric contribution to the world's limestones. Reefs range from frameworks tens to hundreds of metres in height composed of successive coral generations, to carbonate sand piles with scattered, isolated corals and algal mats. The earliest mats ("stromatolites") are >3.4 billion years in age; there have been successors in the record ever since.

Most limestones contain some proportion of insoluble impurities, chiefly silicate sands and clays, which increase the closer deposition is to river deltas or other sources of terrestrial detritus. There is a continuous gradation in nature from (nearly) pure carbonates to sandstones, etc. with carbonate cements, as shown in Figure 2. Most karst develops where there is >90% limestone or dolostone but it is occasionally found on impure carbonates or even on calcareous sandstones. More than a few percent of clay inhibits most development because it clogs the initial dissolution channels.

Diagenesis is a term describing processes of compaction and/ or cementation of the initially unconsolidated carbonate mud and debris (Moore, 2001). Very young rocks may harden quickly where raised above sea level and exposed to rainfall that dissolves surficial material and reprecipitates it in the interstices below: for example, in the Bahamas, carbonate sand dunes of the last interglacial (125000 years ago) are now hard rocks with good karst and caves. However, most limestones have experienced

deep burial and compaction. Part of the dissolved load is precipitated from sea water as it is expelled, cementing the debris with coarse calcite crystals, "sparite". A rock may be fully recrystallized during the process, destroying much or all of its original fabric and fossils. At depths of several kilometres much of the limestone itself may be dissolved, leaving insoluble residues concentrated along highly irregular solution surfaces termed "stylolites". Marine silica skeletal debris is dissolved and reprecipitates as nodules or layers of chert ("flintstone") in the limestone. These processes reduce the bulk porosity of the rock from initial values greater than 40% to 5%, or less in most instances, at which the beds become essentially impermeable. Rocks with lesser diagenetic alteration and consequent higher porosity such as chalk (15–40%) tend to develop poor karst and few caves because of the dispersal of the dissolutional attack.

Dolostone is a major product of diagenesis. It is composed of the double carbonate mineral, dolomite (CaMg·2CO₃) and has a hexagonal structure, forming rhombohedral, massive, or sugary (saccharoidal) crystals, with a density of 2.85. Some dolomite is precipitated directly, usually in evaporitic lagoonal or supratidal settings. Most, however, is created whexn Mg-rich sea water passes through earlier aragonite and calcite deposits, dissolving and reprecipitating them, with Mg²⁺ substituting for up to half of the Ca²⁺ ions. Dolomitization may be complete, altering an entire formation, or affect only particular beds within it, or merely patches within a bed. Reefs are particularly prone, due to their greater porosity. Presence of dolostone is most important in cave and karst landform development because the mineral is much less soluble than calcite. The majority of dolostones may develop karstic (dissolutional channel) drainage given sufficient time but caves large enough for human entry are quite rare. Dolostone beds often function as aquitards. Surface landforms are more limited in type and scale.

Metacarbonate (Marble) is produced when limestone or dolostone are metamorphosed by heat. With mild heat (low-grade metamorphism) smaller grains and outer surfaces of larger ones become annealed. With higher grade there is complete melting followed by recrystallization upon cooling, producing a dense, homogeneous rock of low porosity that is ideal for sculpture. Small natural sculptural features such as dissolutional karren and scallops attain their sharpest form on fine marble.

Carbonatites are intrusive igneous rocks composed of 60–90% carbonate minerals, chiefly calcite. They are very rare but a few instances with dolines and caves are known, for example in Precambrian Shield rocks in northern Ontario, Canada (Bell, 1989).

Fissure frequency: In most limestones and dolostones the effective permeability is controlled by penetrable bedding planes, contacts, and joints (products of deposition and diagenesis), and/or by later faults (Klimchouk & Ford, 2000). Density of joints is inversely proportional to thickness of the host beds. Bedding thickness may vary considerably within or between carbonate formations. Those with only thin (<10 cm) or medium (<30 cm) bedding tend to develop poor karst because (as with chalk) the dissolutional attack is widely dispersed. Thick (>30 cm) to massive (>100 cm) bedding with joint separations of 100–300 cm are the most suitable for full cave and karst development, although "sandwich" sequences of a few thin beds between massive ones are also effective. Metamorphism may seal earlier bedding planes and joints, which inhibits karst development in many marble formations. A notable exception is the Nordland marble stripe karst of Norway (see Stripe Karst).

CARBONATE MINERALS: PRECIPITATION

The primary reason for precipitation of calcite is loss of carbon dioxide leading to supersaturation. This entry explains the chemical processes involved. The precipitation of calcite from supersaturated $H_2O-CO_2-CaCO_3$ solutions can create spectacular tufa deposits, such as the sinter terraces of Pamukkale, Turkey, or the Huanglong Ravine in China (see entries on Pamukkale and Huanglong and Jiuzhaogou). The reaction is also responsible for the production of speleothems in cave environments. To understand how these processes operate over geological timescales, it is necessary to know the rates of calcite deposition. Precipitation from a supersaturated solution can be described by the rate law of Plummer, Wigley & Parkhurst (1978) (known as the PWP equation):

$$R = k_4(\text{HCO}_3^{-})_s(\text{Ca}^{2+})_s - k_1(\text{H}^{+})_s$$
(1)

 $- k_2(H_2CO_3^*)_s - k_3$

where the parentheses denote the chemical activities of the ions at the surface of the mineral (see Dissolution: Carbonate Rocks). This implies that precipitation is driven by the same three elementary chemical reactions as is dissolution. However, since the solution is supersaturated with respect to calcite, the reverse reactions (precipitation) within the first term of equation 1 predominate over the forward reactions (dissolution) contained in the negative terms. Therefore all chemical and physical processes that affect dissolution simply have to be reversed. As an example: during dissolution, 1 mole of CO_2 has to be converted into H^+ and HCO_3^- to release 1 mole of $CaCO_3$ into the solution. To deposit 1 mole of $CaCO_3$ this must be reversed, and consequently 1 mole of HCO_3^- and H^+ must react to give CO_2 , which can outgas from the solution. Precipitation rates can be written as:

$$R = \alpha(c - c_{\rm eq}) \tag{2}$$

where *c* is the actual calcium concentration in the solution, and c_{eq} is the equilibrium concentration with respect to calcite. The units are mol cm⁻³=mmol l⁻¹. Owing to the complex processes involved, the kinetic constant a depends on *p*CO₂, temperature, the ratio *V/A* of the volume of the solution, and the surface area on which the calcite is deposited, and also on the hydrodynamic flow conditions. For details of the processes that determine the reaction rates, refer to Dissolution: Carbonate Rocks. Values of a for

various geological situations are listed by Liu & Dreybrodt (1997) and Baker *et al.* (1998). The theoretical predictions have been verified experimentally in batch experiments and by observing precipitation from solutions contained in porous media of limestone (Dreybrodt *et al.*, 1997). Close to equilibrium, inhibition occurs, which reduces the reverse reaction, such that an apparent equilibrium is reached at about 1.1 c_{eq} . Field observations also show that precipitation from natural streams is inhibited for saturation indexes (SI) less than 0.8.

Speleothems grow where thin layers (c.0.1 mm thick) of supersaturated water flow in either a laminar or turbulent way. When the flow of these films is laminar, the precipitation rate can be obtained from equation 2 by using Figure 1. The figure shows values of a for various temperatures and thicknesses δ of laminar-flowing films open to the atmosphere, with $pCO_2=3\times10^{-4}$ atm, as being common in caves. The values of a are almost independent of PCO_2 for values between 3×10^{-4} and 5×10^{-3} atm. For cave atmospheres, c_{eq} is about 0.6 mmol 1^{-1} . Figure 2 shows growth rates for various film depths, δ , in relation to the calcium concentration (Baker *et al.*, 1998). For waters dripping from cave roofs to form speleothems ($c=2.5 \text{ mmol } 1^{-1}$), the maximum growth rates are about 0.2 mm a⁻¹.

When water is supplied as drops at time intervals of *T*, the average growth rate R_{av} is reduced to:

$$R_{\rm av} = (c - c_{\rm eq})[1 - \exp(-T\alpha/\delta)]\delta/T$$
⁽³⁾

(see Dreybrodt, 1999). Baker *et al.* (1998) have observed drip rates, and have recorded the chemistry of drip waters feeding stalagmites in caves in England and France. They determined the growth rates of stalagmites by counting annual laminae and found that these agreed well with those predicted by the model. Growth rates of stalagmites were also measured in the laboratory, by dripping a defined supersaturated solution on a $CaCO_3$ sample cut from a stalagmite and observing its weight increase (Buhmann & Dreybrodt, 1985a, b; Dreybrodt, 1988). Again good agreement with the theoretical predictions was obtained.

When supersaturated water flows turbulently, equation 2 remains valid. Since mass transport is now effected through a laminar boundary layer, it becomes dependent on its thickness ϵ (see Dissolution: Carbonate Rocks). Furthermore, due to the slow conversion of HCO₃⁻ into CO₂, a is also dependent on the depth of the water layer. For a water with pCO₂=1×10⁻³ atm, as is common in streams depositing calcite and ϵ = 0.01 cm at 10°C, α =2.19×10⁻⁵ cm s⁻¹ for δ =0.1 cm, it rises to 3.04×10⁻⁵ cm s⁻¹ for δ =2 cm and to 3.28×10⁻⁵ cm s⁻¹ for δ =10 cm. For higher values of δ >10 cm its ϵ value stays constant. Values of a dependent on δ =*V/A*, ϵ , *p*CO₂, and temperature are listed by Liu & Dreybrodt (1997). Figure 3 illustrates the precipitation rates for various values of ϵ for δ =2 cm. Note that at realistic conditions (ϵ =0.01 cm) the rates drop by about a factor of 5 compared to the hypothetically full turbulent flow (ϵ =0) shown by the uppermost curve.

Field observations of deposition of calcite on to marble tablets in calcite-precipitating streams (Dreybrodt *et al.*, 1992; Liu *et al.*, 1995; Bono *et al.*, 2001) revealed deposition rates between 0.5 mm a^{-1} and 3 mm a^{-1} in close agreement with theoretical predictions. One observation is of particular significance. Rates of deposition on to marble tablets located in fast-flowing water across a rimstone dam were higher, by a factor of about 4,

than those measured from tablets placed in the still water of the pool, some metres away from the dam, although the chemistry of the water was identical. This stresses the importance of the boundary layer. Its thickness ϵ becomes smaller with increasing flow velocity.

In summary, precipitation rates of calcite cannot be calculated by use of the PWP equation (equation 1) from the bulk concentrations of the solution as obtained by chemical analysis. Due to slow conversion of $HCO_3^-+H^+\rightarrow CO_2+H_2O$ and diffusional mass transport involved during precipitation, the

Carbonate Minerals: Precipitation: Figure 1. Values of a as a function of temperature for film thickness δ =0.005 cm (A), δ = 0.0075 cm (B), and δ =0.01 cm (C). Flow is laminar. From Baker *et al.* (1998).

Carbonate Minerals: Precipitation: Figure 2. Precipitation rates at various values of film thickness A (0.005 cm), B (0.0075 cm), C (0.01 cm), D (0.02 cm), E (0.04 cm) as a function of the calcium concentration. Flow is laminar. From Baker *et al.* (1998).

Carbonate Minerals: Precipitation:

Figure 3. Deposition rates from solutions in turbulent flow with a depth δ of 2 cm, for various values of boundary-layer thickness.

rates depend not only on the chemical composition of the solution but also critically on the V/A ratio of the solution, and also on the hydrodynamic flow conditions. Each geological situation must be analysed to determine these parameters. Uncritical use of the PWP equation leads to overestimations of the rates by up to a factor of 10. Only when the V/A ratio is high and when the thickness of $\varepsilon < 10\mu m$, such that neither CO₂ conversion nor mass transport are significant, does equation 1 yield the correct results.

CARIBBEAN ISLANDS

The Caribbean region, also known as the West Indies, consists of hundreds of islands scattered roughly between latitudes 10°N and 28°N and longitudes 59°W and 86°W. The islands can be grouped into three main geological categories: the Bahamas (including the Turks and Caicos Islands), the Greater Antilles, and the Lesser Antilles. Limestones range in age from Holocene to Jurassic (0–200 million years). More than half the total land area of the region consists of karst, i.e. 130000 km², of which 90% is located on the Greater Antilles (Troester *et al.*, 1987).

The Caribbean region has a very unusual geologic history. It did not exist until North and South America began to drift apart during the Triassic, about 200 million years ago. As a result, the oldest rocks in the region date back to only the Middle Mesozoic (about 190 million years ago). They are volcanic in origin and form the nucleus of most of the islands.

The climate is classified as tropical marine with no distinctive summer or winter, but with a dry and wet season. Mean annual temperatures, and temperature difference between the warmest and the coolest months, exhibit a distinctive south to north gradient, while rainfall does not conform to such a systematic pattern because it depends on latitude as well as the geometry and topography of the islands. Temperatures average about 27°C in the summer and about 24°C in the winter. Rainfall ranges from 500 mm a^{-1} in some places to as much as 5000 mm a^{-1} in mountainous areas.

Caves may be found everywhere in the Caribbean, but especially on the Greater Antilles, the Bahamas, the limestone islands of the outer arc of the Lesser Antilles, and the Netherlands Antilles. Submerged caves containing speleothems exist on many of these islands, indicating that they were above water at some time in the past.

The Bahamas archipelago consists of about 700 low-lying carbonate islands and cays located on several carbonate banks or platforms that have a water depth of <10 m. Most of the islands are long narrow strips because they are old dune ridges that were formed during glacial periods in the Quaternary when reduced sea levels exposed the entire banks. Most caves are formed in these dunes. Soil cover is either very thin or absent, and the exposed rocks show signs of extensive dissolution resulting in razor-sharp edges on rillenkarren that is often referred to as phytokarst because of its biologically controlled genesis.

Several different types of caves can be found on these islands. On San Salvador Island, flank-margin caves formed along the margins of the freshwater lenses just beneath the flanks of the dune ridges. This formation appears to be controlled primarily by sealevel position (Mylroie & Carew, 1991). Flank-margin caves are found all over the Bahamas, and have since been described on many other islands in the Caribbean and elsewhere in the world. Other types of caves commonly found are pit caves, banana holes, and blue holes. Pit caves are vertical shafts, 1–2 m in diameter and up to 15 m deep. Unlike flank-margin caves, pit caves do not appear to be related to past sea-level positions, but are believed to have formed in the epikarst by localized vadose flow. Banana holes are wider than they are deep and are only found at elevations of 6 m or less. They occur in lowland plains, away from the margin of the ridges. Banana holes are of phreatic origin and formed along previous water-table positions where fresh groundwater mixed with infiltrating rainwaters and where oxidation/reduction reactions from decaying organic material enhanced dissolution as well. The last category, blue holes, is described in detail in the entry on Blue Holes of Bahamas.

The Greater Antilles lie astride the Cayman Trough, which is the northern boundary of the Caribbean Plate. They comprise Cuba and the Cayman Islands on the northern side of the trough, with Jamaica, Puerto Rico, the Virgin Islands, and Hispaniola (Haiti and Dominican Republic) on the southern side. The islands have a complicated surface geology with volcanic, metamorphic, and sedimentary rocks. Only the Cayman Islands and Isla de Mona consist entirely of carbonate rocks. Raised limestone marine terraces along the coasts suggest that there was a dome-like uplift during the Quaternary centred on the passage between Cuba and Haiti. The reef terraces were formed during sea-level high stands and were gradually uplifted out of the reach of following high sea-level stands, and were thus preserved. These terraces have been extensively karstified and contain many caves.

A larger variety and some of the most spectacular examples of both surface and subsurface tropical karst occur in the Greater Antilles due to the large size of the islands, the thickness of the limestone deposits (up to 1500 m), and the presence of noncarbonate rocks. The original Indian populations knew of, and used, a large number of caves as is evident from the cave art discovered on all the large islands. The caves contain thick deposits of bat guano that have been mined for fertilizer and gunpowder. Cuba (see separate entry) has a variety of extensive karst areas, which includes the famous cone karst or mogotes and the marine terrace karst. Hispaniola is the most mountainous of the islands and much of its interior consists of uninhabited cone karst in Cretaceous and Tertiary limestones; the name Haiti is actually the local term for cone karst. Haiti is 36% karstified whereas the Dominican Republic is 52% karstified and has five major karst regions. The marine terraces are most abundant on the west coast of Haiti and reduce in number and maximum elevation towards the east coast of the Dominican Republic, from 28 terraces with a maximum height of 640 m in the west to 8 terraces attaining a maximum height of 100 m in the east. Most explored caves are within these Pleistocene reef limestones because of their easy accessibility, unlike the rugged mountainous interior. The caves on Hispaniola reach a maximum of 170 m deep (Bim Sejouene, Haiti) and a maximum length of 1.7 km (Trouin Sene) in Haiti, and 10 km long (Cueva Fun Fun or Boca del Infierno) in the Dominican Republic.

Jamaica has outcrops of Tertiary limestones across two-thirds of its area. The mountainous interior is dominated by karst hills except across the Central Inlier and Blue Mountains which are formed of older non-carbonates. The Cockpit Country (see separate entry) has the finest landscapes of cone karst, with endless tracts of forest-covered hemispherical hills and intervening dolines, but cone karst is the dominant landform across large areas away from the Cockpit Country. The largest of many poljes lie around the edge of the Cockpit Country, and other areas have a rolling terrain with more subdued hills on chalky facies of the limestones. Streams from the Central Inlier drain through the karst, with the longest underground routes beneath the Dry Harbour Mountains, just east of the Cockpit Country. Quashies

River cave is the finest of many very active stream-sink caves (Waltham & Smart, 1975), but all routes drop quickly to sumps, where the long phreatic passages beyond remain unexplored. Scattered through the karst are a number of collapse dolines and impressive open shafts 100–200 m deep, but none leads into long cave systems. Fragments of abandoned phreatic trunk caves survive within the karst (Figure 1); many passages are more than 20 m high and wide, and are liberally decorated with secondary calcite deposits. Also notable among the many caves on the island (Fincham, 1997) are Jackson's Bay Caves, with 3300 m of large and beautiful water passages beneath a dry region of low-lying, cactus-covered karst near the south coast.

Puerto Rico is 28% limestone. Within the northern limestone zone, 35% of the area is covered by blanket sands and alluvial soil. The remaining 65% is known as the Karst Belt and shows extensive surficial karst features (Monroe, 1976). Mogotes are isolated karst towers that rise from the blanket sands in the northern section. Towards the south, mogote karst changes into cockpit or cone karst and doline karst. The Arecibo Observatory, the largest radio-telescope antenna in the world, is located in one of the dolines. There are numerous caves. River caves are formed by rivers that originate on non-carbonate rocks disappearing underground at the contact with carbonate rocks. They are enlarged by solution as well as abrasion and are by far the largest on the island. The longest caves on the island are Sistema del Rio Encantado (17 km long and 250 m deep, see separate entry) and the 9 km of passages in unconnected sections along the Rio Camuy. There is also significant karst on the Isla de Mona, located between Hispaniola

and Puerto Rico, described in the Mona entry. The karst of the Cayman Islands closely resembles that of the Bahamas and Isla de Mona.

The Lesser Antilles are multiple chains of islands, most with volcanic cores. The Windward Islands (or the Volcanic Caribbees), from Guadeloupe to Grenada, are entirely formed of Tertiary volcanics, except where active volcanism continues today, and they have no carbonate caves. The Leeward Islands (or the Limestone Caribbees) were planed down by the sea and buried beneath thick limestones, all within the Tertiary. Some of the islands, notably Anguilla, Barbuda, and Antigua, are largely karst terrains, but the only known caves are less than 200 m long. The southern islands are more varied, and include the Netherlands Antilles, Trinidad and Tobago, and the limestone island of Barbados, outside the main Antilles arc.

Raised marine terraces occur on Barbados and the Netherlands Antilles and are also the result of a combination of continuous tectonic uplift and Quaternary sea-level fluctuations. On the Netherlands Antilles, there are four terrace levels of which the highest reaches 170 m. They show a limited extent of surface karst, and contain many caves less than 500 m long. On Curaçao as well as Aruba, the highest caves are found in the Higher Terrace at 60 m, whereas the highest cave on Bonaire is in the Middle Terrace at 30 m above sea level. The caves on Aruba are, in general, longer and deeper than those on the other islands, with Lago Colony Cave as the longest at 480 m and Huliba Cave as the deepest at 35 m.

Barbados consists entirely of limestone and is highly karstified. It has over 20 caves of which Harrison's Cave is a tourist cave 780 m long. The longest cave is Bowmanston Cave, 1700 m long and 90 m deep. Trinidad and Tobago are only 15% karstified and little is known about the caves of these islands. On Trinidad, Dunstan Cave is known for its colony of oilbirds (or guácharo); Aripo No. 1 Cave houses a large bat colony, and the longest cave is the 220 m long Oropouche Cumaca.

CARIBBEAN ISLANDS: HISTORY

On 18 May 1494 Columbus saw two powerful karst springs on the south coast of Cuba, probably in Bahía de Cochinas. This was reported by his contemporary Andres Bernáldez (1930) who heard it from Columbus himself:

In the ground beneath it [the sea shore], there sprang forth two springs of water, so abundant that the outlet [of] each was the size of a very large orange, and this water spouted up with force. When the tide was coming in, it was so cold and such and so sweet, that no better could be found in the world

Also in Cuba, the fact that native fishermen lived in caves in the western peninsula of Guanahacibibes was recorded by Bartholomé de Las Casas about 1512 (Núñez Jimínez, 1980). Then in the neighbouring island of Hispaniola the seaward end of a limestone cave (probably Boca del Infierno) in Bahía de Samaná was entered by Andreas Morales in the summer of 1513 (Martyr, 1555). So it seems that the earliest written records of karst and caves in the Americas all refer to the Caribbean, within 11 years of Columbus's first landing.

Although the Caribbean area is a geographical entity there has been no common thread in the study of its caves and karst, due largely to the different languages and cultures derived from the European countries who developed the islands. Investigation progressed only by a series of isolated explorations in the various islands. Also relevant were the cave-related "industries" that grew up—water supply, guano, edible birds, paleontology, and early tourism.

In Cuba, of which some 70% is karst, a submarine spring off the coast was noticed in 1734 but it was the European geologist Humboldt whose visit in 1800 made the existence of submarine springs widely known (Humboldt, 1856). He also mentioned sinking rivers and caves in the Matanzas region. It was there that the cave of Bellamar was discovered in 1861 and shown to visitors for \$1 "including guides and lights" (see Figure). Cave fish from Cuba were described by Poey in 1856, only 14 years

Caribbean Islands: History: Bellamar Cave, Cuba, in 1870.

after those in Mammoth Cave (Kentucky) were recorded. Commercial exploitation of bat guano in the early 20th century led to more cave discoveries, some with fossil bones. After 1945 scientific study of the karst developed rapidly, with a geographical institute in Havana and a national cave society.

Jamaica, also with 70% limestone, is another island where caves were recorded quite early. Hans Sloane (1707) noted his 1688 observations on underground rivers, stalactite caves, and guano caves. Long (1774) published a six-page description of Runaway Bay Caves, near Dry Harbour where Columbus had landed, and also Riverhead Cave at the source of the Rio Pedro and another cave no longer known. The Geological Survey Memoir of 1869 contains a vast amount of detailed information on the island's hydrology and caves, including those in the more remote areas. It made the Jamaican karst well known worldwide and was cited by Cvijić and by Martel. Besides the usual bat guano exploitation the bats themselves were studied about 1860. Extensive cave exploration and underground water tracing has taken place since the 1940s, inspired by the University of the West Indies and aided by visits from Europe.

Caves in the Bahamas were noted in 1725 and studied in the 19th and 20th centuries, mainly by geologists and those concerned in guano extraction. Thus McKinnnon (1804) gave an account of a cave in Crooked Island. The submerged cave shafts or Blue Holes in the area, first noted by De Kerasoret (1753), were recorded on charts about 1840 and attracted much attention in the 1890s when it was appreciated that they were evidence of land subsidence. It was in 1853 that the fresh groundwater was shown to exist as a lens

floating on top of salt groundwater, with its implication for the depth to which wells should be sunk.

The caves of Trinidad attracted great interest in the 19th century, primarily because of the presence within them of the cave-dwelling bird, the guácharo. Continuing study of the bird and its haunts was supplemented from the 1890s by work on bats, which later culminated in research to control the rabies epidemic of the 1930s. Geological aspects of the caves tended to take second place despite the Geological Survey Memoir of 1860. The guácharo was a desirable food, so finding it had commercial as well as scientific value. Although already well known in Venezuela, the earliest reference to a Trinidad cave (Latham, 1823) is also the first example of the bird living there:

...it is at the time of the new and full moon, in April and May, that the people...resort thither; when finding the young ones not sufficiently fledged to be able to fly, they speedily fill their boats, not, however, despising the old ones, many of which are knocked down with sticks.

Descriptions of Trinidad caves themselves occur in the Geological Survey Memoir of 1860 and in accounts of travellers' visits, which were more usually limited to guácharo caves. By 1903 such visits were common enough to cause photographs to be issued on picture postcards. Cave exploration for its own sake began in the 1940s, with the increased number of foreigners working there, and cave fauna studies have also become important.

The cave now known as Bat's Cave in Antigua was shown on a map of 1749 and described in detail by Mrs Lanaghan (1844). In the 1890s a small-scale attempt was made to sell bat guano from it. In Barbuda, three inland caves were marked on charts of about 1814. Caves in the Caicos Islands were mentioned in 1773 and guano caves there were described in 1884. In the Cayman Islands, too, there are caves but they were not recorded until the 20th century.

The extensive karst of Hispaniola is relatively little known. After the 1513 Samaná visit already mentioned, caves near the city of Santo Domingo attracted attention from 1849 when Cueva de Borbon was discovered. Caves near Santanna were already much visited by 1873, and 20th-century guano extraction led to others being recorded.

The caves of Curaçao and the other Dutch islands have been well investigated in the 20th century and the cave of Hato was described by Teenstra and others from 1828.

Caves in Puerto Rico have mainly been studied since the 1950s, but guano was being taken from some in the early 20th century and at least one cave was commonly visited by travellers in the 1890s.

CARLSBAD CAVERN AND LECHUGUILLA CAVE, UNITED STATES

Located in the Chihuahuan Desert of New Mexico and Texas, the Guadalupe Mountains contain little surface karst but are known for spectacular caves, including Carlsbad Cavern and Lechuguilla Cave (DuChene & Hill, 2000; Figure 1). Carlsbad Caverns National Park, which contains both caves plus at least 90 others, was established in 1930 and is administered by the National Park Service. The Park was designated a World Heritage Site in 1995 because of its geological significance and the beauty of its cave features. Carlsbad Cavern is open to guided and self-guided tours year round and receives

up to 650 000 visitors each year. Off-trail activities, under permit, are limited to research and mapping. Several other caves in the Park are open to "wild" caving under permit. Access to other caves, including Lechuguilla, is limited to researchers and surveyors. Of the Park's 190 km², 70% (including Lechuguilla Cave) has been designated a wilderness area.

The Guadalupes consist of an uplifted Permian reef complex (Figure 2). The abrupt Guadalupe Escarpment, forming the southeastern border, consists of massive Capitan Limestone, a bryozoan-sponge-algal reef with a fine-grained matrix. To the northwest are prominently bedded back-reef dolomites and limestones, which form a high dissected plateau. To the southeast, the reef is bordered by an apron of reef talus, which merges diagonally downward with deeper-water strata of the Delaware Basin. These basinal rocks are overlain by Permian evaporites, mainly gypsum. The Guadalupes owe their height to late Permian, Mesozoic, and especially late Cenozoic uplift, accompanied by faulting, folding, and southeastward tilting. The present crest of the upland is 1300–2300 m above sea level, with the highest point at 2667 m at Guadalupe Peak. The surrounding plains lie at about 1000 m. The average annual rainfall in the Guadalupes is only about 360 mm, and surface karst is limited mainly to scattered karren. In this dry climate, hypogenic cave development is favoured.

The Guadalupe Mountains contain perhaps the world's foremost examples of cave origin by sulfuric acid (Egemeier, 1987; Hill, 1987). Hydrogen sulfide escaped in aqueous solution from oil and gas fields in neighbouring and underlying strata, migrated toward zones of lower head in the permeable reef complex, and oxidized to sulfuric acid at and near the water table. This acid rapidly formed caves in the carbonate rocks, and the dis solved load was carried to springs. This process is episodic and presently dormant.

Guadalupe caves typically have ramifying patterns consisting of irregular rooms and mazes with passages branching outward from them at various levels (Figure 1; also see Patterns of Caves entry). Maps resemble inkblots, with many overlapping tiers. Branches do not converge as tributaries, but instead are distributary outlets at successively lower elevations. Some caves, or parts of caves, have network or spongework patterns. Some involve simple widening of one or more fractures.

Carlsbad Cavern is one of the world's most spectacular caves. Its single natural entrance, located at the highest point in the cave, was originally an outlet for ascending water. It drops into the steeply descending Main Corridor, which leads downward to the main levels, which include the Big Room, the largest known chamber in any US cave. An elevator gives direct access to

Carlsbad Cavern and Lechuguilla Cave: Figure 1. Outline surveys of Carlsbad Cavern and Lechuguilla Cave, at the same scale.

Carlsbad Cavern and Lechuguilla Cave: Figure 2. Diagrammatic profile through the Capitan reef, showing the structural locations of the Carlsbad and Lechuguilla caves. the Big Room level. In the opposite direction, the Main Corridor contains one of the largest bat colonies in the United States and was the site of early 20th-century guano mining. The dominant speleothems in the cave are massive dripstone. The cave's surveyed length is 49.7 km and its depth is 316 m.

Lechuguilla Cave is the world's fifth longest cave (180 km) and the deepest limestone cave in the United States (478 m). It was discovered in 1986 through digging at the bottom of a 25 m entrance shaft, which, like the Carlsbad entrance, once served as a water outlet. Lechuguilla Cave's passages and rooms are not as large as those of Carlsbad, but they are far more complex, so that many parts of the two-dimensional map are virtually incomprehensible (Figure 1). The steeply descending entrance passage leads to the main levels, which branch in three directions. Each section of the cave contains a variety of steeply inclined passages interconnected with complex spongework mazes. The cave contains some of the world's most spectacular gypsum speleothems, including crystalline "chandeliers" up to 6–8 m long.

Many rooms and galleries in these and other Guadalupe caves form nearly horizontal levels discordant to lithologic boundaries (Figure 3). Deep fissure-like rifts descend from the floors of major levels and pinch downward in narrow constrictions. Steeply sloping passages represent former paths of rising H_2S -rich water below the water table. This water converged with, and mixed with, oxygen-rich water fed by infiltration at higher elevations. Depths of mixing and dissolution extended over vertical ranges as much as 200 m below the water table (Palmer & Palmer, 2000).

The reaction of sulfuric acid with carbonate bedrock produced extensive gypsum deposits. These include rinds on bedrock up to half a metre thick, as well as massive deposits on cave floors that precipitated from saturated solutions (Figure 3). Inherited textures show that some of the gypsum rinds replaced carbonate bedrock on a roughly volumetric basis. Light isotopic ratios of sulfur show that the gypsum is not primary, but instead a by-product of microbially mediated redox reactions (Hill, 1987).

Besides the spectacular calcite and gypsum deposits described above, Guadalupe caves contain a variety of unusual speleothems. Perhaps unique in the world, subaqueous helicities are produced by the common-ion effect, where calcite-saturated water reacts with gypsum-rich water in pools (Davis, Palmer & Palmer, 1990). Some minerals are by-products of sulfuric acid speleogenesis, including sulfur, alunite, hydrated halloysite, and dickite. Evaporation produces aragonite needles in bushes up to 3 m high, as well as lesser deposits of magnesium-rich minerals such as huntite, hydromagnesite, magnesite, and dolomite. Condensation corrosion takes place on upper-level surfaces where moist air ascends from warmer lower levels. Dissolution of bedrock and speleothems by condensation moisture is common, and the dissolved minerals are drawn to zones of evaporation by capillary potential, where they precipitate as speleothems and crusts. Intense wall weathering in some areas has produced a thick corrosion residue of clay and metal oxides harbouring a rich microbial community (Cunningham *et al.*, 1995). In places microbial filaments were coated with later calcite to produce finger-like speleothems of either subaqueous or subaerial origin.

Dissolution by flowing vadose water is virtually absent. However, some bedrock floors and walls contain deep rills apparently

Carlsbad Cavern and Lechuguilla Cave: Figure 3. Lebarge Borehole in Lechuguilla Cave, a horizontal level at 1190 m above sea level, 240 m above the local water table. Note massive gypsum on floor and gypsum wall crust from the reaction of sulfuric acid with the local limestone. The massive reef limestone is clearly shown here. The pool is a perched water body fed by local infiltration. (Photo by Art Palmer)

formed by highly acidic water, but with no corresponding ceiling features. The following process can be observed in still-active H_2S caves: Infiltration or condensation forms droplets and films of fresh water on cave walls. They absorb H_2S that escapes from the water into the cave air, in addition to oxygen from the air, and they react to form sulfuric acid. This reaction depletes the content of the two gases, allowing more of each to be absorbed and to react. The carbonate bedrock is soon replaced by a gypsum rind, which prevents the acid from being neutralized. The pH drops to measured values as low as zero. Rills form where these droplets fall onto carbonate bedrock.

Argon dating of alunite in the Guadalupe caves by Polyak *et al.* (1998) shows consistently increasing age with elevation. Since the alunite is a by-product of the speleogenetic process, these dates indicate the true ages of the caves. The highest levels are 12 million years old, indicating that most tectonic uplift took place since then. Ages decrease downward at a decelerating rate, indicating a decrease in uplift rate and water-table decline with time. The lowest dated cave level is the Big Room of Carlsbad Cavern, at about 4 million years old.

Despite the essentially horizontal water-table control of many passages and rooms, these levels do not correlate well between neighboring caves, or even within individual complex caves (Palmer & Palmer, 2000). Clearly the cave-forming process involved local episodes of H_2S release along different paths at different times. As the water table dropped, bursts of cave enlargement occurred at those times and places where H_2S was rising to the water table in significant quantity, probably during uplift and deformation. When these releases coincided with rather static water tables, distinct horizontal levels resulted.

CARMEL CAVES, ISRAEL: ARCHAEOLOGY

The caves of the Mount Carmel area, Israel, along with inland caves and open-air sites, have contributed to the resolution of two major issues in human evolution. The first is the question of when and how anatomically modern humans (*Homo sapiens sapiens*) succeeded the Neanderthals (*Homo sapiens neanderthalensis*). The second concerns the first evidence for the domestication of plants and animals in mesolithic or epipaleolithic times.

The archaeological caves of the Levant occur as recesses in the reef front of Cretaceous—Eocene limestones (Figure 1). The reef front runs parallel to the Levantine coast and culminates in Mount Carmel at Haifa, at an elevation of about 200 m. There are valleys running from the interior that cut through the reef front, and about 20 km south of Haifa and at the mouth of one of these—Wadi el-Mughara (Wadi of the Caves)—are found, in close proximity, the caves of Tabun, Jamal, El-Wad, and Es-Skhul. Further south is the important Neanderthal site, Kebara. The caves lie inland of a coastal strip about 3.5 km wide and from 40 to 60 m above sea level (Jelinek, 1982). It is not certain how these caves formed initially. Although some of the interior sediments are derived beach sands, suggesting a possible origin as former sea caves, their position at the mouth

of the wadi and the phreatic form of their chambers suggests that they once functioned as resurgences, possibly below a former sea level. The age of cave formation is not known. El-Wad, Tabun, and Kebara possess curious funnel-shaped pits in the floor, now filled with sediment, that suggest a possible link to lower chambers and it is possible that water flowed up these pits in the early, active phase.

The sediments in the pit at Tabun (as at Kebara) slipped down even while the cave was being occupied in Paleolithic times, and it is curious that Acheulian stone tools and flakes are now aligned at steep angles within the steeply dipping sediment, parallel to the walls of the pit. There are no speleothems that might be dated by U-series methods. Further inland, Hayonim Cave, in which remains from the Mousterian and Natufian cultures have been found, contains fallen, partially rotted, stalagmites and flowstones of poor quality that date from over 250000 to about 90000 years ago.

The caves of the Levant were first excavated systematically by Dorothy Garrod, head of the Archaeology Department at the University of Cambridge, mainly from 1929 to 1934. Her work culminated in the two volumes of Garrod & Bate (1937), *The Stone Age of Mount Carmel*. Her analysis and divisions of the Levantine paleolithic to neolithic stone cultures, guided by her knowledge of French lithic typology, have largely stood the test of time (Belfer-Cohen & Bar-Yosef, 1999).

Figure 2 reproduces Garrod's section at Tabun. The skeleton at X, known as Tabun I or C1, has a skull that possesses characteristics of the Western European Neanderthals (e.g. prominent brow ridges and receding chin). Unfortunately, it was not clear to Garrod, or to anyone since, whether the remains truly belonged to layer C, or were interred into layer C but belong in time to layer B. From unpublished Garrod notes, the current estimate is that it belonged to layer B (Bar-Yosef & Callander, 1999). There is a distinct faunal break in both large and small fauna between the two layers, yet the change in lithic assemblage is not that great. In addition to the faunal and cultural associations of Tabun 1, there is the question of whether the skeleton (probably female) is an actual Neanderthal burial. Even more important is the question of how Tabun I is to be dated, since the layer to which it belongs determines the dose rate estimates for TL (thermoluminescence) or ESR (electron spin resonance; see Dating Methods: Archaeological). An attempt to date Tabun I by nondestructive U-series gamma-ray spectrometry gave a tentative and controversial late age of 34 ka (Schwarcz et al., 1998; Millard & Pike, 1999; Bar-Yosef & Callander, 1999). Tabun II is a jawbone found at the base of layer C. What is intriguing is that this jaw looks like it belongs to a more anatomically modern human (AMH; it has a recognizable chin), which implies that, for a few tens of thousands of years, AMHs preceded the Neanderthal types or overlapped with them.

Carmel Caves, Israel: Figure 1. Archaeological caves of Wadi Mughara, Mount Carmel area, Israel (from Garrod & Bate, 1937). Inset (a) is the Levantine coastal strip. Inset (b) is a plan of El-Wad.

The controversy about Tabun I is part of the issue of how and when the AMHs succeeded the Neanderthals. Up until the modern phases of excavation in the 1970s–1980s, it was widely believed that the Levantine Neanderthal—AMH successions followed in similar fashion to those of Western Europe, namely that the AMH types followed the Neanderthals, the latter dying out at about 35000 to 30000 years ago. In addition to Tabun I, Neanderthals were excavated from Kebara Cave, further down the coast, and from Amud Cave near to the Sea of Galilee (see also Shanidar Cave, Iraq: Archaeology). Then AMH remains were found round the corner from Tabun at Es-Skhul

and in Qafzeh Cave, near Nazareth. By studying the faunal successions of fossil small rodents from these caves, Einat Tchernov and Ofer Bar-Yosef suggested that the AMHs actually preceded the Neanderthals in the Near East. Unfortunately the remains were outside the range for the ¹⁴C dating method. So this gave the impetus to apply other radiometric dating studies (and in no small measure to their development) using U-Th (of teeth), TL (of burnt flint), and ESR (of teeth). These studies showed that the Qafzeh AMH remains date to 110 ka and possibly 120 ka and those at Es-Skhul to 100 ka, whereas the Amud Neanderthals date to 50 ka and those from Kebara to 60-64 ka. There are certainly problems with some of the age assignments, the chief of these being the mismatch in ESR ages for the Tabun layers with the older TL ages estimated from burnt flint in these same layers. But whatever may be the present inconsistencies, the chronologies are good enough to confirm that the AMHs preceded the Neanderthals in the region. The Levant AMHs thus precede those of Europe. The dating of these various remains helped to promote the idea that the AMH peoples originally evolved in Africa (sub-Saharan Africa) and that some of them migrated out of Africa, over 100000 years ago, and into Europe and Asia, with the Near East acting as a corridor. The earlier migration of Homo erectus out of Africa between about 1.5 to 2 Ma is known as the "Out-of-Africa I" migration, so the subsequent AMH migration is known as the "Out-of-Africa II" migration. Bar-Yosef speculated that it was the onset of the last glaciation that induced a subset of the Neanderthal population to colonize the Near East from the north following changes or migrations in the animals on which they depended. As far as the emergence of modern humans is concerned, the Out-of-Africa II migration is set off against the alternative hypothesis of a more general multiregional development (see discussion in Delson et al., 2000).

Dorothy Garrod also excavated the terrace at El-Wad and confirmed the presence of the Natufian culture which she assigned to the Mesolithic (Boyd, 1999). This is now thought to represent the earliest transitional culture to adopt sedentism through the cultivation of cereal. The Natufian is actually named after Wadi en-Natuf in the Judean hills where Garrod excavated a cave in 1928. The El-Wad terrace contained several burials with shells and other ornaments. In addition, excavation turned up a large number of backed stone blades displaying "a high degree of polish along the working edge", together with a number of "sickle hafts". In 1932 a complete grooved bone sickle haft was excavated from Kebara Cave, and Garrod suggested that it was used in a primitive form of agriculture. Since Garrod's time, further work on Natufian sites has added to the idea of cereal cultivation, but—with the possible exception of dogs—not to the domestication of animals. Whereas Garrod had guessed the Natufian to be about 4000–5000 BP, ¹⁴C dates from early Jericho place it at 8000–10000 BP. A major review of the Natufian by various contributors is given in an edited volume by Bar-Yosef and Valla (1991).

CASTLEGUARD CAVE, CANADA

Castleguard Cave is the longest currently known cavern in Canada (20 km) and the foremost example anywhere of a cavern extending underneath a modern glacier (Figure 1). It displays many striking features of interaction between glaciers and karst aquifers, a complex modern climate, rich mineralization, and a stygobitic fauna that has possibly survived one or more ice ages beneath deep ice cover in the heart of the Rocky Mountains (Ford, 1983).

Relief in the region rises from an altitude of 1500 m (trunk valley floors) to summits at 3500 m. Mean annual temperatures are 0 to -14° C across this height range. The tree line is at ~2100 m. The Columbia Icefield is 320 km² in area and 200–300 m thick with valley glaciers radiating out for up to 10 km. Ice thickness and extent were much greater during the major glaciations, when only the mountain peaks protruded as nunataks. The karst rocks are resistant carbonates of Cambrian age. The Cathedral Formation (>560 m thick) is massively bedded, crystalline limestone that contains the cave. Above it, the Stephen Formation (80 m) is a leaky calcareous shale aquitard overlain by further thick-bedded

limestones and dolostones (Pika and Eldon Formations). The summit strata are weaker shales, sandstones, and dolostones (Figure 1). Stratal dip is S-SE at $4-6^{\circ}$.

On the surface, the Cathedral limestones host a suite of small but typical alpine karst forms such as karren, dolines, and shafts, many of which were overridden and lightly eroded by glaciers during the Little Ice Age of the last 500 years. The glaciers are now receding. In some places streams can be heard sinking into shafts beneath them.

Cave Morphology and Genesis

Explorers can only enter the cave at its downstream end, at an altitude of 2010 m in the north wall of Castleguard River valley, more than 300 m above the valley floor. From there the cave ascends 386 m to terminations underneath the icefield (Figure 2). There are three distinct morphologic sections:

- a Headward Complex of inlet passages created by repeated glacial blockage and rerouting of sinking waters in the past. The passages are plugged by ice or debris today. Younger vadose shafts pass through and become blocked by constrictions or debris below;
- 2. a Downstream Complex of low tunnels in one major bedding plane, created by flooding and obstructions by glacial ice in Castleguard Valley in the past;
- 3. the Central Cave, a sequence of remarkably long, straight conduits created where one master bedding plane is intersected by a pair of vertical joints that are linked by a sedimentary dyke crossing them (Figure 3a).

Castleguard Cave: Figure 1. Schematic section through Castleguard Mountain, Alberta, Canada, showing the geology and locations of Castleguard Cave and Castleguard II.

Castleguard Cave: Figure 2. The ice plug at the end of Castleguard's main tube. The ice is squeezed down from the floor of the Columbia Icefield where it sits across the truncated end of the old phreatic tube, but exactly how far the ice has flowed along the tube is unknown. (Photo by Tony Waltham)

The cave possibly originated beneath the Stephen impermeable cover rocks as a single phreatic loop of >370 m depth (Ford *et al.*, 2000). More certainly, as Castleguard Valley was entrenched below the Stephen Formation, the cave became enlarged to its modern dimensions as shown in Figure 3b, two shallow, principal loops consisting of vadose entrenchments up to 15 m deep draining into phreatic tubes of beautiful circularity (Figure 4). Following this main phase, the cave drained through undercapture passages in the bottoms of the loops (Figure 3c). The undercaptures channel local invasion waters today and the Downstream Complex can be flooded from another lifting shaft, Boon's Blunder, and discharged through the explorers' entrance, closing it.

Hydrology

Modern waters drain from the glacier soles, alpine karst, and meadows to a set of springs extending 3 km downstream from Big Springs, dramatic overflows 15–40 m above the valley floor (Figure 1). The waters flow through the putative series of inaccessible caves, Castleguard II (Smart, 1983). Artesian Spring, lowest in elevation, is perennial. As the melt season progresses, upstream springs such as Gravel and Watchman begin to flow.

The Big Springs, 100 m higher than Artesian Spring, have a maximum discharge >7 m^3 s^{-1} and handle mean summer

Castleguard Cave; Figure 3. (a) The initial phreatic passages in the Central Cave and Downstream Complex, showing the master bedding plane and intersecting vertical fractures that guided them. (b) The cave at the close of the principal enlargement phase. Drawdown vadose canyons supplied water to a succession of shallow phreatic loops. (c) The modern cave;

small invasion vadose streams have cut shafts and underfit trenches in the drained galleries, and are lost into impenetrably small, undercapture passages continuing on down into Castleguard II.

Castleguard Cave: Figure 4. "The Subway" at the lower end of Castleguard Cave, a "textbook" example of a phreatic solution conduit. It is straight and maintains the form and dimensions shown here for a distance of 500 m. (Photo by Tony Waltham)

floods. Their capacity is exceeded when there is very strong melting on the icefield. Groundwater then backs up in the aquifer until it floods the Downstream Complex of the cave, 270 m above Big Springs: cave discharge can be $>5 \text{ m}^3 \text{ s}^{-1}$. Tracer dye placed in glacier edge stream-sinks such as Frost Pot reaches the Big Springs, 4 km distant and 750

m lower, in as little as 3.5 hours. This is a "textbook" example of a dynamic alpine karst aquifer. The large number and great height range of its springs are attributed to repeated disruptions such as debris pluggings, during the glaciations.

Cave sediments, speleothems, and dating

Subglacial boulders, gravel, and sand were swept or bulldozed into the head of the cave. Many were partially cemented by calcite and later eroded, indicating a long history of filling and removal. Throughout the Central Cave there are remnants of three partial fillings with varved silts and clays, separated by phases of erosion or calcite deposition. They are deposits of glacier flour, settled out of suspension when the cave became backflooded with subglacial waters.

Despite its location beneath glaciers or alpine desert, the cave is well decorated with calcite speleothems. There is one double layer of cubic cave pearls, a unique deposit. In the warmer central sector (temperature 2-3°C, relative humidity 95%+) there are small evaporative aureoles of aragonite, huntite, hydromagnesite, gypsum, mirabilite, and epsomite; evaporation in these extreme conditions is due to a strong draft blowing through the cave when not in flood.

U-series dating and paleomagnetic studies of speleothems show that the cave became relict (i.e. Castleguard II was well developed) more than 780000 years ago. The varved clays are younger. This antiquity is typical of multi-level alpine caves.

Stygobitic fauna

Colonies of two stygobitic crustaceans, blind and unpigmented, live in pools in the Central Cave. An isopod, *Salmasellus steganothrix*, is known elsewhere in the Canadian Rockies. An amphipod, *Stygobromus canadensis*, is known only in Castleguard. It is possible that the cave served as a subglacial refugium for these species during the last glaciation or even longer (Holsinger *et al.*, 1983).

CAUCASUS, GEORGIA

The Caucasus is a large range of fold mountains, structurally continuous with the Crimean Mountains and the Mediterranean Alpine fold belt. It occupies the isthmus between the Black Sea and the Caspian Sea (for location, see map in Russia and Ukraine entry). By both its structure and topography, the Caucasus is divided into three main regions: the Great Caucasus (or the Principal Caucasus Range), the Minor Caucasus, and the Kura-Rionsky depression that separates them. The formation of the large anticlinoriums of the Great Caucasus and Minor Caucasus, as well as of the intervening synclines and depressions, is attributed mainly to late Alpine folding. Since the end of the Pliocene, through the whole Pleistocene, differential uplift continued and caused the formation of the complex tectonic structure and mountainous relief.

The Great Caucasus stretches for about 1500 km, from the Kerchensky channel that connects the Azov and Black seas, to the Caspian Sea near the city of Baku. The Principal Caucasus Range is divided into the Western Caucasus, Central Caucasus (with the highest peak, Mount El'brus at 5633 m), and Eastern Caucasus. Two large monoclinal ranges located to the north of the Principal Caucasus Range, the Peredovoy and Skalisty ranges, are termed the North Caucasus. Most of the Great Cau casus lies within Georgia and its autonomous republic Abkhasia. The Northern Caucasus and the extreme western flank of the Principal Caucasus Range lie within Russia, while the Eastern Caucasus stretches through Azerbaijan. The Minor Caucasus lies mainly within Armenia and Azerbaijan.

The high mountain alpine relief with jagged ridges, large glaciers, and summits exceeding 4000–5000 m is characteristic of the Great Caucasus, while altitudes in the Minor Caucasus are generally lower. The Great Caucasus shows some similarity to the Alps in the regional distribution of karst, with fore-ridges composed of karstified Upper Jurassic and Lower Cretaceous limestones girdling the glaciated core zone of igneous rocks. While the Caucasus holds a diversity of karst types on various lithologies, it is high mountain alpine karst on carbonates that is the most remarkable in the region because of its spectacular glaciokarstic landscapes, tremendous vertical relief, and very deep caves.

On the northern slope of the Great Caucasus, karst is developed in monoclinal and folded structures in Mesozoic limestones, dolomites, and gypsum. Alpine karst massifs and deep caves are known in the western sector of the Northern Caucasus and at the western flank of the core zone of the Principal Range. In the former, the Zagedan Massif, part of the Abishyra-Akhuba range, holds Gorlo Barloga Cave, the deepest and the highest cave in Russia (depth 900 m, length >3000 m) developed in a Devonian and Carboniferous sequence of metamorphosed limestones and schists. Other significant caves in this massif include Zagedanskaya (570 m deep, 5300 m long), Rostovskaya (500 m deep, 1000 m long), and Alekseeva (465 m deep, 4410 m long). The Dzhentu Massif is notable for Majskaya Cave (500 m deep, 4410 m long) with its abundant crystal formations of gypsum and mirabilite. The most spectacular alpine karst is situated at the western flank of the core zone, in the Fisht Massif of Upper Jurassic limestones and above Lower Jurassic volcanic and sedimentary rocks. With its high glaciokarstic terrains (up to 2876 m altitude), the massif holds the westernmost glacier in the Caucasus. Deep

caves include Krestik-Turist (633 m deep, 14000 m long), Parjashchaya Ptitsa (565 m deep, 4500 m long), and Ol'ga (520 m deep, >3500 m long).

On the southern slope of the Great Caucasus, a chain of limestone massifs stretches for about 400 km, parallel to the Principal Range and mainly along the Black Sea shore. The belt of Mesozoic limestones starts near the town of Sochi in Russia and extends through Abkhasia to Western Georgia, where it goes inland. In the Sochi area the Alek, Akhtsy, Vorontsovsky, Dzukhra, Akhshtyr, and Akhun massifs constitute a marginal recharge area of the Sochinsky artesian basin (Dublyansky *et al.*, 1985). With altitudes ranging between 600 and 1000 m and patches of Paleogene insoluble cover in the limestones, these massifs are not alpine karsts, but they have many allogenically fed caves up to 500 m deep.

Further to the southeast, in Abkhasia, the limestone belt continues throughout the Gagrinsky and Bzybsky ranges, where the large Arabika (490 km²) and Bzybsky (550 km²) massifs represent outstanding examples of high mountain alpine karst (see Figure 1). The massifs have strongly pronounced glaciokarstic landscapes (Figure 2) and caves at elevations ranging predominantly between 1900 and 2400 m, while the highest peaks rise to 2705 m in Arabika and to 2634 m in the Bzybsky Massif. Both massifs were glaciated during the late Pleistocene, when recharge from glaciers, focused along fissured zones in glacier bodies, contributed considerably to the development of large caves (Klimchouk & Rogozhnikov, 1984; Vakhrushev, Dublyansky & Amelichev, 2001). The most remarkable characteristic of these massifs is the great vertical magnitude of karst groundwater drainage. This has been proved to be up to 2300 m by groundwater tracing from sinking streams to springs in both massifs. However, it might be even greater in reality. In Arabika, karst groundwater is also discharged by submarine springs, some of which rise from the floor of the Black Sea at depths of up to 400 m (Buachidze & Meliva, 1967). Moreover, boreholes near the town of Gagra, at the foot of Arabika are reported to encounter open karst cavities at depths as great as 2300 m (Maruashvili, 1972). It is therefore not surprising that the Arabika and Bzybsky massifs have yielded many deep caves, seven of which are now known to exceed 1000 m and three of which are over 1500 m deep, including the world's second deepest, Krubera (see Krubera Cave, Georgia). These features place the Arabika and Bzybsky massifs among the world's major karst and cave regions.

The Arabika Massif is bordered by the Black Sea shoreline to the southwest, and by the deeply incised Bzyb River valley to the east, separating Arabika from the adjacent Bzybsky Massif. Tectonically, Arabika is on a large anticline in the sub-Caucasian northwest-southeast trend, with a gently dipping southwestern flank and a steeply dipping northeastern flank. Several low-order folds and large faults complicate the major anticline. The core of the massif is Upper Jurassic limestone resting on Lower Jurassic volcanics, while Lower Cretaceous limestones are present on ridges and peaks in the central part and in the fringing foothills. The limestones dip continuously to the Black Sea shore and dip below the modern sea level.

The several hundred caves known in Arabika include Krubera (1710 m deep), the nearby Arabikskaja system (Kujbyshevskaja-Genrikhova Bezdna, 1110 m deep) in the southwest, the Iljukhina system (1240 m deep) in the centre, Dzou Cave (1080 m deep) and Moskovskaja Cave (970 m deep) in the northeast, and Sarma Cave (1530 m deep) in the southeast. Development of the large caves is strongly controlled by the block fault

structures. Explorations and groundwater tracing tests have identified at least three large karst hydrological systems (Klimchouk & Kasjan, 2001). The central system has Krubera, Arabikskaja, and Iljukhina caves connected to the large springs on the coast about 2300 m below; in the northern system the Dzou and Moskovskaja caves drain to the Gegsky Vodopad spring in the Gega Valley about 1700 m below. Sarma Cave is presumed to drain to the Goluboe Ozero spring 2100 m below.

The Bzybsky Massif is the structural continuation of Arabika to the southwest, between the Bzyb and Aapsta Rivers. Its southern border is the Kaldakharsky fault which brings Mesozoic limestones into contact with Paleogene non-karstic sediments. The central part is a plateau that is less entrenched by glaciation than the Arabika Massif, at altitudes of 1900–2100 m, with summits rising above 2500 m. Like Arabika, the overall tectonic structure of the Bzybsky Massif is a large asymmetric anticline complicated with several low-order folds. The large Chipshirinsky longitudinal fault divides the massif into the northern and southern blocks, the latter being uplifted about 700 m relative to the former. Many lesser faults further divide the folded structure into a complex system of blocks that exert strong control over

Caucasus, Georgia: Figure 1. Karst features of the Arabika and Bzybsky massifs in the western Caucasus of Abkhasia, Georgia.

cave development (Vakhrushev, Dublyansky & Amelichev, 2001).

More than 400 caves have been explored in the Bzybsky Massif since 1971, with 55>100 m deep. The deepest caves are Pantjukhina Cave (1508 m deep, 5530 m long), Snezhnaja-Mezhennogo System (1370 m deep, 19000 m long), Napra (970 m deep, 3170 m long), Pionerskaja (815 m deep, 1700 m long), Grafsky Proval (770 m deep, 1750 m long), and Forel'naja (740 m deep, 1500 m long). The most remarkable is the Snezhnaja-

Mezhennogo System, with its branchwork pattern, an underground river reaches at depth of about 700 m below the Snezhnaja entrance, the large and long river passage, and many large chambers modified by breakdown. The total volume of the cave is estimated to be about 1.7×10^6 m³. Most of the known deep caves, located within the southern block drain to the Mchishta Spring, the largest spring in the Caucasus with its average discharge of 9.3 m³ s⁻¹ and maximum discharge of 197 m³ s⁻¹. The spring is on the Kaldakhvarsky fault, and its underground catchment is estimated at 160 km². Tracing tests have shown a direct connection to Mchishta from the Snezhnaja-Mezhennogo System (1930 m above) and Napra (2300 m above). Divers in Mchishta have discovered a large cave of total length 4200 m (of which 780 m are underwater) and a volume of 380 000 m³. The cave starts with a siphon 340 m long and 45 m deep with an underwater shaft in which a depth of 75 m has been reached. The entrance siphon leads to the eastern and western series, which have quite different morphologies. The eastern series is a 3-D maze about 1 km long. The western series is a 1400 m long, linear gallery, 5-20 m high and wide, leading to another siphon 320 m long and 48 m deep. It is hoped that further exploration in Mchishta Cave may give access to the main collector of southern Bzybsky. The northern block of the massif drains to springs in the Bzyb River valley. A tracer injected in Boguminskaya Cave appeared in Pantjukhina Cave at -600 m, and came out at the Bzyb Spring, located just in front of the Goluboje Ozero Spring, which is across the river. The depth of the karstic drainage in this case is 1920 m.

To the north of the Bzybsky Massif, the high Achibakh Massif also demonstrates features of alpine karst, although deep caves are not yet known. Further to the southeast, along the southern slope of the Great Caucasus, the limestone belt continues through Western Georgia, where many important karsts and caves are known at low altitudes (Tintilozov, 1976). Several massifs rise above 2000 m, including Ohachkue, Kvira, Mingaria, Askhi, and Rachinsky, but they have neither signs of glaciation nor deep caves. ALEXANDER KLIMCHOUK

CAVES

Various kinds of cavities occur widely beneath the Earth's surface, both natural and artificial (created by humans). The term "cave" is commonly applied to natural openings, usually in rocks, that are large enough for human entry. This definition is clearly anthropocentric, relies on the ambiguous criterion of accessibility by man, has no genetic meaning, and is therefore non-scientific. It also implies that a cavity is connected to the surface through entrances. Caves can be distinguished from surface landforms by morphometric criteria: caves are forms in which the long dimension (length or depth) is greater than the cross-sectional dimensions at the entrance. The anthropocentrism of the above definition of a cave implies that it is largely air-filled, but advances in underwater cave exploration during the second half of the 20th century have dramatically relaxed this limitation. The concept of a cave is, rather, an exploration notion.

Caves are formed by different processes in many rock types and unconsolidated sediments. They can be classified according to their origin and the lithology of host rock or the type of sediment. However, speleogenetic processes differ greatly and many of them do not depend strongly on host rock composition. Numerous attempts have been made to develop genetic classifications that would encompass all caves and relate them to host rocks (e.g. White, 1988; Dubljansky & Andrejchuk, 1989) but none of them appear to be quite harmonious in grouping the processes and genetic types of caves. Instead, some kind of heuristic approach, only partly genetic, is commonly used in distinguishing the most significant classes of caves. The great majority of natural caves, including the largest ones (see Figure), are solution (or karst) caves, that is, caves that have been created princi pally by the dissolution of bedrock by water circulating through initial openings such as fissures and pores. Solution caves are the most important to cave and karst scientists and so are the principal focus of this Encyclopedia; they are also most important in terms of their interference with human activities. Caves produced by processes other than solution occur in many types

Caves: An example of a large abandoned trunk passage, Beimo Dong, in the Bama karst of Guangxi, China. (Photo by Jerry Wooldridge)

of rocks and are sometimes referred to as pseudokarst or karst-like features (see Pseudokarst entry).

Solution caves occur widely in limestone and gypsum, and, less commonly, in salt, quartzite, and clastic rocks cemented by soluble material (e.g. some sandstones and conglomerates). Although dissolution is the dominant process, other processes such as erosion and gravitational breakdown may take part in their development, particularly at later stages. The lower limit of the size of a conduit (the precursor to a cave) is accepted to be about 5–15 mm. This range encompasses the important thresholds which permit turbulent flow through initial openings under common hydraulic gradients and temperatures, switch calcite dissolution kinetics to boost up the growth rate, and trigger effective sediment transport (Ford, 1988; Palmer, 1991; White, 1977; 1988; see also entry on Speleogenesis). It therefore allows conduits to be distinguished from proto-conduits, and from pores that form during diagenesis of sediments. Speleogenetic consideration implies that conduits can be partly or entirely filled by water, air, and sediments during various stages of their development.

Volcanic caves are formed in several ways (see Volcanic Caves entry), of which the most important is the evacuation of fluid lava from a cooling lava flow. The process operates mainly in pahoehoe basalt flows and is responsible for some very large cave

systems, such as the 65.5 km long and 1101 m deep Kazumura Cave in Hawaii. Caves of this type are also termed lava tube caves.

Glacier caves are formed by melting of the ice of glaciers (see Glacier Caves and Glacier Pseudokarst). They form along crevices in the ice and along its contact with bedrock, through the action of invading water usually derived from ice melting on the surface of the glacier. Glacier caves tend to be ephemeral, but some form quite large integrated systems, e.g. Paradise Ice Caves (Washington State, United States) which extend for over 24 km.

Crevice caves may form in any massive rock by disjunction due to various forces (see Crevice Caves). This group includes true tectonic caves, whose openings were formed by tectonic tension forces, and dilatancy/gravity caves usually formed along cliffs and steep slopes due to the combined effect of unloading and gravitational mass movement.

Littoral caves (or sea caves) may form in many types of rock at sea cliffs, due to wave action that involves abrasion (see Littoral Caves). They are abundant in many coastal areas around the world; the most famous cave of this type is Fingal's Cave in basalts of the Hebrides Islands, Scotland.

Piping caves (or suffosion caves) develop in fine-grained, poorly consolidated sediments such as peat, loams, clays, and particularly loess, by removal of tiny clasts suspended in water (see Piping Caves). The process may involve dissolution to facilitate decomposition of the bedrock material but most of the mass transport is mechanical. Piping caves rarely attain a length of more than 100 m.

Erosion caves (or stream-cut caves) form in soft rocks such as shales by mechanical action of water streams. They are numerous in cliffs, being commonly shelters rather than caves. Erosion caves develop best where some resistant bed overlies a weaker bed, though large high-gradient streams may also produce erosion caves in solid rock. Illustrative of the conditional character of the process-based classification of caves is the fact that me chanical erosion plays a considerable part in the formation of many solution caves and it may become the dominant process in mature stages of their development if the caves carry large streams. Some other processes, such as aeolian deflation, hydration, crystallization and contraction, and underground pyrolysis, can also form non-solutional caves, although they are small and rare.

Caves are characterized by their shape and size, the latter being measured by various dimensions considered in the entry on Morphometry of Caves. While most caves do not exceed 1 km in length and 100 m in depth, hundreds are much larger. The longest cave is the 563 km long Mammoth Cave System in Kentucky, United States, the deepest is Gouffre Mirolda (-1733 m) in the Chamonix Alps, France, and the largest underground chamber, by both area and volume, is Sarawak Chamber in Malaysia (respectively 160000 m² and 12 million m³). The shape of caves, or their morphology, is extremely variable and can be described in several scales. Micro-morphology characterizes minor forms that constitute relief of the host rock surface within passages. Meso-morphology expresses the geometry of the main elements of a cave, that is, of passages (elongated segments in which the length is considerably greater than width or height) and chambers (cave elements in which the width or height is larger compared with adjacent passages). Passages can be linear, angulate, or sinuous, and be horizontal, inclined, or vertical. Vertical passages are termed pits or shafts. (For more details of micro- and mesomorphology features, see Morphology of Caves.) The simplest caves consist of single

elements but most are assemblages of passages and chambers with various relationships to each other. Macro-morphology of caves is expressed by cave patterns, overall orientation relative to the gravity field, and tier structure. Several distinctive types of cave patterns are recognized: single-conduit caves, single-void caves, branchwork caves, and maze caves (the latter are further subdivided into network, anastomotic, ramiform, and spongework mazes). Patterns of solution caves are controlled mainly by hydrogeologic factors, by the recharge mode and type of flow in particular (Palmer, 1991, 2000; see also Patterns of Caves). These and other important controls change in regular ways throughout the evolution of karst aquifers, giving rise to the changes of karst/speleogenetic settings and respective karst types (Klimchouk & Ford, 2000). Several settings are recognized that generate distinct styles of solution cave development (see entries on Speleogenesis). The above evolution may result in the presence of different cave patterns in the same region or in their combination in the same cave system.

Caves are sometimes classified according to their orientation relative to the gravity field into horizontal, inclined, and vertical caves, although large systems commonly have elements of various orientations. Vertical caves are dominant in mountain regions where thickness of karstified rocks and the vadose zone is great. Although there are many truly vertical caves that consist of single-drop shafts (up to 640 m deep, as is the Vrtiglavica shaft in the Kanin massif in the Julian Alps, Slovenia), most vertical caves are actually composed of shafts interspersed with inclined passages and have a stair-step profile. In many caves passages are stacked in tiers or levels, often superimposed and interconnected to form complex 3-D cave systems. A number of other approaches have been suggested to further classify solution caves as the most diverse, abundant, and scientifically and practically important category. They are overviewed in Ford & Williams (1989, pp.243–48). Some genetically based classifications are outlined in the entry on Speleogenesis.

Tens of thousands of caves have been explored so far but this is still a small proportion of the underground world represented by explorable cave passages. Caves constitute a particular environment with their specific 3-D morphology, hydrology (see Hydraulics of Caves), sediments, and minerals (see entries on Sediments, Minerals in Caves, and Speleothems), climate (see Climate of Caves) and biota (see entries on Biology of Caves and on Micro-organisms in Caves), and so they can be regarded as special complex natural systems. During long time spans in some distant past many caves functioned as traps for animals that lived at that time (see Paleontology: Animal Remains in Caves) while others served as shelters and dwellings for ancient man who left there many marks of his activity. Being well protected from destructive processes operating on the surface, caves are unique repositories of various forms of information about the past, imprinted in their morphology and contents. This justifies the exceptional scientific value of caves, recognition of which has dramatically increased during recent decades. For the above reasons, and due to the fact that caves offer spectacular scenery with striking natural marvels, beautiful mineral formations, and other unique features, a number of them have been recognized under the UNESCO World Heritage Convention and instituted as protected sites or areas on the national level (see World Heritage Sites).

CAVES IN FICTION

For as long as humans have walked the Earth we have wondered at and feared what might lie within the dark reaches of caves. For some, the mere mention of caves brings on claustrophobic nightmares, and reading about them is as close as they want to get. Thankfully, there are hundreds of books that take readers to the farthest depths of the Earth from the comfort of their favourite chair. Many of the early stories associated with caves and the underworld invoke images of a dark and mysterious place, inhabited by gods and demons, and of course the final resting-place for the souls of the dead. The stories in Greek and Roman mythology are filled with journeys to the underworld. Many of these underground travels are exemplified in *The Iliad* and *The Odyssey* written by Homer, and in Vergil's, *The Aeneid*.

One of the first writers to combine mythology with the science and religion of the day was Danté Alighieri in *The Divine Comedy*. Written in the early 1300s, this epic poem elaborately describes Danté's spiritual journey through Hell, Purgatory, and Heaven. The most popular of these three books is *Part I: The Inferno*. Here Danté, led by his trusted guide, Virgil, takes the reader down into the centre of the Earth and gives us a guided tour of Satan's kingdom and all its horrors. As they pass into Hell, above its gate they read the inscription "Abandon all Hope, ye who enter here." Deep in the underworld they encounter bizarre scenes, and a cast of characters and demons that would rival any modern-day science fiction film, culminating in an encounter with Satan at the Earth's core. This work is considered a literary masterpiece, and the foundation from which all underground fiction would emerge.

In one of his most famous works, British poet Samuel Taylor Coleridge writes about the underground world in *Kubla Khan*. This elegant poem describes a kingdom where the Alph River flows "through caverns measureless to man." In his writing he describes the cave as "a savage place" that is both "holy and enchanted." It is said that Coleridge found inspiration to write this poem after reading about Florida's springs.

Other writers envision the Earth as hollow, brimming with lost worlds and civilizations. With so much life teeming above ground, why not below too? In 1864 Jules Verne wrote in *A Journey to the Center of the Earth:* "The words which make up the human language are inadequate for those who venture into the depths of the Earth." Although this may well be true, with this book Verne wrote the definitive story against which all other hollow-earth fiction would be judged. In the grandest of styles, Verne mixes scientific fact with fiction and gives us a view of the interior of our planet, filled with vast oceans, prehistoric monsters, mountain landscapes, and man-like creatures. In one of his last books, Verne once again returned to the subterranean, in *Underground City*, also called *Child of the Cavern*. H.G.Wells is considered by many to be the father of modern science fiction. In his 1901 book, *The First Men in the Moon*, he combined the thrill of space travel with the underground exploration of Earth's moon.

Using the hollow-earth theme, Edgar Rice Burroughs produced a seven-novel series that began in 1914 with *At the Earth's Core*. Whereas Verne simply entered the Earth through an extinct volcano, Burroughs uses a rocket-powered burrowing machine to reach his inner-earth world, complete with a miniature Sun, Moon, extinct dinosaurs and mammals, and an intelligent ape-like race. Other cave-related books of his include *Cave Girl* and *Tarzan and the Cave City*.

Even Dorothy and the Wizard of Oz find themselves at the centre of the Earth in L.Frank Baum's *Dorothy and the Wizard in Oz*. After falling into the Earth following an earthquake, the two are reunited and they make a perilous journey back to the surface. In 1865, Lewis Carroll wrote *Alice's Adventures in Wonderland*. Originally *titled Alice's Adventures Underground*, this is the story of a young girl's accidental fall into a rabbit hole and her discovery of an underground world filled with strange people and unusual places.

Many fiction books are modelled on true events and real places. In Robert Penn Warren's novel, *The Cave*, set in a Tennessee cave, he writes of a young man trapped

alone in a cave as the world above watches the tragedy unfold. This story and all its characters bears striking resemblance to—and was based on—the plight of Floyd Collins as he lay trapped and ultimately died in Sand Cave in Kentucky in 1925.

One of the best-known writers of the macabre was H.P.Lovecraft. His well-known short story, *The Beast in the Cave*, tells of a man lost from his tour group and stalked by a wild beast in the bowels of Mammoth Cave.

Authors also use the dark, constricting, and unknown passages found in caves as effective means for what they symbolize. Plato, the great Greek philosopher, uses a cave in one of his most famous works, *The Allegory of the Cave*. In it we find helpless prisoners chained in a cave since childhood and unable to move or see each other. They are led to believe that what they are shown by their captors is reality. The cave is a metaphor for understanding the level of human knowledge and its relationship to its surroundings.

In E.M.Forster's 1924 novel, *A Passage to India*, caves play a central role in the mystery and understanding of the story, and they serve as a physical manifestation for the events that take place. Written at a time when Britain ruled over India, we see the caves as complex, confusing, and ungovernable. Forster skilfully uses the caves as a powerful symbol of what happens when two cultures collide.

Caves also make great places to hide from one's enemies. In Ernest Hemingway's *For Whom the Bell Tolls*, loyalists fighting in the Spanish Civil War use a cave as a strategic position as they plan their offensive against the fascists.

The use of caves is prevalent throughout many of the novels written by Mary Shelley. In *Frankenstein*, the monster finds refuge in a high mountain ice cave, and in *The Last Man*, the story focuses on the famed Sibyl's Cave, located in Naples, which contained the "Sibylline Leaves", used to predict the future.

For young readers, nothing beats the danger and adventure that caves can hold. Their dark and mysterious world makes the perfect setting for finding lost gold and solving crime. In Mark Twain's 1876 classic, *The Adventures of Tom Sawyer*, much of the story centres around McDougal's Cave and the trouble that Tom and his friends find in it. Today the cave is called Mark Twain Cave and it is one of Missouri's most popular show caves. Victor Appleton's Tom Swift novels (*Tom Swift in the Caves of Ice* and *Tom Swift in the Caves of Nuclear Fire*) also continue the adventure theme. In Franklin W.Dixon's popular *Hardy Boys* series, *The Secret of the Caves* is just one of the many books where we find our young cavers searching for clues to their latest mystery. And where would we be without the magic words, "Open Sesame!" spoken by Ali Baba in the classic book, *The Arabian Nights*. Speaking these words opened the mouth of a hidden cave containing the treasure of the Forty Thieves.

Caves are used throughout the writings of J.R.R.Tolkien. His popular books *The Hobbit* and *The Lord of the Rings* tell of adventures with orcs, goblins, dwarves, dragons, and a cave troll, all found under the Earth. The strange creature Gollum lived by a subterranean lake beneath the Misty Mountains and his eyes gradually grew big to be able to see in the dim light.

Delving into the Earth is still as popular as ever. Many of Clive Cussler's adventure novels find action underground. His *Inca Gold* takes readers on a wild ride on an underground river in search of treasure. In Jeff Long's *The Descent*, Danté meets Verne as a scientific expedition is launched into the underworld in search of Hell and its ruler.

Nevada Barr takes murder underground in *Blind Descent*, a gripping novel, set in New Mexico's Lechuguilla Cave, that pits man against man in the dark wilderness below the Earth's surface. In *Cavern*, by Jake Page, cavers discover that not every prehistoric beast died during the last Ice Age. David Poyer stirs up a mystery in the chilly underwater caves of Florida with his book, *Down to a Sunless Sea*, and Anne Mclean Matthews turns a cave into a blood-soaked killing ground in her disturbing psychological thriller, *The Cave*. James Rollins finds a lost civilization and the answer to one of mankind's biggest mysteries in *Subterranean*, and Paul Preuss follows in the footsteps of Verne on his way to the centre of the Earth in *Core*.

It seems that the lure of caves will forever be ingrained in works of fiction. We have only just begun to unravel a few of the mysteries that lie beneath the surface of the Earth. Every year we plunge deeper and deeper into its dark voids, discovering new life-forms and charting new worlds. Perhaps some of this fiction might one day become fact.

CAVES IN HISTORY: THE EASTERN MEDITERRANEAN

The caves of the eastern Mediterranean region are perhaps the most historically important caves in the western hemisphere. The first historically documented caves are those of Iskender-i-Birkilin, at the head of the Tigris River in Kurdistan. By 1100 BC they were already a well-known attraction on an important trade route. In that year, King Tiglath Pileser of Assyria left a dated cuneiform inscription commemorating his visit. Some 250 years later, King Shalmaneser III also left commemorative inscriptions at the caves and on various monuments in his capital city. Here, the decorations on a bronze gate band included the earliest known depiction of a cave (Figure 1 and Halliday & Shaw, 1995). This and a black obelisk with an incised inscription about the cave are now exhibited in the British Museum. Alexander the Great, known throughout the Middle East as Iskender, is said to have bivouacked his army in the Birkilin Great Cave some five centuries later. The Iskender-i Birkilin caves have borne his name ever since.

Throughout the ancient world, Greek and Roman folklore was full of references to caves, not all of which actually existed. Two different show caves in Crete (and another on the island of Naxos) are advertised as the mythological birthplace of the great god Zeus. Hermes Cave near Corinth was named for the gods' messenger, supposedly fathered by Zeus on the nymph Maia in this cave. Ancient stories related that the orphaned in-

Caves in History: Figure 1: Section of the hinge from the Bronze Gates of Shalmaneser III, with engraving of the Birkilin stream cave (lower panel). © The British Museum.

fant Dionysos (another son of Zeus, by Semele, who had a jealous husband) was fostered in what now is called the Cave of Dionysos, in Arcadia.

Homer's fictional hero Odysseus was noted for amazing spelean adventures. In far northeastern Greece, the town of Maroneia is one of several which claim various caves where he had to blind the one-eyed giant Polyphemus in order to escape captivity (Mallorca's Cave of Arta also has a strong case). Near his mythical home on the island of Ithaca, the Cave of Marmarospilia is listed as the Cave of the Naiads, where Odysseus briefly stashed his treasure before reconnoitring his home, in disguise. The best claimant to the legendary River Styx or River Lethe appears to be in the Cyrenaica karst east of Benghazi, Libya (Preble, 1945). However, the supposed Labyrinth, in Crete, is merely an underground limestone quarry.

In western Turkey, the builders of the long-ruined city of Hieropolis must have known of "Plutonium", "Pit of the Jinns", or "Dog Cave", as a travertine cave in the world-famous terraces of Pamukkale has been variously termed. This cave opens downward within the complex ruins of the Temple of Apollo. Its shape traps hypoxic concentrations of CO_2 released by the thermal springs. Old tourist leaflets announced—probably without much exaggeration—that the classical writers Strabo and Dio Cassius discussed its lethal effects.

The Bible and the Koran contain numerous references to caves, although most biblical caves are mere rock shelters or grottoes. However, in his analysis of caves mentioned in the Bible, Stebbins (1947) confirmed that others were important, both historically and scientifically. One was discussed in Buckland's 1824 *Reliquae Diluvianae*. Bethlehem's famous Grotto of the Nativity and St Paul's Grotto on Malta are not mentioned in the New Testament, and there is doubt that either is a natural cave. Historic Ghar Dalam and

many smaller caves in Malta are natural, and some authorities have suggested that a tiny part of St Paul's Grotto was also originally natural.

By the time of the Prophet Muhammad, the fable of the Cave of the Seven Sleepers a Rip van Winkle precursor—had become a beloved folk tale. The Prophet used it effectively as a parable. Today, at least two cities claim this cave: Ephesus and Tarsus. The better-publicized site is about 3 km east of the principal ruins at Ephesus, near Turkey's Aegean coast. It has been commemorated on a Turkish postage stamp that actually depicts the ruin of an ancient religious complex built against a hillside containing at least two phreatic caverns. Like Scotland's King Robert the Bruce, the Prophet Muhammad was saved by a spider web spun across the entrance of a cave where he was hiding on Mount Thar south of Mecca (the Prophet's enemies were certain that since the web was intact, no one had approached the cave for days). His people were so familiar with caves that this account was accepted universally. This cave also has been commemorated on postage stamps.

In the karsts of Lebanon, a Roman temple was built on top of one of the resurgences at Afka Cave. The site for another Roman temple was a magnificent field of spitzkarren. On the other hand, most of the "cave monasteries", cave temples, and refuges of Lebanon are merely beneath overhangs or in grottoes, rather than in true caves. Although the splendidly decorated inner portions of Jeita Cave are 20th-century discoveries, the great resurgence from its entrance was utilized in antiquity. Israel's well-known Qumran Caves are noted for their caches of religious manuscripts—the famous Dead Sea Scrolls. Israel's largest and most important caves are in salt karst known since biblical days (see Sedom Salt Karst). No hieroglyphic inscription is known in or about any true cave in Egypt, but the history of the caves and karstic spring at St Anthony's Monastery (in the presently arid Eastern Desert) can be traced to about 305 AD.

Throughout Greece, caves and karst have been an integral part of ordinary life since prehistoric times. The Acropolis and the heights of Delphi are formed of well-developed karst. At Delphi, the 100 m Corycian Cave was supposedly the seat of the famous Delphian oracle; the centre of the universe. At a less lofty level of life, well into the 20th century pregnant women in Crete rubbed their bulging bellies ("just for luck") against a pregnant-looking stalagmite in the cave shrine of Eileithya, once worshipped as the goddess of childbirth and motherhood, as well as the mother of Eros. The 260 m Cave of the Dragon, located within the town of Kastoria, has long been a favourite topic among Grecian storytellers. Large littoral caves served as convenient boat houses, refuges, and pirate dens. The vanishing current of sea water disappearing into the rocky shore at Argostoli on the island of Cephalonia must have perplexed early man, but this did not stop him from constructing mills to harness its power. Inland in the Peloponnesus, the famous *katavothres* of the plain of Mantineia—gaping stream-sinks—must also have bemused him.

Pre- and post-Christian shrines and memorials to victims of wars and persecutions are almost innumerable here. Graffiti in the Cave of Antiparos have been dated back to Archilochus (728–650 BC). Near Athens, in the fourth century BC, a skilled sculptor transformed the entire cave of Nympholeptos into a marvellous cave shrine complete with carved statues of nymphs, the Graces, Apollo, Pan—and himself. The shrine at Ton Limnon Cave in the northern Peloponnesus is credited with curing insanity, at least in

mythological times, when some unfortunate women were reputedly cured of the delusion that the gods had changed them into cows.

Fine 14th- and 15th-century Byzantine paintings can be admired on the walls of Panagia Eleousa Cave in northern Macedonia.

Greece's Cave of Antiparos (on the island of that name) was the first cave to become celebrated in the mainstream of modern Western thought, but at a terrible cost. In 1673, M.de Nointel, the French ambassador to Istanbul, explored this steeply sloping cave and celebrated Mass in its largest chamber. Subsequently J.P.Tournefort described the events in Jules Verne style. His account was translated into several languages (Tournefort, 1718), accompanied by splendid, highly imaginative engravings which made the cave seem approximately ten times life size. Fanciful illustrations of some later accounts depicted even grander scenes (Figure 2; see also Figure in Speleothems: History). Despite their exaggerations, these wonderful engravings of the Cave of Antiparos had a salutary effect on the dominant establishment of northern and western Europe. Even in enlightened intellectual circles, predominant conventional wisdom heretofore had populated caves with evil trolls and other loathsome imaginary beings; obviously caves were thus places to shun and abhor. Suddenly they now became places of beauty, interest, and curiosity. Isolated Antiparos became a frequent port of call and its cave became more and more celebrated. Unfortunately, huge smoked inscriptions soon defaced the cave, and its glories

Caves in History: Figure 2: Artist's conception of the Grotte d'Antiparos, drawn 1776 by J.B. Hilair. From *Voyage pittoresque de la Grèce,* vol. 1, 1782, by M.G.A.F.de Choiseul-Gouffier. The artistic merit of this and

other early engravings of scenes in this cave profoundly influenced European views about caves but enormously exaggerated the size of rooms and passages. William R. Halliday collection, courtesy of Trevor Shaw.

lived on only in the imaginative engravings. Today, the Cave of Antiparos preserves only traces of its former beauty. This once-great cave remains a sad monument to the impact of fame on unprotected caves everywhere. Hopefully it will remain a truly unforgettable lesson of history.

CERKNICA POLJE, SLOVENIA: HISTORY

The seasonal lake of Cerknica occupies a level depression immediately south of the town of Cerknica and 10 km east of Postojna. The floor area of this depression is 38 km^2 , of which two-thirds is flooded every winter to form the lake. Its regular water supply is two-

fold: underground from the Obrh stream which sinks nearby in Loško Polje, and also from a few surface streams such as the Cerkniščica. In addition, when the local water table rises as a result of large amounts of rainfall, water pours out of holes (estavelles) in the level bottom of the "lake" and from caves around its edge. When the water table drops again, the lake flows back into many of these holes. It also drains into several overflow caves such as Velika and Mala Karlovica at its northwest corner, with most of the water going underground to feed karst springs in Planinsko Polje.

With such a large, almost flat surface as the "lake" bed, the appearance and disappearance of the water can seem remarkably rapid, and this is what drew attention to it long ago. So strange did this seem, that the place has a long recorded history. A little before 7 BC, Strabo referred to it as the "marsh called Lugeum". In 1551 Wernher published a map of the lake (Figure 1) and stated that: "where not long ago men were fishing you may now bring in a harvest, and even sow for the next one, and trade in the produce; and at the turn of the year go fishing again". When Lazius published his map of the region in 1561, the lake was shown four times too large in comparison with its surroundings. Clearly it was regarded as important. No doubt this early popularity was due in part to the fact that the place was close to the ancient salt road from the Adriatic into central Europe. Once written about, it remained a "tourist attraction" well into the 19th century.

The early fame of the polje inspired writers who sought to explain the mechanism of the disappearing lake. In 1537, a Latin poem by Leonberger left it to the water nymphs to explain. More than a century later, the Jesuit polymath, A.Kircher, in 1665, made the remarkably modern suggestion that the fluctuating level of the lake was due to changes of water level in a natural reservoir beneath the mountains—a kind of water-table hypothesis. This suggestion was disregarded when investigators started to give the lake's behaviour more serious consideration. Their explanations included:

- 1. Simple flow in single channels such as can easily be simulated in a laboratory experiment;
- 2. Complex flow through many channels and siphons;
- 3. Diffuse flow beneath what amounted to a water table.

J.W.Valvasor, well known as a topographer in Slovenia, was also a cave explorer (see Speleologists entry). In 1687 he put forward a simple explanation for the seasonal flooding of the

Cerknica Polje, Slovenia: History: Figure 1. Wernher's 1551 map of the Cerknica Lake, showing the main water sinks. South is at the top of the map.

Cerknica Polje, Slovenia: History: Figure 2. Valvasor's diagram of 1689, showing supposed subterranean lakes associated with the Cerknica Lake, and the channels and siphons connecting them. Cerknica Lake. The lake, he said, was an overflow from underground lakes beneath the surrounding hills, which normally drained elsewhere. This idea was in fact partially correct. Unfortunately, two years later, Valvasor evidently felt that he needed to explain the sudden onset of floodwater flow into the lake. To do this he modified his simple explanation unrecognizably to a system consisting of the lake itself, an underground lake beneath it, more underground lakes in the hills, channels connecting them all, and no fewer than six siphons (Figure 2).

Some 30 years later, F.A.von Steinberg produced a theory that was different but just as complex. It was written about 1720 and published in 1758. He postulated several levels of caves within the hills, interconnected and with siphons. To explain the sudden start of flooding into the lake he supposed that the air entrained in the underground waterfalls caused pressure to build up in some of the caves.

So much for the two really complicated theories. J.A.Nagel produced a simple and elegant theory, not unlike Valvasor's earlier one. Water, he said, will appear in the surface lake only if the rate of supply to an underground system is greater than the off-take. Thus Nagel was basically correct and would have been entirely so if he had not confined his water flow to single channels. His manuscript account remained unpublished in Vienna, so it is not known to what extent he influenced the ideas of his successors.

With the next writer began a trend towards the concepts of groundwater and a water table in limestone. F.Hacquet, in 1778, referred to Steinberg's theory as unnecessarily complicated and he himself produced a refined version of Valvasor's first explanation. The mountains round the lake, he said, are filled with caves and act like a sponge. Only when they are full does the Cerknica Lake begin to fill.

Finally, Tobias Gruber, in 1781, postulated what amounted to groundwater in the rock beneath the lake. This was in effect a multichannel version of Nagel's ideas, which he may or may not have been aware of. He expressed his explanation more clearly than Hacquet, who in any case was concerned with waterfilled caves around the lake rather than beneath it. Thus Gruber wrote in his *Briefe hydrographischen und physikalischen Imhalts aus Krain* (pp. 111–12):

Beneath the Zirknitz [Cerknica] lake and its surrounding mountains there flows continuous water...All the caves and passages taken together make an underground river bed which stretches away invisibly for so many miles. Only here and there does it break into daylight a little as in the river of Rakov Skocjan and, intermittently, in the Cerknica Lake.

CHEJU-DO LAVA CAVES, SOUTH KOREA

Cheju-do, the largest island (1792 km² in area) of Korea, is located in the Korean Strait, c.90 km south of the Korean Peninsula. The island is a long ellipse, 74 km east-west and 39 km north-south. Mt Halla, the highest peak (1950 m) in South Korea, is located near the centre of the island. Geologically the island is a complex shield volcano, which extends with a gentle slope to the coastal region; it is notable for its numerous parasitic cones. Cheju Island is almost wholly composed of volcanic rocks, mainly trachyte, trachy-andesite, and esite, and basalt, with some sedimentary formations (Won, 1975; Lee, 1982). The pre-volcanic basement of the island is not exposed, but the results of a regional gravity survey together with the presence of granitic xenoliths found in the effusive rocks and in a basaltic breccia near the base of the exposed succession suggest that the basement is composed of pre-Tertiary (probably Bulgugsa) granite. According to Won (1975), the sequences of the volcanic eruptions and some sedimentary rocks in Cheju Island are grouped from oldest to youngest as follows: the Upper Pliocene Sogwipo Formation; the Lower Pleistocene Pyosonri basalt, Sogwipo and Jungmun trachytes; the Lower—Upper Pleistocene Seongsan, Hwasun, and Sinyangri Formations; the Upper Pleistocene Jeju and Hahyori basalts and Beopjeongri (including Sanbansan) trachyte; Siheungri, Seongpanag basalts; Hanlasan basalt and trachy-andesite; Baegrogdam basalt; Lower Holocene Volcanic cone I and Volcanic cone II; and the Upper Holocene AD 1007 and 1002 episodes of volcanic activity; Shell-sand Formation.

The basalt is the most widely distributed rock, followed by the trachyte and trachyandesite, and the sedimentary formations are the least abundant. These volcanic flows erupted more than 79 times during the history of volcanic activity. There are a couple of old manuscripts which date several eruptions to 1002 and 1007 AD.

Cheju Island is a major vulcanospeleological area and one of the main show cave regions in South Korea. The lava caves of Cheju Island have been systematically surveyed since 1977 as a joint project between the Japanese Vulcanospeleological Society and the Speleological Society of Korea. There are 57 lava caves recorded, but some of them have not yet been scientifically surveyed. About 80% of the lava caves are in Pyosonri basalt, and the rest are distributed among the Jeju, Hahyori, Siheungri, and Halasan basalts (Speleological Society of Korea, 1988; Sameshima *et al.*, 1988).

Man-jang Cave is located in the northernmost part of the island. The name of the cave derives from "Man" (ten thousand)—"jang" (c. 3 m long), meaning "so long that it reaches 30000 m". The total length of the Man-jang Cave is actually 8928 m, with the lower major cave measuring 5164 m, and the upper two caves 2031 m and 1733 m respectively, and the cross-sectional area of the main passage is among the largest in the world (see Photo). At the upper end of an upper cave, there are four floor shafts, which connect to the main cave at the lower level. There are also large-scale lava bridges in the lower reaches of the upper cave. The K-Ar age determination on a lava bridge on the third floor dates it as 190000 years old (Sawa & Inoue, 1999). Twenty-one lava balls were found in the main cave. The lava balls were probably left on the cave floor because of the slow movement of the lava flow or due to the thinness of the lava. "Turtle Rock" is

a large lava ball on a terrace, which has a prominent rim on its side, indicating the lowering of the lava-flow level since the ball was carried down. The other typical features of this cave are "tube in tube" structures, lava pillars, silica pillar formations (lavatites), ripple wave marks, and long ribs/ledges at multiple levels on the walls, left by past stages of lava flowing through the cave. The K-Ar age of the two lava column samples (taken from the area of the ceiling) 1060 m from the entrance of the main show cave, have been dated at 30000–50000 and 320000–420000 years ago, respectively (Sawa *et al.*, 1990). Gypsum formations and coralloidal diatom speleothems also occur (Kashima *et al.*, 1989). Man-jang Cave (with the associated Kim-nyong Cave) was designated as a Korean Natural Monument in 1962.

Bil-le-mot Cave is situated in the southern area, in Aewol district and was discovered in 1971. This cave is developed in the Siheungri lava, where the lava was ponded by a ridge of the Pyosonri lava. Systematic investigations have been carried out since 1989 as a joint project between Korean, Chinese, and Japanese speleologists. The narrow entrance barely allows a person to go through but leads to grand halls and an extremely complex cave system with passages branching and crossing both horizontally and vertically. There is even a spiral passage between upper and lower parallel caves. The main cave is 2917 m long, but the length of the complex branch caves is 8832 m, making the total length 11749 m. There are lavatites 28 cm long in this cave, and the largest lava ball is 7 m long and 2.5 m wide and high. It also contains calcite, opal, quartz, and trona (Kashima *et al.*, 1989). This cave was designated as a Korean Natural Monument in 1984. However, it is not open to the public.

The Hyop-jae cave system is in the Hallim district near the northwest coast of the island, in Pyosonri basalt. Ok-san Cave, So-cheon Cave, Han-dul Cave, Ssang-ryong Cave with Hyopjae Cave were together designated as Korean Natural Monument

Cheju-do Lava Caves, South Korea: List of lava caves longer than 2 km on Cheju Island (compiled by T. Ogawa and I.Sawa in July 2001). Location abbreviations: PJ=Puc-Jeju-Gun; NJ=Nam-Jeju-Gun.

Name of cave	Location	Length (m)	Depth (m)
Bil-le-mot Cave	O-um-Ri, Aewol-Up, PJ	11749	255
Man-jang Cave	Kim-nyong-Ri, Kujwa-Up, PJ	8924	125

Cheju-do Lava Caves, South Korea: The main passage in Man-jang Gul is unusually large for a lava tube, and has a kilometre of its length lit for tourist access over a smooth lava floor. (Photo by Tony Waltham)

No. 236 in 1971. A total of 17 km of passages has been mapped in the many caves in this area. This cave system is well known for its abundant carbonate speleothems. Microcoquina sand dunes are widely distributed in the Hallim district, overlying the cavernous Pyosonri basalt. Carbonate-bearing groundwaters percolated into the Hyop-jae cave system and deposited carbonate speleothems (dripstone, flowstone, and other speleothems) which cover the bare lava walls and coexist with lava speleothems (Kashima *et al.*, 1989).

CHEMISTRY OF NATURAL KARST WATERS

Karst water represents a subset of groundwater whose chemical composition is controlled fundamentally by climate, the type of source materials being dissolved, and residence time. In the case of climate, temperature and rainfall control weathering rates of system solids, with both parameters constraining seasonal and short-term variations in chemical composition. Soil temperature and saturation govern microbial production of CO_2 , which dictates the capacity of soil solutions to dissolve carbonate, and are therefore parameters of particular importance in limestone and dolomite karst areas, although not relevant to the formation of gypsum karst.

Source rocks yield solutes at highly varying rates (in the order of fast to slow): ion exchange on clays, dissolution of gypsum, metastable carbonate (aragonite, Mg-calcite, crushed calcite), limestone (calcite), pyrite, dolomite, and finally silicate phases. The atmospheric zone is also a source of karst water solutes, delivering atmospheric dust, pollutants, and marine aerosols in incident rainfall, and organics and particulate matter washed from plant foliage to the ground surface via rain throughfall.

In the dual-porosity soil and aquifer zones (Figure 1, Tooth & Fairchild, 2003), residence time is controlled by hydrology, which determines the nature and degree of water/solid interaction. Primarily, residence time is a function of storage capacity and the distribution of matrix and preferential flow routes in the soil (Figure 1A), and of matrix, fracture, and conduit routes (Figure 1B) within the aquifer. Secondarily, temporal variations occur in soil and aquifer zone flow pathways, in response to rainfall inputs of differing duration and intensity. Resultant karst water chemistries are also constrained by the relative abundance and degree of reactivity of soil and aquifer zone materials. A

Chemistry of Natural Karst Waters: Figure 1. Potential hydrological controls on karst water geochemistry; A. soil zone flow routes; B. aquifer zone flow routes; C. aquifer reservoir head space and nature of the gas phase; D. mixing in piston flow reservoirs.

further control on geochemistry is the relative dominance of the processes of carbonate dissolution and precipitation (Figure 1C) during aquifer throughflow to the cave exit point or spring.

Many geochemical parameters have been measured in karst waters, depending on the purpose of the study. Water hardness represents the amount of dissolution of carbonates (dolomite and calcite) and can be approximated in several ways. Controls on water hardness (technically equivalent to alkalinity) in karstic regions have been extensively investigated by use of electroconductivity (EC), a surrogate for total ionic content, and hence total amount of carbonate rock dissolution in carbonate terrains. Whereas EC can be readily logged automatically, individual species normally have to be analysed on individual samples. Determination of pH close to the time of sampling is also needed to determine the relative saturation of solutions for calcite and dolomite. Alkalinity (bicarbonate and carbonate) is determined by titration with a strong acid, although it can also be approximated by calculating the ionic charge balance, particularly if EC data is available, as this provides an independent check (Rossum, 1975). Determination of the major ions (Ca²⁺, Mg²⁺, K⁺, Na⁺, HCO₃⁻, SO₄²⁻, Cl⁻, and NO₃⁻) is essential for studies of solute sources, supplemented as required by trace species. Measurement of the intensity

of UV-stimulated fluorescence of cave waters is a powerful tool in reconstructing the input of soilderived dissolved organic material, particularly humic and fulvic acids (e.g. Baker, Barnes & Smart, 1997). Another indication of the introduction of short residence time waters is the dilution of species known to be generated by slow dissolution (e.g. pyritederived sulfate). In recent years there has been a surge of interest in the chemistry of cave waters in relation to that of precipitated speleothems, in order to provide modern calibrations for paleoclimate studies of the speleothems. Much work has focused on isotopic parameters, particularly δ^{18} O, because of its relationship to environmental temperature, but also δ^{13} C because of its relation to the carbonate system and soil processes (e.g. BarMatthews *et al.*, 1996). Strontium isotope ratios (87 Sr/ 86 Sr) reflect cation sources which, in favourable cases, can be correlated with the recharge regime and hence used as a proxy tool for estimating past rainfall (Banner *et al.*, 1996). Isotopes belonging to the decay series of U isotopes, as well as ¹⁴C, have also been studied in relation to modern processes that affect our understanding of radiometric dating of speleothems.

An extensive study of spatial and temporal variation in the sinking creeks and springs of south-central Kentucky in the Mammoth Cave area (Hess & White, 1983), clearly demonstrated the importance of seasonal temperature variations and dissolution along the flowpath in controlling water hardness. Rainfall events caused dilution of spring water because flow was concentrated in conduits with limited opportunities for carbonate dissolution. However, in other cases with differing plumbing (Figures 1A, B), piston flow effects (Figure 1D) can lead to an initial increase in ion content. In some cases, the karst above a cave system can be precipitating calcium carbonate, particularly if falling water levels in a conduit or fissure lead to degassing of carbon dioxide into an air space subject to ventilation (Figure 1C). This process leads to characteristic increases in δ^{13} C (BarMatthews et al., 1996) and also in Mg/Ca ratio (Fairchild et al., 2000), as the CaCO₃ precipitates have much lower Mg/ Ca than that of the precipitating solution. Thus, in many cases, the Mg/Ca and other ratios in cave water solutions (and speleothems) reflect the water saturation state of the cave and hence could be used in paleoclimate studies. Nevertheless, adjacent drips may have different chemistries, reflecting their differing flowpaths, and long-term evolution of the regolith will also lead to changing elemental compositions (Fairchild et.al., 2000).

Chemistry of Natural Karst Waters: Figure 2. Piper diagram illustrating some process trends in karst water chemistry (see text for explanation of the numbered trends and the literature sources of data). Points have been selected as representatives from larger data sets in each case. The total dissolved solids in the upper (diamondshaped) diagram are shown by the size of the circles around the data points (scale in upper left).

Figure 2 illustrates some major trends in the composition of karst waters. Coastal karst lies above a marine—freshwater mixing zone, such that samples at progressively greater depths will show increased proportions of the major ions present in seawater (Na, $Cl>SO_4>Mg>Ca$, $K>HCO_3>CO_3$). This explains the trends shown in the Bermuda data (trend 1 in Figure 2; Plummer *et al.*, 1976), whereas in the freshwater part of the aquifer, the dominant changes are due to the dissolution of aragonite and Mg-calcite and the

precipitation of calcite. Data from the Canalobre Cave, southeast Spain (trend 2, Figure 2; Andreu *et al.*, 1999) show a clear evolution from the unsaturated zone in Cretaceous limestones to the saturated zone, in response to dissolution of subsurface calcium sulfate (gypsum), although a soluble salt source of Mg is also required. Complex longer-term processes are responsible for the evolution of groundwaters in the London Chalk Basin, United Kingdom, away from the main recharge zone (trend 3, Figure 2; Elliott, Andrews & Edmunds, 1999) including carbonate dissolution-reprecipitation reactions, infiltration of sulfate-rich waters from oxidation of pyrite, and mixing with older, more saline waters. Finally, the trend of waters from the Clamouse cave in southern France (trend 4, cation diagram, Figure 2; Fairchild *et al.*, 2000) reflects varying amounts of prior calcite precipitation.

CHILLAGOE AND MITCHELL-PALMER KARSTS, AUSTRALIA

Chillagoe is a small town, about 150 km west of Cairns, in tropical north Queensland (see map in Australia entry). West of the Great Dividing Range, the perennial Walsh, Mitchell, and Palmer rivers drain the area to the Gulf of Carpentaria. The Mitchell-Palmer karst extends for 100 km between those two rivers, in remote terrain accessible only by minor tracks. The region has a tropical monsoonal climate, with an annual average rainfall of 830 mm, most of which falls in the short wet season from December to March. Daily maximum temperatures frequently exceed 38°C in the wet season and over 25°C in the dry season. The dominant vegetation of the area is savannah woodland, with Eucalyptus and Corymbia trees. The main land uses are extensive cattle grazing, and minor quarrying of the limestone for lime and building stone. Aboriginal occupation of the area dates back at least 20000 years, and many caves and overhangs have rock art and prehistoric occupation sites. Europeans settled the area in 1872, when alluvial and reef gold was discovered on the Palmer River. Today marble is quarried at Chillagoe. In spite of the remoteness of the area and the small local population, there is an active caving club that has documented the area and its caves. Tourist caves are well established, receiving between 10000 and 14000 visitors each year, and they have developed some specialized ecotourism programmes.

The Silurian to Early Devonian Chillagoe Limestone outcrops for 300 km along the Palmerville Fault as a belt several kilometres wide. The limestones accumulated in shallow marine conditions on a gently sloping ramp. To the west of the Palmerville Fault, are Precambrian metamorphics, while to the east, the Ordovician to Late Devonian Hodgkinson Province is composed of sandstones and siltstones. Compression of the region, during the late Devonian to early Carboniferous, resulted in intense deformation of the limestones, producing near-vertical bedding, coupled with widespread brecciation. Later, broad downwarping of northwestern Queensland in the early Mesozoic

Chillagoe and Mitchell-Palmer Karsts, Australia: Royal Arch tower, located 6 km south of Chillagoe. A broad pediment abruptly meets the steep cliffs of the tower. (Photo by David Gillieson)

resulted in deposition of Jurassic sandstones which unconformably overly the limestones. Since marine retreat in the mid-Cretaceous, the region has been continuously exposed to weathering.

The Silurian limestones form prominent and spectacular towers up to 70 m high near Chillagoe, and are separated by lower undulating terrain formed on chert, sandstone, and volcanic ridges. The ridges and towers lie approximately parallel to the regional strike, which is northwest—southeast near Chillagoe and more northerly in the Mitchell-Palmer karst. The towers are typically up to 1 km long and 300-400 m wide (see Photo). Surrounding the Chillagoe towers are low-angled pediments, several hundred metres wide with rock pavements, thin veneers of rubble, and spalled blocks. Close to the major rivers, the karsts are alluviated at their margins and swamp slots are present. In the Mitchell-Palmer karst, the towers are flanked by steeper bedrock ramps with skeletal soils and some scree. Most of the towers have very well-developed rillenkarren (solution fluting) which drain the upper surfaces of the pinnacles and feed larger rinnenkarren (solution runnels) which may be up to 50 m long and 30 cm deep. There are extensive kamenitza (solution pans) on the upper surfaces of the towers, along with deep grikes (vertical slots) and solution corridors. On the larger towers, large depressions and amphitheatres divide the major limestone blocks; their origin is not clear, but some may relate to cave collapse.

Over a thousand caves have been recorded and mapped in the Chillagoe and Mitchell-Palmer karsts (Chillagoe Caving Club, 1982). The longest is the Queenslander Cave, a joint-controlled maze with 6 km of passages. Few cave entrances are known from the pediments, and most caves are entered from the upper surfaces of the towers or from the angle between the cliffs and the pediments. The dominant passage shapes are rifts that narrow upwards and may intersect the surface to produce daylight holes. Larger chambers 30–50 m wide are located at joint intersections. Solution pendants and spongework suggest that early cave development involved phreatic solution. Speleothem deposits are common and may completely block passages. Cave coral is widespread and phytokarst is common near entrances. False floors of flowstone are to be found up to 20 m above the present cave floors. Cave floors are composed of a mix of breakdown blocks and flat silt or clay; many caves also have deep guano deposits. Deep shafts extend down from the upper surfaces of the towers and one (Christmas Pot) reaches the water table at a depth of 15 m below the pediment.

Palaeokarst features are found at Chillagoe and lend support to a long geomorphic history. There have been at least three phases of sinter copper mineralization in pipes, associated with regional volcanism and faulting. Fissure deposits of chalcopyrite, cuprite, and minor azurite in several caves, suggest that at least some cave passages had formed by the most recent phase 280 Ma ago. To the south of the Mitchell River, the unconformity between the Chillagoe Limestone and the Jurassic sandstone has a local relief of at least 60 m, with steep contacts. In addition, *in situ* sandstone is found at the base of some towers and also has been reported from their summits. This suggests that at least some of the towers had formed in the Mesozoic.

The major rivers of the area, such as the Walsh, Mitchell, and Palmer, are dominantly fed by catchments on non-carbonate rocks. Some of their tributary streams rise from karst springs but these may cease to flow during the six month-long dry season. There are extensive deposits of porous calcite tufas on most streams draining the karst, either as small tufa cascades or as stream bed and bank terraces. The terrace deposits are typically dense and horizontally laminated; limited uranium series dating indicates ages between 260 ka and 80 ka. In the dry season, the water table lies between 10 to 15 m below the plains, and water can be seen in a few caves. During the wet season, deep pools form in many caves, but drain over a period of a few weeks. This water flows directly into the caves from the bare tower surfaces via fissures or down many open shafts. In many caves, horizontal flood lines of organic matter indicate maximum depths, while minor solution notches can be seen in some caves, for example Carpentaria Cave. Small waterfilled cavities have been encountered during drilling at depths up to 90 m, but it appears that the karst aquifer does not have a well-integrated subsurface conduit system This is supported by lack of drawdown in drill holes adjacent to a 300 m deep open cut gold mine.

CHINA

China has an enormous variety of karst, extending over more than 500000 km² (see map in Asia, Northeast entry), including the world's most extensive and most important karst terrain, largely in the provinces of Guangxi and Guizhou (Figure 1). The karst occurs on limestones that dominate the stratigraphy of southern China from Devonian to Triassic, and most notably on the massive Qixia and Maokou facies of Permian limestones. Climates vary with mean temperatures and annual rainfalls ranging from 20° C and >1200 mm in southern Guangxi to -5° C and <250 mm on the Qinghai-Xizang Plateau. Karst morphology is equally variable, but is dominated by the extensive fengcong and fenglin karsts of southern China. Fengcong (peak cluster) is essentially a mature cone karst with steep hill profiles, which develops over time from doline karst. Fenglin (peak forest) is better known as tower karst with isolated steep-sided towers rising from an alluviated plain. Fenglin is an extreme form of karst that only develops where dissolution rates, tectonic uplift, and alluviation maintain a critical balance (Zhang, 1980). More people live on karst in China than in any other country. Environmental impacts are therefore significant; man has modified the karst, especially within the last 50 years, but the karst has also influenced mankind's development in the region. There is vast exploitation of karst groundwater, while there are numerous cave dams, underground diversions, and even hydro-electric power stations inside caves. China has more subsiding dolines than any other country, with houses, villages, roads, railways, fields, and reservoirs lost in collapse events. Karst research in China is major, but has little contact with Western research; valuable insights are provided by Yuan (1991) and Lu (1986). It should be noted that statistics from China can be misleading-areas of karst generally include large zones where limestones are buried beneath other rocks with non-karstic surface morphology, and cave lengths generally refer to groups of related caves not yet physically connected.

Guangxi is the world's most important karst with respect to its surface morphology. It has extensive outcrops of folded Paleozoic limestones, broken by anticlinal hills of Devonian sandstone that provide allogenic drainage and sediment. Landscape evolution throughout the Tertiary has created many areas of fenglin—the famous and spectacular tower karst on flat alluvi-

China: Figure 1. Simplified map of the karst regions of southern China. Small areas of non-karst occur within the regions marked as karst, and there are small outcrops of limestone within the non-karst regions. Located sites are referred to in the text, and sites outside this area are located on the map in the Asia, Northeast entry.

ated plains. These are interspersed with wide zones of fengcong that create inhospitable terrains of steep hills and deep isolated dolines. Some of the finest examples of both fenglin and fengcong are traversed by the Li Jiang (River) at Yangshuo (see Yangshuo Karst entry), south of Guilin. West of Guilin, the karst plains and fenglin extend across the Hongshui plain around Liuzhou and onward into Vietnam, while fengcong dominates

in an adjacent belt to the north that fringes the rise onto the Guizhou Plateau. The most deeply dissected, and some of the most dramatic, karst landscapes occur along this intermediate zone, including that in the Hongshui Basin (see Hongshui River Fengcong karst entry).

The fenglin towers have active foot caves and also relicts at high levels that preserve sediments proving their origins over long timescales. Towards the western end of the fengcong karst there are many major caves distinguished by very large passages. Just west of the Hongshui, the Panyang caves of Bama County contain over 40 km of very large passages, including those of Mawang Dong (10 km long). Each cave lies under a fengcong cluster and is truncated in the marginal dolines (Gill, Lyon & Fowler, 1990). Just to their south, Solue Dong has 7 km of large river passage, but has not yet been followed to the Fulon Dong resurgence. Further northwest, the caves of Leye County lie between giant dolines (tiankengs) and have a total of 30 km of very large passages, chambers, and deep shaft entrances in five disconnected segments (Figures 2 and 3).

Guizhou is a huge, complex, dissected, rolling karst plateau on a folded pile of Paleozoic carbonates up to 3000 m thick. It is surfaced with fengcong hills of all sizes, between isolated basins, perched karst plains, and inliers of non-carbonates (Zhang, Yang & He, 1992). A broad sequence of landscape evolution, from doline karst to fengcong with depressions (Figure 4) to fenglin plains, and then to rejuvenated fengcong with canyons, has been recognized in the Longgong karst, near central Anshun (Smart *et al.*, 1986) and in the southern Dushan area (Song, 1986). Cones with lower slope angles are formed on dolomites, and are known as qiufeng karst. Large rivers cross much of the plateau, and some are deeply entrenched in canyons that cut clean through mature fengcong cones. Many rivers pass through short caves and under high natural bridges; the Ganhe natural

China: Figure 3. The main river cave out of the Dashiwei tiankeng in Leye County. (Photo by Andy Eavis)

bridge north of Shuicheng stands 136 m above the river. Travertine barriers and cascades are a feature of the plateau; they include the Huangguoshu Falls, 70 m high over a knickpoint on the Dabang River.

Hundreds of caves have been mapped in Guizhou. Many contain relict passages and chambers with massive stalagmites, and dated material shows a long spread of ages in the Middle and Late Pleistocene, with peaks of deposition at 80–115 ka and 31–49 ka (Zhang & Barbary, 1988). The show cave of Daji Dong, near Zhijin, is notable for its giant stalagmites and columns, and the nearby Santang Dong is 7.2 km long. South of Anshun, Gebihe Dong has 11.9 km of very large river passage (broken by an undived sump). The sink entrance is an arch 116 m high, there is a skylight shaft 370 m deep above the river passage, and a chamber near the rising is one of the world's largest, 700 m long and 200 m wide (Collignon, 1992). In the southwestern county of Anlong, Ban Dong is 17.8 km long and contains a chamber 300 m by 150 m and a shaft of 225 m as one of its entrances. Near Shuicheng, Saguo Dong has a streamway with a succession of 17 shafts dropping into a segment of the underground Fala River, and the nearby Wujia Dong is 430 m deep. In northern Guizhou, the karst around Houping has over 23 km of mapped caves.

Yunnan contains a western extension of the Guizhou Plateau, but its fencong karst is generally not as well developed. There are some spectacular river sinks and long underground drainage routes, but few major caves have yet been mapped. The province is best known for its many stone forests of pinnacle karst, including the type site at Shilin

(see Shilin Stone Forest entry). Baishuitai is the most spectacular of a number of large flights of travertine terraces. Yanzi Dong at Jianshui is China's largest tourist cave with a huge river passage upstream from its resurgence into some very large and well-decorated chambers.

Sichuan has areas of karst distributed around the sandstone core of its Red Basin. The western part of the province rises towards the Tibet Plateau, and has outcrops of limestone at altitudes up to 5000 m. In the northwest, the Minshan area is

China: Figure 4. Conical hills of the fengcong karst rise above the Shuicheng basin in Guizhou. (Photo by Tony Waltham)

China: Figure 5. Outline map of the giant dolines at Xingwen, Sichuan, in relation to the known cave passages beneath and beside them.

too dry and cold to support mature alpine karst; karren are small, and there are no known caves larger than natural bridges and frost pockets in the spectacular crags. The valley floors contain travertines including those of Huanglong and Jiuzhaigou (see separate entry). South of the Red Basin, the dip slope of the Xingwen escarpment of Permian limestone is carved into a spectacular karst of dolines and small pinnacles. It contains extensive large caves, both active and relict, largely orientated along the strike, with 30 km of passages mapped to date (Waltham, Brook & Bottrell, 1993). They open into the sides of two giant collapse dolines, of which Xiaoyanwan is 650 m long, 490 m wide, and ringed by vertical limestone walls over 100 m high, Three stages of doline evolution are seen, and Xiaoyanwan is the middle, mature stage. Dayanwan is an older degraded doline higher up the dipslope, and Zhucaojing Cave has a series of large chambers that will eventually collapse to form the next of Xingwen's giant dolines (Figures 5 and 6).

Chongqing is now its own municipality, so has taken some of the finest karst out of Sichuan. In the east, the Chang Jiang (Yangtze River) drains out through its famous gorges, with high vertical cliffs that cut through massive escarpments of impure

China: Figure 6. The large chamber beneath the entrance shaft of Zhucaojing Cave which will eventually collapse to form part of the next giant doline in the Xingwen karst (see map, Figure 5). (Photo by Tony Baker)

carbonates. Just south of the gorges, deeply dissected karst in pure limestone contains Di Feng Dong (see separate entry) and also many other caves that contain huge, old passages in parts completely filled with clastic sediments, as well as some very large chambers. The karst of the Wulong region, astride the Wu Jiang, is notable for some deeper caves developed in Cambrian limestones. Furong Dong contains an ancient tunnel richly decorated with aragonite crystals and also a shaft 200 m deep, both beyond large passages developed as a show cave. Higher in the mountains, Qikeng Dong has a shaft system that meets a major streamway 700 m down, and continues to a depth of 920 m. San Qiao has three giant natural bridges surviving as roof remnants across a spectacular collapse gorge, and also a tributary cave 4 km long through from a separate tiankeng (giant doline).

Hubei and Hunan have the eastern part of the main region of mature fengcong karst in their western sectors, though most of its conical hills have lower profiles than those in Guangxi. The downstream half of the Yangtze Gorges is in Hubei, and the continuing limestone belt south of them contains the great caves of Tenglong. There are 10 km of active caves containing the Qing River, and a high-level dry cave 8700 m long is an earlier route of the same river. Hunan has a northern continuation of the Guilin karst with large areas of fengcong and less of fenglin. Wanhuayan is a cave notable for its large river passages nearly 6 km long, partly developed as a show cave.

Northern China lacks any continuation of the Upper Paleozoic limestones that support the extensive mature karst further south. Cambrian and Ordovician limestones have large outcrops in Shanxi, notably forming the Taihang Mountains. These are wellfractured rocks, so they act as diffuse-flow aquifers with only a small proportion of conduit flow. These feed many large springs, of which the largest is Nyangziguan with a flow of 10–16 m³ s⁻¹ from a catchment of 3500 km². At the north end of the Taihang, in Hebei, the fissure caves of Zhoukoudian are famous for their fossils of "Peking Man" (see China: Archaeological Caves) in a sediment sequence over 40 m deep, where the 780 ka magnetic reversal occurs at a depth of 34 m. There are also zones of gypsum karst along the flanks of the Taihang in Shanxi. Shandong has extensive fengcong karst with low relief on outcrops of thinly bedded Paleozoic limestones and dolomites. Some fluviokarst here is a relict of colder conditions during the Pleistocene, and there are some very large risings but no known caves of significant extent. The arid northwest of China has very little recorded karst. A belt of alpine karst with observed cave entrances lies just south of Aqqikkol Lake in the Kunlun Ranges of southern Xinjiang. Both this and the limestone outcrops of the Tien Shan await exploration and investigation.

Tibet (now the Chinese province of Xijang) may have over 100000 km² of carbonate outcrop, but most are of impure limestones interbedded with shales, all of which have been structurally deformed and metamophosed to some extent. In the cold, dry, periglacial environment limestone is resistant to weathering; many slopes and crags have pinnacle features, but these were formed by frost shattering and are not karstic. The only karstic landforms are widespread microkarren and isolated rinnenkarren downslope of snow patches. Tufa is widespread, but is largely related to geothermal sources; most is inactive and some has been dated to Pleistocene interglacial stages. Modern karst processes are minimal, with very low measured rates of dissolution (Zhang, 1999). A cave at Rutog in the far west has 100 m of passage, but all other known caves are less than 20 m long. Most of these caves are only short fissures; some stalagmites have been dated to >350 ka, but few caves are recognizable as fragments of old systems that were more extensive. Bygone concepts of Tibet having remnants of Tertiary karst features have not been validated by field data. Any karst formed in wetter environments prior to uplift of the Himalayas appears to have been destroyed by subsequent periglacial processes.

CHINA: ARCHAEOLOGICAL CAVES

China is abundant in geological and cave resources, attracting hundreds of foreign cavers and organized expeditions each year. The Karst Dynamics Laboratory (KDL) in Guilin, a karst-rich city in southern China, has led karst studies in China. The major research goals of this lab include basic theory in karstology, rehabilitation of rocky desertification, development and harnessing of karst water resources, and geological hazards prevention. Paleoenvironmental reconstructions using karst records have been especially useful, with KDL establishing continuous records for southern China for the past 36 ka (http://www.karst.edu.cn/, 1995–2002).

The Chinese people have long known of the fossil riches that lay within their hills and caves (see entry Asia, Northeast: History). Called "dragon bones" (long gu) or "dragon teeth" (long ya), these fossils were systematically harvested for centuries, with the occupation of dragon bone-digger passing from father to son (Boaz & Ciochon, 2001). These "dragon" products were sold in turn for medicinal purposes in apothecaries, since at least the Lungshan Period (and late Xia Dynasty), 5-4 ka. It was some time, though, before the formal disciplines of archaeology and human paleontology gained recognition in China (the early 1920s), and they did not rise to prominence until sometime later. In the years before China was liberated (prior to 1949), these disciplines mainly fell to foreigners, since Chinese citizens were forbidden to research the fossils they discovered (Jia & Huang, 1990). The situation has changed, however, and archaeology has returned to the everyday people of China, who have, with renewed enthusiasm, begun to deluge the Chinese Academy of Sciences with reports of new discoveries (Jia, 1975). China is rich with fossiliferous caves, the most noteworthy being the Middle Pleistocene deposits of Zhoukoudian, where the famous "Peking Man" was discovered (Jia & Huang, 1990). In addition to Zhoukoudian, four other cave sites figure prominently (Figure 1).

Zhoukoudian World Heritage Site: "Peking Man Site at Zhoukoudian" was added to UNESCO's World Heritage List

China: Archaeological Caves: Figure 1. Map of China with the location of five significant archaeological cave sites depicted.

in 1987. The Middle to Late Pleistocene cave and fissure deposits are located 45 km or so southwest of Beijing. The site consists of many fossiliferous deposits, the best known of which is Locality 1, preserving a column of more than 40 m of stratified infilling (Pope & Olsen, 2000), and the source of the largest collection of *Homo erectus* fossils from any single site (Figure 2). KDL notes that "Peking Man Cave at Zhoukoudian...and the polje at Zhoukoudian are examples of paleokarsts that formed under the warm and humid paleoclimate in Neogene" and are "mainly composed of high peaks, stone pillars and deep gorges..." (http://www.karst.edu.cn/, 1995–2002).

Excavation at the site was initiated in 1921, and still continues in some localities (though not at Locality 1). So far, work at Longgushan (Chinese for "Dragon Bone Hill"), as the site is called, has uncovered the remains of *Homo erectus*, along with a large sample of stone implements and tool-making debris. These remains have recently been re-dated to between 470 and 670 ka (Grün *et al.*, 1997). Additionally, the remains of *Homo sapiens sapiens* that date to 8–11 ka were found in the Upper Cave above Locality 1. Thousands of faunal remains have also been found within the 40 m thick deposits that once filled the cave.

China: Archaeological Caves: Figure 2. View of Locality 1, Zhoukoudian from the perspective of Pigeon Hall. During the years from 1978 to 1980, a massive multidisciplinary campaign was carried out at Zhoukoudian with the leadership of the Institute of Vertebrate Paleontology and Paleoanthropology (IVPP) in Beijing. Furthermore, with the founding of the Zhoukoudian International Paleoanthropological Research Center at Beijing's Institute of Vertebrate Paleontology and Paleoanthropology in 1993, a new era of multidisciplinary work began (Boaz & Ciochon, 2001).

With this reinvestigation of Zhoukoudian, the site has yielded new estimates of its age and number of hominid specimens represented (now over 50 individuals), igniting new debate. Early interpretations by Henri Breuil and Franz Weidenreich portrayed the site as the cave home of "Man, the Great Hunter", where fire was utilized and even cannibalization may have been present. These ideas have since been overturned, beginning in the late 1920s and 1930s. In later years, paleoanthropologists Noel Boaz and Russell Ciochon have individually re-examined the original casts (regrettably, the Longgushan fossil assemblage mysteriously disappeared on December 7 1941, during the aftermath of the World War II Japanese invasion of China, after being packed for shipment to the United States; only their casts remain) and all new specimens collected since the mid-1960s. Boaz and Ciochon found that giant hyaenas, Pachycrocuta brevirostris, were the most common and complete fossils represented, suggesting that they, and not humans, were the principal cave tenants. Though alternate interpretations abound, the preponderance of the evidence, along with the condition of the human remains, have led specialists to speculate that the hominid fossils may be the remnants of an ancient giant hyaena cache and not the result of a prolonged cave occupation after all (Boaz & Ciochon, 2001). The results of this most recent research have shown that twothirds of Longgushan's Homo erectus fossils show carnivore damage. This pattern of damage on the skulls is consistent with hyaenid chewing of the delicate facial area in an effort to dine on the fat-rich brains (Boaz & Ciochon, 2001) (Figure 3). In addition, recent analysis by geochemist Steve Weiner has uncovered no evidence of controlled hearths (Weiner et al., 2000). Still, despite this lack of evidence (and apparent evidence to the contrary), proof of human occupancy and of controlled hearths may simply not have been preserved. Only further fieldwork will reveal the truth.

In conclusion, UNESCO boasts, the site of Zhoukoudian "is not only an exceptional reminder of the prehistorical human societies of the Asian continent, but also illustrates the process of evolution" (http://www.worldheritagesite.org/, 2002).

Longtandong: "Dragon Pool Cave", the English translation for the site, is located in Hexian County, Anhui Province (Figure 4). The cave is formed from Cambrian dolomitic limestone, and the in-filling can be divided into five sedimentary layers: (1) brown-red clay, (2) red clay, (3) yellow-green silty and sandy clay, (4) brown-yellow fossiliferous (human and non-human) sandy clay, and (5) yellow-gray sandy clay (Wu & Dong, 1982).

In 1980, Huang Wanbo and his IVPP colleagues excavated a heavily fossilized *Homo erectus* skullcap, mandibular fragments, and four teeth, all presumed to belong to a young male. Further excavation in 1981 yielded additional *Homo erectus* fossils: parts of the frontal and parietal bones, and five teeth (Wu & Dong, 1985). More recently, the left side of a fairly robust mandible and seven teeth, all bearing some resemblance to similar elements from Zhoukoudian, have been found (Wu & Poirier, 1995).

China: Archaeological Caves: Figure 3. Composite image of Pachycrocuta brevirostris, the giant hyaena, and Homo erectus skulls illustrating how hyaena ingestion of the human face may have proceeded. Pachycrocuta was likely responsible for the bulk of the accumulation of human and other animal remains found in Locality 1 at Zhoukoudian.

In 1982, Wu Rukang and Dong Xingren postulated a close relationship between the *Homo erectus* specimens from the Hexian find (as it is referred to) and from Zhoukoudian Locality 1 (Wu & Dong, 1985). Still, "certain progressive features are noted in the Hexian individual. For example, the postorbital constriction is not as pronounced as in 'Peking Man' and is, in fact, less marked than in the Dali hominid from Shaanxi Province, which is thought to be archaic *Homo sapiens*" (Wu & Dong, 1985:87).

After further investigation, Wu and colleague made the stronger statement, "the Hexian remains document the

China: Archaeological Caves: Figure 4. View of Longtan Cave, Hexian County, Anhui Province, eastern China. This site yielded the latest dated occurrence of *Homo erectus* in China.

youngest-dated *Homo erectus* finds in China and are perhaps the last known occurrence of this taxon anywhere in the world" (Wu & Poirier, 1995:7). More recently, however, Swisher *et al.* (1996) have dated *Homo erectus* remains from the site of Ngandong in central Java to 27–54 ka. Nevertheless, the remains of *Homo erectus* from Hexian still rank as one of the latest occurrences in the world, and their importance should not be underestimated.

Huludong: This limestone cave is situated on Tangshan (Chinese for "Warm Spring Hill") near Tangshan town, 26 km east of Nanjing, the capital of Jiangsu Province, in eastern China. Huludong (in English, "Calabash Cave") is separated from the Hexian site by 100 km and also by the Changjiang River (Yangtze River). The Hulu karst cave actually is made up of two parts, a major and a minor cave. The minor cave, as the name suggests, is smaller and connects to the larger major cave by a channel. However, the minor cave is the more archaeologically significant because it is where the human remains were found. The Hulu Cave (as the major/minor cave complex is called) developed in Ordovician limestone and has four different layers of infilled sediments. From top to bottom, these layers are: (1) travertine, (2) brown-red sand and silty clay

layer, (3) brown-red fossiliferous (human and non-human) clay layer, and (4) brown-red clay (Xu, 1993).

In 1990, local farmers discovered mammalian fossils during quarrying, which they dutifully reported to the Nanjing Institute of Paleontology and Geology (NIPG), Academia Sinica. Excavation was undertaken for a short time in January 1993 by a joint IVPP/NIPG team. However, it was in March 1993 that local workers came upon a hominid skull while clearing the cave in preparation for making it a tourist attraction (Wu & Poirier, 1995). The faunal remains allowed for biostratigraphic age estimates that all of the fauna (including the human skull) belonged to the later Middle Pleistocene. "The specimen is an almost complete anterior portion of a human skull, including an almost complete frontal bone, the left half of the face, a portion of the parietal bones, a part of the occipital, and a small part of the right upper face" (Wu & Poirier, 1995:91). The frontal and brow ridges are robust, with the frontal being very constricted behind the orbit. This skull is attributed to *Homo erectus*.

Longgupo: Known in English as "Dragon Bone Slope", the early Pleistocene site of Longgupo is located 20 km south of the Three Gorges area of the Yangtze River in eastern Sichuan Province (Huang *et al.*, 1995). The strata have yielded *Gigantopithecus blacki* and a hominid, which is for the time being classified as early *Homo*, as well as stone artefacts (Figure 5). Paleomagnetic and biostratigraphic determinations, as well as aminoacid racemization and electron spin resonance, have dated the strata where the hominid remains were discovered at 1.8–2.0 Ma. These same deposits have also been interpreted as being younger (Olsen, 2000).

China: Archaeological Caves: Figure 5. Excavation diagram of Longgupo, Sichuan Province, with the locations of early *Homo*, stone artefacts, and *Gigantopithecus* remains indicated. Some researchers view this site as containing the earliest evidence of human occupation in Asia. New excavations in 2003 by a French-Chinese team will test this assertion. Computer-generated image produced by Autumn Noble from a colour drawing by Will Thompson.

Scientists have not reached consensus on the identity of the hominid remains, with some citing similarities with *Homo habilis* and *Homo ergaster*, and others believing them to be either pongine in origin or indeterminate (Olsen, 2000). What is incredible is that, if the hominid interpretation is true (which some prominent researchers do not support; Schwartz & Tattersall, 1996), the 2 Ma age suggests an earlier human arrival from East Africa to Asia than was previously imagined (Larick & Ciochon, 1996a). "The Longgupo finds suggest that soon after evolving in Africa a primitive hominid migrated to Asia with the aid of an elementary technology. They also confirm scattered and ambiguous evidence that *Homo erectus*, once believed to have been the first hominid to colonize Asia, may instead have developed there from an earlier form" (Larick & Ciochon, 1996b: 51). New archaeological excavations by a joint French-Chinese team will begin in 2003 at Longgupo.

Liujiang (Liuchiang or Liukiang) Cave: The "Liujiang Man" remains were discovered in a small cavern near Tongtianyan, in Liujiang County (for which the cave is named), Guangxi Province. Liujiang township has long been a tourist attraction because of its magnificent karst formations. The cave mouth is about 5 m above the ground, at the bottom of a limestone hill (Jia, 1980).

In 1958, local farmers digging up some of the Tongtianyan cave's deposits for fertilizer came upon a human skull and other fossils. The head of the farm reported the matter to the government who sent an IVPP field team (Wu, 2003). Unfortunately, the farm workers could not recall where exactly in the cave the fossils had come from, so provenance could not be ascertained. This has led to many controversies regarding the dating (Wu, 2003).

The human fossils discovered here include: a complete female skull (Figure 6), four thoracic vertebrae with four ribs of varying lengths still articulated, a complete set of lumbar vertebrae, a sacrum, a right pelvic bone, all belonging to a mature male; right and left female femoral fragments were also found. Accompanying these human fossils were miscellaneous faunal remains, which served to date the cave finds as belonging to the Late Pleistocene (Compiling Group of the Atlas, 1980).

It was noted at the time that the hominid-bearing deposits were loose and damp, which was very different from the hard and yellowish mammalian deposits found elsewhere in Guangxi. Researchers Pei Wenzhong and Jia (Jia) Lanpo concluded that the deposits must be of different ages (Jia, 1980). The date of "Liujiang Man" has been projected to be Late Pleistocene by looking at the morphology, itself, and the degree of fossilization present. Calcified plate (stalagmite) dating of the cave provides an age estimate of 67 ka

(\pm 6 ka), whereas the U-series dating puts the dates at 101 to 227 ka (Wu, 2003). However, these dates are problematic since the original location of the fossils cannot be precisely determined. Therefore, "nobody can be sure of the association between the human fossils and the samples used for doing *[sic]* dating. Never!" (Wu, 2004). Still "Liujiang Man" may represent an early type of Mongoloid and even "the earliest Neoanthropic man ever found in China" (Compiling Group of the Atlas, 1980:139). In fact, some studies suggest that South China may be the birthplace of Mongoloids, and even of modern *Homo sapiens* itself!

In summary, human origins have long been the primary concern of paleoanthropology. Africa has yielded many answers to

China: Archaeological Caves: Figure 6. Female skull of modern *Homo sapiens* found in Liujiang Cave, Guangxi Province, southern China. Some scholars view this specimen as evidence for the earliest occurrence of anatomically modern humans in China.

the ageless question of where humans came from, but Asia in general, and China in particular, have also provided some intriguing explanations. Despite much work, many questions remain, such as: How long has the genus *Homo* been present in Asia? What is the role of *Homo erectus* and Asia in the process of human evolution? What is the earliest evidence of anatomically modern *Homo sapiens* in Asia? These questions and others drive the scientists today who continue to unearth the answers, just as did the dragon bonediggers of old.

CHIROPTERA (BATS)

The Chiroptera form an easily recognizable mammalian order, the only one capable of true flight; colugos (Dermoptera), a few rodents (Rodentia), and some marsupial ringtailed possums (Diprotodontia) are gliders. Approximately 925 species of bat are currently recognized (Koopman, 1993), which makes them one of the largest mammalian orders, second only to rodents. Bats are divided into two sharply differentiated suborders: Megachiroptera (including only the Old World fruit bat family Pteropodidae with 166 species) and Microchiroptera (the remaining 16 families). The vast majority of microchiropterans are grouped in three families: horseshoe bats (Rhinolophidae; 130 species), American leaf-nosed bats (Phyllostomidae; 143 species), and vespertilionid bats (Vespertilionidae; 318 species); two families (Kitti's hog-nosed bats—Craseonycteridae, and New Zealand short-tailed bats—Mystacinidae) are monospecific. New species are still being discovered; for example, 28 new names were proposed between 1983 and 1993, and several new species were recently recognized even within Europe (e.g. Helversen *et al.*, 2001).

Molecular evidence and adaptations to flight favour a monophyletic origin for bats the view receiving most support today (Simons, 1995). However, the morphology of the nerve paths between the retina and the mid-brain places megachiropterans closer to primates (Primates) and colugos than to microchiropterans, thus suggesting that chiropterans are diphyletic. There is a gap in the fossil record connecting bats with the Upper Cretaceous eutherian ancestors, and the oldest well-preserved true bat (*Icaronycteris index* from the early Eocene) already shows the key characteristics of modern chiropterans. Modern families with the oldest fossil record (horseshoe bats, vespertilionid bats, funnel-eared bats or Natalidae), all of which are microchiropterans, had already appeared by the early Eocene. The remains of fossil bats, which are rare, are mostly found in limnic sediments or in fissure and cave sediments (Storch, 1999). Bats have a worldwide distribution, being absent only from the polar regions. The greatest number of species live in the tropics, with those in tropical America outnumbering those of central Africa and Southeast Asia (Hutson *et al.*, 2001).

Bats range in weight between 2 g and 1600 g, with the vast majority of species weighing 10-40 g; the largest sizes are attained by the megachiropterans. The bones of the hand support the elastic and thin wing membrane (patagium) which stretches between the body, the highly modified bones of the hand (i.e. the much elongated forearm, metacarpals, and fingers) and the hind legs, occasionally also enclosing the tail vertebrae. Because of the demands of flight, movements of the wrist, elbow, and knee joints are restricted to a single plane (Feldhamer et al., 1999). Skeletal modifications for flight also involve fusion of the vertebrae (the seventh cervical and first two thoracic ones), formation of a pectoral ring by the first two ribs and modification of the sternum, the scapula, and the proximal end of the humerus. The hind limbs are thin and rotated 180°, so that the knees point backwards. The work of extending and flexing the wings is done by the large proximal muscles (the pectoral muscle alone forms c. 12% of the lean body mass) and transmitted by the nearly inelastic forearm muscles (Vaughan et al., 2000). All muscles contain large amounts of myoglobin, and the special fasttwitch muscle fibres have high to medium densities of mitochondria (Ransome, 1990). The lungs, although not structurally specialized, are relatively large, and the heart is nearly twice the weight of that of a terrestrial mammal of similar size.

All aspects of bat biology and natural history reflect their ability to fly. Unlike birds, bats use a slow but highly manoeuvrable flight, with a consequently low wing loading (the ratio of the body mass to the wing area). During flight, bats emit high-frequency high-intensity sound pulses (with frequencies >20 kHz) from the larynx. They use these sound waves to provide information about the environment from the returning echoes (echo-location). The pulses are either frequency-modulated (FM; as in vespertilionid bats) or constant-frequency (CF; as in horseshoe bats); with the latter, moving objects are detected by their Doppler shift. Calls are emitted either through the nose or through the mouth, which involves a basic dichotomy in skull shape. Complex skin folds ("nose leaves") surrounding the nostrils are characteristic of nasal emitters (horseshoe bats, American leaf-nosed bats). Megachiropterans rely on vision, and only the genus *Rousettus* is capable of echo-location using low-frequency tongue-clicks.

Flight has allowed bats to fill many ecological niches, and the adaptive radiation within the Phyllostomidae is particularly spectacular. Bats can feed on insects, fish, small terrestrial vertebrates, blood, pollen, and fruits. Species with narrow, pointed-tipped

wings and low-energy flight are insectivorous and forage in open habitats. Bats living in closed habitats have broad wings with rounded wing-tips and exploit various food sources. In temperate regions with seasonal food supply and cold winters, bats have developed torpor (hypothermia), a strategy which allows them to decrease their normal body temperature to a level closer to the ambient temperature. Daily and winter torpor (hibernation) are widespread in temperate bats; the latter involves a preparation phase (the accumulation of body fat in late summer and early autumn) as well as energy-saving physiological changes during the cold period (low heart and breathing rates, suppression of shivering, vasoconstriction, etc.). At ambient temperatures near 5°C, hibernating bats maintain a body temperature about 1°C above the ambient temperature. As the body temperature drops to a minimum critical level (which is close to freezing in some *Myotis*) bats are in danger of freezing to death. If ambient temperatures drop below 5°C, bats spontaneously raise their metabolic rate and become fully alert, or regulate their body temperature and remain in hypothermia. The period of uninterrupted hibernation is usually up to 30 days, but may reach over 80 days in the little brown bat *Myotis lucifugus* (Ransome, 1990).

Bats will survive torpor only in places providing suitable microclimatic conditions (constant low ambient temperatures and high humidity to compensate for water losses through evaporation) and safety from predation and disturbances. Frequent arousal from hibernation is energetically costly and may exhaust bats' energetic reserves; several studies show that mortality rates are highest at the end of hibernation (Raesly & Gates, 1987). Consequently, bats are sensitive to disturbance in their roosting places. There are two common extremes of roost type used by bats. Tree holes are exposed to considerable variations in temperature and humidity, while caves provide a more stable environment and are thus important hibernation sites for many bat species. As a consequence, temperate tree bats more frequently show long-distance migration to cope with seasonal changes, while cave-dwelling bats rely on hibernation or combine short-distance migrations with hibernation.

Bats show considerable variability and plasticity regarding roost-type selection. Sites may change with the time of the year and even the time of the day, but will also depend on the local geography. This makes it difficult to classify species simply by roosting site (Ransome, 1990). At least 42% of bat genera (N = 177; Koopman, 1993) seek shelter in caves, and 16% are mainly or exclusively associated with this type of roost (data from Nowak, 1999); the roost types of many genera are still little known. Hill and Smith (1984) suggest that caves shelter more bats than most other roost sites combined. Depending on the species and the region, caves may serve as year-round (particularly so in the tropics) or transitional shelters, hibernation sites (in temperate regions), places for maternity colonies (mainly in the tropics), and for copulation. They provide bats with suitable microclimatic conditions (larger roosts may encounter sufficient microclimatic variability, thus reducing the need to change sites) and reduce the risk of predation. If possible, bats will tend to stick to those roosts with less chance of disturbance. Bats are able to become familiar with high-quality roosts where they maintain beneficial social relationships (e.g. stable territorial borders result in decreased aggression between territory holders). The habitat value of a cave can increase as a result of occupancy, simply because guano and urine accumulations stabilize temperature and humidity (Lewis, 1995). The disadvantages of roosting in caves include the risk of bats falling prey to predators that have learned the location of a roost, exposure to external parasites (many insect and mite parasites lay eggs on the walls of the roost or attach to the walls as pupae) and pathogens associated with guano accumulations. Bats occupying spatially scarce and permanent roosts are likely to show higher roost fidelity (Lewis, 1995), and some cave bats are known to return to the same cave for a number of years. As a rule, bats select sites within a roost according to their microclimate preferences, and can change their position (e.g. Ransome, 1990; Betts, 1997). However, selection of hibernation sites is not only influenced by microclimate (temperature and humidity in particular), but also by the structural properties of the site and the landscape surrounding it (e.g. the presence of foraging areas; Raesly & Gates, 1987). In caves with more than a single species, nonrandom associations are common (Rodríguez-Durán, 1998).

A large number of bats may use a single roost; up to 20 million Brazilian free-tailed bats *Tadarida brasiliensis* are found in some Mexican caves, reaching densities up to 3000 bats per square metre (Hutson *et al.*, 2001). A significant amount of organic matter is transported into the caves by bats in the form of guano (annual production in certain north Mexican caves is 18700 tons) and as a result of mortality in the roosts (for example, at six weeks after parturition, non-volant Brazilian free-tailed bats fell to the cave floor and died there at rates of five to twenty per hour in Davis Blowout Cave, Texas; Wilkins, 1989).

Bats are K-selected mammals with a long lifespan (over 30 years in some species) and a slow reproduction rate (usually a single young per female per year; four is the maximum). All this makes them vulnerable to disturbances, and as many as 778 microchiropteran species (out of 834) are included in one of the six IUCN "red list" categories of threatened species: four are already extinct, 15 are critically endangered, and 30 are endangered (Hutson et al., 2001). Cave dwellers are particularly sensitive, especially in areas where caves are scarce and serve as a key habitat. Kitti's hog-nosed bat Craseonycteris thonglongyai, the sole member of its family, is restricted to 21 limestone caves in a small area of Thailand. The stronghold of the southeastern bat Myotis austroriparius has always been in Florida, where an estimated 380000 individuals lived in 15 nursery colonies in caves; only five of those caves were still found to contain bats during a 1991–92 survey (Whitaker and Hamilton, 1998). Reported declines in bat numbers caused by human disturbance are 90% in the greater horseshoe bat Rhinolophus ferrumequinum in British caves, 99% in the Brazilian free-tailed bat in the caves of Texas, 50% in the southeastern bat in Florida, 76–89% in maternity colonies of the grey bat Myotis grisescens and up to 73% in hibernating Indiana myotis Myotis sodalis; in eight out of ten caves in northern Mexico cave-dwelling bats declined 67-100% due to burning, tourism, and mining (Hutson et al., 2001). In addition to habitat destruction and modification, other threats to cave bats include roost disturbances due to mining and quarrying activities, guano mining, bird (cave swiftlets) nest collecting, caving, the expansion of tourism, deliberate disturbances, and sealing of caves and mines (Hutson et al., 2001). Eradication measures against some pest species (the Egyptian fruit-bat Rousettus aegyptiacus and the vampire bat Desmodus rotundus) in their cave roosts resulted in the destruction of other non-target, mainly insectivorous bats (Hutson et al., 2001). In Israel, several cave bats (Blasius's horseshoe bat, Rhinolophns blasii, the lesser and greater mouse-eared bats Myotis blythi and M. myotis, and Schreibers' bat, Miniopterus schreibersii) which were still numerous several decades ago, are now

extremely rare or even locally extinct (Makin, 1988), following fumigation of caves to control the Egyptian fruit-bat. On the other hand, proper conservation measures have already had a short-term positive effect on populations of roosting bats. For example, counts of hibernating bats in the Moravian Karst in 1983–87 showed an increase in the populations of several species, while populations of the lesser horseshoe bat *Rhinolophus hipposideros* remained stable (Bauerová *et al.*, 1988). Periodic catastrophic events can also have a major impact on cave bats. For example, the entire population of 85000 southeastern bats in Sneads Cave, Florida, was destroyed by flooding in 1994; this was 27% of the total population of the species (Whitaker & Hamilton, 1998).

Some cave bats which used to be primarily strict cave-dwellers have found suitable conditions in man-made structures (mines, tunnels, and buildings). The cave-dwelling big brown bat *Eptesicus fuscus* has begun to hibernate in heated buildings, but not in unheated ones (Whitaker & Gummer, 1992). The fortification tunnels of Nietopierek in western Poland, which are used by *c*. 30000 bats of 11 species, are one of the most important hibernation sites in Northern Europe. This is the largest concentration of bats anywhere in Europe.

CLIMATE OF CAVES

Caves are usually closed environments, because the energy exchanges with outside are generally small and only become important when a watercourse flows through a cave. In any case, the climate of caves tends to be rather constant, though it is influenced both by the outside seasonal variation (in the vicinity of the entrance) and by heat exchange from inner parts. Roughly speaking, the average air temperature of a cave is very close to the outside average temperature. Water temperature depends on the average temperature of the hydrological basin supplying the water, corrected for the transformation of work into heat (a theoretical increase of 0.234° C per 100 m of fall). A cave's climate is characterized mainly by temperature, relative humidity, and airflow but air quality is also important, for example carbon dioxide and radon.

The oldest known reference to cave climate is in Titus Lucretius Carus' poem *De rerum natura* (1st century BC) but it concerns hydrology and radon only (Cigna, 1993). These same arguments were considered later by Leonardo da Vinci in his book on the nature, weight, and movement of waters written from 1506 to 1510 where he described the hydrology of a cave in the North of Italy (probably the Grotta di Fiumelatte close to Lake Como). In 1678 M.J.Herbinio added information on cave airflow to a description of underground hydrology. In particular, he observed that airflow was not constant and changed direction and strength according to the seasons and other factors. In 1712 the French scientist Billerez explained that caves seem to be warm in winter and cold in summer simply because their range of variation of temperature is smaller than the outside range. Therefore, even though on an absolute scale caves are colder in winter and warmer in summer, the sensation of a visitor is the opposite because cave air is colder than outside air in summer and warmer in winter.

Probably the first published paper on cave climate was published by G.-A.De Levis in 1795. He described a small artificial cave excavated in sandstone, containing a small pond of water during summertime, decreasing in wet periods and increasing in dry periods. He found also that the mean air temperature was about 1.2°C higher than the outside air temperature and the water temperature about 0.6°C lower. In the 19th century cave climate started to be studied for scientific purposes, particularly in Germany and

Austria (Crammer, 1899), although only temperature was measured and airflow was recorded qualitatively.

During the first half of the 20th century, studies continued to be mainly devoted to recording data without any further development of theory or an explanation of the mechanisms involved that would enable forecasting of climate. In 1913 H. Bock published an outstanding paper in which he developed a mathematical treatment of data from ice caves, both dynamic and static, but unfortunately this paper was totally ignored by the scientists of that time. Only in the second half of the 20th century was mathematics again used in cave climatology and the description of phenomena upgraded from qualitative to quantitative (e.g. Cigna, 1961; Wigley, 1967; Wigley & Brown, 1969). Later, such studies developed to cover most aspects of cave climatology and physics. Andrieux (1970–72) and Badino (1995) are the most complete papers in this field. Since the 1970s technological developments (in particular, inexpensive data loggers) have facilitated more detailed research. The provision of financial support by some show caves for environmental research and evaluation of visitor impact has also been instrumental in the development of cave climatology.

Temperature

Air temperature in the inner part of a cave is mainly in equilibrium with the rock and water temperature. However, near the entrance, changes in the outside temperature propagate into the cave mainly by convection, i.e. mechanical transport of air masses. Such changes of temperature, when considered over a time interval of at least one year, may be treated as "thermal waves". Only in the case of a shaft in thermal equilibrium conditions (i.e. when air density increases with depth) will the heat exchange occur mainly by conduction. In this case the length along which the temperature variation between outside and inside occurs is generally rather short (a few metres). When the mechanism of convection prevails, such a length is of the order of tens of metres. The transmission of heat by conduction through the rock is negligible in most cases because the attenuation of the thermal wave is very large: e.g. a reduction factor of 200 with a delay of about 6 months is found through a 15 m layer of limestone. Therefore, if a thermal wave is recorded inside a cave at distances of hundreds of metres, the propagation from outside must have occurred by means of a displacement of air masses. Calculation of the delay (displacement of a maximum of the sinusoid in days or months) and the attenuation gives important information on the influence of the outside climate on the cave through the propagation of the thermal wave (Figure 1). In the past, spot measurements were made by using a thermometer (alcohol or mercury) but now electronic instruments often coupled to data loggers are used with resistance thermometers. Such probes may easily detect a temperature variation as low as 0.01 or 0.001°C

Relative Humidity

In caves the relative humidity (expressed as a percentage of the saturation value) is generally very close to 100% other than in passages close to an entrance. The simplest form of forced ventilated hygrometer is the sling or whirling hygrometer, while a more professional instrument is the Assmann hygrometer (sometimes referred to as a "psychrometer") which is still used for calibration purposes or for spot measurements. However, to a large extent these devices have been replaced by humidity sensors which can be classified into two categories: capacitive sensors and dewpoint probes. Capacitive sensors have a serious problem because, when the relative humidity is close to 100% (as is common in caves), they give incorrect results on account of condensation occurring over the sensor. Dewpoint probes are not affected by such condensation but their cost is about one order of magnitude greater than the cost of the capacitive devices. The high cost can be reduced by using an Assmann hygrometer with the thermometers replaced by a multiway differential thermocouple or by a ventilated capacitive sensor. It is also possible to avoid condensation around 100% humidity by heating the sensor and correcting the result obtained. Nevertheless it must be stressed that the solutions reported above are acceptable only when the relative humidity

Climate of Caves: Figure 1. Air temperature in the Kartchner Caverns (Arizona, USA). In the upper part, the

thermal wave outside (first maximum: day 154); in the lower part, the thermal wave of Station 4–"Grand Central" inside the cave (first maximum: day 214). The delay is of 60 days and the attenuation is about 1/20. Dots: experimental values; line: sinusoidal best fit; horizontal axis: days (Jan 1, 1996=0); vertical axis: °C.

is not very close to 100%. When it is necessary to distinguish, in the vicinity of 100% humidity, between condensing or evaporating conditions, the error affecting the measurements is too large and no longer acceptable. In this case evaporimeters could be used but this technique has still to be developed and tested the cave environment.

Airflow

Air circulation in a cave depends on the number of entrances and the general shape of the cave. Near the end of the 19th century Crammer (1899) showed that a cave with a single entrance may act either as a warm trap (if the entrance is in the lower part of the cave) or as a cold trap (if the entrance is in the upper part) where the outside air is "trapped", respectively, in the summer or in the winter season (Figures 2 and 3). When there are two entrances at different altitudes, the difference in air density between the cave atmosphere and the corresponding outside air column results in airflow. The flow is directed from the lower to the higher entrance in winter and the reverse in summer (Figure 4). In general the driving force depends on temperature, warm air being less dense than cold air but when the outside temperature is close to the cave temperature relative humidity may play a role, since humid air is less dense than dry air. Where there are more than two entrances, the airflow pattern may be more complicated, being influenced also by the shape and the size of the passages involved.

Climate of Caves: Figure 2. Cold

trap. Upper figure: in winter the cave air, which is warmer than the outside atmosphere, flows upward. Lower figure: in summer the cave air, which is colder than the outside atmosphere, remains in equilibrium (below the level b-d) and there is only a limited circulation at the entrance (from: Crammer, 1899).

The airflow in caves may also be due to other causes such as the drag of a waterfall or changes of the external atmospheric pressure. A decrease of atmospheric pressure will lead to cave air flowing to the outside and the reverse occurs when atmospheric pressure increases. However, atmospheric pressure does not only

Climate of Caves: Figure 3. Warm trap. Upper figure: in summer the cave air, which is colder than the outside atmosphere, flows downward. Lower figure: in winter the cave air, which is warmer than the outside atmosphere, remains in equilibrium (above the level a-b) and there is only a limited circulation at the entrance (from: Crammer, 1899).

Climate of Caves: Figure 4. Wind cave. When two entrances (at different altitudes) are present, the difference of air density between the cave atmosphere and the corresponding outside air column results in airflow. The flow is directed from the lower to the higher entrance in winter and the reverse in summer. In general the driving force depends on temperature, warm air being lighter than cold air; when the outside temperature is rather close to the cave temperature, then the relative humidity may play a role, since humid air is lighter than dry air.

vary steadily, but also has a number of oscillations with many frequencies. Hence a cave may behave as a very large Helmholtz resonator, being excited by the oscillations with the frequency of the cave itself. This is the same phenomenon as occurs when someone blows across the mouth of a bottle and a note is produced, but, in the case of a cave, the frequency is so low that no sound can be heard, the most common values being around a fraction of 1 Hz. An interesting application of this phenomenon is in the evaluation of the volume of a cave when it consists of a large chamber connected to the outside by a small passage (in comparison to the chamber size). If an entrance to an unexplored passage is found to "breathe" (i.e. with an airflow directed alternatively in and out every some seconds or minutes) then, by applying a formula, it is possible to obtain a rough evaluation of the size of the cave without entering it (Cigna, 1967).

The vane anemometers usually employed in meteorology are not used in caves because the slow air speed (often less than 0.1 m s^{-1}) is outside their range. Hot wire anemometers are more suitable but they detect only the velocity and not the direction of the airflow that, in caves, may have two ways (in or out, with reference to a given environment). The direction may be identified by using two probes, one of which is shielded. By swapping the position of the shields, it is possible to determine the direction of air flow since the probe that is shielded from the prevailing air flow will record a lower air velocity.

Cave Climate Monitoring Networks

Most scientists concerned about the conservation and protection of cave environments recommend that the atmosphere in all show caves should be monitored to determine whether operation of the cave is having any adverse impacts. While spot measurements of air quality are quite common (see entries on Tourist Caves: Air Quality, Radon in Caves) only a few show caves are equipped with climate monitoring stations, although the numbers are increasing. Monitoring networks generally consist of a number of sensors in different parts of the cave, each measuring a separate parameter. Each site, or even each sensor, may have a separate data logger but increasingly sensors are linked to multichannel loggers, or even directly to computers inside or outside the cave. Threshold levels may be established for each parameter being monitored so that an immediate warning can be given if something moves out of the normal range.

COASTAL KARST

Coastal processes on karst rocks often produce markedly different small-scale forms than those on non-soluble rocks. These small-scale dissolutional and bioerosional forms, called "coastal karren" or "littoral karren", range in size from submillimetre to some tens of metres and develop in the subtidal, intertidal, and supratidal zones. They are often delicately etched yet spectacularly jagged, the forms varying with wetting regime, energy levels, biological activity, and vegetation or sediment cover. The most important requirement is that abrasive tools are rare: close to beaches the rock surface is often smoothly abraded like any other rock type. The second requirement is that the rate of cliff recession is relatively slow: where retreat is fast a steep fracture surface results, as with any other rock type. The most striking coastal karren develops in warm climates, usually behind the protection of an offshore reef.

Coastal processes include abrasion, hydraulic action, wave action/quarrying, wetting and drying, corrosion, dissolution, bioerosion, bioconstruction and, in cold regions, frost action. The balance of processes varies with position above sea level; for example, wetting and drying are maximum at mid-tide. In karst rocks, bioerosion and bioconstruction may be dominant, with dissolution playing a. small role. Bioerosion results from: (1) colonization of surfaces by epilithic algae and cyanophytes; (2) boring into rock surfaces by endolithic algae and cyanophytes, fungi, lichen, invertebrates such as gastropods, echinoderms, clionid sponges; and (3) grazing of epi- and endoliths by, e.g. chitons, gastropods, echinoderms, crabs, and parrot fish. Bioconstruction results from the build-up of carbonate encrustations of calcareous algae, vermitid gastropods, and serpulid worms. Protector organisms, such as mussels, are neither bioeroders nor bioconstructors: they simply protect the rock surface from erosion. Coastal karren erosion rates in sheltered areas are typically ~1 mm a^{-1} ; they may exceed 2.5 mm a^{-1} in exposed regions, but where bioconstruction dominates over bioerosion, they may reach only 0.17 mm a^{-1} .

Littoral zone processes do not preferentially etch joints and bedding planes. The most common form of coastal karren is subcircular basins, often in a hierarchy of sizes up to several metres in scale, with intervening pinnacles. The overall form varies according to organisms present, exposure levels, tidal range

Coastal Karst: Figure 1. Coastal karren of a temperate region, Co. Clare, Ireland.

and regime, input of fresh rainwater, and to some extent, lithological and structural variations. Tropical karren, because of the effect of encrusters, show some unique intertidal features. Otherwise the erosional ramp with pinnacles and basins is the typical form. Most show a morphological zonation corresponding to biological zonation in relation to tidal levels.

In cool and temperate regions, the pinnacle-and-basin ramp is well developed. The example in Figure 1 is from the west coast of Co. Clare, Ireland. Here the spray zone (lichen zone) is characterized by flat-bottomed, steep-sided, shallow, isolated pans cut into the rock "plateau". The pans grade downshore to the splash zone (periwinkle zone), with deeper, round-sided, somewhat round-bottomed, and less isolated basins. The upper intertidal zone (barnacle zone), shows relatively flat-bottomed basins with overhanging rounded edges and barnacle-encrusted rounded inter-basin plateau remnants. The lower

intertidal zone (mussel/echinoid zone), shows sharp, jagged, narrow pinnacles encrusted with mussels, separating deep, rounded to conical basins that are lined with echinoderm pits. The subtidal zone shows subdued relief, with no basin or pit karren; in some regions there is a shallow cliff at low tide with a slight subtidal notch.

In warmer regions, the erosional ramp with pinnacles and basins is supplemented by unique intertidal and subtidal features that relate to organisms present, exposure levels, and wave energy. Four units may be present, although not all coasts will have all of these units (Figure 2).

The splash and spray zone is usually a ramp with basins and pinnacles showing sharp, jagged projections between relatively flat-bottomed basins, often with overhanging rims. Direct bioerosion is minor. Jaggedness increases with increasing splash. Where splash is minor, basins dominate, $\sim 3-4$ m wide and ~ 1 m deep. In the intertidal zone, biogenic activity, abrasion, hydraulic action, and solutional activity focused at the water level produces a notch, incised typically from 1 to 5 m. The roof and overhanging rock forms the visor, the topmost surface of which is often pitted and fretted.

In sheltered and/or microtidal environments, processes are focused on a small vertical expanse of cliff, where the notch of small height digs deeply into the rock at mid-tide level. As tidal range or exposure increase, processes are spread out over a larger expanse of cliff face; the notch will be less incised but taller. In higher energy regions, where water is warm and turbulent, carbonate-encrusting organisms abound and a tidal platform develops. Calcareous algal coatings, vermitid gastropods, and serpulid worm encrustations protect the rock from erosion. The encrusters, intolerant of emersion, concentrate below mean tide level. The rock above, without this protection, is open to normal notching processes. Thus, over time, the upper notched part retreats while the encrusted zone remains intact. The remnant form is the tidal platform. The outer edge may have a thick accumulation; in some localities a tidal platform is built out from a steep rock surface by encrustation alone. In higher energy

Model of tropical coastal karst development with increasing energy levels

Coastal Karst: Figure 2. Coastal karren of tropical regions.

environments, the tidal platform often has a ramped surface, made up of a series of steps separating wide, shallow pools or "vasques". Each riser is a narrow, sinuous, lobed ridge,

protected by encrusters that thrive on the rims over which water continually drains. Beneath the tidal platform, where encrustations are less important and bioerosion can continue, a low-tidal or subtidal notch develops.

All four units may not be present at one location; the coastal profile that develops relates to exposure level. A dynamic equilibrium develops as the cliff edge, notches, and platform retreat together. In the splash zone, downcutting is important in addition to lateral retreat: as the splash zone basins and pinnacles are eroded down they are transformed into the tidal platform with vasques.

COCKPIT COUNTRY CONE KARST, JAMAICA

Jamaica's Cockpit Country is the spectacular humid tropical "type example" of what is sometimes described as the "egg-box" style of polygonal karst. Centred on Trelawny Parish, in northwestern Jamaica, the Cockpit Country covers about 600 km². The cockpits, which dominate the landscape (Figure 1), are steep-sided, more-or-less enclosed lobate depressions, some over 100 m deep and 1 km in diameter, surrounded by residual

hills or ridges, and are so named because they resemble the arenas formerly used for cock fighting. The residual hills and ridges are notched by elevated saddles, and many cockpits are connected to one or more of their neighbours by a lower corridor. Some cockpits are elongated, reflecting structural influences or inherit

Cockpit Country Cone Karst: Figure 1. Air view of a small fraction of the tree-covered cones and cockpits that constitute Jamaica's distinctive Cockpit Country. (Photo by Tony Waltham)

ance from abandoned surface drainage courses. The term "cone karst" is in some ways inappropriate, since the residual hills are rarely conical or isolated, rather being linked at their bases as irregular ridge remnants, and it is the enclosed depressions, rather than the hills, which are the focus of geomorphic activity.

Cockpit slopes and the surrounding hilltops and ridges are highly irregular, with patchy clay soil cover. Slopes consist of combinations of vertical cliffs, inclined bedrock surfaces, "staircases", or talus accumulations. By contrast, the depression bases often have a deep regolith cover, and some contain relict, debrischoked vertical shafts. Internal drainage is centripetal, although dominantly vertical (Day, 1979). Regional drainage is largely autogenic and northward, although there are some allogenic inputs on the southern boundary. On the northern periphery, underground drainage emerges at a series of springs, which feed rivers draining to the north coast.

Most of the Cockpit Country is developed in Eocene carbonates of the White Limestone Formation, although some of the southern area is developed on older rocks of the Yellow Limestone group. The White Limestones are generally extremely pure, mechanically competent, and well-bedded, with blocks of strata dipping towards the north—northwest and separated by northwest-southeast and northeast-southwest-trending faults. The oldest formation, the Troy-Claremont, is approximately 300 m in thickness. The Troy Limestone is generally unfossiliferous, recrystallized, and dolomitized; the Claremont is a fossiliferous, biomicritic limestone. The younger Swanswick Formation, which outcrops in the northern part of the Cockpit Country, is a rubbly, fossiliferous biosparite up to 100 m in thickness. There continues to be uncertainty about the origin of the bauxite deposits that occur in the vicinity of the Cockpit Country. Zans (1959) and others considered them to have been derived from the non-carbonate Central Inlier and deposited within the karst as alluvial clays, but others, including Smith *et al.* (1972) were convinced that the material is a weathered residue derived from the insoluble component of the White Limestone itself. A third possibility, perhaps the most plausible, is that the bauxite is derived from Miocene bentonitic clays of volcanic origin (Comer, 1974) (see also Bauxite Deposits in Karst).

Cave systems, associated with the Cockpit Country, include some active river caves flanking the Central Inlier to the south and some large abandoned phreatic conduit systems around the periphery. Although the most important type of cave in Jamaica is the very gently graded, large river passage, and these presumably exist at depth beneath the surface, most known caves within the Cockpit Country proper are either debris-choked pits within cockpits (Smith *et al.*, 1972) or fragmentary dry passages within the residual hills and ridges (Brown & Ford, 1973). Few caves show any evidence of being developed along fault planes, although bedding and joint-plane control is important in some

Cockpit Country Cone Karst: Figure 2. Topographic map of a small part of Jamaica's Cockpit Country with contours at intervals of 50 feet (15 m) to show morphology of the

conical hills and depressions. The outline of Windsor Great Cave is superimposed; it has a large old passage, and a smaller streamway in from Bamboo Bottom.

areas, and lithology plays an important role in influencing cave morphology (Wadge & Draper, 1977a,b). Many of the larger peripheral caves, such as the spacious, old phreatic tunnel of Windsor Great Cave (Figure 2), have significant bat populations and have been commercially exploited for guano (Fincham, 1997).

The dramatic Cockpit Country landscape attracted the attention of 19th-century European geologists, such as J.Sawkins in 1869, but the first systematic geomorphological studies were undertaken in the 1950s by the Jamaica Geological Survey under the direction of V.A.Zans (Zans, 1951) and by visiting Europeans such as Herbert Lehmann, Marjorie Sweeting, and Harold Versey. In 1955, Zans and Sweeting traversed the Cockpit Country via the Troy-Windsor trail, an ambulation that convinced Sweeting (1958) that the terrain was the result of surface dissolution, rather than collapse or groundwater upwelling. Versey (1972) nevertheless continued to stress the mechanical significance of groundwater upwelling during heavy rainfall events, particularly in peripheral areas where large, complex depressions, such as Bamboo Bottom, have deeply alluviated floors with incised drainage channels and estavelles.

The surficial dissolutional origin is clearly complex, and it has been noted by Conrad Aub in particular that the vegetation canopy obscures the true irregularity of the cockpit slope surfaces, and that "rafting" of rain by the canopy results in approximately 14% more water reaching cockpit floors than the surrounding summits (Aub, 1969).

The Cockpit Country vegetation includes a range from wet to dry limestone forest, in which there is considerable floristic diversity and an extraordinary number of endemic species. The Cockpit Country fauna is also significant, including threatened species such as bats, snakes, frogs, and all but one of Jamaica's 28 endemic bird species.

Human influences have, to date, been limited by inaccessibility and lack of surface water, although there exists an extensive trail system, and many peripheral cockpits have been used for agriculture. In the 1700s, escaped slaves known as the Maroons used the Cockpit Country as a base for guerrilla activities against the British army. Treaties gave the Maroons a degree of autonomy that they have maintained ever since.

Since 1950, much of the Cockpit Country has been designated as a Forest Reserve, although there has been little enforcement of conservation directives. The immediate vicinity has a population of some 10000 people, and is exploited for bauxite mining and agriculture. In the Forest Reserve, illegal logging, farming, hunting, and trapping for the pet trade are particular problems. More recently, the Cockpit Country has been pro posed as a UN World Heritage Site, and there are currently plans to inscribe it as a national park.

COLONIZATION

Colonization of a cave by an animal or plant species may be either primary or secondary. Primary colonization may be defined as the establishment of a population in an area not previously occupied by the species. A cave open to primary colonization may lack a species because of recent origin (e.g. during the karstification process), recent catastrophes (e.g. lava flows, glaciations), or geographic location (e.g. isolation). Secondary colonization is more characteristic of small locally confined areas less isolated from colonizing populations; in these areas the species disappeared following minor

environmental alterations (e.g. marginal areas of a karstic massif after the retreat of a glacier, or polluted areas after recovery). Both primary and secondary colonization may be considered as continuous processes; nevertheless, colonization rates may increase or decrease owing to adverse climatic conditions, depletion of resources, high competition rates, or strong predation pressure.

In the biospeleological literature the term colonization refers mainly to the colonization of a cave by a surface population; however, subterranean organisms are active and apparently cognitive subjects, and their dispersal in new habitats, and hence the colonization of new caves, may be considered a relatively common event.

Considering the modalities of colonization, biospeleologists put great emphasis on active and passive colonization mechanisms. Usually active colonization is understood in the sense of colonization by means of the locomotory apparatuses and is the opposite of passive transport. However, some biospeleologists do not use the term "active" to refer to the mechanical method used to reach the subterranean environment, and view active colonization as synonymous with voluntary colonization. Indeed, one of the most common questions on colonization addressed by biospeleologists is not how epigean species colonized the subterranean domain, but why they did so. This is an old question due to the interpretation of the subterranean environment as a special one (the refugium model): caves have long been considered as refugia against climatic vicissitudes for the ancestors of troglobites, especially those of Pleistocene animals in temperate zones. Rouch & Danielopol (1987) challenged this idea, stating that there are no compelling forces to colonize the subterranean environment: the active colonization model replaced the refugium model. The refugium model is considered incompatible with the accumulated evidence that subterranean organisms occur on a worldwide scale, even in the absence of unfavourable climatic conditions; moreover, it does not explain the contemporary colonization processes of subterranean habitats and the fact that many hypogean animals are not relicts. The active colonization model proposes a unique scenario to explain colonization of subterranean habitats; for this reason, it was criticized by Botosaneanu & Holsinger (1991). They reported several examples for and against hypogean relicts and the refugial character of subterranean environments, stating that no unique explanation can be found to explain the colonization events. Finally, Stoch (1995) formulated an "adaptive zone model", suggesting that surface populations invade subterranean habitats to exploit a new set of resources; colonization may be followed by niche specialization and adaptive radiation. Most modern biospeleologists do not support the old hypothesis that the origin of subterranean animals must differ in certain instances from that of other animals: instead it is argued that caves are no more than one of several types of environments that ecologists deal with.

Several colonization models have been developed to explain the origin of groundwater fauna, some of them dealing primarily with interstitial fauna (see Interstitial Habitats: Aquatic). Among several others, the following models are mentioned herein: regression model (Stock, 1980); zonation model (Iliffe, 1986); two-step model (Notenboom, 1991); "modèle biphase" (Coineau & Boutin, 1992); three-step model (Holsinger, 1994); and adaptive zone model (Stock, 1995). Some of these models can also be applied to terrestrial fauna; however, detailed colonization models dealing separately with terrestrial habitats were developed for caves (three-step model, Juberthie, 1984) and lava tubes (adaptive shift, Ashmole, 1993).

Coineau & Boutin (1992) synthesized most of the models outlined above for groundwater fauna. According to these authors, the stygobites living in inland subterranean waters belong to two groups: limnicoid stygobites, the marine ancestors of which lived in surface freshwaters before groundwater colonization, and thalassoid stygobites, which colonized continental groundwaters from the marine environment through the littoral interstitial zone during a marine regression. The two groups of stygobites settled into the inland groundwaters after two ecological and geographical transitions ("modèle biphase" or "two-step model") involving a "vertical transition" (active colonization of the littoral interstitial environments) and a "horizontal transition" (active or passive colonization of the continental interstitial groundwaters) (Figure 1).

Holsinger (1994) developed a "three-step model" of colonization of continental groundwaters; these steps (designated A, B, and C) are best regarded as components in a graded series or phases in a transition and not as rigid stops and starts. Species at step A are epigean benthic forms with little or no apparent troglomorphy, living in freshwater or in shallow littoral or sublittoral sea zones and demonstrate little specialization; most of these taxa remain potential epigean ancestors of stygobites. Species at step B are semi-hypogean organisms, with strong preadaptation to life in subterranean waters; eyes and pigment are typically rudimentary. Species at step C are stygobites; either limnostygobites or thalassostygobites, commonly troglomorphic and restricted to life in subterranean waters.

Ashmole (1993) summarized the theories on the origin of subterranean terrestrial species in volcanic islands, distinguishing between "ecological colonization" and "evolutionary colonization". Ecological colonization of lava flows commences as soon as the rock is cool; populations of "lavicolous" scavengers build up both on the surface and in cracks and dry caves, exploiting the "biological fallout", mainly windborne insects. On the other hand, evolutionary colonization of the deep cave zone (both mesocaverns and saturated caves) is the process by which some individuals from one type of habitat move into a different habitat that imposes new selection pressures, thus leading to adaptive divergence and speciation of the colonizing population. This "adaptive shift" may occur when preadapted epigean individuals accidentally penetrate cavities and form populations that are poorly or rarely influenced by gene flow. The shift involves rapid adaptive evolution in morphological and physiological characteristics.

Juberthie (1984) illustrated the theories on colonization of cave habitats by terrestrial species, dealing mainly with the role of the MSS (Mesovoid Shallow Substratum: see Interstitial Habitats: Terrestrial). Juberthie's scenario is a three-step model. During the first step, some populations inhabiting soil litter or mosses colonize the lower layer of forest soils, becoming preadapted to the subterranean environment. Next, they invade the MSS: during this step, the colonizing populations inhabit both compartments. Finally, MSS populations invade the "deep hypogean compartment" (e.g. caves); the isolation of cave-dwelling populations is related to geographical location, degree of karstification, and history (e.g. glaciations).

Finally Stoch (1995) clearly separated the colonization process from the speciation process (see Speciation), and developed

Colonization: Figure 1. The two ways of colonization of continental groundwaters according to the "two-step model" (modified after Coineau & Boutin, 1992): transition via surface freshwaters (limnicoid stygobites) and transition via littoral interstitial waters (thalassoid stygobites).

a multiple step model (called "adaptive zone model") to explain the origin of subterranean biodiversity following two different methods: colonization-speciationadaptive radiation (e.g. rapid phylogenetic diversification via niche differentiation) or multiple colonization-speciation (when radiation does not occur) (Figure 2). Both active and passive colonization mechanisms are allowed by the adaptive zone model, but the refugium model is clearly ruled out. Following this model, climatic fluctuations and other events such as marine regressions clearly enhanced colonization rates, but speciation is not a consequence of colonization and an increase in the rate of colonization is not necessarily followed by increased speciation rates. Generalist colonizers accomplish the expansion of their range due to efficient dispersal adaptations and, after arrival, the establishment of a viable population at the new site. Repeated colonizations into the same site are likely to occur and colonization rates may be high. But generalist colonizers do not appear to speciate: the efficiency of colonization effectively prevents the accumulation of genetic differences from the source, and a speciation event in this case is unlikely. Following the adaptive zone model, only stochastic colonization by a foun

Colonization: Figure 2. Origin of troglobitic species according to the "adaptive zone model" (Stoch, 1995); two different ways are possible: multiple colonization followed by speciation, and colonization by a single ancestor followed by speciation and adaptive radiation.

der with preadaptation to the new site is an event conducive to speciation.

Several hypotheses have been proposed to date the colonization processes, for example marine regressions, the Messinian salinity crisis for the Mediterranean area (Hsü, Ryan & Cita, 1973), and glaciations for temperate zones. Unfortunately, in most models based on historical events the age of colonization is confused with the cause of colonization. For example, some biospeleologists advocated that the Mediterranean salinity crisis (when most of the Mediterranean Basin dried up) forced isopods and amphipods to colonize groundwaters where they remained "stranded" ("regression model" developed by Stock, 1980). Following this model, the age and cause of colonization are determined by the same historical event, but an alternative explanation is possible. According to the adaptive zone model, Stoch (1995) supposed that the Messinian event simply interrupted the genic flux between brackish water and marine populations; epigean brackish water species may have colonized surface freshwaters and subsequently cave waters following the development of karstic areas. Therefore, these stygobitic species may be considered a recent limnicoid stygobite instead of older thalassoid stygobites, and an active colonization model may be advocated opposed to a refugium model.

Unfortunately, most of the theories dealing with the colonization process remain highly speculative and untested: for this reason, the debate between active colonization and refugium model supporters is still a central focus in the current biospeleological literature.

COMMUNICATIONS IN CAVES

On deep or wet pitches, communicating by means of whistleblasts is an established practice and, in many situations, this or perhaps a loud voice will be sufficient. However,

for cave rescue, expedition management or the execution of projects such as photography in a large chamber, communication by radio or telephone is often essential.

Possibly the first use of a telephone in a cave was during the exploration of Lamb Leer Cavern (Mendip, United Kingdom) in 1880 (Williams, 1995). Despite the disadvantage of having to lay a cable, telephones continue to be used because they are simple and robust. A variety of other cable-based systems exist—single-wire telephone, "guide wire" radio, and optical fibre. True "wireless" communication is difficult because rock, being conductive, absorbs radio waves. For line-of-sight work within cave passages, high-frequency (HF) walkie-talkies and CB radios are used, but magnetic induction equipment is usually necessary for communication through the rock itself. The technique of "earth current injection" was developed during World War I but is rarely used now although an enhancement, using a low-frequency (LF) carrier, is the basis for the latest high-performance induction radio/earth-current "hybrids" now used in the United Kingdom and Europe.

The single-wire telephone (SWT) (also known as an earthreturn telephone) uses the conductivity of the ground to provide a return path for the current. The obvious advantage is that only half the weight of cable has to be carried. The devices used by cavers feature electronic amplification and will often operate without any specific earthing other than through the caver's body. SWTs are cheap, rugged, easy to build by amateurs, and are preferred to the traditional army field telephone. They are popular with expeditions and rescue groups throughout the world, and are also convenient for providing flood warnings to cavers.

If, instead of audio, an LF radio signal is passed along an SWT cable, it will work without any earthing, because the signal is able to jump gaps by a capacitive coupling effect, implying that the handset does not need to touch the cable either. Commercial equipment based on this principle is used for mine rescue. HF radio can also be guided along a cable placed in close proximity, although the principle of operation is quite different. For commercial use at VHF, "leaky-feeder" cable presents yet another mode of operation. Confusingly, all these systems are sometimes referred to as "guide wire" radio.

Rock is electrically conductive, which causes it to absorb radio waves, so HF radio is mostly limited to use within cave passages. Rescue teams use HF walkie-talkies (27 or 49 MHz) to communicate on pitches while manhandling an accident victim in a stretcher. Photographer Gavin Newman has used a modified CB radio to coordinate photography in Illu River Cave, Irian Jaya. He also found the radios useful to warn of impending flooding in this huge cave system (Newman, 1993). HF radio will penetrate a few metres into rock and can be used for locating dig points on the surface, although this normally requires specialized equipment (see separate entry, Radiolocation). In 2001, a CB radio was used to verify the surface location of the top of the Titan shaft in Peak Cavern (Derbyshire), with communication through 10 m of fill. Radio waves can travel for some distance along mineralized fault lines or dry well-jointed rock, so occasionally quite deep penetration of a cave is possible.

Low frequencies are attenuated less than high frequencies—long wave broadcasts, such as BBC Radio 4 (198 kHz) can be detected at the bottom of deep caves. Unfortunately, detecting a radio signal is easier than transmitting it—a 200 kHz signal would require an antenna some 750 m long, which is normally only feasible for mining installations. From the early 1960s, cavers began to experiment with loop antennas.

Because of their small size (typically 1 m diameter) these radiate very little "true" radio energy, and mainly generate a magnetic field, which couples to the receiver loop by the principle of magnetic induction, and operates over a limited range of just a few hundred metres. Early systems used "baseband" audio but it was soon realised that there were benefits to using radio frequency modulation. Experimental induction systems have covered 27–185 kHz (i.e. most of the long-wave broadcast band), and most have used single-sideband (SSB) operation. The most notable designs have been Bob Mackin's commercially produced Molefone, dating

Communications in Caves: Using an induction radio with a ribbon-cable antenna in Ogof Ffynnon Ddu. (Photo by Mike Bedford)

from 1979, which has seen widespread use in Britain and Ireland, and Ian Drummond's CB Transverter, used mainly in the United States and Canada.

Two of the latest designs are John Hey's HeyPhone and the French "Nicola System" which was developed as an aid to flood warning in the Gouffre Berger. Both operate at 87 kHz SSB and are published designs. They are intended to work with induction loops or earth-current antennas, thus reviving the early–1900s trench-communications technique. With earth electrodes, the Nicola system has been demonstrated to work through 1000 m of rock. In 2001, working with the Cave Radio & Electronics Group (CREG)—a special interest group of the British Cave Research Association—the British Cave Rescue Council issued over 50 HeyPhones to British cave rescue teams (Bedford, 2001). This is the first time that a national organization has systematically equipped its rescue teams with such advanced equipment. The South Wales team soon had occasion to test their HeyPhones. A caver dislocated his shoulder some 5 km into Daren Cilau—a

formidable cave protected by a daunting 520 m entrance crawl and requiring an underground camp to explore the far reaches. While the injured caver slowly made his way to the camp, two of his companions made a strenuous exit and raised the alarm. Some 28 hours later, the medical team was able to communicate with the surface to report that the casualty had been attended to, and would not require a stretcher carry (which, it had been estimated, would take up to three days to complete). Use of the HeyPhones (and of an SWT in the entrance crawl) considerably eased the logistics of this rescue, which involved 63 personnel (*Caves and Caving*, 2001).

Cave radios have been coupled, experimentally, to mobile telephones and HF radios on the surface, and messages relayed automatically over long distances. System development seems likely to continue, with the aim of providing extra functionality, for example medical data logging, text messaging, and digital image transmission.

CONDENSATION CORROSION

Condensation corrosion occurs when a chemical reaction takes place between condensed water vapour and bedrock or speleothems in caves and can be classified as a form of chemical weathering (Fairbridge, 1968). The process has been proposed as a mechanism by which caves are enlarged and as a factor in the degradation of speleothems. Speleothems are an important natural resource and tourist attraction, hence the majority of studies of condensation corrosion have been aimed at establishing the rate of speleothem degradation in tourist caves. Evidence for the existence of condensation corrosion is greatest in caves in karst rocks.

Features attributable to condensation corrosion are particularly noticeable in cave entrances and in passages with unstable microclimates. Some of the features characteristic of the process include etching of wall rock (James, Jennings & Dyson, 1982), small pits only centimetres in diameter on flat roofs, and much larger bell holes (Tarhule-Lips & Ford, 1998). The degradation of speleothems, although not stand-alone evidence for the process, is to be expected where aggressive condensation waters are found. For instance, the deposition of calcite as cave coral, associated with areas of solution of both wall rock and speleothems, is regarded as evidence for the process (Hill & Forti, 1997). The same features are mimicked on a micron scale. Scanning electron micrographs of speleothems degraded by condensation corrosion reveal micro etching and pitting. Other karst processes, particularly erosive ones such as bio-karst processes and salt weathering, produce similar features.

In order for corrosion to take place, the water vapour in the cave atmosphere must first condense. Condensation can be observed as clouds in large chambers, sparkling droplets on roofs and walls, and as a thin film of moisture on surfaces. For water to form, the temperature of mixed air has to drop below the dew point. This takes place either when cold surface air flows into caves and encounters the warm wet air, a winter phenomenon, or when hot wet surface air comes into contact with the colder cave air, a summer phenomenon. Once a mist has formed, it can wet any surface that it comes into contact with. Mixing of two air masses is not essential, however, as water vapour in warm air will directly condense onto cold bedrock and speleothems. The drier the air, the greater the temperature drop required for it to reach its dew point. Condensation is possible in all caves. The probability of condensates forming is greatest where the surface temperature range is large. Goede *et al.* (1990) stated that evidence of condensation corrosion is particularly noticeable in cave entrances in arid and semi-arid zones, where there is a large diurnal temperature change. In this case, moist air, at the average temperature of the area from within the cave, condenses on encountering cold night surface air.

Whether condensation corrosion takes place deep inside caves is controversial, for the essential temperature differential between air and rock is nonexistent or small at depth. Despite this, many of the features attributable to condensation corrosion are found deep in caves. Far from the cave entrance, the cave air is likely to be saturated with water vapour; consequently only small temperature changes are required for condensation to occur.

Many authors have referred to the phenomenon of condensation corrosion, but few have examined the mechanism beyond qualitative interpretations of calcite dissolution reactions. Two sets of experimental data are required to assess the corrosive potential of condensation waters on speleothems and thus model the rate of corrosion for sites within a cave. The condensing waters have to be collected and analysed, two difficult procedures because of the small quantities of water available and the exceptionally low concentrations of chemical species in them. Studies at Jenolan Caves (New South Wales, Australia) showed that condensation waters contained dissolved salts and gases. From these analytical results, saturation indices for calcite were calculated and led to the conclusion that condensing waters can be exceptionally aggressive to speleothems. Additional modelling showed that such waters are even more aggressive to calcite when they contain dissolved acid gases or salts of non-common ions. To complete the model, a budget of how much water condenses is needed. Experiments to assess the volumes and patterns of condensation have been made in the Glow-worm Cave, Waitomo, New Zealand (Schmekal & de Freitas, 2001).

An alternative approach is to measure the actual corrosion. Because of the roughness of the corroding surfaces, use of a micro-erosion meter is not practical. A method trialled by Avramidis *et al.* (2001), using slabs of Carrara marble as a substitute for speleothem calcite, has proved to be promising. In their initial experiments, Avramidis *et al.* were able to compare rates of condensation corrosion at a number of sites, and showed that in a three-month experiment, condensation corrosion was measurable with a maximum erosion rate of 1000 μ m (100 a)⁻¹ and varied significantly between sites. Kinetics of calcite dissolution are slow, so there has been some debate as to whether the residence time of the aggressive condensate on speleothems is long enough to allow dissolution. The above experiments, and those at Jenolan Caves where condensation waters, confirm that the residence time is adequate for dissolution.

Most caves have enhanced levels of the acid gas, carbon dioxide (see Carbon Dioxide-Enriched Cave Air). The presence of carbon dioxide above atmospheric levels is believed to substantially increase corrosion (Pearce, 1999). Carbon dioxideenhanced condensation corrosion can be viewed in many caves and is dramatically demonstrated in Odyssey Cave, Bungonia, New South Wales, Australia (James, 1977). Speleothems, in areas with atmospheres containing 2–3 v/v% carbon dioxide, exhibit the features of condensation corrosion listed above. Where levels are continuously above 4 v/v%, all speleothems have disappeared and the wall rock is deeply etched.

CONE KARST

Cone karst (Kegelkarst) landscapes represent some of the most spectacular and complex terrain developed on carbonate rocks, particularly in the humid tropics. The generally conical carbonate hills (cones) may be isolated from each other visually or share lower ground surfaces such as pedestals or ridge remnants. In some cone karst areas discrete cones protrude from a near-planar surrounding corrosion surface, which may be alluviated and traversed by allogenic rivers that flow from outside the karst area. In other areas the cones have overlapping flanks and/or are separated by more-or-less enclosed depressions (cockpits), such that the cones form deeply serrated ridges surrounding depressions in a polygonal arrangement that has been described as "egg box" topography (Ford & Williams, 1989).

Some of the best-known cone karst landscapes are in southern China, particularly around Guilin in Guangxi and in Guizhou (see Photo). Other notable examples occur throughout Southeast Asia, particularly in the Gunung Sewu (Thousand Hills) of Java (see Sewu entry), elsewhere throughout Indonesia, and in Malaysia, Papua New Guinea, Burma, Vietnam, Thailand, Cambodia, Laos, and the Philippines. There are also extensive cone karst areas in tropical areas of southern Mexico, in Belize and Guatemala, in Central America, and throughout the Caribbean Greater Antilles, in Cuba, Jamaica, Puerto Rico, and Hispaniola.

The cones themselves may dominate the landscape or may be subsidiary to pronounced enclosed depressions or to an extensive planar surface. Individual cones usually arise from a continuous carbonate surface, although this may be obscured by alluvium or by other sediments. In some instances cones are seated on non-carbonate rocks, for example in the Rio Frio area of western Belize, where they rest upon a granite base, but this is uncommon. The morphology of cones may be extremely variable, ranging from steep-sided peaks to subdued hemispherical hills or cupolas. Some cones attain a height of over 100 m and a diameter up to 500 m, yet most others are measured in the tens of metres. Cones, or conical hills, are of variable morphology and they have been classified on the basis of their height/width ratio by Balazs (1973) and others. This approach was extended by Day (1981) to incorporate cone shapes into an overall classification of tropical karst landscape styles. This approach produced a simple tripartite framework. In type I landscapes enclosed depressions are dominant and interspersed with subdued hills; in type II landscapes enclosed depressions and residual hills attain approximately equal prominence; and in type III landscapes isolated residual hills dominate intervening near-planar surfaces.

Quantitative approaches to cone karst landscapes are relatively straightforward where individual cones are isolated, but far more problematic where their bases are common or intersecting (Day, 1981). There is no definitive distinction between cone karst and tower karst, since both contain assemblages of residual hills of variable morphology. Karst towers are usually discrete, steep-sided individual hills set in a corrosional plain and representing one end of the spectrum; individual, closely spaced karst cones are intermediate; and coalescing conical hills separated by enclosed depressions and valleys represent the other extreme. It is this last assemblage that represents the classical Kegelkarst, as

Cone Karst: Conical hills in the Zhenning karst of Guizhou, China. (Photo by John Gunn)

described by Lehmann and later termed cockpit or polygonal karst. The Cockpit Country of Jamaica provides a typical example, in which conical hills dominate the skyline but the intervening depressions represent the active foci of dissolution.

Establishing a meaningful, objective classification of cone karst landscapes has proven problematic, although it is clear there are, in fact, underlying morphologic patterns. The seminal morphometric studies of Williams (1971, 1972) were the first to identify organization within cone karst landscapes, in particular serving to illustrate their essential polygonal morphology and spatial organization, and the essential similarity of their hydrological function to that of other types of fluvial drainage basin. Field measurement of cone karst is arduous and time-consuming, but maps, air photographs, and satellite imagery generally do not provide sufficiently detailed information at a suitable scale to be acceptable substitutes. Comparative data on the density and spacing of residual hills is relatively easily assembled, but meaningful measurements of height and threedimensional shape, for example, are far more problematic. Where field data are available, usually for relatively restricted areas, a variety of approaches to measurement and classification have been employed. For example, in the context of general or overall landscape morphometry, surface roughness has been utilized as a discriminator of cone karst landscape styles, and wavelength variance within cone karst has been analysed by use of Fourier models. Development of more rigorous GIS models may be expected to contribute to further mathematical analysis of cone karst landscapes.

Various names have been ascribed to the cones themselves and to the overall landscape. In China, groups of residual hills sharing a common exposed bedrock base are known as fengcong (peak cluster) and isolated residual towers on a plain are termed fenglin (peak forest); intermediate categories include peakcluster-depression, where the cones enclose discrete depressions, and fengcong-valley karst, where the cones are separated by valley networks (Ford & Williams, 1989; Smart *et al.*, 1986). Elsewhere throughout the world residual carbonate hills, whether conical or not, are known as mogotes, Kuppen, pitons, pepinos, or hums.

Although some cones approach true conical symmetry, most are actually asymmetrical in at least one directional plane, reflecting structural or other geological influences and a degree of intrinsic heterogeneity. Asymmetry of the mogotes of northern Puerto Rico was considered by Monroe (1966, 1968) and others to be the result of directional preference in surface induration or case-hardening related to predominating trade winds, but was shown by Day (1978) to be directionally inconsistent and related rather to structural control and basal undercutting. In most instances, degree of symmetry is a function of scale and perspective; most approximately conical hills stripped of their vegetative cover prove to have highly asymmetrical slopes. As the cones themselves are erosional remnants, it is the intervening depressions and lowlands that are the focus of current karstic dissolution and fluvial geomorphic activity and, by comparison, the cones themselves are relatively inactive, although they are subject to a range of mechanical slope processes. Cone summits are rarely accordant, although in some areas there is a suggestion of dissected plateau remnants, and it is not unusual for conical hills in cockpit karst areas to be aligned in a pattern suggesting that they are the remnants of interfluvial ridges, although this is less clear in locations where isolated cones are set in a corrosional plain. Lehmann (1936) identified aligned or directed residualbordered cockpits and depressions, which he termed Gerichteter karst.

Regional drainage in cone karst landscapes is largely autogenic, with individual hillslopes contributing runoff and throughflow to discrete depressions. Although this centripetal and vertical drainage may seem chaotic, and indeed the surface component is highly ephemeral, each depression and the surrounding hills constitute an organized drainage basin, with integrated epikarstic components. Locally there may be allogenic inputs from adjacent non-karst terrain, and many cone karst areas are fringed by springs and pocket valleys which debouche the regional underground drainage. Individual conical hills set in alluvial plains often have their own set of peripheral springs, whose behaviour can be altered radically by removal or modification of the natural vegetation cover.

Cone karst slopes and hilltops are highly irregular, often with a very patchy soil cover that is deepest in fractured pockets. Slopes may consist of combinations of small vertical cliffs, inclined bedrock surfaces, "staircases", or talus accumulations. By comparison, the intervening depressions and lowlands may have deep accumulations of colluvial sediment. Cone karst is developed in a wide range of carbonate rocks that are able to support slopes of variable steepness and continuity. Softer, more friable carbonates often have a surface induration, often referred to as case-hardening and in some cases exceeding a metre in thickness (Monroe, 1966). Bedding, jointing, faulting, and lithological variation also influence cone morphology.

Cave systems associated with cone karst include vertical shafts and small centripetal systems that evacuate drainage from individual cones and depressions, deeper regional conduits, and largely abandoned systems riddling the cones at higher elevations. Some summits contain large vertical shafts, which, given the restricted present surface catchment areas, are presumably relict features inherited from prior phases of the regional surface and underground drainage system. Paleomagnetic studies of sediments from caves in karst towers are potentially valuable in deciphering the chronology of cone karst landscape evolution (Williams, 1987), suggesting that they are time-transgressive landforms, with their summits being older than their bases.

Spectacular cone karst landscapes attracted the attention of early Chinese travellers such as Xu Xiake, and Grund (1914) adapted the landscape as the "mature" stage in his karst evolutionary cycle. It was not until the mid-20th century, however, that the first widely available and systematic geomorphological studies of cone karst were undertaken in Asia and the Caribbean by Herbert Lehmann (1936, 1954) and others. Some of the most detailed observations of cone karst were made in the 1960s by Conrad Aub (1969a, b), who drew particular attention to the intrinsic variability of the slopes and to the fact that rainwater throughfall was greater in the enclosed depressions than on the surrounding hill summits.

Several models of cone karst formation and evolution have been proposed. Although it is now generally accepted that preferential near-surface dissolution is the primary mechanism involved, with surface collapse playing only a minor role, the influence of regional groundwater levels and occasional surface inundation by floodwaters or upwelling groundwater is still not fully understood. Of particular concern is whether isolated karst cones represent a sequential evolution from previously linked conical hills, or whether the two develop independently under differing geological and environmental conditions; while both are possible, most evidence supports the latter hypothesis. In Jamaica, for example, it is clear that so-called "degraded" cone karst has developed independently where insoluble sediments are most voluminous, and not by modification of pre-existing "normal" cone karst. Another contentious issue is the extent to which surface drainage systems, developed prior to extensive karstification, have influenced cone karst morphology. In some cone karst areas, such as Puerto Rico, Belize, and Guatemala, there is a clear imprint of regional paleodrainage patterns, but in other areas this inheritance has been rendered undetectable by subsequent karstification.

Although cone karst is most often associated with humid tropical climates, relict examples occur in locations where equivalent climatic conditions formerly prevailed. Such relict cone karst has been recognized in central Europe. Similar near-conical residual hills have also been identified in temperate karst areas, and non-carbonate analogs exist in the inselbergs, bornhardts, and other residual hills of non-karst landscapes.

Cone karst landscapes have been subjected to a wide range of human land uses, many of which have proven to be unsustainable. Because of their ruggedness and remoteness, some cone karst areas have remained relatively unscathed by human influences, and represent significant biological reservoirs. Many cone karst landscapes contain significant archaeological remains, and they are also important in terms of agriculture, forestry, and tourism. Portions of many significant cone karst areas have been demarcated as protected areas, although this has infrequently involved explicit recognition of their karstic nature. Elsewhere, human encroachment has resulted in geomorphological and biological degradation, particularly as a result of uncontrolled forest clearance, unwise agricultural practices, urbanization, and industrial activities, including quarrying.

CONSERVATION: CAVE BIOTA

Many cave biota have very restricted ranges, and limited opportunities for dispersal. Consequently they are strongly affected by even moderate environmental variability or pollution. The main threats come from a destruction of the habitats by quarrying; increased visitor numbers and vandalism; pollution by heavy metals, herbicides, or pesticides; excess nutrient input; or invasion by an epigean species. The majority of subterranean fauna is not considered in existing national or international protection laws. Only five world conventions are applicable to cave biota and habitats: the Ramsar Convention (1971) in which 12 karst and subterranean hydrological systems are included in 1150 designated wetland areas (see Ramsar Sites); the UNESCO World Heritage List (1972) which includes 13 caves (just 1.8% of the known world caves; see World Heritage Sites); the Washington Convention on International Trade in Endangered Species of Wild Fauna and Flora (1973) where some subterranean species are listed (bats, guácharo or Steatornis caripensis, Proteus anguinus); the Rio Convention (1992) for the protection of biodiversity-although this does not include a detailed list of threatened species; and the International Union for Conservation of Nature and Natural Resources (IUCN) which published a "Red List" of 95 threatened cave biota (Baillie & Groombridge, 1996). There is no specific conservation list for cave flora. Despite these conventions, protection of species from subterranean habitats remains extremely difficult and requires measures to reduce or mitigate the negative impacts of human activities. The main conservation procedures for cave biota are: limitation of visitors in sensitive caves; closure of the most valuable caves; reduction of vandalism; ending pollution from external sources and removal of internal pollution left by cave explorers; rehabilitation of degraded karst ecosystems; and public education and information.

Limestone quarrying has a direct impact on landforms, as well as impacting on karst processes, groundwater systems, and the epikarstic biospace of cave fauna. In process terms the principal impact is the removal of stone with the potential for the complete destruction of caves in some areas, but it may also include depositional components such as the creation of spoil heaps. Gunn and Gagen (1989) have estimated that during the 20th century quarrying has been responsible for the removal of over 900 million tonnes of limestone from the Peak District (England), about the same as has been removed by natural processes over the whole of the Holocene. To reduce these major impacts on subterranean sites as well as on ecosystems, it is vitally important to set up a databank of the most interesting karst areas (from the geological, biological, and archaeological perspectives), and to limit industrial activity to the less important areas. Moreover, it is essential to oblige quarry companies to restore affected landscapes so as to redress damage to the environment and to the countryside.

All visitors to caves—occasional cavers, tourists, and scientists—have an impact on the cave itself and on cave biota. The main effects are compaction of the sediments, introduction of energy sources (mud, food residues, faeces, and lint), and the destruction of biotopes. These impacts are enhanced by increased visitor numbers and intentional vandalism or souvenir gathering of geological features (mainly speleothems) and cave biota (mainly bats, but also several terrestrial or aquatic invertebrates). A conservation policy must include controls on the number of visits and visitors by gating of cave entrances; the creation of protected areas that encompass the catchments of the most interesting caves with troglobitic taxa; the repression of vandalism; and the education of cavers and visitors. It is necessary to explain the importance of cave biota for scientific studies (evolution, speciation, population genetics, adaptation) using periodicals, books, the internet, and interpretation tours within selected caves. Degraded ecosystems could be restored by depollution campaigns including the removal of waste material (such as spent carbide) and speleothem repair (see Restoration of Caves and Speleothem Repair).

It is well known that industrial activities such as iron and steel plants produce dust containing heavy metals such as cadmium, chromium, copper, nickel, lead, and zinc. Karstic sites do not escape the problem of dust deposition and pollution of groundwater by heavy metals. For example, heavy metal pollution has been found in the Sloans Valley Cave System, the third longest cave system in Kentucky (United States), endangering the fragile ecosystem which contains a rare troglobitic species, the blind fish *Typhlichthys subterraneus* (see Pisces: Amblyopsidae).

In addition to industry, agricultural activities and residential and commercial developments have been shown to impact on groundwater quality in limestone and karst terrains and hence on cave biota. Of particular importance in intensively farmed karstlands is disruption of the ecological balance by the introduction of agrichemicals such as herbicides into groundwater. The most commonly used herbicides are Atrazine, Alachlor, Metolachlor, Glyphosate, 2-D, Imazaquin, Imazerahir, and Pendimethalin. Positive correlations between agricultural land and herbicide concentrations in springs and groundwater have been found in the United States and England. Pesticides such as Aldicarb, Carbaryl, Carbofuran, Dianizon, and Parathion, and toxic chemicals such as petroleum also impact subterranean ecosystems. It has been estimated that in the Unites States 3.5–21 million pounds weight of pesticide reach ground or surface water before degradation each year, and a significant amount of this is in karstlands. These products are carried by water through the soil into groundwater through the processes of infiltration, leaching, and percolation. All of these substances persist in the environment, being slowly, if at all, degraded by natural processes; in addition, all are toxic to life if they accumulate in any quantity. Residential and commercial development may increase the amount of the chemicals released into soil and water. In November 1981, 10000 Salem cave crayfish (Cambarus hubrichti) and 1000 Southern cavefish (Typhlichthys subterraneus) were stressed or killed in Meramec Spring, Missouri, because of a fertilizer pipeline failure that released 80000 litres of liquid ammonium nitrate.

The problem of an excess nutrient input into groundwater and cave streams is worldwide. For instance, the US Environmental Protection Agency (1998) reported that agricultural activity (primarily the application of fertilizers) is the leading source of pollution threatening the water quality of rivers and lakes in the United States. However, agriculture is not the only human activity affecting groundwater: an estimated 3 billion cubic metres of sewage (mainly human waste) and wastewater are discharged to surface waters every year in the United States, increasing the nutrient input in groundwater. Eutrophication is commonly defined as a process that increases nutrients, especially nitrogen and phosphorous forms in aquatic ecosystems. This frequently leads to an increase in algae populations and a decrease in biodiversity in surface waters. Nutrient pollutants alter the oligotrophic nature of groundwater ecosystems and severely alter groundwater food webs. The introduction of organic pollution can extirpate the indigenous fauna or completely replace the community with epigean fauna. Excess organic loadings create a biological oxygen demand that can quickly deprive fauna of dissolved oxygen. To fight excessive organic loading, legislation to control wastewater must be strengthened and waste treatment plants developed, especially in karst areas.

Infestation of epigean species in the subterranean environment, and their potential competition with the cave biota, fortunately seems rare. Indeed, the harsh ecological conditions of caves restrict the invasion of new species. Most of the cases are linked directly or indirectly with human activities. The fauna introduced by human activities is especially noticeable on islands, and sometimes this highlights important problems for native communities. For example, several species have invaded lava tubes in the Canary Islands. In show caves, visitors introduce lint, skin flakes, soil particles, food scraps, microflora, and fungi. These provide a rich source of food which benefits some cavernicolous species, but may also permit colonization by pre-adapted epigean species. The most important environmental alteration permitting new species is the use of artificial light, which allows the growth of several species of algae, mosses, and ferns that do not normally occur in the cave system (see Tourist Caves: Algae and Lampenflora). A very interesting case of a recent invasion of an exotic species occurred in the United States. The Red Imported Fire Ant (Solenopsis invicta) (Hymenoptera: Formicidae) was inadvertently introduced from Brazil in the 1930s and has gradually spread to cover 300 million acres in 12 southern states. These ants use their stings for not only defence but also for prey capture and pheromone dispersal. Elliott (1992) reported that S. invicta began invading the caves of central Texas in 1988. The colonies live in soil mounds, but the workers invade caves during summer and forage intensively for moisture and food in the caves. They can kill the Texas cave crickets (Haedenoecus subterraneus) and carry off other cave dwellers. They also attack the cave crickets outside the caves during their nocturnal foraging period. There is no efficient method to specifically protect the subterranean system from this invasion and the only technique is to progressively eradicate the external colonies.

There are many case studies from karst areas throughout the world that show how limited legal, contractual policies, or spontaneous initiatives are in protecting the subterranean environment, including cave biota, which is increasingly deteriorating as a consequence. An important tool to assist conservationists is the development of data banks showing the distribution of troglobites and particularly vulnerable cave biotypes. These should receive the highest level of protection both in terms of habitat preservation (prevention of mineral extraction and controls on access) and pollution control.

CONSERVATION: PROTECTED AREAS

There have always been protected areas in the natural landscape, some of which have probably been in existence since the Stone Age and are now often perceived as sacred sites. The popular idea that the concept of protected areas commenced with Yellowstone (United States) is a fallacy—probably the only genuine innovation at Yellowstone in 1872 was the use of the term "National Park". Nevertheless, the area has served as a flagship for modern nature protection.

The latter part of the 20th century saw an immense proliferation of protected areas, and almost as much proliferation of formal titles for such areas. Recognizing the confusion that has arisen from the complex patterns of nomenclature, the IUCN (International Union for Nature Conservation) established a world classification in an endeavour to provide an effective basis for comparability. There is only space here for a brief summary of this classification (see Table), and its proper application demands reference to the published manual (IUCN, 1999).

An obvious difference in national usage arises in relation to the use of the term "national park" in the countries of Europe. For instance, most of the UK National Parks are probably best placed in the IUCN Categories of Protected Landscapes (V) or Managed Resource Protected Areas (VI). This does not imply

Conservation: Protected Areas: IUCN Categories and Management Objectives of Protected Areas.

Category Ia: Strict Nature Reserve Protected area managed mainly for science

Category Ib: Wilderness Area Protected area managed mainly for wilderness protection

Category II: National Park Protected area managed mainly for ecosystem protection and recreation

Category III: Natural Monument Protected area managed mainly for conservation of specific natural features

Category IV: Habitat/Species Management Area Protected area managed mainly for conservation through management intervention

Category V: Protected Landscape/Seascape Protected area managed mainly for landscape/seascape conservation and recreation

Category VI: Managed Resource Protected Area Protected area managed mainly for the sustainable use of natural ecosystems

they are of any less importance, but simply that they are based upon a totally different set of objectives and criteria to those, say, in the United States.

A further dimension which does not provide any further legal protection, but which strengthens the political dimension of protection, arises from international recognition of various national protected areas. The first of these was the Man and the Biosphere (MAB) programme launched in 1968 and which led to the declaration of Biosphere Reserves. These have a threefold role. Each reserve usually includes a protected area that meets conservation objectives, but the reserve as a whole also provides for development activities on a culturally and ecologically sustainable basis. Finally, it is expected to provide a basis for continuing research, education, and information exchange on the issues around the conservation-development nexus.

The Ramsar Convention (first agreed in 1971; see Ramsar Sites) provides for the international recognition of wetlands and fosters their conservation and sustainable use. Although some surface wetlands in karst were recognized, it was not until 1996 that the concept of subterranean wetlands was accepted, and now provides new opportunities for the recognition of karst sites. The World Heritage convention followed in 1972, and focussed upon furthering the protection and conservation of both the natural and cultural heritage of the world. World Heritage Areas are discussed in a separate entry and will not be given further attention here other than to emphasize that the convention does not, in itself, confer legal protection—that remains the responsibility of host governments.

There are some specific problems in the declaration of protected areas in karst regions:

- The focus of popular attention upon caves led to many of the early protected areas in karst simply containing a single cave—or perhaps only the entrance area of a cave. These reserves fall within the National Monument category, but are usually totally inadequate in karst protection. Much of the subterranean karst may well fall outside of the karst system of which the cave is only a part, and the immense importance of the watershed is totally neglected.
- 2. Similarly, protected area boundaries may well be determined on the basis of surface divides, as the subterranean divide is often unknown or unrecognized, and so the system remains vulnerable to impacts generated outside of the protected area boundary.
- 3. Much of the community, and hence political, perception of the values to be maintained in protected areas is based upon the visible and aesthetically attractive higher animals and plants. This position is strongly reflected in the staffing of protected area management agencies—most employ biologists, but it is rare to find geologists or other earth scientists. So, protected area decision making focuses upon fur, feathers, and leaves! Only the most monumental scenery has been readily acceptable as a rationale for the protection of geological characteristics and values.
- 4. Even when karst is protected, the general public and most managers over-emphasize the importance of cave speleothems; the often virtually invisible ground water and cave biota are neglected. An even bigger problem is that the floors of caves, which may well be the most scientifically important element of a cave system, are freaccess. quently neglected, trampled, or dug away to improve

Virtually all protected areas face new threats of increasing visitor numbers without an equivalent increase in the resources to provide for adequate environmental protection. This is compounded by decreasing budgets and the demand that parks should earn their own budget through visitor charges and special events, which in turn distorts the central objectives of the park. Karst parks are forced to give priority to the development of tourist caves and the ways in which income derived from commercialization of these may help solve the fiscal problems.

There are also new demands being made of protected areas, notably by forestry, mining, grazing, and other exploitive industries that are increasingly seeking access to the resources "locked away" in parks. All too often this is proposed under the ambit of so-called "wise use" without any real recognition that this is contrary to the very basic objectives of protected areas. At the same time, a new interest in Integrated Conservation and Development Projects is emerging, often with real leadership or partnership being offered by the more responsible industrial leaders.

Another social dimension of protected areas is the rapidly growing call for collaborative management, particularly in joining with indigenous or oppressed people. Protected area managers have come to realize the extent to which, in the past, they may have neglected the rights of these people in trying to ape the "Yellowstone model" and in so doing lost an immense treasure of inherent knowledge and understanding of the natural environment and its meanings.

CONSTRUCTION ON KARST

The dissolution features of karst provide problems for all forms of construction activity. Built structures demand special treatment on karst, in many respects similar to the approaches used for highways. Dams and reservoirs encounter a different set of problems related to potentially major leakage, while caves create special hazards in the excavation of tunnels (see Dams and Reservoirs on Karst; Highways on Karst; and Tunnelling and Underground Reservoir Construction on Karst). For surface structures, karst provides hazards and problems that fall into three groups, related to rockhead, to caves, and to dolines (sinkholes).

Rockhead creates problems due to its irregularities in most karst. In immature karst terrains, installation of piles may require longer elements for some parts of a site, reinforced ground beams can be designed to span any small new dolines that may develop, or raft foundations may be incorporated as a precaution. In. karst that is more mature, rafts or groundbeams may still be appropriate for bridging cavities (see Figure 1). In Florida, either rafts or preparatory grouting are preferred where new dolines are recorded locally at rates above $0.05 \text{ km}^{-2} \text{ a}^{-1}$. Heavy geogrid (a planar mesh manufactured from polymeric materials) stabilizes a soil profile, and can be designed to span a potential void in order to reduce the impact of any subsequent catastrophic collapse. Grouting of soils over a highly fissured rockhead, before installation of spread footings within the soil profile, may require works on a large scale. A site of 10000 m² on karst in Pennsylvania took 1200 m³ of compaction grout through 560 boreholes that averaged 9 m deep; this was still more economical than piling to rockhead that was mostly 6–12 m deep.

Pinnacled rockheads in tropical karst terrains generally require that structures are founded on sound limestone, either by piling to rockhead at whatever depth it is encountered or spanning foundations between sound pinnacle tops. Driven piles may be bent, deflected, or poorly founded on unsound pinnacles (Sowers, 1986). Bored piles are preferred, though they can be difficult to place on steeply inclined rockhead. The founding of each pile tip is probed to ensure integrity; probing depths for cavity detection are outlined below. Undersized or unstable pinnacles may require assessment by probes splayed at 15° from the vertical from the founding point. A light structure can bear safely on the soil profile over a deeply pinnacled rockhead, after due care with respect to drainage modification and precautionary placement of geogrid where appropriate. Rockhead pinnacles up to 50 m high, which occur in some tropical karsts, offer some of the worst ground conditions possible for heavy structures that have to be founded on bedrock. Every pile location has to be treated as an individual ground investigation, and the contractor has to adapt to unique ground conditions as they are revealed by excavation.

Caves provide difficult foundation conditions largely because it is impossible to predict both the number and the size of caves beneath any given karstic site. Each site has to be assessed individually within the context of its geomorphology, and engineer

Construction on Karst: Figure 1. Various ways of achieving safe or unsafe foundations for buildings on soil-covered karst (largely after Sowers, 1986).

ing works must respond to the local conditions. Local records and observations may indicate the typical and maximum cave sizes previously encountered. The cave size determines the engineering philosophy whereby a defined minimum of sound rock should be proven by drilling beneath every foundation pad and pile tip. For typical karst in strong limestone, a cover thickness of intact rock that is 70% of the cave width ensures integrity. This guideline covers limestone with a normal density of fractures and bedding planes; local zones of heavy fissuring may reduce cave roof integrity, and thicker cover may be required in some softer limestones. Large caves at shallow depths provide the major hazard. Statistically they are rare, but their absence may have to be proved by extensive probe drilling. Caves with open entrances are best assessed by direct exploration. Small shallow cavities may be collapsed by a monitored surcharge or by dynamic compaction, especially in chalks and weak limestones. Where caves are found at critical locations beneath planned foundations, the normal remedy is to fill them with mass concrete. Grout injection through boreholes may incur considerable losses by flowage into karstic cavities that extend far off site, and perimeter grout curtains may therefore reduce total costs. Alternatively, creating access to a cave may allow installation of shuttering and removal of any weak floor sediment before filling. Relocation of footings is usually an expensive option, but can prove essential over complex caves (Waltham, Vandenven & Ek, 1986). Bored piles can be placed through a cave to sound footing in the rock below; geotextile sleeves can be used to cast the concrete through the cave, but total cave filling is often preferred for its simplicity, at costs that may be little different.

Dolines are a significant hazard to structures founded on the soils that overlie karstic limestone. They are commonly known as sinkholes by engineers, especially when their floors are actively subsiding or collapsing, and the key to the minimization of sinkhole failures in any karst is the proper control of groundwater flows. Design codicils appropriate for any karst site include a ban on soakaway drains (dry wells) in or adjacent to the site, use of flexible lines and junctions on all drainage elements, diversion of inbound surface flows, and avoidance of reducing soil thickness over shallow rockhead. Dry wells can be employed where they are sealed onto open fissures and cased below rockhead, and retention basins in dolines require lining if needed by flood control regulations.

Control of water abstraction is also critical, especially where the original water table is close above rockhead. Florida's Disney World stands on 20–30 m of soils over limestone, and all its wells are monitored so that pumping can be switched when a local water table decline is detected; sinkholes have not occurred on the site. Dewatering by quarrying incurs legal responsibilities, and has been stopped at some sites by legal action to prevent further ground failures.

Grout sealing of rockhead fissures, prior to foundation works, is appropriate on less mature karst, but pinnacled rockheads require more elaborate cap grouting with cement slurries after plugging known open fissures with more viscous grouts (Kannan & Nettles, 1999). Compaction grouting (with a viscous cement mix) forms a solid block within the soil that can bridge over fissures, densifies the adjacent soil, and can lift subsided structures. It has been used to remediate sinkholes in soils over pinnacled rockheads, but its use requires caution because the

Construction on Karst: Figure 2.

The result of indiscriminate house building on thick soil cover over mature karst is the occasional loss of structures to the random development of destructive doline collapses. The garages of this house in Ripon, England, were lost when the ground collapsed above cavernous gypsum. (Photo by Tony Waltham) grout flow cannot be controlled and its placement may not remedy the initial cause of a failure. Where rockhead cannot be seen or treated, sinkhole activity can be reduced by laying geogrid into the soil; this is additional to proper drainage control.

A covered sinkhole that collapses or subsides beneath an existing structure requires individual remediation. Such features may develop in any karst, though their width and depth are limited by the soil thickness. They may involve only modest soil subsidence, with no development to rockhead, but structural underpinning with friction piles generally fails again within a few years unless the underlying fissure is sealed at the same time. A permanent sinkhole repair requires exposure of rockhead and choking of the causative fissure or cave throat with chunk rock, covered with graded fill, with or without a concrete slab or geogrid mat. Whether such action is preventative before site development or remedial after a failure, depends largely on how well the ground has been investigated and how well the problems of karst are understood.

CREVICE CAVES

Crevice caves are narrow rectilinear crevices of natural origin; unitary or in somewhat rectilinear networks; with little or no dissolutional speleogenesis; large enough for human entry and investigation; and extending beyond daylight. In granite, coarsegrained sandstone ("grit"), basalt, and a few other rocks, some are curved instead of rectilinear. Many are an intermediate stage of breakup of competent rock masses. They occur in
many types of competent rocks, including limestone, and also in glaciers where they are known as crevasses. Commonly other pseudokarstic and occasionally some karstic processes interact with crevice caves, producing multiprocess caves. Some spectacular examples in quartzites in tropical rainforests have spawned vigorous debates in recent decades.

Because of the variety of their genetic processes and the variety of terrains in which these caves exist (and also because of limited communication), local terminologies have arisen, including breakaway caves, cambering caves, closed joint caves, crack caves, crevasse caves, crevasses, earth cracks, earthquake cracks, eruptive fissures, fissure caves, gravity-sliding caves, gulls, gull caves, joint caves, mass displacement caves, mass movement caves, open joint caves, rift caves, rifting caves, rock topple caves, sliding fracture caves, slope movement caves, tectonic caves, tilting caves, toppling caves, and windypits. "Windypit" is a local British term for crevice caves formed by "valleyward sliding" of large masses of bedrock (Cooper, Ryder & Solman, 1982). In other parts of England, those formed by lateral spreading are called gulls or gull caves. "Camber" is a related, largely British, engineering term. In this entry, the term "crevice cave" is used to conform to definitions of the 4th edition (1997) of the American Geological Institute's *Glossary of Geology*.

Significance of Crevice Caves

Where karstic caves are readily accessible, all but the largest crevice caves are commonly ignored. Thus they are not nearly as rare as the English-language speleological literature seems to suggest. In Poland, where most of the country is non-karstic, 530 crevice caves are documented in flysch sediments alone and 17 of these are more than 100 m long (Klassek, 2000). In addition to being objects of curiosity and popular sites for strenuous recreation, crevice caves commonly shelter small to large forms of plant and animal life. Several in the United Kingdom have been designated Sites of Special Scientific Interest (Cooper, 1983). Especially in Europe and Asia, some have been locations of notable archaeological discoveries. A few (e.g. Hematite Cave, Oregon, United States) are locations of unusual mineralogical occurrences. Others (e.g. Pit H Cave in the Great Crack of Kilauea Volcano, Hawaii) permit observations of patterns of magma flow deep in volcanic rift systems (Figure 1) and in shallower eruptive fractures. Several are show caves. They are a common cause of engineering problems. Vertical piping of soil into crevices is a valuable warning of incipient catastrophic bedrock movement.

Classifications

Classifications of crevice caves reflect local nomenclature, local processes, local topography, and local lithology. None has yet encompassed the full range from littoral caves to rift zone fractures. Perhaps the simplest classifications consider whether the cave extends into a cliff or slope, or parallels it, or is formed along a bedding plane or other structural feature, or opens vertically (Figure 2). Finlayson (1986) classified those in granite as open joint caves and closed joint caves. Vitek (e.g. 1989) has published limited classifications of pseudokarstic caves in several areas. Overall he has specified "fissure-type" and "crevice-type" caves, "selective weathering" crevice caves on bedding planes (up to 100 m long), mass movement "crevasse" and "block" caves, and "combined type"

caves. Cooper (1983) classified mass movement caves in terms of their relation to slope: plateau-top, head-of-slope, slope, cliff, scree (talus) slope, and detached block forms.

Distribution, Forms, and Speleogenetic Mechanisms

A variety of processes, somewhat beyond the scope of this entry, initiate and enlarge crevices, singly, or in combination. Some of these are frost and ice wedging and heaving, tectonic movements, minor dissolution along bedding planes, dykes, fractures and mineral veins, gravitogenic mass movement, block creep or glide on granular, slick or incompetent structures, the complex of littoral processes, and upward or lateral movement of magma.

Locations of crevice caves depend largely on the processes which form them. Excluding glacier crevasses, most crevices occur on or near cliffs or steep slopes, but some are found at the top of batholithic domes, on gentle to moderately sloping lava fields, and in eroded plains and other areas of comparatively low relief. In volcanic regions, circumferential crevices form around many craters and calderas; a few persist as crevice caves.

Crevice caves occurring parallel to cliffs tend to be especially impressive. In Montana (United States), Campbell (1968) described crevices and crevice caves over 60 m deep behind cliffs more than 300 m high, at distances up to 800 m from the cliff edge. Elsewhere in the United States, some in New York State and New England are especially well known.

Mass Movement or Gravity-Sliding Caves

Simple crevice caves are narrow roofed passages with flat, near-vertical walls. They occur singly or in small networks. Rooms tend to form at crevice junctions. If offsets are present along a crevice, they are angled sharply and "fit features" are evident unless erosion or dissolution has blunted them.

Crevice Caves: Figure 1 Plan and vertical section of Pit H Cave on the Great Crack of Kilauea Volcano, Hawaii. Courtesy Don Coons.

Crevice Caves: Figure 2. Vertical entrance of a crevice cave in sandstone and conglomerate, on Vancouver Island, Canada. (Photo by William R.Halliday)

These caves may be roofed by part of the original rock surface, by chockstones, by tilted blocks, and/or by soil andvegetation.

On hillsides and in terrains affected by lateral spreading, gravity eventually begins to widen such crevice caves and form new ones. This occurs more rapidly if an incompetent

or slippery stratum or vulnerable bedding plane underlies a hard, dense formation. Other joints tend to form nearby, and enlarge into crevices. In some caves, they convert unitary crevices into networks. Block sliding, rotation, forward or backward tilting, and/ or basal sapping play roles in determining the predominant form. In complex cases, major crevices commonly are parallel to slopes or cliff faces, with parallel and cross-crevices forming a network or an en-echelon pattern.

Under the influence of gravity, passage widths enlarge downslope, but the network pattern remains intact until blocks begin to rotate or slide independently. Especially on cross-crevices, "tilt features" then demonstrate misalignments, displacements, and/or rotation. At this stage, caves generally are roofed by offsets in fracture lines, slippage on bedding planes, chockstones, and/or soil and vegetation.

As displacement and rotation increasingly supplant tilting and sliding, erosional agents increasingly modify the caves, unroofing them, or converting them into talus caves or merely masses of talus. Sometimes, mapping of what appears to be an ordinary hillside talus cave reveals a persistent rectilinear pattern consistent with a sliding fissure. The rate of change commonly varies in different parts of such caves. The 1.6 km Bat Cave (North Carolina, United States) is a well-known combination of sliding fissure and talus cave.

Mass Movement and Other Crevice Caves in Basalt

Because of its brittleness, basalt tends to fracture into innumerable small cracks rather than large, cave-sized forms. However, some important crevice caves exist in volcanic areas. Curved crevice caves with accreted lava linings are present in the walls of craters on Japan's Miyake Island, and rectilinear examples (e.g. Roadcut Cave) exist hundreds of metres back from caldera cliffs on Hawaii's Kilauea Volcano. Some radial eruptive fissures on Italy's Mt Etna continue downslope as lava tube caves.

Along the Southwest Rift Zone of Kilauea Volcano, the Great Crack ("17 Mile Crack") is a narrow zone of en-echelon crevices, small grabens and crevice caves. Here, 600 m of passages have been mapped to a depth of 183 m in Pit H Cave, along three levels (Figure 2), and exploration of nearby crevice caves has barely begun. The levels of Pit H Cave are largely formed by chockstones; single rope techniques are needed between them. Individual chambers are many metres in width and length (Coons, 2001). At several levels, accreted lava demonstrates unconfined longitudinal magma flow. This is a different pattern from that in nearby Wood Valley Pit Crater, where lava tubes formed within a crevice cave. The Great Rift in Idaho (United States) also contains notable crevice caves. Preliminary study suggests that such crevices are self-propagating as lava is forced laterally into and through them.

Earth Cracks in Northern Arizona (United States)

Some of the partially open "Earth Cracks" in limestone in northern Arizona are associated with faults and grabens. Most show little or no evidence of dissolution ("Bottomless Pits" or Rio Frio Sink near Walnut Canyon National Monument is an exception). With a length of 452 m, Doney Fissure is considered the longest and 0.6 m of vertical displacement is present at the entrance. Displacement is only 5 cm at Sipapu Cavern, which is shorter but 152 m deep. Also in northern Arizona, Paiute Cave is a single, steeply sloping chamber 165 m deep without evidence of dissolution. Recent studies of karstic features in this general area suggest that at least some of these features

are secondary to deep-seated evaporite karst. If so, they should be considered interface phenomena rather than purely pseudokarstic.

Karstic and Pseudokarstic Processes in Quartzite Caves

The role of dissolution in speleogenesis, karstification, and pseudokarstification of poorly soluble quartzite, conglomerate, and quartzose sandstones has been debated in recent years. Somewhat similar features in ferruginous metamorphics have also been discussed. All these areas are characterized by surface landforms, which appear more or less karstic, and by especially impressive crevice caves, some of which have been modified by karstic and/ or other pseudokarstic processes. Their caves vary considerably in morphology and extent. Some are largely or entirely vertical. The world-famous pits ("shafts") of the Venezuelan rain forest plateaux are as much as 314 m deep and 350 m wide. From some of these, subhorizontal conduit caves extend as much as 2500 m, with cross sections from rectangular to oval (see Quartzite Caves of South America). Enormous volumes of clastic mate rial have been removed by piping and by stream erosion so that the pits and conduits were not choked in their own debris. Laminar transport of colloidal silica presumably occurs as an inception mechanism.

Quartzite caves have been particularly studied in southern Africa, Venezuela, and Brazil. In some of these areas, underground drainage and conduit features correspond poorly to surface karstification. In the lapiazed quartzite area of the Mpumalanga Escarpment of southern Africa, underground drainage underlies less than 1% of the lapiazed surface (see Silicate Karst). Thus it is correct morphologically to refer to the Mpumalanga karst as a small quartzite karst within the large Mpumalanga piped crevice pseudokarst. Even there, however, the volume of rock removed by piping must have been much greater than that removed by intergrain dissolution. From the standpoint of process, therefore, it is correct to refer to the entire Mpumalanga lapiazed area as pseudokarstic.

This seeming conflict may be resolved by considering the caves as multiprocess features in an interface between karst and pseudokarst. A continuum exists between caves formed by piping and by dissolution. Even in very pure limestones, cave streams in karstic conduits carry small loads of insoluble residue freed from bedrock in the dissolution process. Other cavernous limestones contain horizons of sand, gravel, and even large boulders of poorly soluble material. After they have been freed during the process of dissolutional. Even some caves in limey sandstones and conglomerates show characteristics of phreatic speleogenesis although the dissolution may be primarily intergrain and thus the process is that of piping.

In clastic rocks with siliceous and ferric matrices, the contin uum is not as clear. However, intergrain dissolution of even these binders has been documented in some quartzose localities (e.g. Striebel & Schäferjohann, 1997). This permits similar transport of siliceous particles by piping and streamflow in pseudokarstic environments, which morphologically may become karstic. For caves in the Venezuelan quartzite plateaux, the relative percentages of piping and of dissolution apparently have not been quantified. The amount of subsurface karstification may be considerably larger than in the Mpumalanga pseudokarst. Colloidal silica speleothems have been documented here.

Piping, however, is a misnomer for the process of erosive widening of vertical crevice caves. Instead, vertical crevice caves undergo an ordinary form of mass wasting common

to bare exposures of many slightly soluble rocks. In basaltic cliffs in Hawaii and elsewhere, this process forms spectacular pseudokarstic karren hundreds of metres high and tens of metres wide.

Other Types of Crevice Caves

Many littoral caves are crevice caves subjected to hydraulic wedging and marine abrasion. Some are found far inland, on ancient shores of vanished lakes and seacoasts (see Littoral Caves). Among other unusual types of crevice caves are deep, extremely narrow stream slots in sandstone (southwestern United States), limestone (Mallorca, Spain) and other rocks. Here, overhanging walls of meandering channels shut out daylight for considerable distances.

CRIMEA, UKRAINE

The Crimean peninsula in southern Ukraine joins the mainland by a narrow isthmus and juts out far into the Black Sea. The peninsula is mostly steppe plains gradually rising to the Crimean mountains in the south (the highest peak is Mt Roman-Kosh, 1549 m). In Crimea the Mountain, Foothill, and Flat karst areas are differentiated (Ivanov, 1961). Karst is developed to the greatest extent in the Mountain area, in a continuous sequence of Jurassic limestones 50 to 1300 m thick. These form the Main Ridge of the Crimean mountains, a massive scarp rising 600 m above the southern coast of Crimea, with more than 340 km² of karst. A distinctive feature of the Main Ridge is its alp-like plateaux. They are occupied by mountain meadow steppes, with thousands of karst sinks and dolines, and wide karren fields. Sink density approaches 90–100 per km² on Chatyrdag and Karabi. Along the edges of high scarps, karst fissures can reach up to 100 m in length at depths of 50 m.

The northern foothills of the Crimean mountains are two monoclinal cuestas with southern scarp faces up to 100 m high and gentle northern dip slopes. They are composed of Upper Cretaceous and Tertiary limestones and marls. The mountains contain small caves (the largest is Zmeinaya Cave, 320 m long, 5 m deep) and numerous Paleolithic and Neolithic sites. In Flat Crimea, limestone outcrops in the Tarkhankut peninsula area. At the base of limestone cliffs up to 30 m high, there are some sites of marine karst with submerged or marine caves, for example Tarkhankutskaya Cave (150 m long, 12 m deep).

The karst of the Crimean mountains was first described in 1915 by Alexander Kruber. The current views on Crimean karst were mainly developed by the 1970s, and form the theoretical basis of Ukrainian and Russian karstology. The research of karst in Crimea and Ukraine improved after B.Ivanov organized his karst expedition in 1958. The caving team of the expedition was headed by the young scientist Victor Dublyansky. Prior to the expedition 82 caves with total length of 1250 m were known in Crimea, and by the end of 1971 their number had increased to 800, and total length to 32 km.

The distribution of karst cavities on karst massifs is shown in the Table. In a morphogenetic classification of the karst cavities of Crimea (Dublyansky, 1977), the corrosive/gravitational,

Massif	Number of caves	Total length, m	Total volume, m ³
Ai-Petri	327	24741	293400
Yalta	24	1134	17020
Nikita	5	308	440
Babugan	32	1222	10990
Chatvrdag	137	11761	352810
Dolgorukovsky	35	22420	280890
Demerddzi	16	1664	13630
Karabi	256	18968	743111
Eastern Crimea	10	769	4990
Foothill Crimea	69	2842	34890
Flat Crimean area	11	512	600.
TOTAL	922	86231	1751971

Crimea: Number and size of karst caves in Crimea. The massifs of the Main Ridge are listed from west to east from Ai-Petri to Karabi.

nival/corrosive, corrosive/erosive, and corrosive/abrasion classes are distinguished.

The corrosive/gravitational class includes karst cavities developed on fractures at the top of steep slopes and scarps. More than 30 caves of this type are known. They have a fissure morphology, and their depth reaches 60–100 m. At different depths they are choked by debris, and in many of them snow is retained in summer. The largest are Gremuchaya, Aryk-Bash, and Suyuru-Kaya, each 100 m deep.

The nival/corrosive class includes shafts formed as a result of corrosion by snow meltwater. There is a close correlation between these caves and stages of Quaternary glaciations. More than 360 such caves are known. The largest are the KuryuchAgai, Inzhenernaya, and Vodyanaya shafts, each nearly 100 m deep. In 40 of these caves there are long-term bodies of snow and ice with a total volume of up to 10000 m³.

The corrosive/erosive class is formed by underground streams. These form the longest karst hydrogeological systems, such as Soldatskaya-Karasubashi (21–26 km, Karabi), Beshtekne-Uzundzda-Chernaya (13 km, Ai-Petri), and Proval-Krasnaya (7–8 km, Dolgorukovsky), which are all unexplored but proved by fluorescin tracing. The systems start at caves and ponors, where permanent or temporary streams sink at the lower edge of limestone residual soil. Among the largest ponors are Soldatskaya Cave, the deepest cave in Crimea (1860 m long; 517 m deep), Molodezhnaya (261 m deep), and Kaskadnaya (400 m deep).

The karst hydrogeological systems terminate at resurgence caves, located at the bases of the karst massifs, at altitudes from 300 to 1300 m. Many of these are open horizontal caves, and today many are dry. The large cave springs are associated with

Crimea: Mramornaya Cave in the Chatyrdag karst massif. (Photo by Alexander Klimchouk)

karst massifs, where large catchment areas are available and there are conditions for longterm influx supply. The longest cave in the Crimea, Krasnaya Cave (20 km long, in the Dolgorukovsky massif) has developed mainly along tectonic faults. There are cascades and chambers up to 30–40 m high at the boundaries between tectonic units. In the entrance zone, cave galleries form at six levels and a large underground river flows in the cave. At the exit it forms a picturesque waterfall 18 m high. Maximum discharge of water is 22.7 m³ s⁻¹.

At the western and eastern edges of the Crimean mountains and Tarkhankut peninsula, where the limestones emerge from under the Black Sea, and are abraded by wave action, there are both corrosional and littoral caves.

Both infiltration of surface waters and underground condensation are important in karst and cave development. The annual precipitation in Crimea ranges from 450 mm (Foothill and Flat Crimea) to 1200 mm (Main Ridge). Condensation in karst fissures can reach 3.8% of the mean precipitation, and during the summer and autumn, drainage of the underground rivers and the flows of karst springs is almost completely supported by

condensation. On the basis of chemical analysis of 2300 water samples from 444 springs, the chemical denudation rate in the Mountain area has been estimated as c. 43×10^{-6} m a^{-1} .

CRUSTACEA

The taxonomic status of crustaceans has long been debated by carcinologists (the scientists who study these arthropods). The group has been assigned to one of the phylum, subphylum, or superclass levels, with five, six, and even ten classes being recognized. The purpose of this essay is not to enter into a taxonomic debate, but to recognize that crustaceans are one of the oldest arthropod groups and certainly represent one of the largest, most diverse, and most successful groups of invertebrates on Earth, with some 40000 species recognized (Hobbs, 2000). Although crustaceans occupy a truly impressive number of aquatic environments (freshwater, brackish, marine), some species have become successful on land as well (e.g. isopods). Crustaceans have a chitinous exoskeleton impregnated with calcium carbonate, with three major body divisions: the cephalon, thorax, and abdomen, and they possess paired antennules, antennae, mandibles, and maxillae.

Not only have crustaceans been successful in epigean (aboveground) habitats, but they have also moved into the hypogean (below-ground) realm, with six classes of crustaceans being recognized as inhabiting cave and other hypogean environments. Additionally, anchialine and interstitial habitats (although many of the latter are not actually associated with karst landforms) harbour troglomorphic crustaceans.

Like many other cavernicoles, many crustaceans are stygobites (aquatic obligate cavernicoles), while a few are troglobites (terrestrial obligate cavernicoles). Both groups exhibit various morphological, physiological, and behavioural adaptations to living in a dark spelean environment where food is in short supply. Their adaptations include reduction or loss of pigments and eyes, attenuated appendages, and lowered metabolic rates.

It is widely accepted that most obligate cavenicoles (including those other than crustaceans) evolved from epigean ancestors with some degree of pre-adaptation to living in hypogean environments and are thought to have evolved by either natural selection or by neutral mutation and genetic drift.

The six classes of crustaceans with subterranean representatives are Mystacocarida, Branchiopoda, Remipedia, Copepoda, Ostracoda, and Malacostraca. The primitive Class Mystacocar ida is a meiobenthic group restricted to interstitial waters of intertidal sand beaches and subtidal sand substrates. It is most closely related to the Copepoda, and less than 20 species and subspecies are known from Africa, Europe, North and South America, and Australia. Because mystacocarids are not known from karstic settings, there will be no further discussion here of this group. Discussion of the remaining five classes of crustaceans follows. (The classes Copepoda and Ostracoda have their own entries in this Encyclopedia, as do three orders—Amphipoda, Isopoda, and Syncarida—of the Class Malacostraca.)

Class Branchiopoda

Only the subclass Diplostraca includes species inhabiting subterranean habitats (the hyporheos—or transition zone between streams and ground water, phreatic zone, caves). Although the Conchostraca (clam shrimps) and Cladocera (water fleas) are included in this subclass, only the latter order has hypogean representatives, with fewer than 100 of the approximately 450 recognized species occupying subterranean waters. These are small (0.2–2 mm), are laterally compressed, and there are only 20+ species that can be classified as stygobites. Subterranean cladocerans (particularly hyporheic species) are known from all continents and most demonstrate only minor troglomorphic adaptations.

Class Remipedia

Remipedia (Figure 1a) are among the most primitive of all extant crustaceans. Twelve species, placed in two families containing six genera (*Cryptocorynetes, Godzilliognomus, Godzillius, Lasionectes, Pleomothra,* and *Speleonectes*), are restricted to anchialine caves in the Bahamas, the Caicos Islands, Cuba, the Yucatan Peninsula (Mexico), the Canary Islands, and the Cape Range Peninsula (Western Australia). These small (up to 45 mm total length), colourless, blind, elongate, centipede-like predators are found in their highest densities in oxygen-deficient waters (<1 mg 1⁻¹), and are often found associated with other stygobitic crustaceans such as caridean shrimps, cirolanid isopods, haziid amphipods, mysids, ostracods, and thermosbaenaceans.

Crustacea: Figure 1. Line drawings of dorsal (d) and lateral (1) views of representative stygobitic crustaceans: **a.** Remipedia (d) *Speleonectes*

lucayensis from the Bahamas (after Hobbs, 2000; total length 19.8 mm); **b.** cyclopoid copepod (d) *Kieferiella delamarei* from France (after Hobbs, 2000; length 740 μ m); **c.** harpacticoid copepod (d) *Novocrinia trifida* from Belize (after Huys and Iliffe, 1998; length 505 μ m); **d.** thaumatocyprid ostracod (1) *Danielopolina wilkensi* from the Canary Islands (after Kornicker and Iliffe, 1995; length 0.41 mm).

Class Copepoda

(See also Crustacea: Copepoda.) Copepods are a large and diverse group of crustaceans, and are the dominant forms of marine plankton. Presently, more than 14000 species are placed in approximately 2300 genera in 210 families, yet the majority of subterranean species are placed in the following six orders: Platycopioida and Misophrioida (occur in anchialine habitats), Gelyelloida (found in caves in France and Switzerland), Calanoida, Cyclopoida, and Harpacticoida. Stygobitic species originated from surface, marine, and freshwater ancestors and reached different groundwater habitats mostly through interstitial and crevicular or karst routes.

Calanoid copepods are mainly planktonic filter-feeders, represented by some 2300 species, yet fewer than 20 are known from subterranean waters in a wide distribution ranging from the Americas to Madagascar and southeastern China. The cyclopoids (Figure 1b) are a poorly studied group, with approximately 150 species recognized from various caves, wells, anchialine habitats, and groundwater interstices. These characteristically blind crustaceans lack pigments and are known from North and South America, Asia, Africa, Europe, and Madagascar. The harpacticoids (Figure 1c) are represented by nearly 3000 species assigned to 40 families, at least 10 of which have stygobiont species. They are widely distributed in caves and various interstitial habitats, as well as in anchialine habitats. These vermiform crustaceans can be observed scraping food from various substrates rather than filtering water.

Class Ostracoda

(See also Crustacea: Ostracoda.) These bivalve crustaceans are fairly successful, being known from virtually all aquatic habitats, but mostly from the marine environment. Some 5700 benthic and planktonic species are recognized and more than 300 are endemic to subterranean waters, many assigned to the Order Podocopida. Although some species are known only from caves (e.g. *Candona jeanneli* in Marengo Cave, Indiana), most subterranean forms have been observed in springs, interstitial waters, and anchialine habitats (Figure 1d). Stygobites are reported from Afghanistan, Africa, Bahamas, Bermuda, Canary Islands, Central and Southern Europe, India, Jamaica, Japan, Java and West ern Malaysia, Mexico, North, Central, and South America, and South Korea.

Class Malacostraca

Clearly this is the largest class of crustaceans, with approximately 23000 species placed in six superorders, four of which contain hypogean species. The Superorder Syncarida (see Crustacea: Syncarida) is a poorly studied, freshwater group that is divided into three orders, all of which share the absence of a carapace or cephalic shield. The Order Anaspidacea (Figure 2a) is known only from Australia, including the island of Tasmania, and occupies a variety of aquatic habitats, including springs and caves, with one family (Psammaspididae) that is exclusively stygobitic. The Order Stygocaridacea (Figure 2b) occupies interstitial waters in epigean and hypogean environments in New Zealand and South America. Fewer than 10 species are assigned to four genera. The Order Bathynellacea (Figure 2c) has the greatest species richness of the three orders, with approximately 150 species recognized from interstitial epigean, well, and cave habitats. This ancient, relict group is known from Africa, Asia, Australia, Europe, Japan, Madagascar, New Zealand, and North and South America.

The Superorder Pancarida is represented by the Order Thermosbaenacea (Figure 2d). These are small (4 mm or less), eyeless (or with greatly reduced eyes), stygobites that evolved from shallow-marine ancestors and moved into anchialine habitats, caves, springs, thermal springs, wells, and occupy freshwater and saline environments. The group is widespread (found in Australia, the Bahamas, Cambodia, Costa Rica, Croatia, Cuba, France, Greece, Haiti, Italy, Lanzarote, Mallorca, Mexico, Morocco, Puerto Rico, Sicily, Spain, United States, and the Virgin Islands) and consists of at least 34 species assigned to six genera in two families.

The Superorder Peracarida consists of eight orders, six of which have known subterranean species. Common characters of this group include a carapace that is never fused to all the thoracomeres, although the carapace in isopods and amphipods secondarily has been lost, the first pair of thoracopods (thoracic somites with a pair of appendages) is modified as a pair of maxillipeds, the females have a brood pouch, and the pleopods lack

Crustacea: Figure 2. Line drawings of dorsal (d) and lateral (1) views of representative stygobitic crustaceans:

a. anaspidacean syncarid (1) *Psammaspides williamsi* from Australia (after Hobbs, 2000; length 6.7 mm); **b.** stygocaridacean syncarid (1) *Stygocaris* sp. an appendix interna (a slender appendage of the endopod). The Order Mysidacea is a diverse group of crustaceans with more than 1000 species widely distributed in marine, freshwater, and groundwater habitats. Stygobitic mysids (Figure 3a) occur in anchialine habitats, wells, and blue holes in Africa (Kenya, Zanzibar) the Bahamas, the Balearic Islands, Bermuda, Bosnia/Hercegovina, Canary Islands, Cuba, India, Jamaica, the Lesser Antilles, Mexico, Puerto Rico, southern Italy, and the Turks and Caicos islands. At least 28 stygobites, most of which are endemics, are recognized and the distribution of most species suggests that the majority colonized ground waters due to stranding and uplifting of their marine ancestors resulting from the regressions of the Tethys and Mediterranean seas. Other taxa have invaded ground waters more recently and are stygophiles.

The Order Tanaidacea is represented by some 850 marine benthic species. Only three species are characteristic inhabitants of marine caves in Bermuda, Koror Island (Palau), and Niue Island (South Pacific) and it is unclear whether or not any of these species are obligate cavernicoles.

The Order Cosinzeneacea was recently erected to house the stygobitic suborders Spelaeogriphacea and Mictacea. The Suborder Spelaeogriphacea is represented by three monotypic genera: *Spelaeogriphus lepidops* (South Africa—Figure 3b), *Potiicoara brasiliensis* (Brazil), and *Mangkurtu mityuula* (Western Australia). All have a small saddle-like carapace which is fused with the first thoracic somite and, anteriorly, is produced into a broadly triangular rostrum. The thoracopods and pleopods are reduced and the abdomen is elongate, often exceeding half the total body length. The Suborder Mictacea is represented by *Mictocaris halope* (Figure 3c), known from marine caves on Bermuda. This non-predatory crustacean swims, rests, or walks on the substrata of anchialine caves.

The Order Bochusacea was recently erected to accommodate three marine species belonging to the family Hirsutiidae, two of which are deep-water marine forms, while *Thetispelecaris remex* (Figure 3d) is a stygobite, inhabiting anchialine and submarine caves in the Bahamas.

The Order Isopoda (see Crustacea: Isopoda: Oniscidea) has more than 11 000 described terrestrial and aquatic species and is widely distributed across most habitats. These crustaceans lack a carapace, are dorsoventrally compressed, and have pleopods modified for respiration. Eight of eleven suborders have subterranean representatives:

Anthuridea, Asellota, Calabozoidea, Cymothoidea, Microcerberidea, Oniscidea, Phreatoicidea, and Sphaeromatidea. Most anthurideans are marine, but approximately 20 species occur in interstitial sediments of rivers, beaches, wells, anchialine habitats, and caves in the Canary Islands, the Caribbean and Indian Ocean islands, Mexico, and South America. The Asellota (Figure 4a) is a diverse group that is divided into five superfamilies. These isopods inhabit ground

waters of caves, wells, springs, thermal springs, the hyporheos, and anchialine habitats in Africa, the Bahamas, Belize, Bonaire, Cuba, Curacao, Europe, the Galapagos Islands, India, Indonesia, Japan, Madagascar, Malaysia, North and Central America, and Polynesia. The Calabozoidea is monotypic, restricted to a phreatic system in northern Venezuela, and this stygobite is closely related to the Asellota. Subterranean representatives of the cymothoideans are restricted to the mostly marine family Cirolanidae (Figure 4b), of which approximately 50 are stygobites. Microcerberideans are slender, blind, pigmentless stygobites of which about 60 species occur in interstices of marine beaches, wells, and caves near coastal areas of southern Africa, southeastern Asia, the Caribbean, Indian Ocean islands, Japan, and the Mediterranean. Oniscideans (see Crustacea: Isopoda: Oniscidea) are mostly terrestrial, although some stygobitic species (Trichoniscidae) inhabit cave waters. Although some 3500 species are known, only 14 families have subterranean representatives and are global in their distribution. The stygobite Phreatoicidea is the most ancient group of isopods, dating back to the Carboniferous. Prior to the breakup of Gondwana they invaded freshwater habitats, and currently most species are epigean, although some are known from wells and caves in Australia, India, New Zealand, and southern Africa. The sphaeromatideans are mostly marine crustaceans, but approximately 36 are stygobites that are restricted to subterranean waters in Southern Europe.

The Order Amphipoda (see Crustacea: Amphipoda) is characterized as being laterally compressed, lacking a carapace, and being generally an aquatic group consisting of more than 6700 species placed in three suborders: Caprellidea, Gammaridea, and Hyperiidea. Stygobitic amphipods are known only from the large Suborder Gammaridea (>5700 species) and the approximately 750 troglomorphic species are assigned to about 160 genera. Although there are more than 30 families, the Bogidiellidae, Crangonyctidae (Figure 4c), Hadziidae, and Niphargidae demonstrate the greatest biodiversity. They are found virtually in all parts of the globe with appropriate habitats, but Central and Southern Europe, the Mediterranean region, eastern and southern North America, and the Caribbean house the largest taxonomic diversity of stygobitic amphipods.

The Superorder Eucarida (see Crustacea: Decapoda) is characterized by a cephalothorax (carapace fused to all thoracomeres) and represents the most highly evolved group of malacostracans. Three orders are assigned to this superorder but only the Decapoda occupy subterranean environments. Decapods are the largest and most diverse order (nearly 10000 species) and possess three pairs of maxillipeds and five pairs of functional pereiopods (hence the name Decapoda). Although widespread in distribution, the subterranean species are concentrated in Africa, Central and North America, and the Philippines and are divided among seven infraorders: Anomura, Astacidea, Brachyura, Caridea, Palinura, Stenopodidea, and Thalassinidea (the last three are not stygobites). The Anomura include crabs such as the marine hermit, porcelain, mole, and sand crabs, yet subterranean species are mostly known from two families: Aeglidae (Aegla cavernicola-Brazil) and Galatheidae (Munidopsis polymorpha-Lanzarote). Assigned to the Infraorder Astacidea are approximately 900 species of crayfishes and chelate lobsters. Only crayfishes have invaded subterranean waters, with 39 stygobitic species assigned to four genera (Cambarus, Orconectes, Procambarus, and Troglocambarus) in North America and Cuba. Brachyurans ("true crabs") are dorsoventrally compressed crustaceans, with about 4500 known species, of which only approximately 96 dwell in hypogean waters. They are widely distributed primarily in subtropical and tropical latitudes. The global Infraorder Caridea (shrimps) is quite diverse, with nearly 2000 species, yet only about 137 species dwell in springs, wells, caves, blue holes, cenotes, and anchialine habitats. They are concentrated in tropical latitudes but are known from Africa, Ascension Island, the Caribbean and western Atlantic islands, Georgia, India, the Indian Ocean islands, Indonesia, Japan, Madagascar, Melanesia, Mexico, Micronesia, the Middle East, Southern Europe, the United States, and Western Australia. A single stygophilic palinuran is known from a sea cave in New Zealand; the stenopodideans are represented by a stenoxene from a lava tube on Lanzarote, and the thalassinidean is known from a cave on Acklins Island, Bahamas.

CRUSTACEA: AMPHIPODA

Amphipods belong to the arthropod subphylum Crustacea and the order Amphipoda. They typically range in size from 2 to 50 mm, although a few are larger. Amphipods are common in aquatic ecosystems throughout many parts of the world, where they inhabit marine, brackish, and freshwater environments. A few species also live in terrestrial ecosystems. The order Amphipoda, which contains approximately 7000 described species, is divided into three and sometimes four suborders: Gammaridea, Caprellidea, Hyperiidea, and Ingolfiellidea. However, the latter may be highly specialized gammarideans that do not merit recognition as a suborder. Gammaridea, with more than 5500 described species, is the largest amphipod suborder and contains all of the freshwater and subterranean taxa. Approximately 21 superfamily groups, 95 families (or family groups) and more than 1000 genera are classified in this suborder (Holsinger, 1994).

Amphipods are important components of aquatic subterranean faunas in many parts of the world and are among the most abundant, widespread, and taxonomically diverse organisms found in subterranean groundwater ecosystems (Holsinger, 1993). The vast majority of subterranean amphipods are stygobites, which by definition are species restricted to subterranean groundwater habitats and characterized morphologically by loss or severe reduction of eyes and pigment, often accompanied by attenuation of the body and/or some appendages. Although body shape is variable among stygobitic amphipods (see Holsinger, 1994 for examples), many species generally resemble the species of *Stygobromus* shown in the Figure. Not all amphipods found in subterranean water are stygobites. Some species occur simultaneously in epigean (surface) and hypogean waters and do not exhibit the advanced level of morphological modification or troglomorphy that is typical of most stygobites. A few rare subterranean species in the family Talitridae are not strictly aquatic but are otherwise restricted to damp cave passages with high humidity.

Taxonomic diversity is significant at the family, genus, and species levels, and species richness is especially remarkable in several large subterranean genera, such as *Niphargus* and *Stygobromus*. Both of these genera contain over 100 described stygobitic species. On a global scale approximately 35 families (or family groups) and 166 genera of amphipods contain stygobites, and many of these genera and even some of the families are known only from stygobites. However, the vast majority of described stygobitic species (approximately 821 out of 866) are classified in 12 families and one unnamed family group. Four families with more than 100 described stygobitic species include Bogidiellidae (widespread), Crangonyctidae (northern hemisphere), Hadziidae (strongly circumtropical), and Niphargidae (Europe and Asia Minor).

The majority of subterranean amphipods live in freshwater, but some are found in brackish and even fully marine water. Subterranean amphipods, like other crustaceans that live in hypogean environments (e.g., thermosbaenaceans, isopods, and shrimps), occur in a relatively wide variety of groundwater habitats. Primary examples of these habitats include drip pools, streams, and occasionally phreatic lakes in caves; anchialine water in caves and crevices near coastal areas that is in contact with the nearby ocean through subterranean connections; phreatic aquifers accessed through wells and groundwater pumps; surface springs and seeps; and interstitial habitats in hyporheic zones beneath surface streams and elsewhere in coarse sediments saturated with groundwater. Probably the most important food source for subterranean amphipods are various forms of decomposing organic material and their associated microorganisms that

Crustacea: Amphipoda: *Stygobromus gracilipes*, a stygobitic amphipod (approximately 10 mm in length) from a stream in Endless Caverns, Virginia. (Photo by Lynda Richardson)

enter hypogean groundwaters from the surface. Much of this material is carried into subterranean channels primarily by filtration through cracks, crevices, sinkholes, and stream bottoms, and by running water that flows directly underground in sinking streams.

Subterranean amphipods are interesting biogeographically because of their taxonomic diversity, limited dispersal ability, and significant geographic isolation and restriction to groundwater aquifers. Isolation and restriction to groundwater aquifers has, in turn, apparently contributed significantly to the evolution of a large number of locally endemic species, which are common in large genera such as *Bogidiella, Niphargus, Pseudoniphargus,* and *Stygobromus.* Moreover, many taxa probably represent old phylogenetic lineages that have persisted in well-buffered groundwater habitats for long periods of time and are genuine relicts, both phylogenetic and distributional. However, not all stygobitic amphipods are old relicts. Some are apparently morphologically closely

similar to epigean forms, suggesting a rather recent invasion and colonization of subterranean waters by the ancestors of these species.

It is commonly believed that stygobitic amphipods evolved from epigean ancestors, which had developed some degree of pre-adaptation for a hypogean lifestyle prior to invasion of subterranean waters. Putative ancestors of stygobites presumably gained access to and colonized hypogean groundwaters from both freshwater and marine environments. For example, the numerous stygobites in the exclusively freshwater family Crangonyctidae are believed to have evolved from putative freshwater ancestors that invaded groundwater from surface habitats. In contrast, stygobites in the Hadziidae complex currently live in brackish-marine waters or in freshwater caves developed in karst areas that were exposed to shallow marine transgressions in the Cretaceous and/or Tertiary. Thus the stygobites in this family complex are a mixture of those believed to be derived from marine ancestors that stranded in freshwater habitats following marine regressions and those derived more directly from marine ancestors that invaded and colonized anchialine habitats in concert with changes in sea level. Observations also suggest that stygobites can evolve from other stygobites through speciation in subterranean waters. Subterranean habitats provide many opportunities for the geographic isolation of local populations, which in turn should enhance speciation and ultimately result in the evolution of new subterranean taxa.

CRUSTACEA: COPEPODA

The Copepoda—small aquatic crustaceans between 0.5 and 5 mm in length—are a large class of Crustacea, with over 12000 species currently known worldwide. Most species are marine. The subclass is divided into ten Orders, four of which live in symbiosis with other organisms or are external parasites; only the larval stages are free-living. Six Orders (Platycopioida, Misophrioida, Calanoida, Harpacticoida, Gelyelloida and Cyclopoida) have free-living adults. The Calanoida and the Cyclopoida are by far the most dominant groups in freshwater and marine zooplankton.

Free-living copepods inhabit a wide variety of habitats, from the deep-sea floor to glacial pools at high altitudes or high latitudes. In subterranean environments, they occupy saturated and unsaturated zones in alluvial plains and karstic areas as well as anchialine caves. In many karstic caves, they are the most abundant inhabitants (Brancelj, 2002).

The name Copepoda is derived from the Greek words *kope* ="oar" and *podos*="foot", referring to their broad oar- or paddle-like swimming legs. The English language uses the adopted Latin name—copepod(s). Others use translations of the Greek name (German: Ruderfusskrebse; Norwegian: Hoppekrebs; Russian: veslonogie rakoobraznye; Slovenian: veslonožci or ceponožci).

The body of free-living specimens is divided into two parts. The anterior part (cephalosoma) includes five somites, bearing antennulae, antennae, mouth appendages, and the first thoracic segment. This is followed by five thoracic segments, each bearing a pair of biramous swimming legs, and a genital segment with reduced legs. The rear part has four limbless abdominal segments, and an anal segment with a pair of appendages called caudal rami. Males differ from females in the structure of the antennulae, swimming legs, and genital segment. They are usually smaller, and some of their appendages are asymmetrical.

The swimming legs on the second to fifth thoracic segments are used for locomotion. In primitive forms, both rami are threesegmented. The adult or the copepodite stage (larva) always possess at least two pairs of swimming legs, and each pair is linked by a flat sclerite (plate), connecting the basal segments.

The Order Gelyelloida (with only two species) is known from karstic waters in France and Switzerland (Rouch & Lescher

Copepoda: (A) Calanoida (*Troglodiaptomus sketi* Petkovski, 1978); (B) Cyclopoida (*Diacyclops slovenicus* Petkovski, 1954); (C) Harpacticoida (*Paramorariopsis anae* Branceli, 1992).

Moutoue, 1977; Moeschler & Rouch, 1988). The Order Platycopoidea (12 species) is known only from the Atlantic Ocean. Two stygobitic genera (*Nanocopia* and *Antrisocopia*) occur in anchialine caves on Bermuda (Fosshagen & Iliffe, 1988). The Order Misophrioida (37 species) is entirely marine, and members occur also in anchialine caves on volcanic islands around the world. Most of the taxa of Misophrioida were discovered since 1980.

Members of the Calanoida, the Cyclopoida, and the Harpacticoida (see Figure) have worldwide distributions, inhabiting marine and freshwater habitats. In fresh water they are represented by about 2600 taxa. About one-quarter of these are subterranean and most of them were discovered in Europe.

The Order Calanoida is predominantly marine, but about 700 taxa are known from fresh water. About 10 taxa inhabit saturated zones in karst. They are known from the Crimea, the Balkan peninsula, France, China, and Mexico. *Speodiaptomus, Spelaeodiaptomus, Stygodiaptomus, and Troglodiaptomus* are exclusively stygobitic genera. Calanoida are an important element of specialized fauna in anchialine caves all

over the world, being particularly common in the Caribbean area (Fosshagen & Iliffe, 1999).

The Order Cyclopoida has 12 families, all marine except one, Cyclopidae. This family is by far the most abundant and successful group of copepods in fresh water. About 180 taxa inhabit different types of groundwater, and the genus *Diacyclops* has the highest number of stygobitic taxa (Stoch, 2001), followed by *Acanthocyclops*. Strictly stygobitic genera are *Speocyclops*, *Graeteriella*, *Allocyclops*, *Austriocyclops*, and *Kieferiella*, and all but *Speocyclops* and *Allocyclops* are restricted to Europe.

The Order Harpacticoida has about 50 families, both freshwater and marine. They are primarily benthic organisms with worm-like bodies. A large number of taxa live associated with other organisms, usually inside their shells. In fresh water there are about 10 families with about 500 taxa living in groundwater. They have been found all over the world, including Australia (Lee & Huys, 1999). The genera with the largest number of stygobitic taxa are *Nitocrella* (about 50), *Elaphoidella* (about 120), and *Parastenocaris* (about 200).

Common adaptations of groundwater Copepoda are lack of pigmentation, reduction or absence of eye apparatus, reduction in the number of segments in the swimming legs and numbers of setae (genera *Speocyclops, Morariopsis, Parastenocaris*) which could also be a neotenic modification (*Speodiaptomus, Troglodiaptomus*). The number of eggs produced is usually smaller in comparison with their epigean relatives, but they are bigger. Body size is smaller and, particularly in Harpacticoida, wormlike, with the genus *Parastenocaris* as the most illustrative example. In predators the maxillipedes can be elongated (Brancelj, 2000).

There is no particular breeding season in groundwater Copepoda. Their lifespan is up to 15–20 times longer than epigean taxa and all developmental stages are prolonged (Rouch, 1968). During copulation, the male attaches an elongate spermatophore to the female, close to her genital opening. Fertilized eggs (one or a few) are carried by the female in two lateral or one central egg sac attached to the genital segment. In some genera, eggs are deposited directly on the substratum. A free-swimming larva (nauplium) is released from the egg and undergoes several moults before being transformed into a copepodite, and then into the adult after additional moults.

The Copepoda are the most common inhabitants of all types of groundwater, and specimens of some taxa, especially in caves, can be collected in large numbers. Nevertheless, the majority of taxa are restricted to small areas of distribution (endemics) (Brancelj, 2001). Some taxa in porous habitats (i.e. the phreatic zone) have very low population densities, and several hundreds or even thousands of litres of water must be filtered to collect one specimen.

Little is known about the feeding behaviour of some groundwater-dwelling groups such as Platycopioidea and Gelyelloida. Others are opportunistic gorgers (e.g. Misophrioida), feed on other animals, or are predominantly filter feeders (e.g. Calanoida). Representatives of the Cyclopoida and the Harpacticoida are omnivorous (feeding on different animal and plant material) or carnivorous. In groundwater there is no particular predator of the Copepoda, only Amphipoda (genus *Niphargus*) can occasionally prey on them.

CRUSTACEA: DECAPODA (SHRIMPS, CRAYFISH, CRABS)

The malacostracans are the largest class of crustaceans, having approximately 23000 species that are assigned to six superorders, four of which have species that live in subterranean environments. The Superorder Eucarida is one of these, and represents the most highly evolved group of malacostracans. Although three orders are assigned to the Eucarida, only the Decapoda are found in caves and other hypogean (below-surface) settings. Decapods are the largest and most diverse order of the Eucarida, with nearly 10000 marine, freshwater, and semiterrestrial species, and are characterized by the possession of a well-developed carapace enclosing a branchial (gill) chamber, three pairs of maxillipeds (mouthparts), and five pairs of functional pereiopods (=10 "legs", thus the derivation of "Decapoda"). These crustaceans are significant components of hypogean, primarily aquatic communities in temperate and tropical regions of the world dominated mostly by volcanic or karst terrains.

For most cavernicolous decapods, very little is known about their behaviour, ecology, evolution, and life history—clearly it is commonly difficult to assign a species accurately to one of the three categories of stygobite, stygophile, or stygoxene.

The order Decapoda is divided into two suborders: the Dendrobranchiata and the Pleocyemata. The Dendrobranchiata (about 450 species, most of which are penaeid and seregestid shrimps) is represented by a single stygoxenic penaeid shrimp found in an East African cave. All remaining decapods, including several types of shrimps, crabs, crayfishes, and lobsters, are assigned to the Pleocyemata. This suborder is represented in subterranean habitats by approximately 307 described species (numerous others remain undescribed) with 168 (54%) classified as stygobites that show varying degrees of troglomorphic adaptations (convergent behavioural, morphological, and physiological characteristics of obligate cavernicoles). Clearly the focus of this article is on the Pleocyemata, and the distinction between this suborder and the Dendrobranchiata is based primarily on gill structure.

Pleocyemate decapods are geographically widespread, and the obligate subterranean species are placed into one of four infraorders: Anomura, Astacidea, Brachyura, and Caridea. Additionally, the stygophilic *Jasus edwardsii* (Infraorder Palinura—the marine spiny and slipper lobsters) is known from an intertidal sea cave in southeastern New Zealand. A sixth infraorder, Stenopodidea, is represented by the stygoxenic *Stenopus spinosus* (restricted to a lava tube on Lanzarote, Canary Islands), as well as by *Odontozona addaia*, described from a marine cave on the island of Minorca, Spain. A seventh infraorder (Thalassinidea—

Crustacea: Decapoda: Figure 1. Line drawings of dorsal (d) and lateral (1) views of representative stygobiont decapod crustaceans: a. aeglid anomuran (d), Aegla cavernicola, from Brazil (modified from Hobbs et al., 1977; carapace length 15.0 mm); **b.** galatheid anomuran (d), Munidopsis polymorpha, from the Canary Islands (after Hobbs III, 2000); c. cambarid astacidean (1), (1), Troglocambarus *maclanei*, from Florida, USA (after Hobbs & Franz, 1986; postorbital carapace length 13.0 mm); d. pseudothelphusid brachyuran (d), Typholpseudothelphusa acanthochela, from Belize (after Hobbs III, 2000; carapace width 37.5 mm); e. atvidid caridean shrimp (1), Typhlatya pearsei, from Mexico (after Hobbs et al., 1977; postorbital carapace length 5.2 mm).

Naushonia manningi, a probable stygophile) is known from an anchialine cave on Acklins Island, the Bahamas.

The Anomura are globally distributed, with approximately 1600 species recognized, yet only two species from two families have been described from subterranean waters. *Aegla cavernicola* (Aeglidae) (Figure 1a) is known from a stream in a single cave in São Paulo, Brazil, and little is known of the life history and ecology of this anomuran. *Munidopsis polymorpha* (Galatheidae) (Figure 1b) is found in a lava tube and wells (marine groundwater) on Lazarote, Canary Islands, and its life history, feeding, reproductive, and agonistic behaviours are well studied.

The Astacidea (including crayfish and chelate lobsters) is a diverse group of crustaceans (more than 500 species and subspecies of crayfishes are recognized) distributed over much of the globe (all continents except Africa). Only a single family (Cambaridae) is known to include obligate cave-dwelling species, yet numerous epigean species often invade subterranean waters worldwide (e.g. Astacidae, Cambaridae, Parastacidae). The following genera are represented by 39 stygobitic species (about 24% of stygobitic decapods) and subspecies restricted to North America (Florida Lime Sink, Appalachians, Interior Low Plateau, and the Ozarks), Mexico, and Cuba: *Cambarus* (11 species), *Orconectes* (eight species and subspecies) *Procambarus* (19 species and subspecies), and *Troglocambarus* (one species—Figure 1c). Most display reduced eyes and body pigments, attenuated appendages, low metabolic rates and reproductive potentials, and have long life histories. They are omnivorous opportunists, and basically consume anything organic—living or dead.

The Infraorder Brachyura (true crabs) is characterized by a cephalothorax that is flattened dorsoventrally and usually expanded laterally, a symmetrical but reduced abdomen that is flexed beneath the thorax, and uropods are rarely present. Most of the 7000 or so species are marine, but freshwater and tropical terrestrial species occur in epigean and hypogean environments. The following families have subterranean representatives located primarily in tropical settings: Gecarcinidae, Gecarcinucidae, Goneplacidae, Grapsidae, Hydrothelphusidae, Hymenosomatidae, Parathelphusidae, Potamidae, Potamonautidae, Pseudothelphusidae, Sundathelphusidae, Trichodactylidae, and Xanthidae. At least 31 species assigned to nine families are considered to be stygobites (the greatest number of species, nine, within Pseudothelphusidae—Figure 1d), whereas approximately 65 species in 11 families are either stygophiles or stygoxenes dwelling in caves, anchialine, and other subterranean habitats, and demonstrate a generally tropical, circumglobal distribution pattern.

The infraorder Caridea includes nearly 2000 species of caridean shrimps, which are characterized by variably enlarged chelate first or second pairs of pereiopods (except for the genus *Procaris*, which lacks chelation of any pereiopod) and a distinctly enlarged second pleuron overlapping the first and second pleura. The following families are diverse and have subterranean species: Agostocarididae, Alpheidae, Atyidae, Hippolytidae, Palaemonidae, Procarididae, and Rhynchocinetidae. Approximately 95 shrimps assigned to 40 genera and six families are classified as stygobites (approximately 56% of all stygobitic decapods), whereas 42 species in 16 genera and five families are either trogloxenes (terrestrial cave-dwellers unable to complete their life history in subterranean environments), stygoxenes, or stygophiles inhabiting a variety of hypogean habitats. Clearly the Atyidae (Figure 1e) are the most diverse, with at least 47 described stygobitic species, followed by the Palaemonidae with 25 stygobites.

The Red List of Threatened Animals (Baillie & Groombridge, 1996) listed 5205 animal species as threatened with extinction globally. This large number indicates that a significant proportion of the world's fauna is in trouble, and this includes stygobitic species of crayfishes (27) and shrimps (10).

CRUSTACEA: ISOPODA (AQUATIC)

While land-based isopod crustaceans all belong to the Suborder Oniscidea, about 6000 species of isopods are found in aquatic habitats, mostly marine. Some 630 species inhabit fresh or brackish groundwaters: these are stygobites.

Stygobitic isopods occur in most of the subterranean biotopes: karsts, anchihaline caves, littoral marine sands, and alluvium of plains and rivers. Most large species of Sphaeromatidae, Asellidae, Stenasellidae, and Cirolanidae live in karst, while smaller species populate sediment interstitial water (see Interstitial Habitats: Aquatic): e.g. stygobite and phreatobite species of *Proasellus* (Figure 1). They have a wide ecological plasticity. Microisopods are strictly interstitial forms.

Isopods are crustacean Malacostraca without a carapace, with a dorsoventrally flattened body which comprises the head; an eight segment thorax, the first one being

fused to the head (the remaining segments form the pereion); and an abdomen (or pleon) of six segments (or pleonites). One to five of the pleonites may be fused to the telson (the terminal part of the body) forming together the pleotelson. Antennae and mouthparts, pereiopods, pleopods, and uropods are appendages of the different body parts. Antennae are uniramous (single-branched). The first thoracopods are modified as maxillipeds. The uniramous pereiopods are ambulatory limbs; most pleopods serve a respiratory function, the second one is specialized for copulation in the male. Eggs are brooded in the marsupium formed by brood plates called oostegites.

Several groups exhibit five free pleonites: the Phreatoicidea, which have existed since the Carboniferous, possess a laterally compressed pleon and ambulatory uropods. *Phreatoicus* is one of the seven stygobitic genera. The Cirolanidae with 21 groundwater genera and 70 species (Botosaneanu, 2001) exhibit a convex and oval body with pleonites fused in varying degrees, and a tailfan (i.e. flat uropods acting with the telson for swimming). Volvation (ability to roll into a ball) may appear. The genus *Typhlocirolana* is highly diversified. The pleonites of the 40 stygobitic Sphaeromatidae are fused medially, the bulky body displays tubercles, or lateral spine-like protuberances in *Monolistra*. The Anthuridea (2.3–20 mm) have a cylindrical body ending as a flower bud, and the pleonites are free or fused (Figure 2).

Crustacea: Isopoda (Aquatic): Figure 1. Large and wide karstic isopods: A. *Proasellus vandeli* Magniez et Henry, 1969 (Asellidae), 4 mm, from southwestern France; Tiny interstitial species: B. *Proasellus albigensis* (Magniez, 1965) (Asellidae), 5 mm, central France; C. Microcerberus haouzensis Coineau, Albuquerque, Boulanouar & Boutin, 1999 (Microcerberidae), 1.8 mm, from Morocco; **D.** Stenasellus chapmani Magniez, 1982 (Stenasellidae), 7.6 mm, from Sarawak. **E.** Metastenasellus leysi Magniez, 1986 (Stenasellidae), 3.3 mm, from southern Algeria; F. Microcharon angelieri Coineau, 1963 (Microparasellidae), 1.1 mm, from southern France and northern Spain.

Crustacea: Isopoda (Aquatic) Figure 2. Large-sized groundwater isopods. **A.** *Crenoicus harrisoni* Nicholls, 1944 (Phreatoicidae), 12.7 mm, adult male

from New South Wales, Australia. **B.** *Typhlocirolana haouzensis* Boutin, Boulanouar, Messouli et Coineau, 2001 (Cirolanidae), 11 mm, from Morocco. **C.** *Monolistra (Microlistra) spinosissima* Racovitza, 1929, 11 mm, female, from karsts of Slovenia. **D.** *Caecosphaeroma burgundum* Dollfus, 1898, 17 mm, male, from northeastern French karsts. After Wilson & Ho, 1996 (A), Boutin *et al.*, 2001 modified (B), Coineau *et al.*, 1994 (C, D).

The Asellota, characterized by one or two free pleonites and the styliform uropods, include the largest stygobite families. The Asellidae (260 species) have two free short and narrow pleonites. The eyes are more or less reduced. *Proasellus* with 118 taxa is the largest genus. The Stenasellidae (3.5–25 mm) display two wide pleonites, and an antenna exopod. The *Stenasellus* genus contains about 30 species. The tiny Microcerberidae (0.6–2.5 mm) show two long pleonites. *Coxicerberus* (50 species) and *Microcerberus* are the most diversified genera. The dwarf Microparasellidae (0.6–2 mm) have one free pleonite. *Microcharon* (85 species) displays long uropods (Figure 1) (Coineau *et al.*, 1994).

Most freshwater stygobitic isopods are derived from marine surface ancestors. The "two step model of colonization and evolution" provides one model of the establishment of marine surface ancestors in groundwaters (Coineau & Boutin, 1992). After active colonization of the littoral sands of the Tethys Ocean (first step), the ancestors passively settled into fresh interstitial groundwater due to marine regressions (second step). The distribution and origin of interstitial Cirolanidae, Anthuridae, Microparasellidae, and Microcerberidae result from such a model. The arrival of some species of Microcharon, Microcerberus, and Typhlocirolana ancestors in the groundwaters of Morocco is thought to be due to the regression of the Tethys at the end of the Turonian (Upper Cretaceous). Species from littoral karsts may also result from marine regressions: the Sphaeromatidae may have later actively colonized continental karsts. The oculated (furnished with eyes) marine ancestors of the Asellidae entered surface freshwaters (first step), and stygobites evolved from these epigean populations (second step). After the establishment of their marine ancestors in littoral karsts or interstitial habitats of the continental shields in Spain, the widespread Stenasellus virei species actively colonized alluvial river channels following Quaternary glaciations. Stenasellids also reached tropical aquifers in the same way (Magniez, 1999a, b).

Plate tectonics has also played a role in the evolution and distribution of ancient genera which occur in both the Old and the New Worlds. Their common ancestors occupied the littoral Tethys (*Microcerberus*, Coineau & Albuquerque, 2001) or freshwaters of continental shields (*Stenasellus*) before the break-up of Pangea and the opening of the Atlantic Ocean. In the same way, the ancestors of the Phreaoticidae were

separated by the breakup of Gondwana (southern part of Pangea) and have evolved separately in India and Australia.

Groundwater isopods inhabit all continents. Many species occur in the Caribbean and the Mediterranean Basin. The Stenasellidae mainly occupy the northern tropical regions, in contrast to the Asellidae which live in a more northern area. Coastal Microcerberidae have a worldwide distribution while freshwater forms are limited to the southern United States, Cuba, Morocco, Central Europe, and South Africa. The Sphaeromatidae are restricted to southern Europe. Most Cirolanidae live in the Caribbean, the Mediterranean, and Africa.

Stygobites walk and sometimes burrow in river alluvium. They are mostly blind, but some asellids (*Proasellus*) are microphthalmic. Karstic species are large and wide, with long appendages (cf. *Stenasellus chapmani, Proasellus vandeli*). In contrast, elongation of the body and small size are adaptive traits to porous habitats (cf. *Metastenasellus leyi, Proasellus albigensis*); the dwarf microcerberids are thread-like with shorter antennae. The smallest interstitial species have a reduced number of pleopods and antenna articles; the microcerberid morphology results from progenesis (heterochrony of development due to precocious sexual maturity resulting in a small adult exhibiting the larval morphology of its ancestors). Microisopods lack an ovary, digestive glands, and optic lobes.

A K-reproductive strategy characterizes groundwater isopods as an adaptation to low energy budget, in contrast to surface relatives. Such evolution towards energy economy involves a reduced number of large eggs with abundant yolk: *Stenasellus* lays 15–60 eggs, *Proasellus walteri* 6–10, *Microcharon* two, and *Angeliera* only one. Egg-laying occurs only twice a year in microisopods, once every two years in stenasellids. Lifespan is elongated with longer development, slower growth, and increased longevity ranging from two years in microparasellids to 15–20 years in stenasellids. Gametes, eggs, and juveniles are protected; *Typhlocirolana* and *Turcolana* are viviparous and there are relatively few breeding females. Reproduction occurs throughout the year without a discernible specific breeding season.

Stygobitic isopods are non-selective deposit feeders, ingesting bacteria, fungi, particulate organic deposits, and microdetritus. Furthermore, anthurids, cirolanids, and stenasellids may be carnivorous and prey upon copepods, oligochaetes, chironomids, or even congeners (smaller individuals of the same species). Small species may be prey for predators such as other large isopods, decapods, and fish that ingest sediments.

CRUSTACEA: ISOPODA: ONISCIDEA (WOODLICE)

The Oniscidea (formerly called Oniscoidea) or terrestrial isopods represent a monophyletic suborder of the Order Isopoda (Crustacea, Malacostraca, Peracarida). They are the only group of crustaceans fully adapted to live on land. With about 4000 described species in 33 families, the Oniscidea represent the largest isopod suborder. Their common names are woodlice, slaters, sawbugs, and pillbugs. They occur in all terrestrial habitats, from littoral to high mountains, and from forests to deserts.

The Oniscidea have a dorso-ventrally flattened body, a cephalothorax with sessile compound eyes and uniramous antennulae and antennae, pereon (thorax) of seven segments, pleon (abdomen) of five segments, and a pleotelson. There are seven pairs of uniramous pereopods (legs), all more or less alike (hence "isopod"), and five pairs of biramous pleopods. Eggs and embryos are carried by the female in a ventral marsupium. The Oniscidea are characterized by (1) extreme reduction (1 to 3 articles) of the antennules; (2) endopods of pleopod 1 and/or 2 in males being elongated, and specialized as a copulatory apparatus; and (3) presence of a complex water-conducting system (Hoese, 1982a). In species best adapted to terrestrial life (e.g. Porcellionidae,

Armadillidiidae, and Armadillidae families) the exopods of pleopods 1–2, 1–3, or 1–5 bear respiratory structures, called pseudotracheae or lungs (Hoese, 1982b). Terrestrial isopods possess general body morphologies correlated to their ecological strategies and behaviour, and can be grouped in four main categories (Schmalfuss, 1984): the "runners", with an elongated, slightly convex body and long pereopods; the "clingers", with a flat broad body and short strong pereopods; the "creepers", with small, convex, and elongated body, dorsum with longitudinal ribs, and slow movements; and the "rollers" (or conglobaters), with a highly convex body able to roll up into a ball.

The majority of terrestrial isopods need a high degree of air humidity for survival, due to their limited ability to preserve water. Hence, it is not surprising that a large number of Oniscidea have adapted to live in subterranean habitats in general, and in caves in particular. About 300 troglobitic species are known but many others are troglophilic or are occasionally found in caves. Many species also live in other endogean habitats such as the MSS (Mesovoid Shallow Substratum) and the nests of ants and termites. It is difficult to define a clear ecological boundary between the different subterranean environments, and many species are often found in caves as well as in the MSS. Troglobitic terrestrial isopods have been recorded from 16 families: Ligiidae, Mesoniscidae, Trichoniscidae, Styloniscidae, Olibrinidae, Scyphacidae, Philosciidae, Spelaeoniscidae, Porcellionidae, Trachelipodidae, Platyarthridae, Cylisticidae, Armadillidiidae, Scleropactidae, Eubelidae, and Armadillidae. The family with the largest number of troglobitic forms is the Trichoniscidae, ac

Crustacea: Isopoda: Oniscidea: Figure 1. *Haloniscus anophthalmus* Taiti & Humphreys, 2001 from groundwater calcretes in Western Australia.

counting for around 70% of all the cavernicolous terrestrial isopods with more than 50 genera in the northern hemisphere. Among the most interesting troglobitic species in this family are some forms which live in fresh water in caves. For example *Typhlotricholigioides aquaticus*, from the Cueva de Ojo de Aqua Grande, Vera Cruz, Mexico; *Mexiconiscus laevis* from some caves in San Luis Potosí Province, Mexico; and *Cantabroniscus primitivus* from several caves in Santander and Burgos Provinces, Spain. According to Vandel (1965) the systematic affinities between *Typhlotricholigioides* and

Cantabroniscus prove their very ancient origin which can be dated back to the Carboniferous, before the fragmentation of Laurasia. It is not clear if aquatic life is a primitive condition for these species, as stated by Vandel, or if they have secondarily returned to water. The latter condition is most probably true for other Oniscidea occurring in subterranean waters, such as Thailandoniscus annae (Styloniscidae) from a cave in Thailand, and four species of Haloniscus (presently placed in Scyphacidae) from anchialine waters in a New Caledonian cave (H. anophthalmus) and from groundwater calcretes in Western Australia (H. tomentosus, H. longiantennatus, Figure 1, and H. stilifer, all described by Taiti & Humphreys, 2001). The Styloniscidae in the southern hemisphere and the Philosciidae in the intertropical belt also include many troglobitic species (about 5% of the global total each). The family Cylisticidae includes both troglobites (e.g. Troglocylisticus cyrnensis from Brando Cave, Corsica, Figure 2) and endogean forms (e.g. Lepinisticus vignai from Monti Lepini, central Italy, and most species of the nasutus group of the genus Cylisticus). All the other families contribute only a very small percentage (in general less than 2% each) to the total number of troglobitic Oniscidea, with a few represented

Crustacea: Isopoda: Oniscidea: Figure 2. *Troglocylisticus cyrnensis* Ferrara & Taiti, 1983 from Brando Cave, Corsica, France.

by single species, e.g. the Trachelipodidae with only *Trachelipus troglobius* from Movile Cave, Romania.

The adaptive traits to cavernicolous life present in oniscidean forms are typical of most troglobitic arthropods: reduction or absence of eyes and body pigment; development of long appendages, especially antennae and pereopods; and reduced metabolism and fertility with a small number of eggs in comparison with closely related epigean species. All ecological categories listed by Schmalfuss (1984) can be found in subterranean

habitats, with a prevalence of "runners" in caves (e.g. Trichoniscidae of the subfamily Trichoniscinae, Styloniscidae, and Philosciidae) and "creepers" in the MSS (Trichoniscidae of the subfamily Haplophthalminae). Conglobating species are also common cave dwellers (e.g. Trichoniscidae of the subfamily Buddelundiellinae, Cylisticidae, Armadillidiidae, Scleropactidae, and Armadillidae). In some cases a few species belonging to conglobating families with a very convex body have secondarily developed a slightly convex body, most probably to penetrate narrow crevices, e.g. *Cylisticus (Platycylisticus) dobati* from a cave in Turkey, and *Armadillidium aelleni* from a cave on Malta.

In general, terrestrial isopods are considered to be very good biogeographic indicators due to their weak dispersal capacity. The troglobitic forms in particular, which at least in temperate regions include relict forms of ancient faunas, are very important from a biogeographical perspective. The areas of the world with the highest number of troglobitic Oniscidea are the southern United States and Mexico, southern Europe and the Mediterranean, and southwest Asia to the Caucasus. Most of these zones border the maximum extent of Quaternary glaciations, and the climatic changes occurring in the late Tertiary and in the Quaternary seem to have played a fundamental role in the adaptation of terrestrial isopods to cave life. Until recently only a small number of troglobitic terrestrial isopods were known from the tropics, which were considered to be particularly unfavourable for speciation in caves due to the limited climatic changes in the past. In recent years new investigations have been carried out and it has become clear that a rich oniscidean fauna is present in some tropical caves, for example in the lava tubes of the Hawaiian islands where four troglobitic species of Hawaiioscia and one of Littorophiloscia (Philosciidae) have been discovered (Taiti & Howarth, 1997; Rivera et al., 2002).

CRUSTACEA: OSTRACODA

Musselshrimps, or Ostracoda, are small, bivalved Crustacea with over 300 subterranean representatives, mainly from interstitial habitats. Their calcified carapace has an average length of c. 1 mm and completely envelops the body, which is largely nonsegmented and has a reduced number of appendages compared to most other crustaceans. Ostracoda are divided into two subclasses, the Myodocopa and the Podocopa (Horne et al., 2002). The myodocopans are exclusively marine and, since most of them have weakly calcified valves, are poorly represented in the fossil record. The podocopans are divided into three Orders: the exclusively marine Platycopida, the ubiquitous Podocopida (to date the most diverse group of Ostracoda, found in marine, brackish, and fresh waters), and the Paleocopida (diverse and widespread in the Paleozoic, but now represented only by the extremely rare marine superfamily Puncioidea). The Podocopida originated in the Ordovician (c. 450 million years ago) and of the five extant suborders, three have representatives in freshwater environments, while the Bairdioidea and the Sigillioidea are entirely marine. Cypridocopina are by far the most diverse podocopidans; they comprise more than 80% of specific diversities on most continents (Martens, 1998). Most cypridid lineages are non-marine, but some are genuinely marine. Cytherocopina are mostly marine, but eight separate invasions of non-marine habitats have occurred. Darwinulidae are fully non-marine, but their extant diversity is low.

Ostracoda abound in the benthic and periphytic aquatic animal communities, but also in (semi-) terrestrial and subterranean environments. Ostracods constitute an important fraction of stygobitic fauna, especially in the interstitial domain. Danielopol & Hartmann (1986) listed 310 subterranean ostracod species from both marine and freshwater environments. However, only about 50 of these were reported from karst and caves, the majority being reported from truly interstitial habitats. This is surprising as ostracods have to calcify their valves after each moult (eight times), and hence would be expected to thrive in karst environments which are rich in carbonates. However, high concentrations of carbonates are not necessarily sufficient to create favourable conditions for ostracods, as the overall water chemistry and other factors such as temperature and food availability determine whether conditions are favourable for moulting and calcification of valves. Moreover, these conditions are thought to be genusor speciesspecific. Karst and cave habitats can also be seen as intermediate systems between epigean and interstitial habitats. Various epigean species, not listed by Danielopol & Hartmann (1986), live in association with karstic water bodies. For example, in the dolomitic Molopo Oog area (South Africa), several tens of ostracod species from various

genera generally considered to be epigean live in doline lakes, upwelling zones in lakes, or in their outflows. Finally, compared to epigean habitats, the interstitial zones of rivers, caves, and karst are relatively poorly studied.

Numerous podocopid and myodocopid ostracods are known from anchialine caves. For example, Maddocks & Iliffe (1986) reported 33 podocopid species from 24 Bermudan anchialine caves, one genus and ten species being new to science. Several other podocopid species belonging to the Bairdioidea, Cytheroidea, Candonidae, as well as Platycopida have been found from anchialine caves on the Galapagos Islands and Jamaica (Maddocks & Iliffe, 1993). Myodocopid anchialine ostracods belong to either Thaumatocyprididae or Halocyprididae. Based on phylogenetic studies, Danielopol (1990) and Danielopol, Baltanas & Humphries (2000) argued that the present-day troglobitic representatives of the genus *Danielopolina*, a genus of Thaumatocyprididae, originated from shallow benthic thaumatocypridinids that lived on the shelf of the Tethys Sea, rather than from deep-water species, as had previously been postulated.

All major freshwater podocopid lineages (cypridoids, cytheroids, and darwinuloids) have representative lineages in continental caves and karst. Of the Cypridoidea, the Candonidae are most successful in all stygobitic habitats, with representatives of at least ten genera being recorded. Some of these are highly endemic, for example Danielocandona spp. and Caribecandona spp. in wells from the West Indies, and Namibcypris spp. from karstic springs in Namibia (Martens, 1992). In Cyprididae, the smaller Cypridopsinae and, somewhat surprisingly, several relatively large Herpetocypridinae lineages are also able to colonize caves and riverbed sediments. The monospecific genus Somalicypris is thus far known only from Somalian wells, while the dozen or so species of Humphcypris are known from caves and springs throughout eastern and southern Africa, the middle East, and India (Martens, 1997). Several species in the Darwinuloidea appear to have developed a General Purpose Genotype and can survive in an exceptionally wide range of habitats (Van Doninck et al., 2002), including caves and karst. For example, Darwinula protracta described from a cave on Mont Hoyo, Irumu, Zaire, is a synonym of the cosmopolitan and ubiquitous D. stevensoni. Most cavernicolous cytheroids belong to the entocytherid subfamily Sphaeromicolinae. Entocytherid ostracods are presently known to live as commensals (semi-parasites) on various kinds of other crustaceans (crayfish, amphipods, isopods), but species of Sphaeromicola are associated exclusively with subterranean isopods.

Subterranean ostracods show various morphological changes that have been interpreted as adaptations to stygobitic life, for example loss of sight, enlargement of chemosensorial aesthetascs, overall reduction in size, and simplification of limb chaetotaxy (mapping of setae on body segments). However, the signal from cave and karst ostracods is confusing. For example, Danielopol & Marmonier (1994) mentioned that loss of sight is not always compensated by enlargement of aesthetascs. Moreover, subterranean herpetocypridinids are generally around 2 mm long, which is relatively large for ostracods. Entocytherids show more adaptations to their commensal than to their subterranean way of life. This has led to the hypothesis that subterranean invasion, including caves and karstic aquifers, is an active process, by which ostracods can establish populations simply because the conditions are favourable. Subterranean invasion would not always be an adaptive process, and would generally be facilitated by preadaptions or by the existence of exaptations (i.e. structures that developed for other

reasons than that for which they are presently seemingly adapted). An alternative hypothesis, the refugium model, holds that animals were forced to invade subterranean habitats under constraints, because of unfavourable epigean conditions, in which case subterranean faunas would have a relict character. Botosaneanu & Holsinger (1991) defend the latter view, but also propose a pluralistic approach, including both models (see also Colonization entry).

Uncertainty also exists about the age and antiquity of cave and karst faunas. Anchialine caves along the margins of the Tethys Sea are thought to have been colonized by Thaumatocypridinae since the end of the Jurassic (c. 150 million years ago). A marine ancestry related to the Tethys Sea is also proposed for the commensal Sphaeromicolinae; here invasion of fresh groundwaters is postulated to have occurred during the Tertiary (or earlier) and the lineage became isolated there, at least in Europe, by the end of the Miocene (5–6 million years ago). Martens (1992) placed the African genus *Namibcypris* and the West Indian genus *Danielocandona*, both from subterranean habitats, in the same tribe (Namibcypridini). He also suggested that this lineage might have existed before the breakup of Africa and South America (65–70 million years ago), implying that this lineage would have lived underground for that period of time. However, Danielopol *et al.* (1994), following the above-mentioned preadaptation scenario, suggested that both groups invaded groundwaters independently from each other and much more recently.

CRUSTACEA: SYNCARIDA

Syncarida is a Superorder of Malacostraca in which the carapace is absent. Fossil Syncarida have been recorded in former brackish lagoons from the Carboniferous through to the Permian. Contemporary stygobitic taxa inhabit fresh interstitial groundwater, although some species still occur within marine beaches. Stygobitic syncarids have a wide ecological plasticity. They occur in astacid (freshwater decapod crustacean) galleries or coarse sediments (*Micraspides*) and in caves (*Koonunga*); psammaspidids, stygocarids, and bathynellids live in interstitial groundwater habitats—freshwater alluvial sediments associated with rivers and lakes in upland and lowland areas, mainly in the phreatic zone, and sometimes cave sediments.

The Syncarida body is long and almost cylindrical and is composed of the head; a thorax with seven or eight free segments—the first of which may be fused to the head; and the abdomen—composed of five free segments and the pleotelson, or of six segments before the telson. Both antennae are biramous, with a peduncle, a long exopod, and a short endopod with various segment numbers. Other appendages are the mouthparts; seven or eight biramous ambulatory thoracopods, the last pair being transformed into the male copulatory organ and reduced in the female of some groups; the pleopods (uniramous or biramous, reduced or absent, in variable number); and the biramous uropods which form a tail fan with the telson when they are foliated. The size ranges from 0.5 to 50 mm.

There are about 240 species belonging to three Orders, of which 21 species are fossils dating from Carboniferous up to Cretaceous times. The most primitive Order, the Palaeocaridacea, has 14 fossil genera and 19 species with stalked eyes, antennal statocysts (a balance organ), eight thoracic and six abdominal segments, eight ambulatory thoracopods, and six biramous pleopods, the two first being modified in a petasma for copulation. They have no furca (the last appendage of the body). The Anaspidacea Order exhibits seven thoracic segments (the first one being fused to the head), six abdominal segments, and a triangular telson. Eyes may be stalked, sessile, or absent. They possess an antennal statocyst, eight biramous or uniramous ambulatory thoracopods, and two to six pleopods (the male petasma is present). The oculated Anaspididae, with three genera, and Koonungidae, with seven genera (two species of which are Cretaceous and Triassic fossils) are the largest (7–56 mm) and exhibit a tail fan formed by the flat uropods

grouped with the telson. The smaller interstitial Psammaspididae and Stygocarididae (1.4–14 mm), with two and four genera, have no eyes and no tail fan, uropods are biarticulated. The Bathynellacea is the most diverse Order: two families, the Bathynellidae and the Parabathynellidae, contain 61 genera and about 200 small eyeless species (0.4– 3.5 mm). The body is composed of eight thoracic segments, five abdominal segments, and the pleotelson. Thoracopods 1–7 are biramous, the eighth being transformed for copulation in the male and reduced in the female; furcae and uropods complete these stygobites. Numerous genera are monospecific (Serban, 1972; Schminke, 1973; Camacho, 1987; Coineau, 1996).

In contrast to swimming anaspidaceans from surface waters, all stygobitic syncarids walk within sediments using their thoracopods and their furca. They are blind and lack pigment. Their small size is an adaptation to interstitial life (cf. the tiny Stygocarella, Nanobathynella, Leptobathynella), which may be due to progenesis (precocious sexual maturity inducing small adults to retain some larval morphology). The minute Acanthobathynella exhibits the post-embryonal morphology of the less derived Parvulobathynella. All Bathynellacea display a zoea (larval) morphology (Schminke, 1981): they are paedomorphic, retaining some larval traits. The slender small syncarid species have no telson, and a reduced number of pleopods, appendage rami and segments. The thoracopod 7 of Hexabathynella and Hexaiberobathynella is absent. Digestive caeca and an ovary are also absent. Syncarids are K-strategists as an adaptation to the lowenergy budget within subterranean environments. Eggs are spawned one after another; in anaspidaceans gametes are protected in spermatophores and spermateca; bathynellaceans lay only one egg with an abundant yolk in sediments. Syncarids also have a long embryonic development within their egg, hatchlings resemble the adult in structure, and have a slow growth for energy economy. They are relatively long lived, up to 2.5 years in Paraiberobathynella (Coineau, 2000).

Stygobitic syncarids are cold stenotherms. Bathynellids reside in groundwater at temperatures ranging from 8 to 11°C and do not inhabit water temperatures greater than 20°C. *Thermobathynella* occurs in thermal waters at 55°C. Syncarids are non-selective deposit feeders. Some parabathynellids may be carnivorous, preying upon copepods. The largest syncarids may be prey for amphipods or fishes in karstic waters.

Syncarids were already a diverse group in the Paleozoic, especially during the Carboniferous and the lower Permian on the Laurentia supercontinent, and later on Gondwana in the PermoTriassic (Schram, 1981; 1984). The distribution of contemporary anaspidaceans covers only limited Gondwanian areas in Tasmania, Australia, New

Zealand, Chile, and Argentina. The disjunct distribution of numerous bathynellid genera results from a Gondwanian origin. Chilibathynella and Atopobathynella occur in Chile, Australia, and New Zealand; the sister groups Parvulobathynella and Acanthobathynella are distributed in South America and the Ivory Coast; Thermobathynella is known from Amazonia and Central Africa, Cteniobathynella from central African area, Israel, and Brazil, and Austrobathynella from the southern parts of Africa and America. The history of the closely related genera Texanobathynella and Iberobathynella is related to the opening of the northern Atlantic. The *Iberobathynella* group is endemic to the Iberian Peninsula, while *Hexabathynella* exhibits a cosmopolitan distribution from Brazil, California, Iberian Peninsula, Bulgaria, Corsica, to Madagascar, Australia, and New Zealand. On a large scale, the Parabathynellidae display a worldwide distribution from temperate to tropical areas. The Bathynellidae occupy more limited regions of the globe, mainly in the temperate northern hemisphere as well as some local areas of the southern hemisphere. Therefore, plate tectonics has played a major role in the distribution and the evolution of the Syncarida through vicariance. According to Schminke (1981), the Syncarida have a freshwater origin. In contrast, other authors (Boutin &

Crustacea: Syncarida: Figure 2.

Badiynellacean syncarids: **A.** Bathynella (Bathynella)paranatans Serban (0.9 mm, Bathynellidae); **B.** Hexabathynella knoepffleri Coineau (1 mm, Parabathynellidae); **C.** Parvulobathynella riegelorum Noodt (0.6 mm, Parabathynellidae). Coineau, 1987; Camacho & Coineau, 1989; Coineau, 1996; Guil & Camacho, 2001) claim that freshwater Syncarida are derived from marine ancestors. These ancestors lived in the interstitial littoral of the Tethys Sea before the break-up of Pangea and of Gondwana, and colonized subterranean freshwater at the end of regressions mainly in the Jurassic and Cretaceous. Most of the extant species are located in areas formerly covered by Tethys gulfs and co-occur with other interstitial crustaceans of marine origin. Paleogeographic data also strongly indicate a marine origin. Tethys regressions, as well as orogenesis in some regions of the world, provide an understanding of the evolutionary history of the Syncarida.

CUBA

The Cuban archipelago, with an area of 110992 km^2 , is composed of the largest island of Cuba (104 km²), the Isla de la Juventud, and more than 4000 smaller islands and cays in the Caribbean. In terms of geological structure, relief, and climate, Cuba can be divided into two regions: the Bahaman-Cuban plains (most of the island and the archipelago) and the mountains of the Oriente (in the southeast of Cuba).

About 60% of Cuba has carbonate rocks at outcrop or beneath thin soil cover: these are mainly of Mesozoic age and form very diversified karst terrains (Figure 1). The geologic structure of Cuba evolved from an archipelago of volcanic islands, with deposition of geosynclinal sediments. The main carbonate rocks were later folded during the Eocene orogeny. Subsequently the Cuban platform period was broken into tectonic blocks separated by faults and flexures. In the Neogene and Quaternary, shallow marine limestones were deposited on the marginal zones of the blocks, and now support a very distinctive littoral karst. Hydrothermal activity continues at mineral and thermal springs on the north coast (e.g. San Diego de los Baños), and some of the caves in this region are of hydrothermal origin.

The major caves of Cuba are extensive, sub-horizontal, multilevel systems. Sistema Cavernario Palmarito is the longest and most complex, with 48 km of passages on three main levels. It lies in the massif of Pan de Azucar, which has classical marginal poljes as well as cone and tower karst in the southern part of Sierra de los Organos. The highest karst massif is the Macizo de Guamuhaya, just to the north of Trinidad in central Cuba, where alternating calcareous schists and crystalline limestones rise in monoclines to a height of 300–700 m. In this region, near Topes de Collantes, Cueva Cuba Magiar (-390 m) is the deepest cave in Cuba.

During the Pleistocene, eustatic sea-level variations reached nearly 200 m in this part of the Caribbean and were of great importance for the development of karst over the whole Cuban archipelago. The most important consequences were the multiple levels of the cave systems, raised sea terraces with karstic and abrasional features, and intrusions of saline water reaching far into the interior, notably on the west coast of Pinar del Rio province, on the Zapata peninsula, and near Cabo Cruz in Oriente province. There are many cenotes in the coastal plains of the northwestern regions of Havana and Matanzas. In the inland phreatic zone below sea level there are extensive cave levels, draining to numerous submarine springs (mainly along the southern coast of western Cuba). Since karst waters are widely exploited in Cuba, saline water intrusions into the aquifers are among the most significant environmental problems. In the middle of the karst plains there are numerous flooded caves, shafts, and dolines.

Marine terraces along the coasts of Cuba are the site of some interesting karst processes. The terraces range from a few metres to 100m above sea level and are characterized by zones of abrasional and karstic landforms. The lowest terraces are subject to mechanical erosion from waves and dissolution promoted by the mixing of saline water and rainfall, and by large-scale biochemical processes caused by algae and other organisms covering the coastal rocks. Among the landforms of littoral karren there are many bowl-shaped dolines, locally known as "casimbas". The finest littoral karst is in the coastal terraces of the Desembarco del Granma National Park, on the Sierra Maestra near Cabo Cruz, west of Santiago de Cuba. The National Park was established in 1986 (and later became a World Heritage Site) to ensure protection of the largest and the best-preserved system of littoral terraces in the world (from 180 m below sea level to 300 m above sea level) and also to protect the endemic sea fauna of the submarine terraces.

The climate of Cuba has annual dry and wet seasons with high amounts of rainfall. Up to 80% of the precipitation falls in the wet season from May till October, and annual totals are 1000–2000 mm. Mean air temperatures are 23–26°C. In these humid tropical climatic conditions, most of the bare surfaces of carbonate rocks within the Cuban archipelago are covered with corrosional microforms. The most common are fine networks

Cuba: Figure 1. Karst areas of Cuba (modified after Núñez Jiménez, 1984).

Cuba: Figure 2. The classic view across the mogotes of the Viñales valley in the Sierra de los Organos. (Photo by Tony Waltham)

of deep, cylindrical, flat-bottomed pits separated from each other by very sharp edges, locally known as "dientes de perro" (dog teeth).

The Guaniguanico mountain system in western Cuba has the most interesting humid tropical karst. Sierra de los Organos and the massif of Pan de Guajaibon (in the Sierra del Rosario) are some of the most extensive areas of cone and tower karst in the world. In the Sierra de los Organos, the most significant karst rock units are the Upper Jurassic to Lower Cretaceous Viñales massive and bedded limestones with flints and the Paleogene Ancon marly limestones and flysch. The dominant residual karst hills are called mogotes and have both cone and tower profiles (though their height/width ratios are lower than for towers of the Chinese karst). They form massifs within which there are small corrosion poljes (called hoyos). Between the massifs, both karstic and non-karstic, there are large karst-erosion poljes. The most famous polje of this type is the Valle de Viñales, which was listed as a World Heritage Site in 1999 due to its landscape values and traditional agriculture (mainly cultivation of tobacco) which has been unchanged for centuries (Figure 2).

The southeastern part of Sierra de los Organos is in the catchment of the Cuyaguateje River. This area of 840 km^2 is a fine hydrological system of mogote karst, with numerous central and border poljes as well as cave systems utilized by the river and its tributaries. In the massif of Sierra de Quemado there is one of the longest and best-known cave systems in Cuba—the Gran Caverna de Santo Tomás, with 46 km of mapped passages. The

Cuba: Figure 3. Section of Sierra de Quemado and multiple cave levels in the Gran Caverna de Santo Tomás (modified after Núñez Jiménez, 1990, modified).

system has six recognizable relict and modern levels of the underground course of the Santo Tomás stream and its tributaries. It links the border poljes of Valle de Santo Tomás and Valle de Quemado (Figure 3). The cave developed in the dark Upper Jurassic limestones, and the border poljes developed on the contact zone with the Lower Jurassic San Cayetano shales and sandstones. The upper cave levels have abundant calcite speleothems, with many forms that are rare elsewhere. Notable are the many exceptionally large cones, some over a metre high, which are made of calcite rafts that

fell to the floor of cave lakes when a frequent drip destroyed their surface tension support. The cave system is also known for its finds of cultural material left by the prehistoric inhabitants of Cuba, including the engravings in Cueva de Mesa and a human skeleton dated to 3000 years in Cueva de la Incógnita. The upper levels of the cave also have extensive accumulations of Pleistocene animal bones. For its multiple geological, paleontological, prehistorical, and historical values, the Gran Caverna de Santo Tomás was recognized as a national monument of Cuba in 1989.

Several caves in the Pinar del Rio, La Habana, and Matanzas provinces have been developed as tourist sites. These include Cuevas de Bellamar and Cueva Grande de Santa Catalina, both located in raised terraces in Matanzas. Both caves are also important for their speleothems, particularly for very large calcite crystals as well as large cones and mushrooms of fallen cave rafts.

CUPP-COUTUNN CAVE, TURKMENISTAN

Cupp-Coutunn, the longest limestone cave in the former Soviet Union, is located in the Kugitang region of eastern Turkmenistan, close to the borders with Uzbekistan and Afghanistan. The cave is internationally famous for its mineralogy, both in the number of mineral species and in the great variety of its speleothem forms. In 1991, Cupp-Coutunn and its associated caves were placed on the Global Indicative List of Geological Sites (GILGES) by a working group of the World Heritage Convention.

The Cupp-Coutunn cave system (Figure 1; Maltsev & Self, 1992) is located on the southwestern flank of the Kugitangtau ridge, which runs north-south for some 50 km and attains an altitude of 3137 m. Low hills to the north connect the Kugitangtau ridge to the southwestern end of the Tien Shan mountain chain, from which it appears

topographically as an outlier. The Kugitangtau is an anticlinal dome with a granite batholith intruded into its core. A major fault, the Eastern Kugitang Upthrust, along the north—south major axis of the anticline, separates the uplifted Kugitangtau from the Uzbek plain to the east. The Kugitangtau cuesta presents a scarp face over 1 km high, topped with a near-vertical wall of upper Jurassic limestone. The dip slope to the west is a gentle 7° to 15°, deeply dissected by canyons. This dip slope is cut by a second major fault, subparallel and of opposite throw to the Eastern Kugitang Upthrust, leaving the central spine of the ridge as a horst block.

The caves of southern Kugitangtau show a complex history. They developed as an extensive phreatic maze, following the then horizontal bedding in the limestone on several levels, probably in late Cretaceous times. These passages were subsequently abandoned as conduits for groundwater flow and infilled with argillaceous sediments. Neogene uplift and tilting of the strata rejuvenated the caves. Detrital deposits were locally eroded by groundwater introduced via a north-south fault set, though in places the consolidated remains of this ancient filling are retained as the walls or roof of the cave. New passage development was restricted to invasive tubes in the immediate vicinity of these faults. The air-filled passages were then invaded by thermal water entering from another (Chilgas) fault set, with chemical alteration of the cave wall rocks and sediments. Alteration effects include recrystallization of the limestone and replacement of carbonates by other minerals, mostly silicates and sulfides. Small amounts of hydrothermal calcite and fluorite were locally deposited within the cave, the calcite sometimes containing microscopic inclusions of metal sulfides. The thermal fluids do not appear to have been particularly aggressive, as no significant passage enlargement has been noted. Stable isotope analysis of rock and mineral samples suggests that the thermal water was an evolved basinal brine (Bottrell, Crowley & Self, 2001).

During the mid-Quaternary, there was some movement of the Chilgas faults. This caused the displacement of cave passages crossed by these faults, and collapse in some of the larger airfilled passages. The modern phase of development is marked by condensation corrosion of the cave walls and roof, the reworking of material from the thermal phase, and the deposition of speleothems. For the most part, the caves are independent of drainage from the surface, though some canyons have cut their beds deep enough to intersect the caves. However, the Kugitang region is semi-arid and significant quantities of water enter the caves about once per decade, locally introducing alluvium or reworking the older sediments.

The international importance of the Cupp-Coutunn cave system is in its speleothem mineralogy, which has been entirely deposited during the post-thermal phase of the caves' development. Some very rare minerals have been formed by the reworking of material from the thermal phase, whether this material was deposited in the cave itself or as vein minerals in fractures crossing the cave. Particularly interesting are zinc alumino-silicates, which are coloured green by trace quantities of nickel. Sauconite was the first to be identified, and then the very rare fraipontite (with only a few occurrences known worldwide, this is its first report as a cave mineral). Si and Al mobility is due to acidic gases released from a red, clay-like coating (ochre) on hydrothermally altered wall rock. Ochre is a variable but stratified material, with sulfate-reducing bacteria in the lower layers and oxidizing bacteria in the outer layers. It is more like a soil than a classic corrosion residue and various secondary oxide and silicate minerals have been identified

within it (Maltsev, Korshunov & Semikolennykh, 1997). Hydrogen sulfide produced within the ocker is oxidized to sulfuric acid, which in turn attacks crystals of thermal phase fluorite. Gaseous hydrogen fluoride is released into the cave air, the evidence for this being tiny dark purple crystals of fluorite that have been found growing on calcite helicities and on euhedral gypsum crystals (Maltsev & Korshunov, 1998).

Cupp-Coutunn has spectacular displays of speleothems of the more common cave minerals. Where surface water infiltrates from canyon floors or from north—south faults, there are calcite stalactites, stalagmites, and even shields. A particularly beautiful banded flowstone (marble onyx) was commercially mined from 1970 until 1982, with three mine adits cut into the cave to provide easier access. The mining was finally halted following a campaign led by Moscow and Ashkhabad cavers. Aragonite is a main speleothem mineral in some parts of the cave, often in association with calcite. This association produces some of the most photogenic speleothems, such as quill anthodite bushes and multi-corallite splays (Figure 2). Helictites are abundant, sometimes with euhedral crystals of clear gypsum or blue celestite growing on their sides. Gypsum is found in most parts of the cave, as beards, flowers, crusts, chandeliers, and as large hollow stalagmites. Rare speleothem forms include solid crystalline stalagmites of gypsum, aragonite pseudo-stalactites, and macro-crystalline calcite stalactites.

Cupp-Coutunn/Promeszutochnaya (combined length 56 km) is part of a more extensive karst system that is still largely filled with ancient sediments. Nearby, and recognized as part of the Cupp-Coutunn system, is Geophyzicheskaya (length 4.5 km, with spectacular gypsum chandeliers) and Hashm-Oyeek (length 7 km, first reported by Diodorus Siculus c. 40 BC). Dozens of other cave fragments have been found in neighbouring canyons throughout southern Kugitangtau. The area was once very popular with Russian cavers, but there have been few expeditions since Turkmenistan became an independent country.

Vladimir Maltsev's team (Moscow) was pre-eminent in both the exploration and the scientific study of the caves during the late Soviet period. Much of our modern understanding of ontogeny is based on speleothem observations made in these caves.

DAMS AND RESERVOIRS ON KARST

The nature of karst presents a great variety of risks associated with the construction of dams and reservoirs. The most frequent difficulties are caverns at dam sites, land subsidence at the bottom of reservoirs, water leakage at dam sites and from reservoirs, induced seismicity as a consequence of artificial storage, endangerment of endemic fauna, and changing of local groundwater balance. Because each karst region is different individual situations are very seldom, if ever, repeated.

Although the need for artificial water storage in karst has been recognized as important for a long time, dam construction projects were initially very rare and mostly resulted in failure. However, there is a long history of smaller-scale hydraulic works including cleaning the entrance and improving the flow capacity of ponors (in the Dinaric karst area, and in Greece, Turkey, and China), construction of small water storage ponds, and construction of water-driven mills at ponors. Dam construction dates from 1700 years ago (Iran, Sassanian era), but dam building in karst environments commenced only in the 20th century (Hales Bar, Tennessee, 1922; Camarasa, Spain, 1927; Wolf Creek, Kentucky, 1941). In the early 1950s the construction of reservoirs in the Dinaric karst region, former Yugoslavia, posed a special challenge. Notable examples were Bileća reservoir on the Trebišnjica River with a storage capacity of 1.28 billion m³, reservoirs in Niksičko Polje with 220 million m³, and the Buško Blato Reservoir with 800 million m³.

Reservoirs in karst may fail to fill despite an intensive investigation programme and sealing treatment. In most cases the leakage occurs during the first filling. Among the largest-known losses were from Keban (Turkey), leakage 26 m³ s⁻¹; Vrtac (Yugoslavia), 25 m³ s⁻¹; Iliki (Greece), 13 m³ s⁻¹; Camarasa (Spain), 11.2 m³ s⁻¹; Lar (Iran), 10.8 m³ s⁻¹; Marun (Iran), 10 m³ s⁻¹; Mavrovo (FYR Macedonia), 9.5 m³ s⁻¹; Great Falls (United States), 9.5 m³ s⁻¹; and Canelles (Spain), 8 m³ s⁻¹.

Persistent, time-consuming and step-by-step sealing treatment can in some cases resolve the problem and justify invested money. For example, the leakage was considerably reduced from Keban, Camarasa, Great Falls, Canelles, Mavrovo, and Marun. However in other cases the hydrogeological conditions were too complex for the available sealing technology and unacceptable leakage still exists at Vrtac, Lar, and Iliki.

According to the generalized geomorphological and hydrogeological features, dam sites and reservoirs in karst can be divided into three groups: dams and reservoirs in deep and narrow canyons; dams and reservoirs in river valleys; and dams and reservoirs in karst poljes. In the first case fluvial erosion is faster than the karstification process and karst features below the river bottom are rare as the water table is connected with the riverbed or is very close. Such riverbeds have limited leakage although the upper parts of the dam site and reservoir banks can be prone to leakage. A grout curtain in the riverbed and into both abutments is usually necessary but is technically and economically acceptable. In the second case the evolution of the karst aquifer proceeds at a similar speed to, or faster than fluvial erosion. Hence caverns and karst channels may be present at significant depth below the riverbed. The most unfavourable conditions occur in valleys with a hanging riverbed situated at high elevation. In such situations the water table is deep below the valley bottom. Deep and expensive grouting treatment and plugging of caverns are likely to be necessary. However, if the river valley is at base level, i.e. the discharge zone for the adjacent aquifer, the chances for safe water storage are better.

In the third case, karst poljes are hydrogeologically very complex places for dam and reservoir construction. Wide and very large zones of concentrated infiltration (ponors) are located in these depressions, particularly along the foothills, and the base of karstification is very deep. During the dry period the water table is deep below the polje bottom. During the wet period of the year, the water table rises abruptly and a considerable part of the floor is under the influence of a strong upwards recharge. The most common and unpredictable defects found during reservoir impounding and operation are collapses, funnels, and huge open cracks in the reservoir bottom. The treatment of karst poljes generally needs long and step-by-step remedial works, including deep and long grout curtains.

Large caverns at dam sites need a very detailed investigational approach using different methods (geology, geophysics, and speleology) and complicated treatment technology. During the construction of the Keban Dam (Turkey) about 30 caverns were treated. To fill the largest one about 605000 m³ of limestone blocks, gravel, sand, and clay were thrown into the cave. The volume of the second largest cavern at the same dam site was 105000 m³ (110 m below the river bed). At the Lar dam site (Iran) a few large caverns were discovered at depths of 250 m to 430 m below the riverbed. Some 117000 m³ of fill was used, but reservoir losses are still very high (Djalaly, 1988). Cavities filled with soft clay at the Wujiangdu dam site (China; Figure 1) were treated down to a depth of about 250 m beneath the river bed (Zuomei & Pinshou, 1982). A grout curtain was used to isolate caverns on both sides of the Sklope dam site (Bozicević, 1971). At the Salman Farsi Dam (Iran) more than 20 caverns were discovered on both sides, along the grout curtain route, the largest being about 60 m long, 40 m high, and 20 m wide.

To reduce water losses from reservoirs in karst areas two alternative methods are applied. First, the surface can be made impermeable by encompassing large ponors with cylindrical concrete dams; isolating large ponor zones by dykes; closing estavelles by concrete plugs equipped with non-return valves; protecting sinking zones in alluvial overburden by surface compacting; protecting sinking zones in alluvial overburden by PVC foil; blanketing of karstified limestone by shotcrete; and dental treatment (filling of cavities) and various similar structures. Second, the underground medium can be sealed by grouting using different types of cement and cement mortar with additives and

Dams and Reservoirs on Karst: Figure 1. A concrete buttress dam built in the limestone gorge of the Wu River in Chongqing District, China. (Photo by John Gunn)

Dams and Reservoirs on Karst: Figure 2. In the Puleirang doline, in Java's Gunung Sewu Karst, a handbuilt concrete dam stands round the entrance to a shaft series that descends 200 m to the regional water table. Chunam concrete seals the limestone around the doline and its floor is a thick clay. The reservoir was a failure, as it drained out when a sinkhole developed in the clay soon after the first wet-season filling. (Photo by Tony Waltham)

cavern fillings (sand, gravel, chemicals, etc); polyurethane foam grouting; grouting with asphalt; construction of concrete plugs in karst channels; and construction of cut-off (diaphragm) walls. In special cases the "bath-tub" solution was applied, linking the dam site with an upstream aquaclude (e.g. Oymapinar, Turkey; El Cajon, Honduras). In some cases the grout curtains are very long (e.g. Buško Blato 6.77 km; Slano 6.2 km; Mosul (Iraq) 6 km) and deep (up to 300 m at Keban; Mratinje (Yugoslavia) 278 m; Wujiangdu 250 m),

The construction of dams and reservoirs in karst regions results in considerable environmental impacts. Mostly the impacts are positive and predictable (flood reduction, water supply improvement, power production, infrastructure improvement, and reduction of deforestation), but in some cases they are negative and unpredictable. The common negative environmental impacts are: severe changes to spring discharge, deterioration of groundwater quantity and quality, threats to endemic fauna, induced seismicity, and induced occurrence of collapse dolines and some other secondary uncertainties. For example, construction of the Trebišnjica Hydrosystem (Herzegovina) is expected to eliminate recharge through many ponors resulting in a loss of recharge to the East Herzegovina karst aquifers of around 6 billion m³ per annum. The low flow discharge of some springs has been increased but the annual average discharge at the large springs has decreased considerably. For example, the average yearly discharge of Ombla Spring was reduced from 33.8 m³ s⁻¹ in natural conditions to 24.4 m³ s⁻¹ after construction. Submergence of the Trebišnjica spring zone by Bileća reservoir prolonged the duration of floods in the Fatnicko Polje.

Induced seismic shocks, i.e. explosions of trapped "air pillows" in karst channels and siphons are recorded by nearby seismological observations. Subsidence induced by extensive water level fluctuation in man-made reservoirs may provoke considerable damage in the surroundings. For example at the Mavrovo reservoir landslides were triggered and many houses were damaged.

The changes in the underground and surface water regimes, as a consequence of dam and reservoir construction, may have very distinct negative effects on underground fauna. One of the best-known cave-dwelling aquatic endemic species of the Dinaric karst, *Proteus anguinus*, was found in 37 localities in the region of Popovo Polje (Herzegovina). However, urbanization and construction of dams and reservoirs have seriously endangered the survival of this and other endemic species by concreting and plugging riverbeds and ponors, thus blocking connections between karst channels and the surface. There is also the risk of *Proteus* being flushed out to the surface during reservoir operations.

DATING METHODS: ARCHAEOLOGICAL

In approximate order of durability, the buried archaeological materials that survive in caves are stone tools, teeth (including ivory), bone, pollen, metal, and vegetable material. The cave environment itself also determines how well objects survive and thus affects the viability of any direct dating attempt. After burial, stone tools survive for millions of years under most conditions. Bone and teeth survive very well in alkaline conditions but pollen does not. Speleothems and bone are both eroded and rotted by bat or avian guano due to acid leached from the decomposing guano. Pollen survives best in anoxic, acid environments and this is also true of wood and leather. Metals survive best if they are in a dry environment although impurities within most metal objects mean that they are liable to pitting. Most developments in dating methods have been aimed at applications to the time period 10 ka to greater than 3 Ma rather than to historical periods, due to the great interest in the evolution of humans and culture. To some extent, these applications have been paralleled by interest in dating the internal and external palaeoenvironment of the cave and in understanding the development of karst landscapes (see Paleoenvironments). Table 1 is a summary of common dating methods as applied to chronological studies of caves, archaeology, and the Pleistocene.

Stone tools cannot be dated directly except, occasionally, by the measurement of a small hydration rim that develops on obsidian, an amorphous (glassy) anhydrous silicate. As obsidian dating is mostly of concern to the relative dating of open-air Meso-American sites and is rarely met in cave archaeology the reader is referred to Friedman *et al.* (1997) for further information.

Stone tools that have been burnt in a hearth can be dated by thermoluminescence (TL). TL dating is a technique that measures the total radiation dose stored in trapped electrons in the mineral, as received from internal and external radioactive emission. The TL method relies on the assumptions that the mineral had no radiation dose upon burial or immediately after heating and that the average dose rate from burial to the present can be estimated from dose rates measured today. The dose acquired since the object was fired is measured by releasing the energy from the trapped electrons by progressive heating to produce a "glow curve". A dosimeter left in the burial environment

Dating Methods: Archaeological: K-Ar, potassium-argon; Ar-Ar =argon-argon. TL, thermoluminescence, OSL, optically stimulated luminescence, IRSL, infra-red stimulated luminescence. *Items in brackets show material that may not be as good for a reliable date. (After Aitken, 1990 and other sources)

Method	Age range	Material*
Dendrochronology	Up to about 10 ka	Wood
Radiocarbon	Up to 50 ka (uncalibrated)	Wood, charcoal, organics
K-Ar (Ar-Ar)	From 40ka to >100 ka	Potassium rich minerals
Uranium Series (by mass- spectrometry).	Up to 500 ka	Speleothem, corals (tooth enamel, bone, peat)
Fission tracks	1 ka to >100 ka	Volcanic glass and minerals
Luminescence (TL, OSL, IRSL)	Up to about 200 ka	Pottery, quartz grains, burnt flint (speleothem)
Electron spin resonance	Up to several Ma	Tooth enamel, quartz (speleothem).
Obsidian hydration ¹⁰ Be/ ²⁶ Al	Up to several Ma Up to several Ma	Obsidian Silica sands and pebbles

for a year, typically, can be used to estimate the dose rate, and thus the age. The method was originally used to estimate ages of fired pottery, where the initial, archaeological dose is known to be zero, and it is frequently used to test for forgeries of antique pottery. One variation of the method relies on zeroing the past dose of quartz grains (and less reliably, feldspar grains) in sediments by sunlight, an effect known as bleaching, and is known as Optically Stimulated Luminescence (OSL). A second variant looks at radiation traps at the infrared end of the spectrum and is called IRSL. The technique can be used on single grains and it has the advantage that those grains that have been zeroed by sunlight can be distinguished and separated out from those within the same sample that have not been sufficiently bleached by sunlight. There seems to be no reason why these methods could not be used more frequently on cave sediments containing quartz grains. TL itself has been used a number of times on burnt flint from caves of the Levant (see Carmel Caves, Israel: Archaeology) where the zeroing occurred when flint was prepared in ancient cave hearths (Mercier *et al.*, 1994).

Carbon–14 dating (Taylor, 1997) is regularly applied to the organic component of bone called collagen, including bones from caves, with varying degrees of success. Radiogenic ¹⁴C is produced in the upper atmosphere by cosmic rays at a more-or-less constant rate. Living organisms take up ¹⁴C as well as the stable isotopes, ¹³C and ¹²C. After death, there is no ¹⁴C replenishment and the ¹⁴C decays by beta particle emission at a rate determined by its half-life of 5568±30 years. As the rate of production of

radiogenic ¹⁴C is not quite constant over time, a correction has to be made using a treering master curve. The resulting date is quoted as radiocarbon calibrated ("cal" for short; e.g. 7680±150 BP cal, where BP stands for "Before Present", and where "present" is 1950). The normal limit of the dating method without calibration is about 40–50000 years, depending on the sample and upon the laboratory set-up. Many samples are now dated using an accelerator mass spectrometer (AMS) that measures the ratio of ¹⁴C to ¹²C isotopes rather than the number of beta decays. Beyond the range of tree-ring calibration, ¹⁴C dates have been cross-calibrated using Uranium-Thorium (U-Th) dates and these indicate that a radiocarbon age of 18000 years is too low by 2000 years and a radiocarbon age of 36000 years may be too low by about 4000 years, though this latter remains to be confirmed.

Although bone is often well preserved in the slightly alkaline conditions of caves, it is porous and there may have been exchange with water in the sediment. Usually groundwater, particularly that coming into contact with limestone, has low ¹⁴C compared to the other isotopes. This "dead carbon" has the effect of making the bone appear much older and it is difficult to make an allowance for it. This is also true of other organic materials that may become buried in a cave.

There are two other direct ways in which bone may be dated, the first being the U-Th method and the second the Electron Spin Resonance (ESR) method. It has been found that buried bone often takes up uranium, which is soluble in groundwater, soon after burial, but not the thorium daughter product, which is insoluble. Any thorium that is present in buried bone must have grown radiogenically from the uranium. For applications of U-series dating to archaeological materials see Schwarcz & Blackwell (1992) or Schwarcz (1997).

The U-Th method is more reliably used on speleothems (see entry on Paleoenvironments: Speleothems). Stalagmites and flowstones are sometimes associated with archaeological material lying above or below it so that U-Th analyses provide either maximum or minimum dates. A good example is the archaic *Homo sapiens* skull at Petralona cave, northern Greece, that was found attached to a wall by a thin layer of pinkbrown flowstone (see Europe, Mediterranean: Archaeological and Paleontological Caves). By ESR and U-Th methods the calcite was found to be about 140–180 ka giving a minimum age for the skull (Latham & Schwarcz, 1992; Grün, 1996). As judged by comparative morphology, most paleoanthropologists think that the skull is about twice this age.

The ESR method (Grün, 2001) relies on measuring single trapped electrons that have accumulated at certain sites in bone phosphate due to the long-term damage by radiation. In this case, the radioactive emitters may be inside the bone, as in the case of U, Th, Ra and other decay daughters, or be in the nearby sediment or arise from energetic cosmic rays. Hence an estimate has to be made of internal and external dose rates to the material being measured and this is done either by direct analysis of the radioactive emitters or by using a dosimeter in the sediment. As for TL, the age of the material is then worked out from the total dose and the dose rate. One of the largest uncertainties is the effect of moisture over the burial time of the bone (or other object) because groundwater carries radioactive material and pore water also acts as a radiation absorber. Although the ESR method has been used on bone, it is thought that it is more reliable to use the enamel of

teeth, as enamel, being made of hydroxyapatite, is non-porous and more resistant to the movement of U in or out of the sample.

Unfortunately, in the case of bone, we are often not quite certain that the uranium was always taken up immediately upon burial and, because of the porous nature of bone, that the system has remained closed to the migration of uranium. In finding out how and when the uranium was taken up in bone and teeth it is usual to consider two model scenarios (Grün, Schwartz & Chadam, 1988; Latham, 1997). In the first, we assume that the object has taken up U soon after burial and the U-Th age or ESR age is then known as the Early Uptake (EU) age estimate. Alternatively, it could be assumed that the U has been taken up at a constant rate from burial till now. This is a linear accumulation of U (LU) giving an LU age estimate. It is usual to compare the EU and LU age estimates to see how close they are and to see which, if any, is concordant with ages estimated by other methods. The models will not work if, however, there has been an unknown delay between burial and uptake of U and, in such a case, the U-Th and ESR ages will underestimate the true age.

Since the Earth's magnetic field reverses its polarity periodically, a magnetic reversal stratigraphy can be correlated to an independently derived timescale (see Paleoenvironments: Clastic Sediments). McFadden *et al.* (1979) used magnetic reversals at the Limeworks Cave, Makapansgat, in South Africa, to give age brackets of 2.0–3.2 Ma for a layer containing *Australopithecus africanus*. Magnetostratigraphic studies are underway at Sterkfontein and other Australopithecine caves in South Africa (see Africa, South: Archaeological Caves). The remains of earliestknown hominids in Europe are those found in the Gran Dolina infilling, Burgos, north Spain, and the reversed polarity of the sediments in which they lie dates them at more than 0.78 Ma.

The first attempts to date the famous Upper Palaeolithic rock art (parietal art) of caves of Spain and France was via a stylistic approach (see Art in Caves: History) in which progressions of style with time were thought to be recognisable. Now more direct methods have been used to date rock art, mostly by ¹⁴C dating of pigments and binders containing charcoal, blood, and plant-derived material (Valladas *et al.*, 1992). The dating of these pigments has been facilitated by the much smaller sample sizes needed in AMS over the older ¹⁴C decay counting method. Studies in Cougnac Cave, Lot, France, showed that earlier paintings mostly of giant elk (*Megaloceros*) in red ochre were partly retouched in charcoal. The ¹⁴C ages showed that the earliest paintings may have been Gravettian (28–23000 BP) and the latest, in the same style, were as young as 14000 BP, 10 millennia later, and of probable Magdalenian culture. The oldest dated paintings are those of Chauvet Cave, Ardèche, at 32–30000 BP followed by those of the Mediterranean coastal cave of Cosquer at about 27000 BP. Samples of bone from the "Red Lady" from Paviland Cave, Gower, South Wales, and associated with the use of ochre and art objects, date to between 25250 and 27450 BP (Aldhouse-Green, 2000).

In summary, it is no exaggeration to say that caves and rock shelters have frequently offered a unique physical and chemical environment for preserving a wide range of archaeological and environmental material and this has enabled the development and testing of a number of dating techniques. Beginning around 1980, these techniques have contributed in no small way to a new understanding of human evolution and culture.

DATING OF KARST LANDFORMS

Most of the absolute dating in karst has been made on speleothems (see Paleoenvironments: Speleothems entry) or clastic sediments (see Paleoenvironments: Clastic Sediments entry). However the absolute dating of karstic and pseudokarstic geomorphological surfaces is even more promising. Very little has been done on this important topic so far, with many karst researchers not aware that this is possible.

Precise dating of surface landforms is a very difficult task that requires measurements of very low concentrations in small samples, with high precision, which cannot be done with con ventional techniques such as a- or β -counting or mass spectrometry. This was solved only when accelerator mass spectrometry (AMS) was introduced 20 years ago, for measurement of cosmogenic isotopes in rock samples. The most precise dating has been achieved with tandem accelerator mass spectrometry (TAMS) facilities.

Absolute dating of surface landforms can be done only by measuring cosmogenic isotopes (e.g. 36 Cl, 26 A1, 10 Be, 41 Ca, and 14 C) produced *in situ* in rocks at the Earth's surface. These isotopes are formed from secondary cosmic radiation, only in the surface few millimetres of the rock, by radiogenic nuclear reactions (Lal, 1988). There are three principal mechanisms by which cosmogenic isotopes are produced in terrestrial rocks: high-energy spallation by nucleons; neutron capture reactions; and muon-induced nuclear disintegrations. Cosmogenic isotope accumulation starts when the fresh rock surface is exposed to cosmic rays. 36 Cl, 26 A1, and 10 Be are formed with annual rates of 10–50 atoms g⁻¹ a⁻¹ in appropriate rocks at sea level, four times faster at an altitude of 2000 m and 30 times faster at 5000 m. So the surface of a rock formed at sea level 1000 years ago can be dated by AMS in a sample of a few tens of grams. Concentration of cosmogenic isotopes depends on the irradiation site and geometry of the rock surface, so datable samples require knowledge of the geometric evolution of the rock.

The rock being dated should be a closed system in respect to its losing or gaining an isotope from the environment. To avoid such processes, it is best to use quartz grains for dating to avoid possible interference from atmospheric cosmogenic isotopes being absorbed into the rock matrix via seeping water, but other rocks without quartz can also be dated. Samples for dating can be divided into two types: samples whose past evolution is known a priori, and samples whose past evolution geometry is known qualitatively but the time constants are not known. The expected isotope concentrations due to *in situ* production can be determined if both the cosmic-ray intensity I(t) and the sample geometry evolution G(t) are known. Therefore, if one of these is known the other can be modelled; the degree of resolution on the parameter evaluated would depend on the number of isotopes studied.

Samples with well-known evolution and geometry—trees, monuments, rock surfaces polished by glaciers—give information about changes of the geomagnetic dipole field of the Earth; movement of the sample's latitude or altitude due to uplift, folding, or plate tectonic drift; and changes in the primary cosmic-ray flux due to solar modulation. Some non-characterized samples have a qualitative history of irradiation derived from geological or geophysical evidence, such as accreting sediments and eroding or denuding rocks. In such cases we can measure the rate of accumulation or erosion (or denudation) of the rock surfaces.

For example, we consider the expected concentration of an isotope *C* in a rock surface, eroding at a constant rate ϵ at a fixed location. Let us further assume that the rock formed from igneous activity at some time *T* in the past; in this case, the initial isotope concentration is zero. After *T* years of irradiation, we would expect the following depth profile for the concentration *C*(*x*) of the isotope (Lal & Arnold, 1985):

$$C(x) = (1 - e^{-\lambda T}) \left[P_o e^{-\mu X} / (\lambda + \epsilon \rho \mu) \right]$$

where P_0 is the isotope production rate at the rock surface, λ is the disintegration constant of the isotope, ρ is the mean density of the rock, μ is the inverse of the mean absorption length for cosmic-ray particles in the rock, and the units of *X*, μ and ϵ are g cm⁻², cm² g⁻¹, and cm s⁻¹, respectively. This equation assumes constant isotope production and erosion rates and no pre-irradiation history of the rock. If several metres of rock have been eroded away, the isotope concentration in the rock is in a quasi-steady state, and the surface concentration C_s becomes:

$$C_s (X = 0) = P_o / (\lambda + \epsilon \rho \mu)$$

with the concentration decreasing exponentially with depth X.

The resulting surface isotope concentration depends on the isotope half-life, the mean erosion rate, and the isotope production rate. We may define two irradiation time periods: the equivalent time T_{eq} (time taken to produce certain isotope concentration) and the effective time T_{eff} (time corresponding to the ratio of the concentration to production rate). We obtain:

$$T_{eq} = \ln(1 + \lambda/\epsilon\rho\mu)/\lambda,$$

$$T_{eff} = 1/(\lambda + \epsilon \rho \mu)$$

Erosion (corrosion) sets a new equilibrium value, lowering the mean lifetime of the isotope by a factor $1/(1+\epsilon_{\rho\mu})$. This is equivalent to saying that erosion mean lifetime is $1/(\epsilon_{\rho\mu})$. The characteristic mean erosion period T_{ero} is defined by the ray attenuation length $(1/\mu)$, the density ρ , and the erosion rate ϵ :

$$T_{ero} = 1/(\epsilon \rho \mu)$$

The mean erosion period T_{ero} becomes comparable to one million years (the order of halflives of ²⁶Al and ¹⁰Be) when $\epsilon \sim 5 \times 10^{-5}$ cm a⁻¹. For smaller erosion rates, the effective irradiation time will be determined by the isotope half-life, and for higher erosion rates, by the erosion rate. From a study of concentrations of isotopes of different half-lives, an exposed surface can be characterized and erosion rate determined. The erosion timescales accessible are simple functions of the isotope half-life (Lal, 1988). Such appropriate pairs of isotopes for limestone rocks are ¹⁴C and Cl or ⁴¹Ca, but for dolomite rocks ¹⁰Be can be used. ²⁶Al can also be used for dating surfaces of volcanic rocks, or limestones with high concentration of quartz (sand), because it is formed from silica-rich material. For silicate rocks, it is best to use ²⁶Al and ¹⁰Be, but for rocks with high Ca or Fe concentration, ³⁶Cl and ⁴¹Ca can also be used. Age determinations are possible only if two or more isotopes are used (Lal, 1987); unless the magnitude of erosion is known a priori, one has to determine both erosion rate and the time of exposure of the surface.

³⁶Cl has been used by Kubik *et al.* (1984) to date limestone landforms. Raisbeck and Yiou (1979) discussed the possible applications of 1Ca for dating of CaCO3 sediments.

Dating of Volcanic Caves

Absolute dating of volcanic caves may use two different types of methods depending on genesis of the caves. Volcanic lava tubes are formed during the cooling of the lava, so have the same age as the bedrock. This allows us to use the conventional isotopic disequilibrium dating methods that produce reliable dates (Faure, 1986). Some lava tubes in active volcanic regions (Hawaii, Iceland, Etna) are very young, but others in paleovolcanic regions (Rhodope Mountains, Bulgaria) are of Oligocene age (Shopov & Kolev, 1992). Appropriate methods are ²³⁰Th/ ²³⁸U dating for 1000 to 400000 year old rocks, K/Ar for 100000 to 2 billion year old rocks, or Rb/Sr dating for rocks older than 100000 years. Many dating methods can be used for volcanic rocks of older age (Faure, 1986). Hekiniam, Chaigneau & Cheninee (1973) dated lava tubes with K/Ar dating.

Dating of denudo-erosional caves formed by weathering of volcanic rocks (Shopov & Kolev, 1992) and volcanic landforms requires use of *in situ* produced cosmogenic isotopes, as in the dating of karst landforms. Phillips *et al.* (1986) discussed the possibility of dating the young surface volcanic rocks by ³⁶Cl.

DENT DE CROLLES CAVE SYSTEM, FRANCE

The Dent de Crolles area is located in the Chartreuse Massif, in the French Northern Prealps (for location, see map in Europe, Alpine entry). At 2068 m in altitude, its summit rises more than 1500 m above the Isère valley (Figure 1). The mountain resembles a ship's prow, surrounded by high cliffs on three faces. The fourth side corresponds to a large cirque opening to the northwest, where the Guiers-Mort spring resurges, at 1332 m altitude. This narrow ridge extends to the north, to the Aup du Seuil, the Alpe and the Granier massifs, which also contain long and deep cave systems. The boat-shaped plateau surface shows bare karren, only lightly covered by discontinuous pine forest on the lower part, and with alpine meadows near the crest.

This original relief owes its shape to the geological structure, a perched syncline some 20 km long, running from the Dent de Crolles to Granier—high above the Isère valley between Grenoble and Chambéry. Each karst system is separated from its neighbours by transverse dextral faults. The heights of the cliffs correspond with the thickness of the Urgonian limestone, which reaches 450 m, overlying impervious Hauterivian marls. The syncline axis plunges south-north, so that water can concentrate in the trough, at the base of limestone in contact with the marls, and then reappear in the Guiers-Mort Cave.

Under a plateau only 1.8 km² in areal extent, runs a cave system more than 50 km long, which can be reached by seven different entrances: the Thérèse and P40 shafts on the plateau, the Glaz hole on the western face, the Annette, Chevalier, and Montagnards caves on the eastern face, and finally the GuiersMort spring (Figure 2). The caves are formed on four levels, sloping to the north: Glaz-Annette (1700–1650 m), Chevalier-Tritons-Seyssins (1450–1550 m), Metro (1500–1400 m), and Collecteur (1450–1330 m). The three upper levels are perched and dry, but the lowest one, on the marl contact, harbours the main drain. Shafts and meander complexes link the plateau with different levels (Lismonde *et al.*, 1997).

The Guiers-Mort and Glaz entrances have been known for a long time, for a distance of several hundred metres. E.A.Martel made a survey of them in 1899. During the 1930s

Dent de Crolles Cave System, France: Figure 2. Simplified plan and profile of the cave passages within the Dent de Crolles, France. The surface profile is drawn directly above the

main mass of cave passages, and the Thérèse shaft lies higher on the plateau which also slopes down from east to

the real exploration began (led by the Jarrets d'Acier-a local speleological club-and continued by Robert de Joly), which reached 119 m depth in 2.5 km of passage. De Joly made the first dye tracing between Glaz and Guiers-Mort, but it is Pierre Chevalier who will forever be connected with the history of the Dent de Crolles. From 1935 to 1947, under very difficult conditions and accompanied by Fernand Petzl, he explored a 17 km underground maze, connecting successively to the Guiers-Mort Glaz (1941), Annette (1946), and finally the P40 (1947), establishing a world depth record (-603 m). He also discovered the huge Chevalier gallery, only connected to the main system in 1984. These explorations were partly carried out during World War II, when travelling was hazardous and food supplies were heavily restricted. He related his discoveries with modesty in his famous work *Escalades souterraines* [Subterranean Climbers], one of the world's bestknown caving books (Chevalier, 1948). From 1959 to 1971, the Tritons, a local speleological club led by M.Letrône, extended the known system to 36 km. They discovered the middle storeys (Tritons and Metro). Later explorations have extended the surveyed length to 55 km, with the main breakthroughs being the discovery of the Thérèse shaft, the system's upper entrance, extending the system depth to -668 m. It is now possible to go through Dent de Crolles from west to east, or from the plateau to the spring, following in Chevalier's footsteps.

Pierre Chevalier also recorded the first European observations distinguishing between vadose and phreatic forms (Chevalier, 1944). The formation of a huge labyrinth under such a small surface area could be explained by the combination of several factors: (1) a synclinal setting which concentrates water flow toward the fold axis; (2) allogenic flows from impervious neighbouring areas and also from glaciers; (3) gradual lowering of the water table, giving rise to the storeys or levels. A rise in the base level due to valley glaciation simply flooded former networks of caves; and (4) lowering of the water level in the looped galleries, giving rise to back-flooded mazes (Lismonde *et al.*, 1997).

To date, three major phases of evolution have been identified (Lismonde *et al.*, 1997; Marchand, 1985):

- 1. At the end of the Miocene, orogenic activity led to the present folded structure. An impervious depression developed at the site of the present Isère valley. Surface flows probably disappeared underground at the limestone contact, feeding the Annette, Chevalier, and Montagnards caves. The south part of the massif was drained toward the Glaz passages, to a base level located near the present-day 1700 m contour, creating the upper cave level. Scallop dimensions show that discharge was around several hundreds of litres per second. The northern part constituted an independent catchment towards an unknown spring.
- 2. During the Pliocene, uplift brought a progressive lowering of the water table. The upper level was drained and the Chevalier-Tritons-Seyssins level was formed, which drained both the northern and southern parts of the system. The position of the spring, located in the northern structural block, which is displaced eastwards, explains the location of this level in the Dent de Crolles eastern limb (and not along the axis of the

syncline). Some mazes progressively drained this level into the Metro lower level, in a transitional period when both of the middle levels were active (Marchand, 1985).

3. A new water-table lowering divides the two structural blocks into two catchments: Chaos de Bellefont to the north and the present Dent de Crolles to the south. The Dent de Crolles main drainage system has developed in the axis of the syncline, on the contact with the marls, forming the lowest level.

The history of the cave system can be reconstructed using radiometric dating (Audra, 1994; Maire & Quinif, 1991). Level 2 was drained a long time before 250 ka. By 370 ka, Chevalier Cave (level 1) was already partly filled by clastic sediments covered by flowstones, but some flows, probably originating from the input of glacial meltwater along the eastern scarp, eroded the flowstones and contributed to the enlargement of this giant gallery during the Riss (Wolstonian) glaciation. This water input, combined with a glacial dam at the spring, led to major flooding and the deposition of glaciokarstic varves. PHILIPPE AUDRA

DI FENG DONG, CHINA

Di Feng Dong, Great Crack Cave, is part of a spectacular karst system situated near the town of Xin Long in Chongqing Province, China (see location in Figure 1 of China entry). The cave is still being explored by members of the China Caves Project, a collaboration between British cavers and the Institute of Karst Geology in Guilin.

Xin Long is located in an area of dissected cone karst approximately 35 km from the point where the Chang Jiang (Yangtze River) enters the Three Gorges. In this area, the geological structure comprises a series of plunging folds with axes oriented southwest to

northeast. Impermeable sandstones and shales outcrop in high mountains to the southeast of Xin Long and provide a large catchment area that drains to the northwest into the limestones near Xin Long.

The limestones are remarkably monotonous. There are more than 1000 metres of finely laminated limestones ranging in age from Devonian to Jurassic, but there are almost no bedding planes, so the limestones give the impression of being one huge bed. Consequently, the only fissures providing easy routes for water are joints and faults. To the north, the Chang Jiang (Yangtze River) and its tributaries have been rapidly incising in response to uplift of the mountains and so all the rivers and caves in the region have experienced a rapid lowering of their base level. This has resulted in the incision of gorges and a series of underground river captures, mostly by caves eroding along the joints.

Within this geological setting the Di Feng karst system comprises four main parts: the Tien Jing Gorge, Di Feng Dong, Xio Zhai Tien Ken, and the Mie Gong He gorge (Figure 1).

The first part of the Di Feng karst system is the Tien Jing Gorge and is an extreme example of river incision in response to uplift. The valley is a broad box canyon with a more recent gorge entrenched in its floor. This gorge, Di Feng (The Great Crack), is almost hidden by trees because it is mostly less than

Encyclopedia of caves and karst science 588

Di Feng Dong: Figure 1. Outline map of the Di Feng Dong cave system beneath the conical hills of the fengcong karst.

10 m wide. However, Di Feng reaches a depth of more than 200 m at the northern end where the cave of Di Feng Dong begins. In many places the gorge is only 2 m wide at floor level.

There are several active sinks at the head of the gorge, near Xin Long, and these take all the water except in times of very serious floods. Hei Yau Dong (Black Rock Cave) appears to be the last, major, active sink, so downstream of Hei Yau Dong the Tien Jing Gorge is normally dry apart from static lakes. Most of the water resurges through boulders and pebbles where the gorge continues into Di Feng Dong, so the cave contains an active river.

The second part of the system, the cave of Di Feng Dong, begins where the Tien Jing Gorge ends. The incision of the Great Crack in the floor of Tien Jing Gorge means that a 180 m abseil is required to reach the start of the cave. Like the gorge,

Di Feng Dong: Figure 2. The giant doline of Xiaozhai Tiankeng seen from the air, with the shadows of its inner doline hiding the entrances to the passages of Di Feng Dong. (Photo by Zhu Xuewen)

Di Feng Dong is strongly controlled by joints, and is typically 3–15 m wide with vertical walls at least 100 m high. Exploration is exciting, with lakes up to 250 m long, rapids, and waterfalls. Unfortunately, a small rise in water levels during exploration would prevent safe return and for this reason the exploration of Di Feng Dong and the

connection with Xiaozhai Tiankeng is still in progress. The river's bedload of pebbles and cobbles clearly becomes suspended in flood, as stainless steel rigging bolts have been found sheared clean off and all equipment is stripped from the cave by annual floods.

The river in Di Feng Dong drains to the foot of the great doline of Xiaozhai Tiankeng (literally, the Big Sky Hole Behind

Di Feng Dong: Figure 3. The tall canyon passage carrying the main stream out into the base of the Xiaozhai doline midway through the cave system. (Photo by Tony Baker)

the Small Village). This giant doline has mostly sheer rock walls, and is about 600 m across and 660 m deep. From the southern wall, the river from Di Feng Dong resurges in an awesome cave passage 15–20 m wide and more than 100 m high. At this point most of the water is captured by a tunnel which takes it to a hydro-electric power station on the Jiu Pan River about 1.5 km to the north. Consequently, the sink on the eastern side of the doline usually takes little or no water, and a traverse of this downstream section is easier. It begins with pitches of 12, 7, and 50 m, all into large and deep pools. The cave then

turns north as a high rift passage with a series of pools, lakes, and pebble banks, and there appear to be larger high-level passages joining from the west in the roof. After 1500 m, the cave turns back on itself and then heads east towards the resurgence. More long lakes and short cascades lead into a narrower canyon, which ends at the lip of a beautiful cascade dropping 40 m into the Mie Gong He gorge.

When exploration of the upstream cave is completed, Di Feng Dong will offer a spectacular through trip 9 km long. The traverse down the great doline and out to the resurgence has already been made and involves a descent of 964 m. Combined with the Great Crack, this is one of the world's great karst sites.

DINARIC KARST

The Dinaric Mountains, which form the western part of the Balkan peninsula, take their name from Dinara mountain at the Croatian-Bosnian border. The Dinaric karst occupies the western part of the Dinaric Mountains, that is the whole Adriatic Sea littoral belt from the Trieste Gulf to the Drim River, and inner part from the Friuli Plain (Italy) to the valley of the Zapadna Morava River (Figure 1). The eastern and northeastern limits are less clear, because the carbonate rocks slowly and discontinuously give way to other rock formations. The inner limit of the Dinaric karst can be traced approximately along the line Tolmin—Novo mesto—Banja luka—Užice—PeĆ. In a straight line, it is about 600 km long and over 200 km wide, covering approximately 60000 km², forming the largest continuous karstland in Europe.

The Dinaric karst developed in Mesozoic limestone. The youngest (Cretaceous, or even Tertiary) rocks form low relief along the coast and on the islands. In synclines, Eocene flysch was deposited and above there are "islands" of erosional relief with short streams, more soil, and vegetation. In some places there are rich bauxite deposits. Further inwards, the surface consists of Jurassic limestone, while in the east and northeast there are Triassic rocks, often dolomitic, but with less karst.

The climate alters from the Mediterranean coast, to moderate continental and mountainous in the interior. The whole of the Dinaric karst has over 800 mm of annual precipitation, with the highest amounts on the mountain barriers immediately above the coast, such as Crkvice (1070 m) above the Boka Kotorska bay, with over 4900 mm per year. On the coast, dry and hot summers and wet and fresh winters are typical. A strong downslope northeast wind bura (bora) is typical of the winter on the Adriatic side of the Dinaric barrier, especially at the bases of high plateaux and ridges. The vegetation cover corresponds

Dinaric Karst: Figure 1. The extent and morphological types of the Dinaric karst. From Roglić (1965).

to climate. Karst, referred to as a limestone desert, is found on the islands and along the coast, especially where the bura wind sprays salt water. Here there is practically no vegetation. The higher parts of the islands and coast-facing slopes have only grass and bush, while on the opposite slopes and inwards, there are mostly forests, some being so-called high (economically important) coniferous and mixed forests. The most common trees are Dinaric fir and birch (*Abieti-Fagetum dinaricum*). The deforestation is partly due to natural conditions (mediterranean climate), and partly due to thousands of years of grazing and burning to obtain pastures. After World War II, when goats were banned and the pressure of agrarian population decreased, forests began to gain ground and bushes now cover a lot of pastures and bare lands.

In spite of the high amount of precipitation, there are only a few surface streams on the Dinaric karst, mainly on impermeable terrain (flysch), or in karst poljes. However there are a few large rivers, with enough water to cut canyons through limestone belts: the Dalmatian Krka, Cetina, Neretva and Morača in the Adriatic basin, and the Kolpa, Una, Vrbas, Bosna, and Drina in the Black Sea basin. The canyon of the Tara River, a tributary of the Drina, is 78 km long and up to 1300 m deep. Sinking rivers, flowing underground from one polje to another, are very common. A typical example is the Ljubljanica River, draining 1100 km² of karst, which has a mean discharge of 56 m³ s⁻¹ and crosses five poljes with eight surface sections between caves.

Along the Adriatic coast, water often flows directly into the sea via undersea springs called vrulja, or to springs on or near the coast. Donjobrelska vrulja, at the foot of Mt

Biokovo, has an estimated low flow discharge of $20-30 \text{ m}^3 \text{ s}^{-1}$. The karst hydrology and the morphology of the shallow sea developed during the Pleistocene, when the sea level was more than 100 m lower than at present. Large conduits feeding karst springs are known from depths of 50 m below sea level, and Donjobrelska vrulja is at a depth of 38 m. Springs on the coast are often located at the bottoms of bays and were once used for water supply and energy (mills), this being the reason for location of some settlements (such as Bakar and Malinska). Along the coast there are some very short rivers with a high discharge, for example the Timavo, 2 km long, with a mean discharge of 30 m³ s⁻¹, and the Ombla near Dubrovnik (at an altitude of 2 m) with a maximum discharge of 200 m³ s⁻¹. The biggest springs in the Dinaric karst are the Buna (maximum discharge 440 m³ s⁻¹), and the Ljuta (300 m³ s⁻¹) in Boka Kotorska Bay. The most important and typical morphological features in the Dinaric karst are poljes (see Dinaride Poljes; Poljes). Other landforms include uvalas, dolines, and corrosional plains (zaravan).

According to the thickness of limestone above the impermeable base, the karst can be divided into deep and shallow types, similar to Jovan Cvijić's holokarst (deep, fully developed with karst poljes) and merokarst (shallow, with only a few karst features). There are over 20000 explored caves, including deep shaft systems (e.g. Lukina Jama, 1392 m deep on Mt Velebit in Croatia) and long caves (e.g. Postojnska Jama—see separate entry; Krizna Jana (Figure 2); and others around the poljes of Cerkniško, Postojnsko, and Planinsko, in Slovenia).

The Dinaric karst is very important for the history of karstology and speleology, as well as in the development of karst science.

Dinaric Karst: Figure 2. The horizontal phreatic tunnel of Križna Jama (Slovenia) with its numerous deep lakes that make a visit to the cave an almost continuous boat journey. (Photo by Tony Waltham) The term karst is derived from the Kras plateau in the northwesternmost part of the Dinaric karst (see separate entry, Kras). Similarly, the international terms polje, uvala, doline, kamenitza, and ponor originate from this region.

The history of exploration varies as the Dinaric karst has been divided into a number of political units (Slovenia was incorporated in Austria; Croatia in Hungary or in the Military Zone; Bosnia, Serbia, and Montenegro in the Ottoman Empire; Dalmatia and part of the coast in the Venetian Republic; and the Republic of Dubrovnik). For the history of the northwesternmost part (nowadays Slovenia), see the entry on Kras. The most important early descriptions of karst phenomena along the coast were written by Nikola Gučetić (in 1585), Alberto Fortis (in 1771), and Ivan Lovrić (in 1776). From the inner part of the Dinaric karst, one of the oldest mentions of the caves is in the work of the Moslem traveller, E.Celebija (1660). Later, Austrian geologists carried out a lot of research in Vojna Krajina (Military Zone), with the aim of understanding the water supply. After 1878, Austrian geologists wrote the first modern studies about typical Dinaric karst in Bosnia, with an emphasis on karst poljes. Well-known karst hydrological theories were developed on this basis by A.Grund (1903) and F.Katzer (1909). One of the founders of the modern karstology, Jovan Cvijić, also based his works (1893, 1901) and theories on the study of Dinaric karst (see entries on Speleogenesis Theories).

DINARIC KARST: BIOSPELEOLOGY

The Dinaric karst covers more than 56 000 km². It is approximately 100 km wide and 600 km long in the region between the Adriatic Sea and the hills that separate it from the Pannonian Valley. It extends from 2000 m altitude to below sea level. Cave temperatures may be 16°C at the coast and 4°C in the Velebit Mountains or even close to zero around small perennial ice deposits in caves. Ecologically, the caves are very diverse, with nearly all the hypogean habitat types that are possible in temperate climates. Virtually all of the caves are ecologically heterogeneous, and have a rich and diverse fauna.

Richness and Structure of the Fauna

The first cavernicolous species in the world were described from the northwestern parts of the Dinaric karst in the 1830s to 50s. Later, some unusual discoveries were made in the central part (Dalmacija and Herzegovina) while the Slovenian section appears to be richest in aquatic species. Dinaric caves and interstitial waters are inhabited by more than 450 stygobitic species, which is by far the highest number in the world, when compared with other regions of corresponding size (Sket, 1999). It is nearly twice as high as any other region, except the east Balkan Province. A recent review of cave fauna revealed more than 790 terrestrial obligate cave species. The inclusion of aquatic and terrestrial subspecies would at least double the number of taxa (Sket, Paragamian & Trontelj, 2003).

The taxonomic composition at the level of order and class appears to resemble other cave faunas in southern Europe. Approximately 45% of the terrestrial species described are beetles from two groups: Cholevidae: Leptodirinae and Carabidae: Trechinae. Other insect groups are largely absent, but pseudoscorpions (Pseudoscorpiones) are comparatively numerous. Among the aquatic fauna, crustaceans are by far the most common, and stygobitic aquatic insects are absent. The Dinaric fauna is not particularly diverse at the higher taxonomic level. Its richness is mainly founded on the diversity within some genera such as *Niphargus, Proasellus, Monolistra, Anophthalmus,* and *Antroherpon*. Apart from their morphological diversity, they also show a high ecological diversity.

Distinctive Features of the Dinaric Hypogean Fauna

There are some Dinaric species that are particularly distinct morphologically. These include troglomorphies such as an accentuated (pseudo)physogastry (an apparently swollen abdomen) in terrestrial Coleoptera (*Leptodirus hochenwartii, Antroherpon* spp.), cuticular spines or outgrowths in aquatic Crustacea (Ni-*phargus balcanicus*, some *Monolistra* spp.) or outgrowths in Hirudinea (*Croatobranchus mestrovi*).

Unlike vertebrates, some invertebrate groups are unusually richly represented. A particularly rich stygobitic gastropod fauna has been found, with 130 species, a diversity that closely approaches that of all non-Dinaric hypogean gastropod species. The diversity of epizoic or parasitic Turbellaria: Temnocephalida, with 15 species, is also high. The mainly marine isopod family of Sphaeromatidae is represented by *c*.30 species and subspecies in the Dinarides, compared with less than 10 in other south European karst areas.

The most interesting species inhabiting Dinaric caves are unique stygobitic representatives of some higher taxa, for example *Eunapius subterraneus* (Spongillidae) is

the only stygobitic freshwater sponge; *Velkovrhia enigmatica* (Hydrozoa: Bougainvilliidae) is the only known stygobitic cnidarian; *Congeria kusceri* Bole (Mollusca: Bivalvia: Dreissenidae) is the only definitively stygobitic clam; *Marifugia cavatica* (Polychaeta: Serpulidae) is the only stygobitic tube-worm; and *Proteus anguinus* (Amphibia: Proteidae) the only non-American stygobitic amphibian. The undescribed terrestrial planarian (cf. *Microplana*) is probably also the only troglobitic species of its group.

The three stygobitic species each for the Cladocera and Copepoda: Calanoida represent a comparatively high diversity, since these groups are extremely poorly represented in fresh waters elsewhere. In addition, the absence of otyglobitic fish species in the Dinaric karst is worth mentioning, although there are a number of endemic stygloxene fish species.

Ecological Diversity

A high ecological diversity (variety of habitats) is characteristic of most larger cave systems in the area, resulting in very rich local faunas. Of 16 caves worldwide containing 20 or more troglobitic and stygobitic species, six are in the Dinaric karst (Culver & Sket, 2000). By far the richest within the Dinaric karst is the Postojna—Planina Cave System (see separate entry), with approximately 50 stygobites and 30 troglobites, and close to 150 stygophilic or stygoxene species. Vjetrenica in Bosnia—Herzegovina (see separate entry) is nearly devoid of non-specialized species, while 40 stygobites and 32 troglobites are known within the system.

Some particularly interesting ecological entities in the Dinaric karst are worth mentioning.

- 1. An epizoic protozoan faunula of no less than seven Ciliata: Peritricha and two Suctoria were found on a single specimen of the isopod *Monolistra spinosissima;*
- 2. A hygropetric-like habitat (a thin film of water running down the rock) known from Vjetrenica in Her zegovina occurs in some other Dinaric (and south Alpine) caves, and is inhabited by some specialized beetles (Coleoptera: Catopidae: Leptodirinae) which are pholeuonoid in shape (with a spindle-shaped trunk and elongated appendages);
- 3. In very specialized conditions in the sink-cave Crnulja in Popovo polje, there are very dense and extensive colonies of the cave tube worm *Marifugia* and thick layers of its tubes have formed a type of hypogean tufa. This used to be inhabited by an interstitial fauna of oligochaetes, acarines, and some crustaceans. Flood prevention work in the polje prevented regular flooding of the cave, killing *Marifugia* and its associated fauna;
- 4. In the vicinity of hypogean ice, rich beetle faunas may be found, including some specialized oligostenothermal (limited to low temperatures) fauna, such as *Astagobius* spp.

Distribution Patterns (Biogeography)

The following distribution patterns (Sket, 1994) can be established for the hypogean Dinaric fauna:

1. widely distributed troglobitic or generalist species (for example, the west Palearctic *Asellus aquaticus*);

- 2. troglobitic taxa with relatives in the western and/or eastern karst areas (Zospeum, Troglocaris, Sphaeromides, Niphargus aggr. rejici);
- 3. holo-Dinaric or holo-Dinaric—South Alpine taxa (*Proteus, Marifugia, Monolistra, Titanethes*);
- 4. merodinaric taxa, i.e. limited to one of three subregions (northwest Dinaric: Anophthalmus, Leptodirus, Hadziella, subgenus Microlistra; southeast Dinaric: Antroherpon, Plagigeyeria, subgenus Pseudomonolistra; paralittoral (mainly along the coast): Hadzia fragilis, Niphargus hebereri);
- 5. narrowly endemic taxa.

In contrast to most other areas, a portion of the Dinaric anchialine fauna in the paralittoral area is of freshwater origin. The composition of the interstitial fauna within the Dinaric area differs from that of cave habitats.

Some Unresolved Problems

Although this is a relatively well-studied karst area, sometimes intensively so, it is far from being thoroughly investigated, even taxonomically. Some apparently well-known taxonomic groups such as *Niphargus, Monolistra,* and *Anophthalmus* continue to yield new taxa; but some groups have been almost completely neglected, e.g. Bacteria, Mycota, Protozoa, Nematoda, Acarina, and parasitic animals in general. Phylogenetic and phylogeographical relations within some large genera distributed across Europe (e.g. *Niphargus, Proasellus*) are completely unresolved.

Biochemical investigations on *Troglocaris* have confirmed the long-held hypothesis that at least some of what have been considered holo-Dinaric species may in fact be species aggregates. Because of the morphological similarity caused by convergent evolution, it will only be possible to investigate this using DNA analysis. An example of one of these taxa is the cave salamander, *Proteus*.

Recent biogeographical analyses have revealed that the ages of cave populations may differ vastly, even within one species. The surprisingly recent immigrations (in some *Monolistra* spp., and in *Proteus;* Sket, 1997) still await confirmation by other means.

The Dinaric Hypogean Fauna Is Endangered

The comparatively high diversity of taxa results in a greater vulnerability of hypogean fauna to disturbance. Fortunately, most phenomena which endanger cave fauna are also harmful to the human population (Sket, 1972). Although most obligate cave species seem to originate from euryoecious (generalist) ancestors, their own tolerances to changes of ecological parameters are largely unknown. In any case, the character of Dinaric cave fauna shows that the species may be highly specialized and diversified, therefore dependent on the habitat diversity. In addition, they are dependent on the environment's stability for their "slow life style" (K-strategy). This is particularly dangerous in combination with their limited distribution ranges. Due to the contiguity of the Dinaric karst it was nearly impossible to avoid endangering its hypogean biota either by draining waste and waste waters underground or by hydrotechnical interventions. Pollutant spills are not uncommon in the karst as well as in interstitial water within alluvial plains. The underground hydrography allows pollutants to spread in unknown and unseen directions. Cave fauna may be endangered either directly by the toxicity of the wastes or by competition with epigean species in organically polluted habitats. Both are common

phenomena all over the Dinaric karst. Land drainage and water resource management, particularly in the southeast (Herzegovina), has changed the surface and subterranean hydrology to such an extent that some hypogean habitats have changed substantially. The drying out of the unique massive tubeworm colonies in the Crnulja in Popovo polje is one of the most severe results of such activities. Similar hydrological interventions have altered the connections between some systems, allowing mixing of previously isolated populations or races and therefore allowing harmful changes in the biodiversity.

DINARIDE POLJES

Approximately 130 karst poljes are located in the Dinaric karst region (see separate entry), which straddles the borders of Bosnia, Herzegovina, and Montenegro (see map in Dinaric Karst). There are more than 50 large karst poljes in the area, generally elongated along the strike of the Dinaric Mountains, i.e. in a northwest—southeast direction.

The first comprehensive study of the Dinaric karst was made by Jovan Cvijić in 1900. In the early 1900s, local investigations focused mostly on draining of the temporarily flooded poljes, providing effective water intakes at the springs, and constructing small storage ponds. After 1945, karst research developed rapidly, stimulated by the need for detailed surveys for hydroelectric power projects in the region, as well as the initiation of reclamation projects.

West Bosnia and Herzegovina

Southwest Bosnia, Dalmatia, and west Herzegovina contain the world's largest concentration of well-developed karst poljes (Figure 1). Poljes are developed at four to five particular elevations, between 1200 and 20 m above sea level (Figure 2). A complex suite of processes governs their genesis in this part of the Dinaric karst, but faults of regional extent, mainly reverse faults, have played a key role, e.g. in Glamočko, Kupreško, and Livanjsko. Many small karst poljes are developed along the same overthrust, e.g. Mućko, Aržano, Vinica, and Rakitno poljes. The highest is Trebistovo Polje at 1278 m above sea level, and the lowest are Bokanjačko Polje and Vrgorac Lake, in Dalmatia, at only 20–25 m above sea level. A few of the very small poljes do not show any surface flow—Bokanjačko, Nadinsko, Dugo, and, without ponors, Posuško and Vir poljes.

Vukovsko and Ravno poljes are hydrologically connected via a short gorge. The longer axis of Vukovo follows an east-west fault and the underlying rock is dolomite. Ravno Polje occurs on limestone and is elongated along the Dinaric strike, northwestsoutheast. Vukovsko and Ravno poljes never flood. Livanjsko Polje is the largest in the region, 65 km long and 6 km wide with a total area of 402 km². Its principal ponors are mostly located in the southwest foothills: Ćaprazlija, Kazanci, Veliki, and Opaki ponors in Livanjsko and Srdjevičko, and Sinjski, Proždrikoza, and Stara Mlinica ponors in the Buško Blato area. Mali Kablić Ponor is situated on the northeast border of the polje. In natural conditions, floods in the southern part of the polje (Buško Blato) lasted four to six months per year, ponding some 200 million cubic metres of water. For the purposes of hydroelectric power generation, all ponors have been shielded against surface leakage by grouting, plugging, and construction of local rock-filled dikes in front

of ponor zones, and water from Buško Blato has been transferred to a man-made reservoir with a capacity of 800 million $m^3 s^{-1}$.

Kupreško and Glamočko poljes both straddle the regional watershed between the Adriatic Sea and Black Sea catchments. Kupreško Polje occurs on a northnorthwest-southsoutheast fault and consists of three connected morphological units, with flooding being confined to the lower part of each. Glamočko has an upper polje and a lower polje. The flooding occurs for 6–10 months per year, and the volume of floodwater exceeds 80 million cubic metres. Kovači Ponor in Duvanjsko Polje is the largest ponor in this region, with a capacity of over 60 m³ s⁻¹.

Huge volumes of Neogene shale, conglomerate, clay, and sandstone have accumulated in these poljes. The lake deposits in Glamočko Polje are more than 700 m thick, they are 2300 m thick in Livanjsko Polje and more than 2500 m in Duvanjsko Polje. In the lowerlying poljes of Western Herzegovina (Posuško, Kočerinsko, Trnsko, and Imotsko poljes) the Neogene deposits are much thinner, e.g. only 145 m in thickness in Imotsko Polje. All of these deposits in the poljes function as hydrogeological barriers.

Eastern Herzegovina

With the exception of Nevesinjsko, all poljes in eastern Herzegovina are aligned along the Dinaric strike (Figure 1). Stepwise poljes are distributed from 950 m down to 50 m above sea level (Figure 2). Underground flows, up to 35 km long, dominate the drainage. Most of these poljes are tectonically controlled, and were developed along reverse faults or overthrusts. All poljes except Mokro are topographically enclosed. In natural conditions all of the poljes flooded periodically. In the rainy season inundation began with the lower poljes, and the highest poljes are the first to dry up.

Popovo Polje is a special karst landform (Figure 3). In its upper part, the alluvial cover is only 1–2 m thick, increasing to 15–20 m downstream. To date, more than 500 ponors, estavelles, and temporary springs have been identified in the polje. Temporary springs predominate in the upstream section, estavel-

Dinaride Poljes: Figure 1. Simplified map of the main karst poljes in Bosnia and Herzegovina.

les in the middle, and ponors downstream. Water loss along the 65 km bed of the Trebišnjica River is more than 63 m³ s⁻¹ in the dry season, and the total sinking capacity of the Popovo Polje ponors is more than 300 m³ s⁻¹. The capacity of the largest single ponor (Doljašnica) is over 60 m³ s⁻¹. However, the winter inflow to the polje is substantially greater and may

Dinaride Poljes: Figure 2. Simplified profile from the Gatačko Polje to the Ombla Spring.

exceed 1000 m³ s⁻¹. The highest observed flow was 1362 m³ s⁻¹ on 2 December 1903. Flooding under natural conditions reached a height of 40 m in the lowest section of the polje, and the average yearly flood duration was 253 days. As part of the construction of the Trebišnjica Hydrosystem, 62.2 km of riverbed was covered with shortcrete. Following the excavation of two large tunnels for the hydroelectric power-plant, the floods have practically been eliminated.

The Fatnicko and Dabarsko poljes are developed along one overthrust of Cretaceous flysch on Eocene flysch. The depth of

Dinaride Poljes: Figure 3. Popovo Polje seen in profile, with the flat floor and sharply defined marginal slopes that characterize a true polje. (Photo by Tony Waltham)

limestone paleorelief below the surface is 150–200 m. Annual flooding in the Fatnicko Polje lasts 79–213 days, and the highest water level can be as much as 38 m above the lowest point, Pasmica Ponor, which has an intake capacity of 25 m³ s⁻¹. During the maximum flood, the volume of accumulated surface water is 228 million cubic metres. The largest inflow into the polje is through the ephemeral Obod Estavelle (0–60 m³ s⁻¹), located at the overthrust contact. Dabarsko and Fatnicko poljes are now interconnected by a tunnel 3.2 km in length.

In Nevesinjsko Polje two areas of water storage are formed, one in the northern part and a second, smaller one in the south, in front of Biograd Ponor. This ponor is the terminus of the Zalomka River and has an intake capacity of $110 \text{ m}^3 \text{ s}^{-1}$. The conglomerate deposits beneath the floor of the polje are 800 m thick. The water table in the dry season is more than 350 m below the surface of the polje. It fluctuates through a height range of 300-312 m.

The small Cerničko, Slato, and Lukavačko poljes are developed along a tectonic line where the limestones are overthrust on Eocene flysch. The Ključka River in Cerničko Polje is a good example of karst polje surface flow. The river originates in a large cave at the contact between flysch and limestone, and terminates about 300 m downstream in a ponor that has a recharge capacity of approximately $20 \text{ m}^3 \text{ s}^{-1}$.

Montenegro

Nikšićko Polje is composed of several different geomorphological and hydrological units: the Upper Nikšićko, Krupac, Slano, and Slivlje poljes. The thickness of the Tertiary sediments (clay and sand) over Cretaceous limestone and dolomite is 9–18 m. About 880 ponors and estavelles have been identified in the polje, with 851 of them being located along its southern perimeter. Slivlje Ponor is one of the biggest ponors known, with a sinking capacity of about 150 m³ s⁻¹ in the whole fissure zone, while the maximum capacity of the main opening itself exceeds 100 m³ s⁻¹. In the past 40 years the natural hydrological conditions have been altered enormously by a number of geotechnical projects, including cylindrical dams around ponors, the plugging of karst channels and more than 12 km of grout curtains.

DISEASE

Most caves are healthy places, and most cavers are exceptionally healthy. Nevertheless, during the 20th century it became evident that some diseases are related to particular caves and their inhabitants. However, current concepts of cave diseases have nothing in common with the lurid tales of folklore.

Only in the 1920s was it suspected that local epidemics of rabies in tropical America might be transmitted by troglophilic vampire bats. This was proven a decade later, in Trinidad and in South America (Pawan, 1936; Torres & de Queiroz Lima, 1936, cited by Turner, 1975). Pawan isolated the rabies virus and developed an effective immunization vaccine.

Histoplasmosis, a lung disease caused by spores from a fungus, *Histoplasmosis capsulatum*, was next to be identified as a "cave disease". In 1947, an outbreak occurred among an Arkansas group that had explored an abandoned underground quarry. The first reports (e.g. Washburn, Tuohy & Davis, 1948) called it "cave sickness". It quickly entered speleological awareness (e.g. Halliday, 1949). Soon it emerged as a newly recognized disease of many parts of the world, both above and below ground. Small epidemics were identified in Mexico, Jamaica, parts of South Africa, Canada, and elsewhere. A few deaths have been reported. One conspicuous fatality was a British caver treated with high doses of steroids (John Frankland, personal communication, 2001).

Later, several cavers in Barbados and elsewhere developed a type of infectious jaundice called leptospirosis or Weil's disease. The infection is carried in rat urine, and cases have developed from contact with infected water in some caves in Barbados, Guam, the United Kingdom, the Irish Republic, and several other countries, especially in the tropics. The causative organism is endemic in rat populations worldwide.

In addition, a common but trivial disease of dusty caves was identified: cave dust pneumonitis or alveolitis. Its principal importance is as a warning that more serious lung disease may also be developing, with a longer incubation period.

With the vast expansion of 20th-century speleology, it became apparent that a host of other diseases may be acquired in caves, but the existence of the cave is relatively unimportant in their transmission. Some of these are the result of unusual cave environments, including but not limited to: mountain sickness in high-elevation caves, hypothermia (including frostbite), hyperthermia, hydrogen sulfide poisoning, and possibly nitrogen dioxide poisoning (silo filler's disease). Some authorities might include diseases resulting from the hazards of cave diving and the bites of poisonous snakes, some of which occasionally penetrate considerable distances into caves. Hydrogen sulfide poisoning in the rare caves with a high level of this chemical, and anoxic brain syndromes resulting from over-long exposure in hypoxic "bad air" caves are the only diseases in this group which are specific to caves. The controversy about radon in caves is discussed below and in a separate entry.

Additional diseases are related to pollution and/or contaminated water, in caves and elsewhere. Human pathogens in groundwater are discussed in the entry on Groundwater Pollution: Dispersed. Chronic carbon monoxide poisoning can result where vehicle exhaust fumes are permitted to enter caves. Poison-ings by hydrocarbons, heavy metals,

radioactive wastes, pesticides, and herbicides may occur as a result of unlawful disposal in dolines, pits, or cracks.

In dry caves, nests of rodents and birds carry a threat of several acute infectious diseases and should be avoided. These include plague, tularemia, hantavirus, Lassa and related haemorrhagic fevers, psittacosis, and possibly rabies (the incidence of rabies in rodents apparently is greatly underestimated). If the nest is moist with rat urine, it may contain the leptospirosis organism. Hantavirus, Lassa and related haemorrhagic fevers, however, occur primarily in parts of the world with few caves. Contrary to a recent best-selling book (Richard Preston's *Hot Zone,* 1995), the Ebola virus is not cave-related (it was briefly suspected in Kenya's Kitum Cave but this cave was reopened as a tourist attraction even before the book was published).

In addition to histoplasmosis, the fungi causing several other pulmonary diseases are at least potentially present in cave dust. These include coccidioidomycosis (San Joaquin Valley fever and its South American variant), cryptococcosis, actinomycosis, blastomycosis, aspergillosis, nocardiosis, and others. Cryptococcosis is especially likely in the presence of pigeon droppings. This group of diseases is a particular problem to persons with AIDS or other impairments of the immune system, and is rarely if ever seen in other cavers. In theory, another related hazard is the presence of some strains of atypical tuberculosis organisms in some soils.

Bites and stings of insects, spiders, and scorpions are of some concern, especially in the entrance zones of caves in areas where a known problem exists. The commonest effects of these are acute anaphylactic reactions to bee, wasp, or hornet stings, just as on the surface. Black widow spider bite is a regional American problem, sometimes presenting with findings suggestive of an acute abdominal catastrophe. Its diagnosis and treatment are more complicated than generally recognized, but fatalities are now rare. The bite of brown recluse spiders is also a regional American problem, but fortunately uncommon in caves. In addition to an acute systemic reaction, a subsequent necrosis of large areas of skin and muscle may result. Danger from scorpion sting is highly speciesspecific. A dangerous species occurs in the southwestern desert of the United States, and others exist in the Middle East and perhaps central Asia. In the United States, deaths now are rare. Danger from centipede sting is also speciesspecific. Some in Japan are said to be especially dangerous. The toxin exuded by millipedes is highly irritating to the eyes if rubbed after handling them.

A long list of serious diseases is transmitted by the bite of ticks, mosquitoes, and tsetse flies. All these vectors are occasionally found in the entrances of caves (and sometimes deeper, as in the case of ticks in some bat caves). But transmission of these diseases rarely if ever occurs in caves, so they are omitted here. Reduviid bugs (kissing bugs), however, not only transmit Chagas disease (a form of trypanosomiasis), but also cause some serious anaphylactic reactions. Cavers thus should use special caution when camping in dry caves in areas where they exist (e.g. the southwestern United States and some parts of Mexico). In a few parts of the world, botflies (and possibly a few related flies also occasionally found in cave entrances) not only bite their victims but lay eggs which hatch in the wound.

In addition to anaphylactic reactions to bee, wasp, hornet, or reduviid bug bites and stings, cavers are at risk from at least two hypersensitivity diseases: "Farmers' lung", caused by a thermophilic actinomycete, and avian protein anaphylaxis. These appear to be only theoretical risks.

Prolonged wetting can cause serious problems. The worst is immersion foot, which is a particular problem for caving expeditions in Sarawak and elsewhere in the tropics, despite well-planned precautions. Another is semi-humorously called "Kazumura crud". It has the form of small festering blisters of the chest and abdomen, seen after prolonged crawling in moist slimy caves in Hawaii.

Histoplasmosis is primarily an acute infection of the lungs. It becomes symptomatic a few days after exposure. In most children and some adults it is so mild that it is thought to be merely a"chest cold", but X-rays show an alarming pattern of small spots throughout both lungs, virtually identical to a rapidly spreading form of tuberculosis. Other patients with similar X-ray findings are acutely ill for several days and recover only gradually. Still others remain ill for months. A very few—especially those with compromised immune systems—develop serious complications: small abscesses in many parts of the body, dense infiltrations around the heart and base of the lungs which impair the circulatory system, or eye symptoms. The latter appear to be immunological reactions. A single attack provides at least limited immunity in most victims, but multiple infections have occurred in some cavers. The most publicized epidemics are those from caves, but the disease occurs widely in many parts of the world, both above and below ground. Its organism grows especially well in bat and bird droppings.

Outside the range of vampire bats, medical science's picture of rabies has changed greatly in the last century. In some aspects, opinions have changed repeatedly. The course of the disease is not as uniform as once believed, and it must be suspected in any person with an acute inflammatory disease of the brain or related abnormalities of muscle groups and nerves. A few people have now survived what formerly was an entirely fatal disease. Varieties of clinical courses are notably explicated in Brass (1994) which, however, fails to note that one of the two supposed victims of aerosol rabies in the Frio Cave of Texas probably scratched a rash on his neck with infected gloves (Constantine, 1967). Cases have now been found in much of the world without any evident exposure to any rabid animal, and research is seeking additional vectors. Most cases are still transmitted by the known bite of an animal, including insectivorous bats. In the United States, most current cases are caused by strains of rabies virus predominantly found in silver-haired bats, which do not live in caves. American and other cavers frequently come in contact with bats, but none of them have developed rabies. Aerosol transmission of rabies to humans is no longer considered a serious threat, and a recent "undetected bite" hypothesis of rabies transmission by insectivorous bats has become untenable. In 1999 the 29th North American Symposium on Bat Research concluded that there was no credible evidence supporting this concept, and it had "moved from hypothesis to fact without adequate testing". Cavers within the range of vampire bats, and those who must handle bats, should be immunized against the disease. Others should avoid them to the greatest degree possible.

Another concept which "moved from hypothesis to fact without adequate testing" is that of lung cancer from high levels of radon and its products, in caves and elsewhere. The anticipated epidemic of lung cancer in elderly American cavers has not materialized. Not even one excess case of lung cancer has been documented in non-smoking American cavers or employees of show caves. Agency silence about the uncertainty of inferred health risks from radon and its daughter elements (Aley, 2000) has blurred the issue, but clearly, lung cancer is not cave-related.

Perhaps the most bizarre of all cave diseases is acute salamander poisoning, reported only after excessive alcohol consumption. The mortality rate is about 50% (Bradley, 1981; Brodie, 1982). Swallowing enough live millipedes would probably have a similar effect!

DISSOLUTION: CARBONATE ROCKS

To understand the evolution of karst in limestone terrains it is important not only to know how much limestone can be dissolved, but also how fast dissolution proceeds. The first topic is related to the equilibrium chemistry of the system $H_2O-CO_2-CaCO_3$, and the second to its reaction kinetics. The knowledge of dissolution rates in relation to a given geochemical situation is the key to understanding important processes in karst.

Depending on its saturation state, water containing carbon dioxide dissolves or precipitates limestone (CaCO₃) by three elementary chemical reactions, which proceed in parallel (Plummer, Wigley & Parkhurst, 1978). They are:

$$CaCO_3 + H^+ \leftrightarrow Ca^{2+} + HCO_3^{-}$$
(I)

$$2CaCO_3 + H_2CO_3 \leftrightarrow 2Ca^{2+} + 2HCO_3^{-}$$
(II)

$$CaCO_3 + H_2O \leftrightarrow Ca^{2+} + HCO_3^- + OH^-$$
(III)

For undersaturated solutions these cause dissolution rates that are given by the Plummer, Wigley & Parkhurst (PWP) equation, which was confirmed later by Chou, Garrels & Wollast (1989):

$$R = k_1(H^+)_s + k_2(H_2CO_3)_s + k_3 - k_4(Ca^{2+})_s (HCO_3)_s$$
⁽¹⁾

The rate *R* is given in mmol cm⁻² s⁻¹. The brackets denote the chemical activities at the surface of the mineral. k_1 , k_2 , and k_3 , are rate constants of the forward reactions (I)-(III). k4 comprises the corresponding backward reactions (I)-(III) (precipitation) and is therefore dependent on the CO₂ concentration in the solution. Reactions (I)-(III) can be summarized into:

$$CaCO_3 + H_2O + CO_2 \leftrightarrow Ca^{2+} + 2HCO_3^{-}$$
(IV)

Thus one molecule of CO_2 is consumed to dissolve one $CaCO_3$ unit. To react with $CaCO_3$, carbon dioxide must be converted to carbonic acid, H_2CO_3 , and to H+and HCO_3^-

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$
(V)

The first reaction is slow (Usdowski, 1982). It takes several seconds to several minutes depending on the pH of the solution and the temperature—until it comes to chemical equilibrium. Therefore conversion of CO_2 to H_2CO_3 plays an important role in the effective dissolution rates. When a solution of volume V interacts with limestone rock of reactive surface area *A*, the number of CO_2 molecules converted per unit time into H_2CO_3 must be equal to the number of $CaCO_3$ units released during this time:

$$V \times (d[CO_2]/dt) = A \times R$$
⁽²⁾

If the ratio V/A is sufficiently small, slow conversion of CO_2 becomes rate limiting. The Ca^{2+} and CO_{3}^{2-} ions released from the surface of the mineral must be transported away into the bulk of the solution by molecular diffusion. On the other hand, CO₂, H₂CO₃, and H⁺must migrate from the bulk to the mineral's surface. Schematics of these processes are shown by Figure 1. Dashed lines symbolize diffusional transport, and solid lines indicate chemical reactions. Due to diffusional transport, concentration gradients build up such that the concentrations in the bulk are different from those at the mineral surface. Therefore equation 1 must not be used to calculate the rates by inserting bulk concentrations. The correct rates have been obtained by involved models (Buhmann & Dreybrodt, 1985a, b; Dreybrodt & Buhmann, 1991), taking into account the PWP equation, conversion of CO_2 , and diffusion. It turns out that the rates not only depend on the chemical composition of the solution but also on its hydrodynamics and the ratio V/A. Figure 2 shows typical results for a water layer with depth δ and stagnant or in laminar flow, which covers a plane surface of limestone ($\delta = V/A$ is given in cm on the curves). The solution is in equilibrium with an atmosphere containing CO_2 at a partial pressure $pCO_2 = 5 \times 10^{-3}$ atm. The dissolution rates are plotted against the calcium-concentration in the solution. Note: 10^{-8} mmol cm⁻² s⁻¹ corresponds to a retreat of bedrock by 1.17×10^{-2} cm a⁻¹. For very thin films $\delta < 5 \times 10^{-3}$ cm, the rates increase linearly with δ at a constant calcium concentration. This is the region where CO_2 conversion is rate limiting. For 5×10^{-3} cm $< \delta < 5 \times 10^{-2}$ cm the rates are only slightly dependent on δ . In this region both CO₂ conversion and diffusional mass transport control the rates. For $\delta > 5 \times 10^{-2}$ cm the rates drop with δ because mass transport takes over. The rates are then given by (Dreybrodt, 1988):

$$R = \alpha_{\lim} (c_{eq} - c)/(1 + \alpha_{\lim} \delta/3D)$$
⁽³⁾

where c is the actual concentration in mmol cm^{-3} and c_{eq} is

Dissolution: Carbonate Rocks: Figure 1. Schematic diagram of chemical reactions and transport during dissolution.

Dissolution: Carbonate Rocks:

Figure 2. Dissolution rates in dependence of the Ca-concentration. A water film of depth δ either stagnant or in laminar flow covers a plane surface of calcite. δ is given in cm at the corresponding curve.

the equilibrium concentration of Ca with respect to calcite. The c_{eq} depends on the CO₂ concentration in the solution. The α_{lim} is the average slope for the curve with δ =1×10⁻² cm; *D* is the coefficient of diffusion. The uppermost curve depicts maximal dissolution rates, which occur in fully turbulent flow with δ >10 cm, when CO₂ conversion is not rate limiting and the constant of diffusion due to eddies is higher by four orders of magnitude compared with the laminar flow. In this case rates are given by the PWP equation.

The significant influence of CO_2 -conversion to dissolution and to precipitation rates has been shown by experiment. The enzyme carbon-anhydrase (CA) catalyses this reaction so effectively that even at µmolar concentrations the CO_2 conversion is effected instantly. Consequently, dissolution or precipitation rates are significantly enhanced upon addition of CA to the solution (Dreybrodt *et al.*, 1996, 1997). When flow is turbulent the bulk becomes completely mixed and is separated from the mineral surface by a diffusion boundary layer (DBL). Mass transport into the bulk by molecular diffusion must then be effected through this layer. Its thickness ϵ depends on the hydrodynamic flow conditions. Figure 3 depicts the dissolution rates for a turbulent layer with depth δ of 1 cm for different values of the thickness ϵ of the DBL. For $\epsilon=0$ the rates are maximal and entirely surface controlled. Since in this case the bulk concentrations of all species are equal to their surface concentrations, the rates can be obtained from the PWP equation. With increasing thickness of ϵ the rates drop and become almost independent of ϵ at values between 0.01 cm < ϵ < 0.03 cm. (Dreybrodt & Buhmann, 1991). All theoretical models have been verified experimentally (Dreybrodt *et al.*, 1996; Liu & Dreybrodt, 1997).

When water is flowing in fractures the CO_2 cannot be replenished and is therefore consumed during dissolution. This can be modelled by a solution contained between two parallel planes

ϵ of the DBL. The rates decrease with increasing ϵ .

with a distance 28 (Buhmann & Dreybrodt, 1985b). The results are similar to those shown above.

In all cases the dissolution rates can be approximated with an accuracy of about 10% by:

$$R = \alpha \left(c_{\rm eq} - c \right) \tag{4}$$

The rate constant a is in the order of 10^{-5} cm s⁻¹. It depends on temperature, *p*CO₂ in the solution, the value *V/A*, flow conditions and whether the system is open or closed with respect to CO₂. Values of a are reported by Buhmann & Dreybrodt (1985a, b), Dreybrodt (1988) for laminar flow, and for turbulent flow by Liu & Dreybrodt (1997). They can be used to estimate rates for many geological situations in karst (see Erosion Rates: Theoretical Models). Equation 4 is also valid for porous carbonate media with average pore diameter *d* (Baumann *et al.*, 1985), provided that δ is replaced by *V/A*=0.15*d*.

Close to equilibrium at concentrations c_t , inhibition of dissolution occurs for natural calcium carbonate minerals. The rates are then given by:

$$R = k(1 - c/c_{eq})^{n}, c \ge c_{t}$$
⁽⁵⁾

where *n* is about 3 to 6 and c_t about 0.8 c_{eq} , depending on lithology and the chemical composition of the rock (Svensson & Dreybrodt, 1992; Eisenlohr *et al.*, 1999). Due to this nonlinear behaviour the rates drop dramatically in comparison to those from equation 3. Therefore in this region the rates are controlled entirely by the surface reaction slowed down by inhibition, and consequently *k* does not depend on *V/A* and flow conditions, in contrast to the region of linear kinetics. This is of utmost importance in the early state of conduit evolution where water flows in narrow fractures with aperture widths of several tenths of a millimetre. The dissolution rates are then given by a linear

Dissolution: Carbonate Rocks: Figure 4. Switch to nonlinear kinetics. The dashed line shows the continuation of the linear rate law.

rate law which switches to nonlinear kinetics at c_r . Figure 4 depicts these rates as a function of c. The drastic reduction of the rates and their nonlinear behaviour are the key to understanding the initial evolution of karst conduits (see Speleogenesis: Computer Models).

Dolomite, MgCa(CO₃)₂, dissolves by three parallel reactions involving H+, H₂CO₃, and H₂O, but due to the structure of two-component carbonates the chemical reactions at the surface are far more complex. Busenberg & Plummer (1982) have suggested a rate law, valid for surface-controlled reactions far from equilibrium.

$$R^{\rm D} = k_1^{\rm D} ({\rm H}^+)_{\rm s}^{1/2} + k_2^{\rm D} ({\rm H}_2 {\rm CO}_3)_{\rm s}^{1/2} + k_3^{\rm D} - k_4^{\rm D} ({\rm HCO}_3)_{\rm s}$$
⁽⁶⁾

In contrast to calcite, the reactions with H^+ and H_2CO_2 exhibit rate terms with a reaction order n = 1/2, owing to complex processes at the surface. Since dolomite cannot crystal-

Figure 5. Comparison of the dissolution rates of calcite, dolomite, and magnesite (Chou, Garrels & Wollast, 1989).

lize from the solution, dissolution is irreversible and therefore equation (6) is not complete. The back-reaction term has been interpreted to result from HCO_3^- ions adsorbed at the surface and inhibiting dissolution. Chou, Garrels & Wollast (1989) found a similar rate law. The rates for dolomite at the same total hardness and pH of the solution are one order of magnitude smaller than for limestone. Figure 5 shows the experimental results of Chou, Garrels & Wollast, which compare the rates of dolomite dissolution with those of calcite at various pH-values, whereby total hardness of calcite and dolomite solutions are equal. Due to the much lower rates of dolomite dissolution, it also seems likely that in natural environments dissolution is surface controlled, or at least conversion of CO_2 and mass transport play a less important role as compared to calcite. However, investigations concerning this have not yet been reported.

Magnesite (MgCO₃) as a one-component carbonate shows the same reaction pattern as calcite, and therefore the rates are described by equation 1. The rate constants, however, are lower by about two orders of magnitude (Chou, Garrels & Wollast, 1989). Figure 5 shows the experimental rates in comparison to dolomite and calcite.

DISSOLUTION: EVAPORITE ROCKS

Evaporites can form karst scenery, for example, gypsum or anhydrite karst covers large areas in the Ukraine, the United States, and Europe. Salt karst is observed on salt diapirs in arid climates (see Evaporite Karst).

To understand the processes in the evolution of karst in evaporite rocks, it is necessary to know the kinetics of dissolution as well as the equilibrium chemistry of the aqueous solutions involved. All evaporites dissolve by detachment of the ions constituting the crystal lattice and by diffusional mass transport from the surface into the solution. In contrast to carbonate rocks, no further chemical reactions complicate the kinetics of dissolution.

The most common evaporite is gypsum (CaSO4·2H2O), which in an aqueous solution dissolves rapidly, with initial rates of dissolution being roughly several 10 mmol cm⁻² s⁻¹. Its equilibrium concentration c_{eq} with respect to calcium at 20°C in pure water is 15.3×10^{-3} mmol cm⁻³. Note that a dissolution rate of 10^{-5} mmol cm⁻² s⁻¹ corresponds with a retreat of the bedrock by 2.3 cm per year. Using rotating disc experiments, Jeschke, Vosbeck & Dreybrodt (2001) found that the surface reaction rates are given by:

$$R_{\rm s} = k_{\rm s}(1 - c_{\rm s}/c_{\rm eq}) \tag{1}$$

where c_s is the Ca concentration at the surface and $k_s=1.1 \times 10^{-4}$ mmol cm⁻² s⁻¹. The Ca²⁺ and SO₄²⁻ ions released from the mineral are transported away from the surface into the solution by molecular diffusion. Therefore concentration gradients exist and the surface concentration differs from that in the bulk. The transport rate RD is given by:

$$R_{\rm D} = k_{\rm D} (1 - c_{\rm B}/c_{\rm eq})$$
⁽²⁾

where k_D is the transport constant and c_B is the concentration of the bulk solution. Since, by mass conservation, R_S must be equal to R_D , one finds an effective rate law.

$$R = k_{\rm eff}(1 - c_{\rm B}/c_{\rm eq}), \ k_{\rm eff} = (k_{\rm s} \times k_{\rm D})/(k_{\rm s} + k_{\rm D})$$
(3)

When $k_s >> k_D$, k_{eff} becomes close to k_D and rates are controlled by diffusion. On the other hand if $k_s << k_D$, k_{eff} becomes k_s and the rates are surface controlled. The region where k_s and k_D are of similar magnitudes is called mixed kinetics. When water flows are laminar in a film of thickness, δ , k_D is given by

$$k_{\rm D} = 2D \ c_{\rm eq}/\delta \tag{4}$$

(see Beek & Muttzall, 1975) where *D* is the coefficient of diffusion $(10^{-5} \text{ cm}^2 \text{ s}^{-1})$. For $\delta = 1 \text{ mm}$ one obtains $k_D = 3 \times 10^{-6} \text{ mmol cm}^{-2} \text{ s}^{-1}$ and the rates are controlled by diffusion.

When water flows turbulently the completely mixed bulk with concentration $c_{\rm B}$ is separated by a diffusion boundary layer of thickness ε from the surface of the mineral.

Mass transport proceeds by molecular diffusion through this layer. In this case the transport constant is given by:

$$k_{\rm D} = D c_{\rm cq}/\epsilon \tag{5}$$

 ϵ depends on the velocity of the flow and its geometry (e.g. flow in films with a free surface, flow in conduits) and decreases with increasing velocity in a complex manner (Beek & Muttzall, 1975). In natural situations ϵ varies between 10^{-2} cm and 10^{-1} cm (see also Dissolution: Carbonate Rocks). Therefore k_D becomes dependent on flow velocity and consequently also k_{eff} . This has been observed by James (1992) for gypsum and anhydrite.

In surface streams, gypsum dissolution rates between 1.5×10^{-5} and 5×10^{-5} mmol cm⁻² s⁻¹ have been observed, with the highest rates at the highest velocities (Navas, 1990). These rates are lower than k_s by about a factor of ten and are limited by diffusion across a boundary layer with $\epsilon \approx 10^{-2}$ cm.

Close to equilibrium at about 0.94 c_{eq} , and only in natural materials, the rate law switches, in a similar way to that in limestone, to higher order kinetics:

$$R = k_n (1 - c/c_{\rm eq})_n, c \ge 0.94 c_{\rm eq}$$
⁽⁶⁾

where $k_n=3 \text{ mmol cm}^{-2} \text{ s}^{-1}$ and n=4.5. Figure 1 shows

Dissolution: Evaporite Rocks: Figure 1. Surface-controlled rates as a function of Ca concentration.

a plot of log *R* versus $log(1-c/c_{eq})$ for the experimental rates obtained in a batch experiment for selenite (Marienglas) (Jeschke, Vosbeck & Dreybrodt, 2001). Note that
the concentrations increase from right to left. At low concentrations the linear rate law is represented by the straight line with slope $n_1 = 1.0$. At $c=0.94 c_{eq}$ the curve bends down into a steeper straight line with slope $n_4=4.5$. This region represents the nonlinear kinetics where, due to the inhibition of dissolution, the rates are controlled by surface reaction. Similar results have been obtained for alabaster and gypsum rock. This nonlinear behaviour is of utmost significance in the evolution of karst conduits (see Speleogenesis: Computer Models).

James (1992) has reported effective rate constants lower by a factor of ten in an experiment where transport control dominates (see equation 3).

Anhydrite (CaSO4) is an evaporite rock with a higher thermodynamic equilibrium concentration c_{eq} =23.5 mmol 1⁻¹ at 10°C compared with gypsum's 14.4 mmol 1⁻¹. When anhydrite dissolves, the solution can become supersaturated with respect to gypsum, but remains still aggressive to anhydrite. Consequently, gypsum is precipitated until all the anhydrite is converted. Therefore dissolution rates can only be measured at concentrations below gypsum saturation. Experiments revealed the rate law:

$R = k(1 - c/c_{eq})4.5, \ k = 6 \times 10^{-6} \ \text{mmol cm}^{-2} \ \text{s}^{-1}$ (7)

The initial rates are lower by a factor of 20 compared with gypsum, and are surface controlled (equation 1). These results are in contrast to the observations of James (1992), who reports a rate law with n=2. In his experiments, however, the hydrodynamic conditions were poorly defined, and both surface rates and diffusion controlled the dissolution rates. It should be pointed out that this must be considered for each natural situation.

To compare the dissolution kinetics of anhydrite with those of gypsum, Figure 2 shows the evolution of Ca concentration

Figure 2. Comparison of the evolution of concentrations of gypsum and anhydrite. The inset shows the first 0.6 hours.

in a batch experiment with gypsum particles of 550 μ m size in comparison to anhydrite particles of the same size in an identical experimental set-up. From such experiments the rate laws shown above are obtained. The experiment shows the much smaller increase of concentration for anhydrite.

The most soluble evaporite rock is rock salt with $c_{eq}=5.4 \text{ mol } 1^{-1}$. Alkattan *et al.* (1997), using the rotating disc technique, have obtained a linear rate law with $k_s=6.7\times10^{-1}$ mmol cm⁻² s⁻¹. This extremely high rate constant in practically all cases of x interest is large compared with transport constants k_D , and the dissolution of rock salt is controlled by diffusion. One extreme case, however, has been observed at extremely high floods in the salt caves of Mount Sedom, Israel, with a bedrock retreat of 0.2 mm s⁻¹ (Frumkin & Ford, 1995). This is close to the maximal value of 0.17 mm s⁻¹ derived from the value of Alkattan *et al.* (1997).

DISSOLUTION: SILICATE ROCKS

Quartz

The dissolution of quartz in water is essentially a simple process involving the formation of silicic acid by hydration (see Dove & Rimstidt, 1994, for more details):

$$SiO_2$$
 (s) + $2H_2O$ = H_4SiO_4 (aq)

where the equilibrium constant at 25°C is:

$$K = \alpha H_4 SiO_4 (aq) = 1.1 \times 10^{-4}$$

Silicic acid (H₄SiO₄) is a very weak acid, barely ionically dissociated under normal karst conditions, and its solubility is low, being constant at about 10 mg 1^{-1} . At pH values above nine, however, the quartz solubility increases markedly, due to the following ionic dissociation:

 $H_4SiO_4 (aq) = H_3SiO_4 - H^+$

This highly alkaline condition is generally unusual in the karst environment, with the exception of rare cases.

Some authors (see references in Martini, 2000) have suggested that complexation of silicic acid with organic acids may increase the solubility of quartz, but mainly at basic

pHs. Because such high pH values have not been observed in the dominantly acidic waters of quartzite karst, this effect is probably negligible, as supported by the low (<10 mg 1^{-1}) silica concentration in these waters.

Another important aspect to consider is the extremely slow rate of quartz dissolution, which is 10^{-17} moles cm² s⁻¹ at 25°C, and is entirely controlled by the rate of bond breaking and hydration of silica on the crystal surface. In the field this is exemplified by the high resistance of this mineral to weathering. The dissolution rate is considerably increased in the presence of organic acids, up to 10-15.5 moles cm² s⁻¹. The latter conditions are encountered in the organic-rich waters of quartzite terrains, and may play a role in karst development.

At 25°C the rate of quartz crystallization is also very slow, as exemplified by the evaporation of water containing silica, which is then not deposited in the form of quartz. During this process, the silica concentration can rise to several hundred mg 1^{-1} , i.e. well above quartz solubility. In this range of high supersaturation, silica occurs dominantly in the form of polymers, such as H₆Si₂O₇, which was present in negligible quantities in the field of quartz undersaturation. Evaporation to dryness leads to the deposition of silica in an amorphous form, which is more or less hydrated (opal), and this later slowly decays into lowcristobalite or tridymite, and eventually to quartz. These silica polymorphs form preferentially due to their rates of deposition, which are higher than those for quartz. The deposition of amorphous silica is illustrated by the formation of opal popcorn in caves and at the surface, and the deposition of silcrete in semiarid climates.

The very slow rate of quartz dissolution is the main factor controlling the speleogenesis of quartzite caves. As groundwater can remain undersaturated in silica, with respect to quartz, for a very long time, it is able to weather the rock penetratively by enlarging crystal junctions. Consequently, the quartzite loses its cohesion, and becomes friable and amenable to the formation of caves by piping, i.e. by the mechanical removal of quartz grains. Speleogenesis therefore starts by an initial phase (dissolution, forming karst), followed by a second phase (piping or pseudokarst) (see Pseudokarst; Piping Caves and Badlands Pseudokarst).

Minor cavities formed by a dissolution process comparable with the speleogenesis in limestone, gypsum, etc., i.e. dominantly by dissolution, have also been observed in quartzite. Cavities of this type are rare, and form at depth by a hydrothermal process at temperatures of several hundred degrees centigrade, or under conditions of very high pH. The rate of dissolution and the solubility of quartz are much higher in this environment, which explains the nature of these cavities.

Silicate Minerals

In contrast to quartz, the dissolution of silicate minerals is more complex. Silica produces the same non-ionic species below pH 9, but the cations—commonly K^+ , Na^+ , Ca^{2+} , Mg^{2+} , Fe^{2+} , Fe^{3+} , and Al^{3+} —form more ionically dissociated species, especially the monovalent and divalent ions. Since H^+ is fixed in nondissociated silicic acid, OH^- is produced to balance the cations, thus generating alkaline solutions. Therefore, under the chemical and physical conditions that usually prevail in the weathering zone, in contrast to quartz, the solubility of silicate minerals is strongly dependent on the pH: from neutrality the solubility increases in proportion to the acidity. Furthermore, the dissolution of most rock-forming silicates is complex and incongruent, i.e. it involves the subsequent formation of intermediate phases. The latter consist generally of minerals containing trivalent cations, like clay minerals, and aluminium and ferric hydroxides, which precipitate close to neutrality. These minerals do not form in extreme acidic or alkaline domains, where the dissolution is then congruent. An example is the dissolution of K-feldspar, which is a common rock-forming mineral:

$$KA1Si_{3}O_{8}(s) + 8H_{2}O = K^{+} + Al^{3+} + 3H_{4}SiO_{4} (aq) + 4OH^{-}$$

Near neutrality, at room temperature, the solubility is a few mg 1^{-1} , but increases to several hundred mg 1^{-1} at pH values below four. Below this pH the dissolution is congruent, but above it kaolinite [Al₂SiO₅(OH)₄] forms, which later decays into gibbsite [Al(OH)₃]. In the pH domain of low solubility, at 25°C, as for quartz, the dissolution rate is sluggish, i.e. $10^{-15.5}$ moles cm² s⁻¹.

Although small stream-caves have been reported in granite, the weathering of silicate rocks is less conducive to speleogenesis than that of quartzite, possibly due to the formation of clay minerals as micaceous particles that tend to clog the joints within the rock. Moreover, because silicate dissolution generally leads to oversaturation of silica with respect to quartz, in quartzite its presence as impurities may prevent the dissolution of the latter mineral. This delay in the dissolution of quartz may last for as long as the silicate minerals have not been leached out. Low-pH waters (<4) that have leached aluminosilicates then precipitate allophane (an amorphous hydrated Al-silicate) speleothems by evaporation or a fall in acidity due to the oxidation of organic acids and the release of CO₂.

DIVING IN CAVES

Water is an essential agent in the formation of most limestone caves and many systems are still in a stage of development at which some parts remain permanently submerged. The desire to explore such underwater sections of cave passage is almost as old as recreational caving itself. A significant number of conventional cavers regard those who wish to dive into these dark flooded tunnels as the lunatic fringe. However, determined individuals who make the financial and time commitments to learn how to operate safely in this so-called "merciless environment", will experience one of the greatest opportunities for original exploration on Earth. The evolution of cave diving techniques has closely followed the development of diving equipment in general. Indeed, cave divers have contributed to the latter many times. This entry briefly reviews over 200 years of underwater achievements by many generations of cave explorers. It is inevitably only a summary of various milestone events from around the world; greater detail is available in Farr (2000), which provides essential reading.

Perhaps the first documented attempt to pass a section of underwater passage (or "sump") took place in 1773, at Peak Cavern in England. Mr Day tried to pass the Buxton Water Sump by holding his breath. He soon got into difficulty and was pulled from the water, on the verge of drowning, by one of the surface party who managed to catch hold of his arm. The explorer was (we are told) "speechless for some time". It has thus been observed that the event might also be considered as the first cave diving rescue! (Note that the earliest documented rescue attempt in a cave, by an equipped diver, probably took place in Austria's Lurloch in 1894.) A far more celebrated (and happily successful) free diving attempt occurred in 1922 when the French explorer Norbert Casteret passed a short sump in the Grotte De Montespan (French Pyrenees). He discovered a dry cave system beyond, which contained important archaeological remains; the scientific potential of cave diving was thus recognized some 80 years ago.

Very few explorers had access to the early brass-helmeted "Standard Diving Equipment", but some notable explorations did take place. The deep Fontaine De Vaucluse (France), the typical example of a "vauclusian resurgence", was explored to 23 m depth by Nello Ottonelli in 1878 (Cousteau, 1953). Two years later, Alexander Lambert (of Seibe Gorman Ltd) made some outstanding dives in the (artificial) flooded Severn Tunnel (England). Although not strictly cave diving, his 300 m penetration certainly revealed the possibilities of the Standard Equipment and early "Fleuss" oxygen rebreather used (the latter efficiently recycling the exhaled gas). Another notable early use of Standard Equipment took place at Le Creugenat (Switzerland), where a 95 m sump was successfully passed in 1934.

Traditionally, in the United Kingdom, cave divers were ordinary cavers who learned to dive in order to pass flooded sections to discover further "dry" cave passages. (Note that this is in marked contrast with other parts of the world, such as Florida, where most practitioners are divers first, then extend their activities to underwater cave visits.) In 1934, Jack Sheppard used a home-made respirator in Swildon's Hole, possibly the first successful use of "self contained underwater breathing apparatus" (SCUBA) to pass a sump (Balcombe *et al.*, 1990). The advantage of such equipment is that the diver is no longer reliant on a link with the surface for his breathing air supply. However, early

SCUBA was not very reliable and exploratory work shortly afterwards (Balcombe, 1935) at Wookey Hole (England) still used Standard Equipment to "bottom walk" along the submerged course of the River Axe. On one notable dive, Graham Balcombe made the first ever live diving TV broadcast from inside his brass helmet, at Wookey in 1935. Those involved in these early UK explorations later formed the Cave Diving Group in 1946, one of the first non-military diving organizations in the world.

Of great significance to underwater exploration globally was the invention of the "Aqualung" in 1943, by Emile Gagnan and Jacques Cousteau. This was the first reliable "open circuit" SCUBA and for many cave dives, it still remains the most appropriate equipment. Although providing less total duration than "closed circuit" rebreathers, the Aqualung was lightweight, robust, and easy to transport through awkward cave passages. Cousteau's "Undersea Research Group" was also largely responsible for the widespread acceptance of free swimming with fins (as opposed to the bottom walking traditionally associated with the Standard Equipment). In 1946 they exploited their new equipment in a well-planned attempt to pass the Vaucluse sump. Unfortunately, the only way on was downwards; they reached a depth of over 60 m but almost died in the attempt due to carbon monoxide poisoning caused by a compressor fault (Cousteau, 1953). Significant explorations were also made soon afterwards in France, at Font Estramar and the Fontaine Des Chartreux; among those involved were Guy De Lavaur, plus Undersea Research Group members Farges and Morandiere. Elsewhere in France, Jean Alinat of the same team, successfully passed a 150 m long flooded section in the Gouffre Des Vitarelles.

The Aqualung helped many other countries develop their cave diving skills in the years following, one good example being the series of deep dives in the early 1950s at Florida's Wakulla Springs (United States). A few years later, the use of the Aqualung had spread to Australia, where underwater caves in the Mount Gambier and Jenolan regions were being explored. In the United Kingdom, postwar developments took a different direction as cave divers initially exploited the relatively easily available frogman's equipment (rebreathers and drysuits), rather than the Aqualung. Of particular note were Bob Davies' dives in Buxton Water Sump (Peak Cavern, England). Many observations of water levels in a "torricellian" airbell here prompted the publication of perhaps the first serious scientific paper, documenting work where scientific research (as opposed to cave exploration) was the main motive for cave diving (Davies, 1950).

From these early foundations, the list of increasingly audacious and successful cave diving explorations around the world grew exponentially in the 1960s, 1970s, and 1980s. Many major advances were made, particularly in the United States and in Europe, including the United Kingdom. The lightweight Aqualung proved ideal for exploration of remote underground sites, such as the downstream sumps of the Gouffre Berger in France, where Ken Pearce's UK team made notable progress on their expedition of 1963. The psychological barrier of being a long way from the nearest entrance was overcome, as witnessed by explorations at the Trou Madame, Emergence Du Ressel, Doux De Coly, and Fontaine Saint-Georges resurgences (France); The Blautopf (Germany); Keld Head (England); and Manatee Springs, Cathedral Canyon, and Wakulla 1987 project (United States). The great underwater systems of Australia's Nullarbor Plain and the submerged lava tube of Lanzarote's Atlantida Tunnel were pushed for impressive distances. Significant dives began to be performed in the Former Soviet Union, where the potential

for large flooded cave systems was widely recognized. In the Bahamian Blue Holes, the early work of pioneers, such as George Benjamin, was followed up by various teams coordinated by Rob Palmer, who carried out much underwater scientific work (Palmer, 1989). The above are but a few examples, taken almost at random, from the extensive record of a superb era of exploration (Farr, 2000).

The other barrier, which was gradually overcome during the above period, was that of depth. Many French and Swiss systems explored were both deep and long, and certain explorations took deep diving to the absolute limits. The descents of Claude Touloumdjian and Jochen Hasenmayer (to depths of 143 m and 205 m, respectively) at Vaucluse, were outstanding, as was the Nacimiento Del Rio Mante (Mexico) dive to a depth of 267 m in 1989 (Exley, 1994). In the United Kingdom, Martyn Farr was the first person to take deep cave diving seriously; his 60 m deep exploration (1982) at Wookey Hole was significant (given the cold water and low visibility of British sumps) as was Rob Parker's 1985 push to a depth of 68 m here. Many of the above sites could not have been explored to such limits without the adoption of various synthetic breathing mixtures, in particular those based on the physiologically inert gas helium.

The 1990s have seen further advances at many of the sites mentioned above and elsewhere. Cave divers have made full use of advanced decompression software, multiple underwater scooters, the latest mixed gas rebreathers, underwater habitats (artificial gas-filled chambers for "dry" decompression stops) and submersible dive computers. Some recent ultra-long dives include the Woodville Karst Plain Project (WKPP) team's 4298 m penetration at Chip's Hole (United States) in 1996 and also Olivier Isler's 4352 m Doux De Coly (France) exploration of 1998 (since extended to 5000 m by a German team). Both of these are major achievements, particularly in view of the significant depth of much of the passages. However, the WKPP's 5506 m dive into Wakulla Springs (United States) in 1998, at an average depth of 87 m, represents a phenomenal technological advance.

Of particular note was a small British team's extension of the French Emergence Du Ressel underwater system. The first sump (1995 m long and 80 m deep) was not passed until 1990, by Olivier Isler. However, in the second half of the 1990s, Rick Stanton and Jason Mallinson, in collaboration with Germany's Reinhard Buchaly, achieved a total penetration (in Sump 5) of over 3000 m. Unlike most of the expeditions referred to above, which had massive budgets, the most recent Ressel explorations were done quietly by a group of enthusiasts without major financial backing, in what has been described as "a triumph of adventure over technology". Conversely, most UK divers, whilst never achieving "record" lengths or depths on a world scale, have continued to develop specialized techniques for use at home. In the United Kingdom, the 1990s was the decade when underwater civil engineering skills were perfected, perhaps best exemplified by the extensive submerged excavations at Malham Cove Rising.

Diving in Caves: Diving in Joint Hole, Yorkshire. Note the roof scallops. (Photo by John Cordingley)

Throughout the last decade, the worldwide quest for ultimate depth has continued. In 1997, Pascale Bernabe reached a depth of 240 m in the Fontaine De Vaucluse (France) whilst Jim Bowden and Sheck Exley's deep explorations of 1993 and 1994, at Zacatón cenote in Mexico, attained a depth of 276 m. Exley, who was arguably the world's greatest cave diver, was sadly killed on this project. The deepest recorded cave dive, however, took place in South Africa, where Nuno Gomes (following on from an earlier deep dive by Exley) reached the bottom of Bushmansgat in 1996, at an astounding 282 m depth.

Increasingly throughout the 1990s, many very long underwater caves were explored in Mexico's Yucatan Peninsula (see separate entry). Here the water is clear and relatively warm, the passages are often spectacularly adorned with speleothems, and more significantly, the depths are usually minimal. All these factors have led to intense activity here in recent years. Many of these "cenotes" (a Spanish word derived from the Mayan word "dzonot", meaning a well) have been linked to give by far the longest underwater cave systems in the world including Ox Bel Ha system (107 km), Nohoch Nah Chich system (61 km), and the Dos Ojos system (56.7 km). The prospect of joining even these supersystems, to create a single network over 200 km in total length, reveals that cave diving has certainly come of age.

So what of the future? International cooperation on cave diving projects and interchange of ideas will continue to flourish. In recent years, an obvious trend has been the increasing reliance on electronic devices. This will continue in future, although sadly it will also eliminate from the cutting edge all but those with substantial financial resources. The three-dimensional highspeed sonar mapping of Wakulla Springs in 1999 is perhaps a pointer to the widespread use of technology that can be expected. There will be an increased utilization of remotely operated electronic devices, which will collect data about the underwater cave automatically. The French have already made excellent use of such vehicles (e.g. the "Telenaute", "Sorgonaute", and "Modexa") at Vaucluse, to explore beyond the limitations of the human diver. Perhaps one day, most underwater cave exploration will be done by such devices and there will no longer be any need for man to get in the water. In contrast, are the current experiments in the use of saturation diving techniques specifically for cave diving, and the development of the artificial gill, both of which will effectively allow man to stay underwater almost indefinitely.

DOLINES

A doline is a natural enclosed depression found in karst landscapes. Dolines are also sometimes known as sinkholes, particularly by engineers and especially in North America. They are usually subcircular in plan and tens to hundreds of metres in diameter, though their width can range from a few metres to about a kilometre. From the lowest point on their rim, their depths are typically in the range of a few metres to tens of metres, although some can be more than a hundred metres deep and occasionally even 500 m. Their sides range from gently sloping to vertical, and their overall form can range from saucer-shaped to conical or even cylindrical. Their lowest point is often near their centre, but can be close to their rim. Dolines are especially common in terrains underlain by carbonate rocks, and are widespread on evaporite rocks. Some are also found in siliceous rocks such as quartzite. Dolines have long been considered a diagnostic landform of karst, but this is only partly true. Where there are dolines there is certainly karst, but karst can also be developed subsurface in the hydrogeological network even when no dolines are found on the surface.

Doline derives from "dolina", a word of Slav origin meaning valley, possibly because these were the most common hollows in the landscape of the Dinaric karst, where there are few fluvial valleys. "Slepe dolina" means blind valley, where a stream disappears underground and so its valley ends in a steep face. The word doline entered international scientific literature largely through the writings of Cvijić (1893), despite the more accurate local term vrtača being current in the "classical" Karst of Slovenia. However, the usage of the word doline is so embedded in karst literature now that it would be fruitless to try to change it.

The term sinkhole is sometimes used to refer both to dolines (especially in North America and in the engineering literature) and to depressions where streams sink underground, which in Europe are described by separate terms (including ponor, swallow hole, and stream-sink). Thus the terms doline and sinkhole are not strictly synonymous. Hence, to avoid the ambiguity that sometimes arises in general usage, further qualification is required, such as solution sinkhole or collapse sinkhole. Indeed, the international terminology that is used to refer to dolines that are formed in different ways can also be very confusing. Table 1 lists the terms employed by different authors, the range of terms partly reflecting the extent to which genetic types are subdivided, and Figure 1 illustrates six main doline types.

It is widely recognized that enclosed depressions in karst can be formed by four main mechanisms: dissolution, collapse, suffosion, and regional subsidence (Table 2). However, in practice the complexity of natural processes often results in more than one mechanism being involved, in which case the doline is polygenetic in origin. A typical case is a depression formed initially by dissolution that later in its development is subject to collapse of its floor into an underlying cave, following a combination of downwards dissolution and upwards stoping of the cave roof. In such a case, the gentler upper slopes of the doline were formed by dissolution and the steeper lower slopes by collapse. Table 2 describes the different processes responsible for doline formation, the various styles of doline landforms produced, and the names used in English to refer to them. Beck (1984), Waltham (1989), White (1988), and Ford and Williams (1989) provide numerous examples of doline form and evolution.

Solution Dolines

The bowl-shaped form of a typical doline (Figure 2) indicates that more material has been removed from its centre than from around its margins. Where the principal process

responsible for this is dissolution of the bedrock, it follows that there is a mechanism that focuses chemical attack. The amount of limestone that can be removed in solution depends upon two variables: first, the concentration of the solute and, second, the volume of the solvent (in this case the amount of water draining through the doline). Variations in either or both of these quantities could be responsible for the focusing of dissolution near the centre of the depression, but if local variation in solute concentration alone were sufficient to explain the occurrence of solution dolines, then they would be found on every type of limestone in a given climatic zone. This is not the case, as illustrated by comparison of landscapes formed on Devonian, Carboniferous, Jurassic, and Cretaceous limestones in England, where dolines are most frequently found on Carboniferous limestones and practically absent on Cretaceous and Jurassic limestones. It follows, therefore, that local spatial variations in water flow must be responsible for focusing corrosional attack.

The development of dolines of all kinds depends on the ability of water to sink into and flow through karst rocks to outlet

springs. The initiation of karst drainage is explained in Ford and Williams (1989) but, essentially, the exposure of limestones by erosion provides an input boundary for infiltration of water and a valley incised into the limestone provides an output boundary. The hydraulic gradient between the two sets up a groundwater circulation and dissolved limestone is discharged at springs. Streams and seepages flowing from non-limestone cover rocks (allogenic runoff) into exposed inliers of underlying limestone sink into the limestone. The recharge is centripetal, converging on the inlier, and so focuses solutional attack with the result that closed depressions are formed at such sites. Consequently, such depressions can be considered to be point recharge depressions. The floors of these dolines are usually in limestone, but their sides may be developed in clastic (non-carbonate rocks such as shales or sandstones) cover beds. These landforms are genetically transitional to stream-sinks.

When all cover beds have been removed, the exposed limestone is subject to diffuse recharge and solutional attack from direct precipitation (autogenic recharge). Rainwater is acidified in the atmosphere and infiltrating water is further acidified in the soil. On percolating downwards this water accomplishes most of its dissolutional work within 10 m of the surface. The highly corroded zone near the surface is termed the epikarst or subcutaneous zone. Within this zone fissures in the limestone are found to be especially enlarged by corrosion near the surface but taper with depth. Consequently, infiltration into the karst is rapid, but vertical water flow encounters increasing resistance with depth as fissures become narrower and less frequent. This produces a bottleneck effect after particularly heavy rain, resulting in temporary storage of percolation water in a perched epikarstic aquifer. Joints, faults, and bedding planes vary spatially within the rock because of tectonic history and variations in lithology, consequently the frequency and interconnectedness of fissures available to transmit flow also varies. Some fissures are more favourable for percolation than others, for example where several joints intersect, and as a result these develop as principal drainage paths. Water in the epikarstic aquifer flows towards them and as a result they are subjected to still more dissolution by a positive feedback mechanism and so vertical permeability is enhanced. The piezometric surface (water table) of the epikarstic aquifer draws down over the preferred leakage path similar to the cone of depression in the water table over a pumped well; streamlines adjust and resulting flow is centripetal and convergent on the drainage zone. By this means solvent flow is focused and, as the surface lowers, the more intensely corroded zones begin to obtain topographic expression as solution dolines. The diameters of neighbouring solution dolines are determined by the radii of intersecting draw-down cones (Figure 2). Small dolines develop in areas with high fissure frequency, typically in thinly bedded and closely jointed limestones, whereas particularly large dolines develop in rocks that are massive and have widely spaced joints.

Dolines formed by the focusing of dissolution either by recharge or by draw-down can occur in any climatic zone where water exists in a liquid state, provided there is unimpeded underground flow from recharge to discharge zones. Particularly large solution depressions often occur in the humid tropics where corrosion processes were uninterrupted by Pleistocene glaciations. In these places the term cockpit is sometimes applied to them after a particular style of landscape in Jamaica, where depressions are incised between intervening conical hills (see Cockpit Country Cone Karst, Jamaica).

Although small solution dolines have formed in 15000 years or so in some mid to high latitude areas that were glaciated in the late Pleistocene, several tens to hundreds of thousands of years are required to develop large solution dolines in limestone. Once formed they may persist in the landscape for several million years provided there is sufficient thickness of limestone for their continued incision. Individual dolines may merge to form compound closed depressions (known as uvalas) and large dolines may subdivide internally into smaller second generation basins. Where all the available space is occupied by depressions, rather like an egg box, the landscape is termed polygonal karst, because the topographic divides of the adjoining solution depressions have a polygonal pattern when viewed in plan (Williams, 1971). However, not all dolines within polygonal karst are necessarily of dissolutional origin, because a small proportion of collapse

Depressions usually less than 1 km in diameter and often	Solution doline/sinkhole Cockpit (in a humid tropical context)

much smaller.

2. Collapse:

This can occur in unconsolidated coverbeds or in compact caprock, and may progress rapidly or slowly.

(i) Sudden or progressive collapse of the roof of a cave into the underlying cavern. Collapse is entirely within karst rocks and may be propagated upwards from tens to hundreds of metres beneath the surface.

(ii) Sudden or progressive collapse of non-karst caprock into an underlying cave. A ceiling collapse within a cave located in interstratified karst rocks stopes upwards into, and through, overlying consolidated caprock causing the surface to collapse. The upwards stoping may occur over tens to hundreds of metres.

(iii) Sudden failure in mechanically weak unconsolidated sediments overlying a subsurface cavity, giving rise to a depression at the surface. Sediments are evacuated downwards through solution pipes in the bedrock creating a void at the bedrock-sediment contact that enlarges by upwards propagation through the clastic coverbeds. The ceiling dome above the void eventually fails.

3. Suffosion and subsidence:

Gradual subsidence of superficial coverbeds (as opposed to sudden collapse) giving rise to a depression at the surface. Formative processes involve the evacuation of superficial unconsolidated sediments through Cylindrical to steep-sided enclosed depressions in karst rocks with debris-filled floor, sometimes with sheer and even overhanging rock walls tens to hundreds of metres high. Some open near their base into the underlying cave; some contain lakes. Up to a few hundred metres in diameter, but often much less.

Cylindrical to steep-sided enclosed depressions in caprock with debris-filled floor, sometimes but not always revealing underlying karst rock. Up to a few hundred metres in diameter, but often much less.

Steep-sided enclosed depressions (sometimes cylindrical when freshly formed) in unconsolidated cover sediments with debrisfilled floor, usually a few metres to tens of metres in diameter. Such depressions are often found in sediment fill near the bottom of a solution doline.

Dimpled surface of enclosed depressions in coverbeds, sometimes exposing windows of underlying bedrock beneath. Such depressions are often found in superficial sediments such as glacial drift. alluvium. Collapse doline Cavecollapse sinkhole Cenote (only when they contain a lake)

diameter, but larger forms can

be produced if the removal of

coverbeds exhumes buried

dolines in bedrock.

underlying solution pipes. Because the nature of cover deposits can vary considerably from uniform clays, silts, and sands through mixed alluvial facies to heterogeneous glacial deposits, the mechanisms involved in their evacuation also vary. Suffosion is one of the processes and involves the gradual physical and chemical downwashing of fines through underlying solution pipes in the karstified bedrock. Plastic flow of clays and silts can also occur with cover sediments sometimes being extruded as a wet slurry into underlying caves. Overlying sediments slowly settle and deform in response to gradual undermining. Coarse materials such as boulders and scree move downwards by gravity as underlying sediments are removed.

4. Regional subsidence:

This process involves gentle, progressive settling of the ground surface over large areas as a consequence of gradual dissolution of deep, underlying interstratal evaporite beds by groundwaters. Strike-aligned depressions are formed when beds are dipping, but otherwise gently sloping depressions are distributed across an undulating surface. Depressions are often of several square kilometres in area and so are very much larger than is generally understood by the term doline. Nevertheless, some smaller depressions are formed in this way.

clastic coverbeds. Sometimes the sediments have completely buried a pre-existing doline, the form of which is being exhumed as the subsidence occurs. Shakehole is a term used in England to describe depressions in bouldery deposits such as glacial drift overlying limestone.

Subsidence depression Solution trough

Dolines: Figure 2. Solution dolines develop in the uppermost weathered zone of the karst rock, termed the epikarst or subcutaneous zone. Drainage within that zone is achieved by leakage of water down fissures such as joints and faults. Major fissures capture most of the flow and therefore are the foci of solvent attack on the bedrock. This results in more rock being removed in solution from these locations than elsewhere, and this gradually gains topographic expression as enclosed depressions as the overall surface is lowered by chemical denudation (from Williams, 1983).

depressions is also likely to be included. The mesh sizes of different polygonal karsts can vary widely and is a direct reflection of the characteristic radii of individual solution dolines, in turn determined by the epikarstic processes described above. Dense fields of dolines constituting polygonal karsts are known from the mid latitudes (e.g. New Zealand and Tasmania) to the tropics, but none has been reported polewards of 50° latitude, probably because of the destructive influence of periglacial and glacial processes on surface landforms during the Pleistocene.

There are few examples of dolines that have survived severe glaciation, although large solution dolines at High Mark near Malham, England, clearly formed before the last glaciation and contain drift deposits in which many small suffosion dolines have developed. In contrast, there are numerous cases of dolines formed prior to the last glaciation and located beyond the ice limits that have been strongly subjected to processes other than dissolution. In many cases they have been partly filled by scree and others have been covered, or even completely buried, by loess. Post-glacial conditions have resulted in some of these materials being removed and in the re-expression and continued development of the underlying doline form. This is the case in the Sinkhole Plain of Kentucky, where many dolines were buried by fine clastic sediments. It follows, therefore, that solution dolines, like valleys in a fluvial landscape, can have long and complex histories over time periods when climates have changed and when the importance of dissolution compared to other geomorphic processes has waxed and waned (see also buried dolines below).

Collapse Dolines

Whereas most authors agree with the designation solution doline, there is considerable variation in nomenclature concerning depressions formed mainly by mechanical processes (Table 1). This is largely because of the variety of materials and processes involved, and the tendency of some authors to group types and of others to subdivide types. Collapse refers to rapid downward movement of the ground, whereas subsidence refers to gradual movement, sometimes without even ripping the surface. These processes can occur in karst bedrock (collapse dolines *sensu stricto*), in caprock that may stratigraphically overly it (caprock collapse dolines), and in veneers of unconsolidated sediments (dropout dolines). In all cases the collapse has to be preceded by dissolution of the karst rock to form a void into which material can fall. The movement may involve little water or may be promoted by lubrication by water and the kind of landforms produced depends upon which of the various materials and processes were involved.

Where collapse dolines form in karst bedrock the void is commonly part of a cave system. Collapse may occur following undermining from below as the roof of a cavity stopes upwards, ultimately causing the surface above to collapse or following dissolution from above that weakens the span of a cave roof, causing it to collapse. For example, solutional attack by drainage water near the bottom of a solution doline may combine with upwards stoping of an underlying cave roof to weaken a span from above and below, thereby causing the doline floor to collapse into a cave. The natural process of ground surface lowering inevitably means that caves will eventually be unroofed and, as the final stage involves failure of their thinning roof, the depressions produced must be regarded as a sub-type of collapse doline. When limestones or evaporites are overlain by a caprock, a void may form by dissolution at the lithological junction between caprock and karst rock. Stoping may then work upwards through the cover rocks and lead to the formation of a caprock collapse doline, which may be entirely within rocks such as shales, sandstones, or even basalt (Figure 3). Such features propa-

Dolines: Figure 3. Caprock collapse doline in basalt overlying limestone near Timahdite, south of Fes, Morocco. (Photo by John Gunn)

gated from interstratal dissolution were termed subjacent collapse dolines by Jennings (1985), and good examples are found in Namurian sandstones around the North Crop of the South Wales coalfield (Thomas, 1974). While many of the South Wales dolines have formed following dissolution at the limestone—sandstone unconformity, some result from collapse propagated upwards from deeper caves that developed entirely within the limestone (Bull, 1980). Stoping has propagated through more than 1000 m of cover rocks at sites in Canada and Russia.

When recently developed, collapse and caprock collapse dolines are steep sided, even cylindrical in form, but over time their sides degrade and bottoms infill with debris, so that superficially they assume the bowl-shaped morphology of solution dolines for which they can be easily mistaken. Only excavation, drilling, or geophysical survey will reveal their true origin. Collapse dolines are on average smaller in diameter than solution dolines, although particularly large examples 700 m along their largest axis and up to 400 m deep are known in the Nakanai Mountains of New Britain (see Nakanai entry, with photo). In China, the name tiankeng (roughly meaning skyhole) is applied to some of these very large dolines, including Xiaozhai over Di Feng Dong (see Di Feng Dong, with

photo) and those at Xingwen (see China entry). Progressive collapse has clearly been important in their genesis, but not all tiankengs are associated with appropriately massive river cave development, and there is debate over whether they are merely very large ordinary dolines or if they represent a different mechanism of doline formation.

Sometimes a collapse extends from a cave below the modern water-table level, in which case the collapse doline will contain a lake. Spectacular cylindrical collapses that descend below the water table are known as cenotes after the type-site in the Yucatan Peninsula of Mexico, although similar features are found elsewhere, such as in southeast Australia. The deepest known case of a collapse doline containing a lake is the Crveno Jezero (Red Lake) in Croatia, which is 528 m deep from its lowest rim, the bottom of the collapse diameter at the surface is about 350 m and at lake level is about 200 m. Recent diving has found an active subterranean river that crosses the doline near its floor. The whole feature is thought to have formed by progressive upwards collapse of the cave roof, much of the collapse debris having been transported away by the underground river.

The capacity of a cave roof to resist collapse depends on the width of the roof span and on factors determining rock mass strength such as the thickness of beds, the composition, texture, and compressive strength of the rock, and the frequency and continuity of fissures. If stress exceeds the rock's strength then it will fail. In the simplest case where bedding is horizontal, each bed can be considered to act as a beam, but if it is fractured then it has less strength and acts as a cantilever. Collapse occurs where a critical span is exceeded for a given thickness and strength. White and White (1969) illustrate this with examples from West Virginia, where 0.5 m beds of carbonate rock can support roofs up to 25 m wide where they are unbroken beams, but only about 10 m where they act as cantilevers. Beams of more thickly bedded carbonates can support spans of 35 m or more, though cantilevered beds as massive as 5 m thick will fail with a span of 30 m or less. Massive reef limestones support the largest spans, which exceed 50 m in the Big Room of Carlsbad Cavern, New Mexico. In the Mulu karst of Malaysia, Sarawak Chamber is more than 250 m wide and about 500 m long. Its ceiling is actively collapsing and working upwards, but with few bedding weaknesses it is developing an arched profile that is stable in compression. Its ultimate evolution into an enormous collapse doline will be due more to surface lowering than to roof stoping.

Another process that increases the effective stress on rock arches and domes is removal of buoyant support by water-table lowering, which increases the effective weight on the span of the roof, resulting in its strength being exceeded and so in its failure and collapse. This occurs because in a fully saturated medium the buoyant force of water is 1 t m^{-3} , and if the water table is lowered by 30 m, the increase in the effective stress on the rocks is 30 t m^{-3} (Hunt, 1984). A gradual lowering of the water table occurs naturally as karstification proceeds, because of the increase in subterranean void space within the rock, but it occurs more rapidly when valley incision occurs, because springs are lowered too, and with them the level of the saturated zone that feeds them. More rapid still is the lowering of the level of saturation caused by sea-level lowering, a process that occurred frequently in the Pleistocene because of repeated glacio-eustatic (vertical movement of sea level caused by glaciation and deglaciation) fluctuations, although this only affected karsts well connected to the coast such as in Florida, southeastern Australia, and Yucatan, where it probably was a significant influence in the development of cenotes.

If unconsolidated coverbeds are drained by water-table lowering, then consolidation and compression occurs, leading to subsiding of the surface and collapse where clastic sediments span de-watered unsupported arches. This has been a common process in Florida where porous sandy formations overlie karstified limestones, but has been much exacerbated by groundwater pumping for water supplies, which has still further reduced buoyant support (Beck, 1984). This process and the resulting incidence of collapse attains dangerous hazardous proportions in karstified areas extensively de-watered by mining activities. These dolines in unconsolidated coverbeds have been referred to as cover collapse sinkholes (Table 1) by Beck and Sinclair (1986) and White (1988). They are genetically transitional to subsidence dolines.

Subsidence (Suffosion/Dropout) Dolines

When unconsolidated deposits such as alluvium, glacial moraine, loess, or sand mantle karstified rock, the sediments are sometimes evacuated downwards through corrosionally enlarged pipes in the underlying karst, resulting in gradual or rapid subsidence of the surface. Hence, the term subsidence doline is sometimes used for any doline in unconsolidated deposits although the term is also used for depressions formed by regional subsidence (see below). The main process by which the sediment moves is known as suffosion and involves the gradual winnowing and downwashing of fines by a combination of physical and chemical processes. The topographic consequence of this activity depends on whether the material is cohesive or non-cohesive. In cohesive sediments evacuation of material may proceed for some time without any surface expression. However, a void is formed that enlarges and stopes upwards resulting in a sudden, and sometimes catastrophic, failure of the ground surface. The depression thus formed is called a dropout doline or cover col-

Dolines: Figure 4. Dropout doline, Santang, Guizhou, China. (Photo by John Gunn)

lapse doline (Figure 4). As the final process is one of collapse, some authors group these dolines with those formed by collapse in bedrock (Tables 1 and 2).

Where the sediment is non-cohesive, the clayey fraction will tend to move as a slurry into underlying cavities, producing dejection fans and mudslides in cave passages, whereas the coarser fraction will tend to remain closer to the surface and line small bouldery depressions known as suffosion dolines that are usually only a few metres in diameter and depth. In Britain suffosion dolines formed in glacial boulder clay overlying limestone are widely referred to as shakeholes, although the term is sometimes applied to any doline. Similar features but in more uniform finer grained materials are referred to as cover subsidence sinkholes in the United States. Often a combination of processes is involved in the development of subsidence dolines, including corrosion and collapse of the underlying bedrock, as well as suffosion, mudflow, and void collapse in the mantling materials. Soil piping and surface collapse can also occur in unconsolidated non-karstic sediments in badland country, leading to a style of topography termed suffosional pseudokarst by White (1988).

Buried Dolines

Changes in the environment may result in bedrock dolines, however formed, becoming filled with sediment. There may be no evidence of such dolines at the ground surface, their presence only being revealed by geophysical prospecting or geotechnical survey. Good examples have been found in the central lowlands of Ireland where the lowest fills are of Tertiary age. Some buried dolines contain sediment of economic importance such as karst bauxites. Where they are no longer hydrologically active they may be regarded as paleokarst but if karstification continues, or is reactivated, in the underlying bedrock then there is likely to be gradual removal of material leading to surface subsidence.

Depressions Formed by Regional Subsidence

Particularly soluble rocks such as evaporites are often interbedded with clastic rocks. During the course of groundwater circula tion the evaporite beds are dissolved away and gradual subsidence of the surface results. Waltham (1989) refers to this process as salt subsidence and provides a discussion of the mechanisms involved and the effects produced. When the beds are dipping, large depressions are produced along the strike. These can be many square kilometres in area and so are too large to be designated dolines and are best considered solution troughs. However, there is a continuum of forms and more localized subsidence can produce doline-sized features that could be termed subsidence dolines, although collapse is also sometimes implicated in their formation. Many have been mapped in the vicinity of Ripon in north Yorkshire, England. Ford and Williams (1989) provide further details and examples.

Mapping of Dolines

For various reasons we may wish to map dolines. This is particularly the case when karst collapses may be hazardous to human activity (Beck & Pearson, 1995). Hence, it is necessary to know how to recognize different genetic types of dolines and their boundaries. In the case of solution dolines, which depend for their development on hydrological and chemical processes in the epikarst, their perimeters are the topographic divides (watersheds), within which water drains centripetally towards the doline bottoms.

In the case of collapse dolines, where the main forcing process is undermining of the surface by cavern collapse, the surface boundary is the outermost surface inflection or break of slope that marks the limit of zone of influence of the failure. This may not be static even in the short term, but can move outwards until stability is attained. The boundaries of suffosion dolines and subsidence depressions are also defined by topographic inflections and breaks of slope at the outer limits of influence of the subsurface processes that formed them. Bearing in mind the polygenetic nature of some dolines, it is possible to map nested features such as collapse depressions within the boundary of a larger solution depression.

Doline Hydrology

Solution dolines have a similar function in karst landscapes to the drainage basin in nonkarstic lithologies: they channel water to an outlet at the lowest point in the doline. Lateral movement is by overland flow and throughflow if there is cover material over the bedrock and by subcutaneous flow. Vertical movement is by shaft flow, vadose flows, and vadose seeps, three points on a continuum of flow routes (Gunn, 1981). Suffosion dolines also form small drainage basins, but the hydrological function of collapse and caprock collapse dolines depends on their form. Where they are narrow and steep sided they may be virtually inert, particularly when they are formed in essentially flat landscapes. However, as they widen the sides usually become less steep and an internal drainage system may develop.

DRAENEN, OGOF DRAENEN, WALES

Located in 1994, Ogof Draenen is Britain's most significant caving discovery in recent years. It is already one of the longest caves in Britain (70 km) and contains the longest continuous streamway (> 2.5 km) and some of the country's largest passages. It also has abundant gypsum flowers, rare gypsum needles and anthodites, plus significant bat-guano deposits. But it is its geomorphic interest that sets it apart and makes it worthy of recognition. Above and up dip from the streamway lie several tiers of abandoned cave passage, most of which are unrelated to modern hydrology. These preserve evidence that the cave system has behaved like a hydrological see-saw, with the flow switching from south to north and then south again in response to landscape evolution and valley incision.

Ogof Draenen lies under the interfluve between the Usk and Afon Lwyd valleys, on the northeastern margin of the South Wales coalfield (Figure 1). The entrance lies close to the hamlet of Pwll Ddu, six kilometres southwest of Abergavenny. First investigated by the Cwmbran Caving Club, the entrance to Ogof Draenen was a small, choked but draughting phreatic tube, almost buried under an old coal tip. The main digging breakthrough occurred on 6 October 1994; by 28 November, over 15 km of passage had been explored and surveyed (Kendall, 1994). Over the next few years, the rate of exploration averaged a remarkable 2 km per month, with many clubs and individuals contributing to numerous major discoveries. A comprehensive detailed survey, initiated by the Chelsea Spelaeological Society, had mapped over 68 km of passage by April 2002. The first geomorphological study of the cave was published by Simms *et al.* (1996) and expanded on in Waltham *et al.* (1997).

Ogof Draenen is developed entirely within the Carboniferous Dinantian Limestone, although some of the larger boulder chokes stope up into the overlying Namurian Millstone Grit. The limestone succession was deposited on a carbonate ramp close to the contemporary shoreline. This, coupled with pre-

Draenen, Ogof Draenen, Wales: Figure 1. The Blaenavon area, South Wales, showing the location of Ogof Draenen and other major caves.

Draenen, Ogof Draenen, Wales: Figure 2. Schematic diagram showing the progressive evolution of Ogof Draenen. Stages 1a and 1b, initial drainage south to the Usk Valley;

Stage 2, drainage reversal and flow orientated northwards to the Clydach Gorge; Stage 3, second drainage reversal and flow to the south again to the Afon Lwyd Valley.

Draenen, Ogof Draenen, Wales: Figure 3. Solutional wall notches in the abandoned conduit of Megadrive survive on the left wall but have been lost by breakdown of the right wall. (Photo by Clive Westlake)

Namurian erosion and overstep by the overlying Millstone Grit, has created a wedge of limestone less than 25 m thick along the eastern margin of the escarpment, thickening westwards to c.80 m in the Pwll Ddu area. The limestone crops out in a narrow band around the escarpment overlooking the Usk Valley and as a re-entrant up the Afon Lwyd Valley. Much of the cave is overlain by less-permeable Millstone Grit, and, in some places, by the Coal Measures, which protect the system from erosion. The geological structure of the area is relatively simple. The rocks dip to the southwest at between 10° and 28°, and are cut by several minor faults, which can be identified underground by lines of boulder chokes. The dominant joint set which strongly influences cave

development runs at 150–330°, slightly oblique to the strike and mirroring the main fault orientations. Some joints have been mineralized with barite and copper minerals.

Ogof Draenen has had a complicated multiphase origin. Evidence of at least four phases of cave development, associated with major reversals in flow direction and resurgence location, can be identified (Figure 2). Essentially, the system can be thought of as four separate vertically stacked cave systems, linked by more recent vadose inlets and passage intersections. Some passages are multiphase and are thus usually much larger than single-phase passages. Major sediment influxes have occurred throughout much of the cave's development, modifying and controlling passage genesis and evolution and creating some fine paragenetic passages. The major trunk conduits trend northwest-southeast along the dominant joint set. Because this coincides with the maximum hydraulic gradient, long unidirectional quasi-horizontal passage segments develop (Figure 3). This permits passage segments to rise or fall stratigraphically while remaining at a constant elevation. Draining into these are downdip vadose tributaries. In places maze networks occur, usually in response to a change in passage orientation.

The earliest phase of cave development is represented by a major conduit system which extends southeastwards from a major northern sink at an elevation of at least 390 m, to a resurgence in the Usk Valley at c.370 m. Once this system was established, a series of down-dip captures began in response to incision in the Afon Lwyd Valley down dip to the west. This shift increased the down-dip component of underground drainage, causing a gradual migration in the conduit orientation to the southsoutheast. These can be identified as a series of maze networks which diverge off south from the initial conduit. The second phase of development occurred in response to rapid incision of the Clydach Gorge, effectively reversing the hydraulic gradient and causing a fundamental 180° reorientation of the underground drainage. This created a joint-aligned conduit system draining northwest, fed by a dendritic series of down-dip inlets, resurging at around 300-310 m. Renewed valley incision, probably following glacial downcutting during the Devensian, in the Afon Lwyd Valley has resulted in a second fundamental 180° reorientation of the underground drainage. Water tracing using fluorescent dyes has shown (Gascoine, 1995) that the water currently sinking around Pwll Ddu drains into the Main Streamway. From here it drains south to the Pontnewynydd Risings, 140 m lower and 8 km distant, in under 100 hours.

Although Ogof Draenen falls within a World Heritage Site, this designation is for the region's industrial heritage. However, the cave system is worthy of international recognition and is a proposed Site of Special Scientific Interest. Conservation has been a paramount consideration since the discovery of the system, and many kilometres of tape have been laid to conserve the undisturbed sediments, guano deposits, and gypsum crystals.

EDWARDS AQUIFER, UNITED STATES

The Balcones fault zone section of the Edwards Aquifer is one of the most permeable and productive carbonate aquifers in the United States. The Edwards Aquifer extends from the Mexico—Texas border near Del Rio, eastward and then northeast for 350 km to near Waco (Maclay, 1995). The aquifer can be divided into four segments by groundwater or surface water divides, the most productive and utilized being the San Antonio segment. This is the primary water supply for about 1.7 million people, and supports a broad base of agricultural, municipal, industrial, and recreational uses. It extends between groundwater divides near Brackettville in the west and just north of San Marcos, a distance of about 280 km (Figure 1).

Southern Texas includes the southern portion of the Edwards Plateau, the Balcones fault zone, and the northern portion of the Gulf Coastal Plain. The Edwards Aquifer is named after and contained in the Lower Cretaceous Edwards Limestone, which was deposited in a complex of subtidal to supratidal, shallowwater marine to deep-basin environments. The limestone thickness is 130–270 m, with an average of 180 m. A series of faults in the Balcones fault zone has exposed the Edwards Limestone at the surface along the southern boundary of the Texas Hill Country. En echelon faulting has dropped the Edwards Limestone to great depth below the surface along the aquifer's southern zone. In some areas, fresh water can be found in the Edwards Limestone as far as 1000 m below sea level. The southern and eastern boundary of the aquifer is generally defined by the "bad water line", where total dissolved solids exceed 1000 mg 1^{-1} . The Edwards Limestone is a noted oil producer in the Gulf Coastal Plain south of San Antonio.

Generally, the Edwards Aquifer is divided into three zones: the contributing or drainage area, the recharge zone, and the artesian zone (Figure 2). Surface streams forming on the contributing area (the dissected Edwards Plateau also referred to as the Texas Hill Country) flow south or east and cross the Edwards Limestone outcrop (the recharge zone), where in low flow conditions most surface water is captured by the aquifer. Rainfall on the recharge zone may also enter the aquifer. Groundwater in the artesian zone moves through the aquifer, generally from west to east, to discharge from a number of sites including Leona Springs (Uvalde County), San Pedro and San Antonio Springs (San Antonio), Hueco and Comal Springs (New Braunfels), and San Marcos Springs (San Marcos). Mean discharges for Comal Springs and San Marcos Springs, the two largest, are 8.3 and 5.6 m³ s⁻¹. Residence time in the aquifer ranges from a few hours

to many years depending upon depth of circulation, location, and other aquifer parameters.

The combined primary and secondary porosity and aquifer permeability of the Edwards Limestone is extremely high. Most wells do not fully penetrate the aquifer yet commonly have yields that exceed $3800 \ 1 \ s^{-1}$ with little or no drawdown. The Catfish Farm Well (near San Antonio), a 76 mm diameter flowing artesian well, discharged over $115000 \ 1 \ s^{-1}$ to create a vertical column of water rising 10 m above the surface when first drilled. Well yields are generally limited by the size of the pump, and not by the yield of the aquifer.

The genesis of the Edwards Aquifer is complex and is the product of numerous geological processes including carbonate deposition, uplift, early karstification (soon after uplift), down faulting, volcanism, and current karstification (Oetting, Banner & Sharp, 1996). Meteoric waters from the recharge zone play an important role in dissolution in the aquifer, including the removal of limestone, dolomite, and gypsum. There is also evidence that mixing corrosion with hydrogen sulfide has resulted in significant permeability enhancement in the artesian portion of the aquifer. Many of the wells drilled south of the bad water line produce hydrogen sulfide.

Because of the extremely high transmissivity of the aquifer, recharge during rain events can be rapid. Monitoring wells in the recharge zone have risen as much as 50 m in response to large rainfall events. However, during drought conditions, aquifer levels in the region's index wells have dropped as much as 700 mm in one day. In July 2000, a pressure wave, created by reductions in pumping stress mandated during a drought, was recorded in wells over a 100 km length of the aquifer in under

Edwards Aquifer: Figure 1. Outline map of the San Antonio segment of the Edwards Aquifer in Texas.

12 hours. Along with the extremely high well yields, this reflects the aquifer's very high transmissivity.

The San Antonio segment of the Edwards Aquifer is managed by the Edwards Aquifer Authority, with statutory ability to protect water quality and control groundwater withdrawals to protect springflow for the dependant aquatic communities. There is a withdrawal limit of $5.548 \times 108 \text{ m}3a^{-1}$ to protect endangered species dependent upon Comal and San Marcos springs. The Authority uses a series of index wells to monitor the potentiometric surface of the aquifer on a daily basis across the region, and also records daily discharges from Comal and San Marcos Springs. On average, the Authority reserves about two thirds of the aquifer's water recharge for withdrawal by pumping, and leaves one third for discharge from the springs, thereby maintaining species habitat and downstream water rights.

Land use in the Edwards Aquifer recharge zone has historically been low-density cattle or goat ranching and, to a lesser extent, row cropping. Water quality in the Edwards Aquifer is generally very high, requiring very little treatment before use. However, urban and industrial development has encroached upon the recharge zone, and analyses do indicate some constituent increases, but all levels remain within drinking water quality standards. Nitrate concentrations are elevated in some areas, with the most likely sources being agricultural and residential use of fertilizers. Ammonium nitrate blasting agents, used in limestone mining, may also be a source of nitrate. Volatile or-

Edwards Aquifer: Figure 2. Cross section of the Edwards Aquifer near San Antonio.

ganic compounds have also been detected in the aquifer in some limited areas, and are most likely related to releases from petroleum underground storage tanks and dry cleaning facilities.

Known caves in the exposed Edwards Limestone associated with the Balcones Fault Zone are mainly small. Many are deeper than they are long, and jointing appears to play a strong role in controlling cave passage development. Genesis Cave, in Bexar County, one of the few caves that intersects the Edwards Aquifer, is 165 m long and 78 m deep. Indian Creek Cave (Uvalde) is the fourth longest cave in Texas with 6700 m of passage including an active streamway, which is very unusual for the area. Bracken Bat Cave (near New Braunfels) is only 130 m long but contains from 20 to 40 million Mexican

Free-Tail bats (*Tadarida brasiliensis* mexicana), perhaps the largest collection of mammals in the world.

Drill bit drops, troughs in the water table, rapid response of groundwater elevations to storm events, and the presence of over 40 endemic species in the groundwater all indicate a very extensive network of underwater caves. However, their great depth and few access points leave very little potential for significant underwater exploration.

EDWARDS AQUIFER, UNITED STATES: BIOSPELEOLOGY

The Edwards Aquifer is associated with the Balcones Escarpment in central Texas. The aquifer serves as the primary source of water for approximately 1.7 million people. It also supplies water for agricultural irrigation and for major springs. The springs provide the base flow of the Guadalupe River system and have been important in the development of the region historically. The portion of the Edwards Aquifer directly located on the escarpment is referred to as the Fault Zone Edwards Aquifer. There are two main areas, the confined (artesian) zone and the water-table zone. Water recharges the aquifer in the water-table (unconfined) zone. Numerous caves and sinks allow surface water to quickly flow to the aquifer. The aquifer is a porous, honeycombed, cavernous limestone made up of several formations. Water travels from the recharge zone downward to the artesian

zone and then slowly to the north primarily through conduits that parallel the escarpment. The aquifer is about 280 km long, and from 8 to 64 km wide.

Extensive biological studies of this system began in the mid-1970s and have continued to the present. Sampling of the biota is done using fine mesh nets placed over the discharge of wells and springs throughout the region. The sampling began on a flowing artesian well at Southwest Texas State University in San Marcos. This well was drilled in 1895 to provide water for a large federal fish hatchery. The well penetrates a 1.5 m wide cavern in the Edwards at 59.5 m. The cavern is the source of water for the well. This well has been sampled almost continuously. This sampling, along with springs and other wells, has produced evidence of a very diverse aquatic community in the aquifer. Some of the deepest wells sampled are between 412 m and 610 m deep in San Antonio, Texas. These have produced two species of blind catfish, Satan eurystomus (Widemouth Blindcat) and Trogloglanis pattersoni (Toothless Blindcat), which are only found at these deep water levels. Numerous invertebrates are also found throughout the aquifer. There are 39 described invertebrates and several more unnamed. The aquifer has also produced 16 described vertebrates (all but two are Plethodontid salamanders in the genus Eurycea). Several more salamanders have been found and will probably be named as distinct species. This assemblage of 55 named species is highly diverse, possibly more so than any known aquatic subterranean ecosystem. The protozoa and other very small invertebrates have not been adequately sampled or described.

The organisms described from the aquifer range from flatworms to catfish. Turbellaria (free-living flatworms) are represented by *Sphalloplana mohri*. This colourless, eyeless planarian exhibits polypharyngy, the unusual condition of having many feeding tubes. It apparently feeds on decaying matter. Nematoda (roundworms) are represented by the species *Rhabdochona longleyi*, a parasite of the Texas Blind Salamander, *Eurycea rathbuni*. Hirudinea (leeches) are represented by the small leech, *Mooreobdella microstoma*, found on the Texas Blind Salamander. It is in the family Erpobdellidae.

Gastropoda (snails) are the most diverse invertebrate group in the aquifer, and represented by 13 different aquatic species in the family Hydrobiidae. The five genera are often less than 2 mm and may be interstitial as well as phreatic.

Crustaceans form about two thirds of the total aquatic fauna. Ostracoda are represented by *Sphaeromicola moria*, a member of the Entocytheridae. Isopoda are represented by four genera and five species. Amphipoda are the second most diverse group in the aquifer represented by 12 described species in eight different genera. These crustaceans are more diverse in this system than any other described surface or groundwater system worldwide. Several of these are marine relicts (having their closest relatives in the marine environment), and indicate colonization of freshwater habitats by a marine environment that last covered the area during the late Cretaceous or early Tertiary. The Thermosbaenacean *Monodella texana* represents another group of typically marine forms. The two described species of Decapoda are both shrimps in the family Palaemonidae.

Of the Coleoptera, three species of stygobitic beetles have been described from the Edwards Aquifer. *Haideoporus texanus* (Texas hell passer) is representative of the dytiscid beetles. It is a small, transparent, eyeless beetle that apparently spends its entire life cycle in the aquifer.

The vertebrates are represented by the two species of blind catfish mentioned earlier and 13 species of lungless salamanders. The most famous of these salamanders is the Texas Blind Salamander, *Eurycea rathbuni* (formerly *Typhlomolge rathbuni*), which is endemic to the aquifer. It is considered by many to be the most highly adapted vertebrate to subterranean aquatic life. It has long slender legs that would not support it on land. It has no functional eyes, only vestiges of retinas buried deep beneath the skin. It is colourless and is highly flattened dorsoventrally. It has adapted by having many special neurosensory structures over its head region for sensing food. Like most of the organisms found in the aquifer it exhibits a relatively long lifespan when compared to surface relatives. This salamander is found only near San Marcos, Texas.

The ecosystem exhibits amazing productivity in terms of the numbers of organisms issuing from wells and springs. There are likely two major energy pathways at work in the system. In the unconfined and nearby area of the aquifer the pathway is similar to that known in caves around the world. Organic matter deposited in the aquifer by recharge serves as food for fungi and other decomposers. Protozoa and larger invertebrates including the planarian, *Sphalloplana mohri*, feed on these organisms. The larger arthropods feed on the smaller organisms depending on their specializations. In the deep artesian area of the aquifer, isolated from organic debris, the source of energy is probably fossil organic matter (peat or oil) found in the Edwards formations. There is evidence of chemosynthesis. There is a salinefreshwater interface, and on the saline side, the water is without oxygen and large quantities of sulfur bacteria occur. The largest numbers of organisms occur at or near the interface. At the top of the food chain are the Widemouth Blindcat in the deep aquifer and the various blind salamanders in the unconfined or nearby areas of the aquifer.

The Texas Blind Salamander (see Plate 2i) was the first species listed as endangered in the Unites States in 1967; two other stygobitic species from the aquifer are listed as endangered (Comal Springs Dryopid Beetle, *Stygoparnus comalensis*, and Peck's Cave Amphipod, *Stygobromus pecki*), and the San Marcos Salamander as threatened. These species' very limited habitats are threatened by reduced spring flows caused by overpumping of groundwater. Overpumping could also cause encroachment of saline water into the aquifer. Another threat to the habitat of these species is the potential for groundwater contamination from sewage and urban expansion.

ENCANTADO, SISTEMA DEL RIO, PUERTO RICO

Sistema del Rio Encantado is situated in the North Coast karst belt on the island of Puerto Rico, 53 km southwest of San Juan and 3 km south of the town of Florida (Monroe, 1976). The cave is an underground tributary of the Rio Grande de Manati which flows north from the Cordillera Central Mountain Region to the Atlantic Ocean. The cave has been surveyed to a length. of 17.1 km (with a vertical extent of 250 m), nearly all along a single continually traversable underground river (Figure 1).

Puerto Rico's North Coast karst belt occupies the northern third of the island, has an east-west extent of 135 km, and ranges in width from 10 to 23 km. The limestones form a rugged tropical karst topography. These lie within a thick sequence of platform carbonates and minor clastics ranging in age from mid dle Oligocene to Miocene. The basement rocks that underlie the limestone belt consist of Late Cretaceous and Early Tertiary volcaniclastic rocks and intrusives. The north-central area of the northern karst belt is known for its variety of karst landforms, which include cone karst and mogote (tower) karst, river caves, alluviated valleys, deep limestone gorges, and zanjones (verticalwalled trenches). The alignment of mogotes, dolines, zanjones, and river segments may be a function of local fracturing and faulting.

In the Rio Encantado area, the Lares Limestone gives rise to a distinctive cone karst with round cones that are capped by vertical cliffs forming small towers. Where jointing has influenced cone development, jagged saw-tooth cones and ridges have

Encantado, Puerto Rico: Outline map of the Sistema del Rio Encantado and associated caves beneath the cone karst of Puerto Rico; the darker areas are forested, and the lighter areas are cleared farmland.

formed. The younger Montebello Limestone forms ridges and cuesta scarps, and near Florida, forms steep cliffs on top of the Lares Limestone which results in a cliffed cone karst. The Mucarabones Sand (contemporary with the Lares Limestone) is present in the valleys between hills capped with Montebello limestone. The sands originated as debris from the volcanic interior, which were carried to the coastal area by rivers during periods between limestone deposition and gradual uplift of the island. These blanket sands have had a significant influence on karstification of the limestone by providing reservoirs of undersaturated water that dissolved the underlying limestone.

The Sistema del Rio Encantado is part of a groundwater basin within the Rio Grande de Manati watershed, one of six major watersheds along the south coast (Guisti, 1978). Tectonic tilt has affected the subterranean drainage systems such that springs are found predominantly on the west side of north-trending valleys. The Rio Grande de Manati forms a north-trending valley and the Manantial de las Aguas Frias, which is the resurgence for the Sistema del Rio Encantado, emerges from the west side of the river valley.

Allogenic streams flowing off the volcanic core formed the caves within the Rio Encantado groundwater basin. Concentrated recharge of this type forms linear cave systems with few side passages. This is apparent in the Sistema del Rio Encantado, which consists of a master river passage and very little base-level side passage development. The current allogenic catchment area for the groundwater basin encompasses only 4 km². It has been postulated that the recharge area was much larger in the past, but the original river may have been pirated either by the Rio Grande de Arecibo or the Rio Grande de Manati (Troester, 1992).

Dry valleys are common in the Encantado area, some containing intermittent streams after heavy rains. These valleys are lined with swallets that carry recharge underground. The autogenic recharge has formed the vertical entrances to the cave, and disjointed upper level passages and domes. The autogenic water also provides the source water that forms many unusual and spectacular speleothems.

The Sistema del Rio Encantado is formed in the Oligocene Lares Limestone. Upstream of the Encantado cave four segments of river passage are separated by collapse; Cueva Chica (50 m); Cueva Yuyu (500 m); an unnamed river segment (100 m); and Cueva Zumbo (1 km). A river draining the volcanics on the south side of the Manati River valley forms the headwaters of the conduit drainage. The river flows for a short distance on the Lares Limestone and then disappears into Cueva Chica.

Sistema del Rio Encantado has five entrances, is characterized by canyon passages (more than 20 m tall) and large phreatic boreholes, and has three rooms over 100 m across. Autogenic recharge has deposited flowstone cascades that cover the walls and floors and form dams in many places in the river. Large stalagmites and draperies abound and showerhead formations are common in the cave. There are four major sumps in the system. Multi-level floodwater mazes occur near the sumped areas of the cave and spectacular soda straw displays are common in these sections. Mazes also occur near collapsed areas of the system. In many places in the river, coral reef fossils stand out in relief against the water-sculpted limestone. Well-preserved dugong fossils have been observed in the walls of the cave.

Cueva Encantada reaches the main river via a walk-in entrance located at the bottom of a doline. Four kilometres downstream from the Encantada entrance is a short section of underwater passage that leads to the "Land Between the Sumps", an extraordinary section of the system consisting of large phreatic passages and tall canyons with many waterfalls. There are several sumps through the upstream end of Cueva Juan Nieves (with a 40 m vertical entrance series to the main river). The downstream section of the cave is a series of smaller pirated zones with older, less active, parallel passages. Ceiling heights reach over 30 m in places, until 600 m from the entrance the river sumps for the last time and reappears 400 m later in the Aguas Frias spring on the Rio Grande de Manati.

The karst surrounding the Sistema Rio del Encantado contains many smaller caves, which are developed at higher elevations than the active cave. These are paleo-segments of the system and are indicative of uplift of the island and sea-level fluctuations, which affect local base level. Surface erosion has lowered the land surface and collapses have dissected the paleo-cave passages leaving remnants of cave in the mogotes. A number of upper level caves have been found in the mogotes above the Rio Encantado. Cueva Viento, the largest and most complex of the paleo-segments, is 2000 m long. This cave has two vertical entrances near the top of a mogote and one horizontal entrance in the side of a dry valley. One of the vertical entrances is named Volcan after the dark cloud of bats that leave the entrance every evening. A sinking stream enters the cave less than 100 m from the valley entrance. The cave consists of sediment-floored canyon passages, a series of complex mazes and loops, and very large breakdown rooms. The sinking stream appears in lower level passages, which extend for over 1 km before sumping. The water has been dye traced to the Agua Frias spring.

The caves of the Encantado karst are home to a variety of cave life. Amblypigids (tailless scorpions), cockroaches, fresh water crabs, and crayfish are common in the river

passages, and ten different bat species occupy the caves. At dusk it is not uncommon to see boa constrictors waiting patiently in mogote cave entrances for the evening bat flights.

Prior to organized exploration, some of the caves within the Encantado groundwater basin were already known to locals who used the caves for a source of water. Taino petroglyphs in some of the dry caves indicate that human use of the caves goes back to pre-history.

Exploration and survey continues in the caves of Rio Encantado, but an expanding population and ever-growing development is posing a threat not only to Encantado but also to the entire North Coast karst belt. Commercial and industrial development projects involve extensive deforestation, landform obliteration, and water diversion and contamination. All of these are seriously impacting the karst regions of Puerto Rico. It is hoped that increasing public awareness of the island's karst areas will stimulate protection efforts and generate government response to the threats confronting the North Coast karst belt and its associated ecosystems.

ENTRANCE HABITATS

Two ecological factors of overriding importance in cave entrance habitats are the amount of solar radiation received and the availability of water. Most cave entrances or "thresholds" extend from a land surface fully exposed to sunlight to a depth where little light penetrates, merging, at a variable rate, into near darkness. For caves with high, open entrances, the light gradient is low, amounting to reductions of 1% or less per metre, while in the smallest entrances (<1m), the gradient may approach 100% per metre. Sometimes the cave entrance will be under water, or within a doline, and receives low illumination with indirect sunlight only. In many cases there are problems for ecologists in deciding where cave entrances begin, particularly where the rock outcrop and entrance is irregular. The limits of the cave threshold communities are likewise poorly defined. Some light penetrates deeply within caves, as it does in the ocean, although at levels undetectable by the human eye. Defining the threshold limit as the depth to which plants can grow is not satisfactory as different species have their own tolerance levels and some

plants may contain chlorophyll and appear green, while growing heterotrophically (without photosynthesis). Oceanographers define а euphotic zone, where photosynthetically available light is > 1 % of its average surface value, followed by an aphotic zone where it is less than this. The scheme could be adapted for caves, but since light varies continuously and often irregularly in caves, the best approach may be to record a series of light levels as accurately as possible and consider the cave system as a continuum without resort to a rigid definition of the threshold. However, a reference level is sometimes useful when comparing caves and their biota, and a zone where >1 % of the external surface light intensity occurs is suggested for the limit of the cave entrance habitat. In mid-latitudes, this level corresponds to a light intensity slightly exceeding 1000 lux (c.18 μ E m⁻² s⁻¹) when the external light intensity is optimal (midday, open sky) (where 1E=6.02×10²³ photons).

The flora of cave entrances is often similar to that of local vegetation, differing only in minor respects where resurgences or air currents of different temperature occur. If the cave floor consists of moist sediment, a local forest flora is often represented as the illumination and humidity will approximate that of the woodland ground flora. Deeper within caves, the flora becomes restricted and a more or less marked zonation is often evident beginning with flowering plants, followed by ferns, mosses, lichens, liverworts, and algae. In European limestone caves, typical threshold genera of flowering plants are Geranium, Urtica, and Viola; ferns Asplenium, Dryopteris, and Phyllitis; mosses Eucladium, Fissidens, and Thamnobryum; lichens Chrysothrix and Lepraria; liverworts Conocephalum, Plagiochila, and Porella, and algae Chlorococcum, Chroococcus, and Gloeocapsa. In some cases, cave entrances provide refugia for plants where the terrestrial flora has been modified externally by man. Such sites have high conservation value and could provide a nucleus for future expansion when conditions outside the cave become more favourable. Most of the cave flora, excluding non-photosynthetic plants such as fungi, are facultative cavernicoles and a few species have been found only in caves. Plants with leaves (angiosperms, ferns, mosses, and some liverworts) show adaptations to low light levels. Leaves often become enlarged (to capture more light), leaf tissues thinner and stomata less numerous (due to high humidity). Stems become elongated, and branching less prolific. Sexual reproduction is often impaired at low light levels. A small group of cave mosses possess specially shaped cells, causing focusing of light onto the chloroplasts (*Mittenia* and *Schistostega*). Some algae show adaptations to low light by increasing the density of thylakoids in the chloroplasts. Cave soils provide a rooting medium for flowering plants but the flora is not confined to them. Rock crevices often provide moisture and support in addition to ferns and bryophytes. Lichens and algae are able to grow on bare rock walls, when the only source of water may be condensation from the atmosphere. Some ruderal species such as the nettle (Urtica) thrive in phosphorus-enriched soils where mammals use caves for shelter and deposit excreta. Aquatic communities, including flowering plants (e.g. Potamogeton) occur at wet cave entrances.

Invertebrates of cave thresholds often contain members of the woodland ground-fauna, with the flora and associated detritus supplying food and shelter. As with plants, a zonation is often apparent as the associated flora diminishes in abundance and diversity. Patterns are more complex for invertebrates since food and shelter can also be provided by allochthonous detritus passing through a cave and by structures within the cave.

Consequently some animals are not dependent upon light and are often found more deeply within cave systems. Invertebrates of cave entrance habitats include several insects such as the mosquito *Culex* and caddis *Stenophylax* which fly short distances into cave entrances for diapause (a form of hibernation), entrances providing moderately equable climates throughout the year. While these species do not feed within caves, others do, and are fed upon by predators such as the Tetragnathid *spider Meta merianae* and gastropods such as *Oxychilus*. These species often form part of a well-defined wall-association, living in crevices or attaching themselves to the exposed rock surface. Cave entrances are also used by birds such as *Hirundo fulva* (cave swallow) and *Pyrrhocorax* spp. (chough), the latter especially in sea caves. Along with bats (e.g. *Barbastella barbastellus*), their excreta and nest detritus provide a rich food source for other animals such as rats, and nutrients for plants and bacteria.

Reptiles, amphibians, and mammals make considerable use of cave entrances. Brief occupations are made by numerous species during periods of inclement weather such as heavy rains, but regular use of caves is restricted to fewer species, many of which are carnivores. Hyenas and wolves make dens in caves where the young are raised. Some burrowing species such as the red fox and badger also make occasional use of caves while others, such as the brown bear, use them for hibernation, but usually venture beyond the cave threshold. Leopards and porcupines are also known to occupy them for considerable periods. During the Pleistocene, cave bears made regular use of caves as dens. Humans are perhaps the most significant users of cave entrances among the mammals. Many early humans made regular use of cave entrances for temporary shelter, permanent accommodation, and for religious or other cultural practices. Some caves remain in use today (see Human Occupation of Caves).

ENVIRONMENTAL IMPACTS ASSESSMENTS

Karst areas are diversely rich in resources, yet are the world's most vulnerable landscapes to environmental impacts. The Earth's most productive springs and water wells occur in karst. The space provided by caves often provides habitats for rare and unusual species, serving as models of evolution and ecosystem development. Other species, such as bats, are internationally important as pollinators, seed dispersers, and controllers of crop and other insect pests. Hydrologically inactive caves offer stable environments that preserve many of the greatest archaeological and paleontological sites from the elements that would destroy them on the surface. Caves and surface karst terrains provide a wealth of recreational and scenic attractions. Paleokarst areas often contain tremendous deposits of oil, lead, zinc, and other fuels and minerals. The karstic bedrock itself, usually limestone, is often quarried for use in construction.

Historically, karst areas have not been heavily populated or utilized, and thus not heavily impacted. People have lived along the margins of karst, enjoying the benefits of springs, but most karst resources were difficult to access or of little direct or recognized economic benefit. However, technological advances in the 20th century changed this situation. Water and mineral resources are now easily extracted from karst, and many urban areas have grown onto karst areas. The underground spaces that offer protection and habitats also allow the consequences of sur face activities, such as contaminants, to easily enter the subsurface and degrade those resources.

Environmental impacts assessments (EIA) are increasingly used to limit the adverse impacts of human activities on resources important to the health of human and nonhuman ecosystems. The unique attributes of karst areas require assessment methods specifically designed for those terrains. DRASTIC (Aller *et al.*, 1987), pump tests, monitoring wells, and other techniques that are effective in assessing and managing nonkarst terrains, are often poorly effective to ineffective in karst. While several scientific disciplines need to be considered in assessing karst, a hydrogeologic EIA should first be conducted, since it defines the physical parameters of a study area and provides a conceptual model of karst development as a foundation for the other fields of research.

Three primary hydrogeologic EIA models for karst have been published and used. One or more can be used within a given investigation, based on the purpose, scale, and detail of study. Doerfliger, Jeannin & Zwahlen (1999) proposed EPIK to assess the vulnerability of karst terrains through the use of air photo interpretation, tracer tests, geophysical data, and geomorphological mapping in karst spring drainage basins. The EPIK system uses the resulting data to define an area's Epikarst (surface karst features), Protective cover (soil), Infiltration conditions, and Karst drainage (degree of solutional conduit development). The characteristics of an assessed karst watershed area are matched to a category under each EPIK factor. The categories have numerical values which are multiplied by a constant for the EPIK factor, and the results are summed to identify the area's degree of sensitivity with respect primarily to groundwater contamination. This vulnerability mapping method has broad application for both local and regional level EIA. A second karst hydrogeologic EIA model was proposed by the American Society for Testing and Materials (ASTM, 1995) and extended by the US Environmental Protection Agency (Schindel *et al.*, 1997). A conceptual model of the karst aquifer under study is first developed based on existing information and modified as new information is collected. Initially, well and spring data are usually most available and used to examine watertable elevations, differences in permeability and chemistry, and responses to recharge. Karst-specific data are then considered, surveying the location, type, and geologic setting (fractures, strata, etc.) of caves and other karst features. The next step, in many investigations, is to design a series of tracer tests to determine groundwater drainage basins, flowpaths, travel times, storage, dilution, and dispersion. These factors change with groundwater discharge and should be conducted, if possible, during base flow and storm flow conditions. Geophysical techniques, such as electrical resistivity and microgravity, can be used where it is necessary to locate voids that are not accessible through known caves. This is usually done for relatively small areas since these techniques are labour, time, and cost intensive.

Veni (1999) proposed a third karst hydrogeologic EIA strategy for areas where tracer testing and geophysical techniques are not possible or available. This method examines geomorphological and hydrological characteristics of karst areas and features to assess their relative permeability and their potential vulnerability. The potential for doline (sinkhole) collapse is often best identified through such methods. This strategy can be applied regionally as well as to specific features, and is adjusted according to the dominant characteristics of karst within each study area. It can also be applied to develop superior conceptual models of the karst and/or better interpret the results of the tracer and other studies. Additionally, this strategy requires defining what level of impacts on karst resources is sustainable in order to truly determine the consequences.

All hydrogeologic karst EIA methods suffer from the failing that they identify areas and features of relatively greater or lesser vulnerability, and land managers not familiar with karst often interpret less vulnerable areas as not vulnerable. Scientists conducting EIA in karst should stress to land managers that by the nature of karst landscapes, all areas are vulnerable, only highly vulnerable areas are distinguished, and that karst cannot be adequately managed solely on a feature-by-feature basis. Studies on the relationship of water quality to non-natural impervious land cover (roads, parking lots, buildings etc.) show adverse environmental impacts significantly increase when impervious cover exceeds 15% of a surface watershed. Veni (1999) recommended a maximum of 15% impervious cover as an effective means of protecting karst aquifers when coupled with protection of critical areas identified by field surveys.

Rare, endangered, or otherwise important species occur in many karst areas. They include aquatic species such as invertebrates, fish and salamanders, and terrestrial species, such as bats and invertebrates. While these species may be protected by the above hydrogeologic EIA methods, specific biological EIA methods are needed where hydrologic protection measures are not present or are inadequate for karst fauna. For example, water quality protection measures may not protect bats as much as not disturbing them during their hibernation. The above geomorphological EIA strategy is applicable to biology, by delimiting areas where important faunas should occur and which species may be present.

Following a review of biological data, the first step of a biological EIA is a presence absence survey for the fauna of concern in the study area. Some rare species will require multiple surveys to adequately determine if they are likely to be present. Others, such as migratory bats, can only be surveyed at certain times of year. A standard for the number and method of surveys may need to be established appropriate to the fauna. US Fish and Wildlife Service (2000) provides an example of karst biological survey standards. Monitoring of the fauna is also a key component of a karst biological EIA, to distinguish natural changes within the ecosystem from induced impacts and to determine what impacts are sustainable. While monitoring is usually not within the scope of a specific assessment, experience from monitoring studies with the species of concern should be incorporated into the karst biological EIA.

A significant portion of karst ecosystems may not be accessible or directly observable through caves and is thus difficult to assess in a karst biological EIA. This problem is especially important where quarries may largely or completely destroy the habitat and fauna, or where the habitat and fauna may be significantly altered and impacted by extensive urban and industrial development. A regional analysis of species localities relative to geologic factors may delineate the species' probable distribution and the degree of impacts they can withstand. Recovery plans for endangered karst invertebrate species have been based on such analyses (e.g. O'Donnell, Elliott & Stanford, 1994).

Karst EIA for cultural and paleontological materials also requires presence-absence surveys. Regional analysis can be helpful to identify areas where such materials are likely to occur but is less reliable than with similar biological studies. Materials present on the land surface may or may not be good indicators of materials in caves. Some past cultures and animals avoided caves while others were drawn to them. In either case, significant deposits may be present in caves due to deliberate or accidental accumulations. Both above and below ground, relatively recent sediments, free of cultural or paleontological materials, may bury or obscure older important deposits.

Cultural and paleontological karst EIA techniques commonly begin with detailed grid searches of the land surface. Such searches are also effective in hydrogeologic EIA in locating karst and other geologic features. Shovel tests are often necessary to evaluate potential deposits. Areas in caves that are likely to accumulate sediments, especially near entrances, should also be shovel tested, although such tests may be insufficient to characterize deep deposits. In some cases, geophysical methods can be used to evaluate a deposit's potential for significant materials and guide excavation or preservation strategies. In areas that may be lost to quarrying or other activities, evaluation methods may need to be modified into salvage operations if detailed studies are not feasible.

The complexity of karst terrains, their multiple and often difficult to define resources, and their high vulnerability to adverse impacts, requires prudence in EIA recommendations. There remains a lot to learn about how to best evaluate some attributes of karst and how to effectively protect and manage them. EIA recommendations should therefore be coupled with strategies recommended for the identification, delineation, and establishment of preserved or protected areas, appropriate management and maintenance of those areas, gating of caves and areas as necessary, and monitoring of resources within those areas, to determine the effectiveness of the recommended actions and the EIA process.

EROSION RATES: FIELD MEASUREMENTS

In karst, as in most other terrains, both chemical and mechanical erosion processes operate and the total karst denudation rate is the sum of both processes. However, as high rock solubility is one of the main characteristics that gives rise to karst terrains, and as chemical erosion is easier to estimate than mechanical, most karst research, with the notable exception of Smith & Newson (1974) has focussed on dissolutional denudation rates. Recent work on the turbidity of karst springs (e.g. Bouchaou, Mangin & Chauve, 2002) provides the potential for more detailed analysis of mechanical erosion rates. The majority of studies of dissolutional denudation rates have been undertaken in carbonate karst and these are the primary focus of this essay. However, as Klimchouk *et al.* (1996) have noted, similar considerations apply to evaporite karsts, and the estimation of gypsum dissolution rates is particularly problematic because of the more rapid solution and the consequently greater spatial and temporal variability of dissolution.

Denudation rates are commonly expressed as mm per 1000 years (mm ka⁻¹), implying that all erosion contributes to surface lowering and that environmental conditions have remained broadly the same for millennia. The former assumption is incorrect, particularly in karst, while the latter is also highly questionable. The preferred unit is $m^3 \text{ km}^{-2} a^{-1}$ and 1 mm ka⁻¹ is equivalent to 1 m³ km⁻² a^{\$T\$ms>1}. Where surface lowering is measured directly then units of $\mu m a^{-1}$ are appropriate.

Solutional erosion rates in carbonate karst may be estimated from knowledge of dissolution kinetics, runoff, carbon dioxide availability, and temperature (White, 1984), but there remains a need for field measurements to obtain actual values of regional denudation/transformation of relief; to compare denudation rates in contrasting environments and by different processes; to understand landform evolution; and to understand how the processes operate in a complex natural environment as opposed to the laboratory. When evaluating results from past studies it is important to understand what was actually measured and how the denudation rates were calculated. Although an early study by Spring & Prost (1883) was based on daily sampling, the vast majority of field measurements of solutional erosion rates in carbonate karst are based on spot samples, with denudation being estimated from the Corbel (1959) formula:

D = 4 ET n/100

Where *D* is the limestone denudation rate (m³ km² a 1), *E* is runoff (precipitationevapotranspiration, dm), *T* is the average CaCO₃ content of the water (mg 1^{-1}) and 1/n is the proportion of the basin occupied by karst rocks. This formula suffers several problems, including the assumption that the bulk density of carbonates is 2.5 g cm⁻³ whereas it can range from 1.5 to 2.9; failure to consider hardness due to magnesium salts; and failure to consider sulfate salts. However, the three most important failings are that *T* is frequently the average of a few spot measurements, with the implicit assumption of a linear relationship between carbonate hardness and discharge; that carbonates present in solution only come from karst denudation whereas some can come from other sources; and that measurements are usually made at only one point, commonly the output of a drainage basin, with the implicit assumption that this is representative of conditions upstream.

Where water samples have been collected over a range of flow conditions it is apparent that the relationship between dissolved load and discharge is usually nonlinear and, particularly in small drainage basins, may be complicated by hysteresis effects (usually higher concentrations per unit discharge on the rising limb). In practice it is virtually impossible to correct for hysteresis, but by collecting samples over a range of discharges it is usually possible to construct a reliable discharge-concentration or discharge-load rating curve. This can then be applied to the discharge curve and the results summed to obtain the total annual solute load (Gunn, 1981). Greater accuracy may be obtained using a logging conductivity meter, developing a conductivity-concentration rating curve, and using this to predict the concentration at each measured discharge. Where discharge records cover only a relatively short time period they may be extended using rainfallrunoff relationships (Williams & Dowling, 1979).

Having computed the total solute load (TSL) at a point it is important to realise that this is made up of total corrosion of karst rocks by both autogenic (CKAu) and allogenic waters (CKAl), less any deposition of previously dissolved material (D), together with corrosion of non-karst rocks by allogenic waters (CNK), solute accessions in rainfall and snowfall (AC), and any anthropogenic inputs such as fertilizers (AN). The gross karst solution is then (CKAu+CKAl) whereas the net karst solution is (CKAu+CKAl-D). Where precipitation of previously dissolved carbonates is minimal then gross and net solution will be similar, but elsewhere failure to account for deposition may result in a significant underestimate of gross denudation, which is the real measure of relief transformation. In contrast, failure to take into account the solution of non-karst rocks and solute accessions in precipitation will result in an overestimate of karst solution. For example, Williams & Dowling (1979) found that CNK and AC respectively made up 9.9% and 4.6% of the total solute load in the Riwaka Basin, New Zealand. Error in estimating erosion rates can arise from many sources and even in a careful study using hydrochemical budgeting and taking into account non-denudational components potential errors of around 25% are likely (Gunn, 1981).

Solutional erosion rates for whole drainage basins derived by sampling of water at the basin outlet are unlikely to be representative of any specific location within the basin. This information may best be obtained by an extension of the hydrochemical budgeting method discussed above. Water samples are collected from the full range of sites in the karst system—bare limestone surfaces, the soil zone, the subcutaneous zone, the main body of bedrock (sampled as vadose flows and seepages), and cave streams in both vadose and phreatic zones. These, together with estimates of the proportion of water following the various pathways through the system, permit the breaking down of the overall erosion budget (Williams & Downing, 1979; Gunn, 1981). Those few studies that have been made show that a high propor

Erosion Rates: Field Measurements. Micro-erosion meter. (Photo by John Gunn)

tion of solution (50–85%) occurs within several metres of the surface in the soil (if present) and subcutaneous zone (uppermost bedrock). Caves account for very little of the erosion when averaged over the whole basin.

The principal drawback of the hydrochemical approach is that it requires frequent, ideally continuous, measurement of discharge and sufficient samples to establish the pattern and extent of variations in solute concentrations. This is not always possible and alternative methods that integrate erosion over a longer time period have therefore been derived. The two most commonly used in karst areas are the micro-erosion meter (Spate *et al.*, 1985) which provides a direct measure of rock surface lowering (see Figure) and rock tablets (Trudgill, 1975). In contrast to the hydrochemical method these techniques are highly site-specific and may only be used to assess erosion rates on bare limestone surfaces, in the soil zone, at the soil-bedrock interface, and in cave streams. Trudgill (1975) suggested that tablets could be used to detect seasonal differences in erosion rates and raised the possibility of making reliable measurements over shorter time scales. However, when Crowther (1983) compared the rock tablet and hydrochemical methods in West Malaysia, he found that the tablets gave estimates two orders of magnitude less than those calculated using hydrochemical data. The most likely explanation is that natural rock surfaces come into contact with larger volumes of water than do isolated rock

tablets, simply because of their greater lateral flow component (see also Erosion Rates: Theoretical Models). Thus, the two methods measure fundamentally different phenomena and the hydrochemical method provides the only reliable means of estimating solutional erosion rates on limestone surfaces. Different problems arise if tablets are placed in cave streams as they will project above the natural surface and as a consequence are likely to erode more rapidly. They are also likely to suffer from abrasion as well as corrosion, although this can be exploited by placing the tablets in nylon cages with differing mesh sizes and comparing the erosional losses suffered.

In some areas it may be possible to estimate long-term average erosion rates for two elements in the carbonate karst system— bare limestone surfaces and cave passages. Surface lowering rates may be estimated from the height of limestone pedestals formed when part of a limestone pavement is protected from solution because it is capped with an erratic or a limestone block. The rate of erosion in cave streams may be estimated by an approach proposed by Gascoyne (1981) that makes use of uranium series dating of speleothems. If an old speleothem can be found in its growth position and near to an active streamway then its height above present stream level divided by its basal age provides an estimate of the mean maximum rate of passage lowering. The main shortcoming is that the routes of cave streams vary through time and if the streamway at the measurement point has not been occupied continuously since speleothem deposition the calculated erosion rate is no longer a maximum value. Care is also necessary in interpreting the results in terms of the overall distribution of solutional erosion since both solution and mechanical erosion are likely to be active in cave floor lowering. Direct comparison of long-term solutional erosion rates estimated from pedestal heights or speleothem ages with the results of modern process studies using hydrochemical or alternative methods is, strictly speaking, unsound. Nevertheless comparisons have been made and it is interesting to note that on the whole there is quite good agreement.

EROSION RATES: THEORETICAL MODELS

Lowering of the Earth's surface in karst areas of soluble rock is primarily caused by dissolution of the bedrock, in contrast to nonsoluble rocks, where mechanical erosion is the main process. Therefore knowledge of dissolution rates in various geological situations (see entries: Dissolution: Carbonate Rocks, Dissolution: Evaporite Rocks) allows estimation of denudation rates.

Direct observation of bedrock lowering (see Erosion Rates: Field Measurements) on bare limestone bedrock exposed to the atmosphere yields rates between 10 μ m a⁻¹ and 50 μ m a⁻¹. Dissolution on bare rock surfaces proceeds under the following conditions. A water film of about 1 mm thickness flows down the rock. Due to the roughness of the rock and raindrops impinging, eddies will occur and render the flow fully turbulent. The water is in equilibrium with CO2 in the atmosphere. Figure 1 shows the rates for full turbulent flow obtained by modelling (Buhmann & Dreybrodt, 1985) for various thicknesses δ (denoted by the numbers on the curves) of the water film. The rates *R* (cm a⁻¹) can be approximated (see Dissolution: Carbonate Rocks) by

$$R = 1.17 \times 10^6 \ \alpha(c_{\rm eq} - c) \tag{1}$$

where α is a constant in cm s⁻¹, c is the calcium concentration in mmol cm ³ in the solution, and c_{eq} the equilibrium concentration with respect to calcite. When a water film

comes into contact with a limestone surface it attains 90% of c_{eq} within a time $T=2\delta/\alpha$ (Dreybrodt, 1988). From Figure 1 one finds T=3000 for a film of 0.1 cm. Therefore the water remains at low Ca-concentration and denudation is determined by the rates at about 20% of c_{eq} . From Figure 1 one reads a lowering of bedrock from about 400 µm a⁻¹ to 200 µm a⁻¹ depending on the thickness of the water film. If one assumes that water films are present only during 10% of the year, denudation rates between 20 µm a⁻¹ to about 40 µm a⁻¹ are obtained in agreement with observation. Rates for downcutting of rinnenkarren are expected to be of similar magnitude. Thus entrenchment of a few centimetres needs about 1000 years.

Water running down a vertical shaft in layers several millimetres thick is in supercritical laminar flow with velocities in the range of 1 to 10 m s⁻¹. Erosion rates range between 300 and 800 μ m a⁻¹ (Figure 1) depending on the thickness of the water film. Therefore where water flows down in shafts continuously, for example Mammoth-Flint Cave, Kentucky, widening of the shaft diameter by 1 m takes about 1000 years.

A common procedure to measure denudation rates is to place bedrock tablets into the soil and measure their weight loss after a defined time. Observed rates are between 10 to 30

 μ m a⁻¹, similar to those on bare rock. This is somewhat unexpected because pCO₂ in soil is higher by at least a factor of 10. One has to consider, however, that dissolution proceeds by slowly moving water contained in the pores of the soil surrounding the limestone sample. The ratio of the volume V of water interacting with the limestone sample, to its surface area A is V/A-0.2d, where d is the pore diameter. This volume must now be taken for δ (Baumann et al., 1985). Soil water is in equilibrium with soil atmosphere with pCO_2 between 1×10^{-3} and 5×10^{-3} atm. From Figure 1 in entry: Dissolution: Carbonate Rocks, assuming c-0.5 c_{eq} , one finds rates of about 30 μ m a^{-1} for pore sizes of 100 µm at a temperature of 10°C, and $pCO_2 = 5 \times 10^{-3}$ atm. For smaller pore sizes (likely in various soils) the rates drop linearly, e.g. to 16.5 μ m a⁻¹ at a pore size of 50 µm. The dissolution rates increase by roughly a factor of two when temperature rises by 10°C. They also increase with increasing pCO_2 (Dreybrodt, 1988). Since the rates depend critically on the saturation state of the water, knowledge of the Ca-concentration in the pore water is of utmost importance. Zambo and Ford (1997) have investigated the carbonate dissolution potential in soils of a doline in upland karst of Hungary. This potential is the amount of calcite which can be dissolved at prevailing conditions: pCO_2 in the soil and mean annual flux of infiltration. From this potential they estimated denudation rates in the range of 10 μ m a⁻¹ at the bottom of the doline. Dissolution of calcite in soil is thus a complex process compared to dissolution on bare rock surfaces, and direct comparison of these two rates is not appropriate.

Dissolution rates are much higher in karst streams and range between 100 μ m a⁻¹ and 800 μ m a⁻¹. In streams the *V/A* ratio is large and rates are no longer controlled by CO2 conversion, but by diffusion through a boundary layer. Its thickness € decreases with increasing flow velocity (see Dissolution: Carbonate Rocks, Figure 3). For example, Figure 2 depicts rates for turbulent flow of water with $pCO_2=1\times10^{-3}$ atm as is common in stream water, for various values of €. At low Ca-concent tration of *c*-0.2 c_{eq} the rates vary from about 800 μ m a⁻¹ for high flow (low €) velocities down to 230 μ m a⁻¹ when flow is slow (€ large). For higher Ca-concentrations the rates drop linearly. They depend only weakly on pCO_2 in the water (see Figure 3 in Dissolution: Carbonate Rocks) but they drop with decreasing temperature. The dependence of bedrock retreat on flow and consequently on ϵ has been observed by Lauritzen (1986). Dissolution rates in an isolated single cave conduit, with only one sink and one spring increased by almost a factor of ten from low discharge (1 m³ s⁻¹) to high discharge at 10 m³ s⁻¹.

Denudation rates in gypsum terrains have been observed by a variety of methods (Klimchouk *et al.*, 1996). Direct retreat of ledges in gypsum and also observation of wall retreat of large gypsum boulders in rivers yield dissolution rates between 10–20 cm a^{-1} (James, 1992). Navas (1990) has observed rates of 20–40 cm a^{-1} on gypsum spheres suspended in rivers. Gypsum rates *R* (cm a^{-1}) can be estimated in such situations by

$$R = 2.3 \times 10^6 \frac{D}{\epsilon} \cdot (c_{\rm eq} - c) \tag{2}$$

(see Dissolution: Evaporite Rocks). $D=10^{-5} \text{ cm}^2 \text{ s}^{-1}$ is the diffusion coefficient, ϵ [cm] is the thickness of the diffusion boundary layer in the order of 10^{-2} cm, and *c*, c_{eq} are the actual and the equilibrium concentrations in mmol cm⁻³. For undersaturated water, c=0, one obtains rates of about 18 cm a⁻¹ for $\mathbf{\epsilon}=2\times10^{-2}$ cm. Depending on hydraulic conditions of flow, variations in ϵ are the reason for the observed variation of the rates. At extremely fast flow ϵ could become lower. For $\mathbf{\epsilon}=2\times10^{-3}$ rates are maximal at 180 cm a⁻¹. Such extreme values are reported by Klimchouk *et al.* (1996).

Measurements with micro-erosion meters on bare gypsum rock exposed to meteoric precipitation yield values from 0.2 up to 1.6 mm a^{-1} (Klimchouk *et al.*, 1996). The rates are correlated linearly with annual precipitation. Conditions for dissolution on gypsum rock are similar to those for limestone discussed above. Flow is fully turbulent. Under such conditions gypsum dissolution is surface-controlled and in contrast to limestone dissolution is fast. (See equation 1 in Dissolution: Evaporite Rocks.) The time *T* to obtain 90% of saturation is short, in the order of 30 s. Therefore the solution flowing on a bare rock is close to saturation and the rates can be estimated by mass balance. At an annual

precipitation W, in mm a^{-1} , 10^{-4} W litres of saturated solution with $c_{eq}=2.5$ g l⁻¹ flow from 1 cm² of bedrock. This yields a denudation rate of 1.1×10^{-3} W mm a^{-1} , which is close to values observed in Italy on exposed bedrock.

In summary, knowledge of the dissolution kinetics of limestone and gypsum is necessary to understand observations in the field.

EUROPE, ALPINE

The Alpine regions of Europe are a complex system of high mountains that formed since Cretaceous times along convergent plate boundaries between the African and Central European plates. The main arc of the Alps stretches from the Mediterranean coast near the French—Italian frontier to the edge of the Vienna Basin and to the edge of the classical karst of Slovenia (Figure 1). There are also significant elements of the same tectonic structural unit, including the Cantabrians and the Pyrenees (and other chains within Spain), the Apennines, and the chain from the Dolomites to the Julian Alps (Figure 1). In eastern Europe, the Carpathians and Dinarides are also a product of the same Alpine orogenesis. The cores of all these mountain chains are schists and gneisses, but their rocks originated from Tethyan sediments deposited between the converging plates. Throughout the Mesozoic these included substantial areas and thicknesses of carbonate shelf oozes, which now form zones of Triassic, Jurassic, and Cretaceous limestones distributed along all the Alpine chains. Most are now strong limestones ideal for karst development, though some are dolomitized and others have been metamorphosed to marble. Evaporites are relatively rare. There are many different types of alpine karst landscapes, and their variability is greater than in other regions of the world of similar extent. The prime causes of this variability, best seen in the main arc of the Alps, are the different ages of the carbonate rocks (mainly Jurassic and Cretaceous in the west, and Triassic in the east), the conditions of their sedimentation, and their different structures. Secondary causes are the different intensities and ages of tectonic deformation during the Alpine orogenesis

Europe, Alpine: Figure 1. Area location map.

(in general earlier in the Eastern Alps, and later in the Western Alps). A third important influence on the evolution of karst and caves in the Alps has been the very different climatic conditions in the past as well as today. The Atlantic climate in the western ranges, the Mediterranean climate on the southern border, the central European transition climate in the northeastern Alps, and the Illyrian climate in the Julian Alps are all different in the amount, intensity, and annual distribution of their precipitation. Temperatures decrease with altitude, so that the high alpine zones have nival and partially glacial karst. During the cold stages of the Ice Age, most karst terrains were covered by glaciers, so that many alpine regions now have polygenetic surfaces. Karst forms are not always dominant on the surface, where they were modified or destroyed by glacial erosion or are now covered by glacial deposits, but underground karstification is still intense.

Most of the slopes and plateaux up to altitudes of about 1700 m are green karst, covered by forests. Higher parts of the limestone massifs alternate between alpine meadows and zones of bare rock (naked karst). Only the very highest basins in the alpine limestone regions retain relatively small modern glaciers, notably on the Diablerets in Switzerland and on Hochkönig and Dachstein in Austria. Within the high alpine karst there are very few true poljes but the relief shows many traces of dry valleys inherited from Tertiary topographies that predate the main karstification.

River sinks are very rare in the Alps. The few great karst springs are fed only by rainfall and snowmelt, which enter the limestone outcrops directly through immense numbers of joints, fissures, and dolines. The catchments of the springs are not always easily defined, but their boundaries are typically independent of surface relief and topographic divides. Most of the karst springs are vauclusian risings, and the karstic cavities of the deep phreatic zone contain very large resources of water. In the French Alps, the best-known example is the Fontaine de Vaucluse. In the Eastern Alps, karst springs are very important for the supplies of drinking water—half the population of Austria (including the inhabitants of Vienna) utilize karst waters.

The importance of rock structure in the formation of specific karst forms is shown by comparison of the best examples of karren fields in the Alps. Within the Swiss Alps, karren are very common on the outcrops of the Cretaceous Schrattenkalk, notably on Schrattenfluh mountain and in the Glattalp-Märenberg region. In the Venetian Alps of northern Italy, the Jurassic Rosso Ammonitico forms the karst on Alpi Lessini and Monte Grappa. In the northern Calcareous Alps of Austria, the Upper Triassic Dachsteinkalk is carved into the alpine karst of the Steinernes Meer, Dachstein, and Totes Gebirge massifs. The characteristic forms of karren are different on these different limestones, and karren are very rare on other limestones within the alpine stratigraphic sequence.

The Dachsteinkalk, a strong limestone with a thickness of >1000 m, contains the longest and deepest known caves in Austria and also forms much of the Julian Alps. The main karst massifs form a chain along the northern Calcareous Alps (see separate entry), all with spectacular alpine karst, extensive karren field, and deep caves. Lamprechtsofen is currently the second deepest cave in the world (1632 m), and is unusual in that it was largely explored upwards from the resurgence. A concentration of karst caves has been explored in the northern part of the Dachstein massif, notably Hirlatzhöhle (87 km long, 1041 m deep) and Dachstein Mammuthöhle (58 km long, 1199 m deep). South of the main Alps, the karst of Styria has many caves including Lurhöhle (with 6 km of decorated galleries) and Drachenhöhle (with very large passages and well known for its rich finds of the fossil cave bear), all developed in Devonian limestones.

The Swiss Alps have a belt of Cretaceous limestones forming high escarpments with spectacular alpine karst from Leysin to Alpstein along the northern side of the Bernese Oberland. Within this belt, Hölloch and Siebenhengste (see separate entries) are the two major cave systems in the Schrattenkalk. Of the Jura mountain chains, only the zone straddling the border of Switzerland and France was strongly folded in the Alpine orogenesis. In these parts of the Swiss and French Jura, mostly forested limestone escarpments are distinguished by some very large karst resurgences. Some of the caves in the Jura are long but not deep, including the fine through-system of the Reseau Verneau with 32 km of passages in the French department of Doubs.

Karst massifs extend along the French Alps and show progressive changes in their geomorphology from the high alpine karsts near Mont Blanc to the softer fluviokarsts of Provence. The finest karst landscapes and the deepest caves are in the massive Urgonian facies of the Cretaceous limestones. North of Mont Blanc, the Desert de Platé is a bare karren field that is under snow for much of the year; its dipping limestone contains the world's first and fourth deepest caves (Mirolda, -1733 m; Jean Bernard, -1602 m), both distinguished by long narrow meandering canyons and numerous small shafts. Notable among the karsts around Grenoble, the three massifs of the Chartreuse each contain their own long and deep integrated network of multilevel caves—l'Alpe (60 km long), Granier (55 km long), and Dent de Crolles (50 km long, see separate entry). South of these lies the spectacular karst of the Vercors (see separate entry). Further south, the Vaucluse

Plateau is a fluviokarst upland with a surface of broken limestone debris inherited from periglacial frost shattering and largely surviving in the modern dry climate. Caves including the deep shaft systems of Caladaire (-668 m) and Jean Nouveau (-579 m) drain to the famous Fontaine de Vaucluse where the water rises 308 m up the flooded shaft. The Grand Canon du Verdon is entrenched more than 800 m between plateaux of limestone distinguished by dolines, grassland, and few known caves.

On the French—Italian border, the Marguareis is a spectacular plateau of degraded glaciokarst with deep cave systems including the Piaggia Bella, 32 km long and 950 m deep with its lowlevel "collecteur" (main drain) partly entrenched into the green schists that underlie the limestone. Within the Southern Alps of Italy, the main carbonates occur east of Lake Garda. The Lessini and Asiago plateaux are pitted with numerous dissolution and collapse dolines in the finest of the karst landscapes in the Venetian Alps (see Asiago Plateau, Italy). Spluga della Preta (-985 m) on Lessini, and Abisso di Malga Fossetta -974 m) on Asiago, are the deepest known shaft systems, and Buso de la Rana is a resurgence cave 24 km long at the foot of the Asiago. Further east, the Dolomites are distinguished by high white cliffs and spectacular glaciated landscapes, but known caves are few in the less karstified dolomite rock. In contrast, the Julian Alps cross the Italian-Slovenian border, where many vertical caves more than 1000 m deep have been explored in Monte Kanin (see separate entry).

The Apennines extend the length of Italy with isolated but significant areas of mountain karst. A long belt of gypsum karst lies along the Po Valley flank, and contains the Spipola-Aquafredda with 10.4 km of passages near Bologna. The Alpi Apuane have an alpine karst with extensive bare outcrops of variably metamorphosed limestones that include the famous Carrara marbles. One of the main groups of active quarries cuts into the side of the mountain drained by the complex cave system of Fighiera-Corchia, 52 km long and 1210 m deep. The mountains hold many other deep shaft caves, with five already explored to more than 700 m deep. Perugia has the high alpine karst of Monte Cucco, with the cave of the same name (31 km long and 945 m deep), and the caves of Fiume-Vento caves (23 km long) and Frasassi (see separate entry) at lower elevations towards the Adriatic coast.

The Pyrenees are a major westerly extension of Europe's alpine fold mountains. They have many areas of spectacular alpine karst with vast karren fields and numerous deep caves (Figure 2). Among the finest are in the karst around Pierre St Martin (see separate entry) with its many deep caves passing under the France—Spain frontier, and also the huge cave system of Felix Trombe/Henne Motre (with 101 km of mapped passages reaching a depth of 975 m). Much smaller but equally distinctive are the galleries of the Grotte de Cigalère, some of which are uniquely well decorated with calcite and gypsum, and the Grotte Moulis with its underground laboratories and its inner chambers decorated with aragonite. On the Spanish side of the Pyrenees, the finest alpine karst covers Monte Perdido, now in the Ordesa national park, due north of Huesca. The ice-filled galleries of Grotte Casteret lie just below the Brèche de Roland (with the Cirque de Gavarnie on the French side). The finest caves lie further east in the Escuain massif, where the Sistema Badalona can be followed through from sink to resurgence over a depth of 1149 m.

Europe, Alpine: Figure 2. Classic alpine glaciokarst in the high Pyrenees, with bare limestone lapiaz fretted with deep karren and broken by small dolines with soil floors. (Photo by Tony Waltham)

Alpine fold mountains continue into Spain as the Cantabrians. The Picos d'Europa (see separate entry) has the highest and most spectacular karst with an amazing number of deep cave systems, but there are other significant karst sites. The Matienzo depression extends over 26 km², largely drained into a ponor that lies 220 m below the lowest col through the perimeter mountains; the karst is underlain by numerous caves, of which >200 km have been mapped to date, with three systems each >25 km long. South of Matienzo, another karst plateau is broken by the 302 m deep Cueto shaft which continues down into large abandoned galleries and an active river passage through to the Coventosa resurgence, making a cave system 32 km long and 815 m deep. Further east, Ojo Guarena is the longest cave in Spain with a rambling maze of 99 km of mapped passages beneath a low escarpment.

Away from the main alpine fold mountains, the high Sierras of southern Spain are formed on huge tracts of limestone with karst landforms that are generally poorly developed in the hot and semi-arid climate. In the high Sierrania de Ronda, behind Malaga, the shafts and meanders of Sima GESM drop to a depth of 1098 m, while, along the coast to the east, the show cave of Nerja is noted for its very large stalactites.

Recent geomorphological and speleogenetic studies seem to confirm that the oldest generation of karst landforms was developed in the late Miocene. These include caves that survive only as tunnel fragments or as roofless caves. The Messinian regression rejuvenated the Western Alps with a lowering of the base level of karstification. In the Eastern Alps, it appears that a paleosurface developed by the early Oligocene has been preserved with minimal modification on some of the elevated karst plateaux. There are many detailed studies of the karst and caves in all parts of the Alps, but much remains to be explored and studied, and valuable results are coming from comparisons of the geomorphologies in the different areas of the region.

EUROPE, BALKANS AND CARPATHIANS

A long temperate karst belt extends through Romania, Moldova, Bulgaria, and former Yugoslavia (Figure 1). However, in the southernmost parts of Serbia and Bulgaria the climate is transitional between Mediterranean type and fully temperate continental type. Despite the complex geological background and the relatively low proportion of karst outcrops, more than 20000 caves have been explored and mapped within this region. This figure may be due to a long tradition of speleological exploration and research. Notable scientists from the above-mentioned countries include Jovan Cvijić (see Geoscientists) and Emil Racoviță (see Biospeleologists). In Bulgaria, where karst is widespread, the study of caves began early in 1878 when the Shkorpil brothers (Karel and Herman) wrote *Krazhki yavlenia*—the first book describing some of the Bulgarian caves. In Romania, by the end of the 1990s, a network of caving clubs had explored more than 12000 caves. This shows that there may be great speleological potential in regions where there is only a relatively small area of exposed karst rocks.

The type of cave encountered in the Balkan region is related to the overall geological history of the area. Apart from the gypsum-karst area of Moldova, whose geological evolution is connected with a transition zone between the East European Platform and the Carpathian foredeep, the karst was strongly influenced by Tertiary uplift of the Carpathians and Balkans. This uplift has broken the unity of most stratigraphic units, thus breaking up the limestone outcrops between the high ridges and the slopes. In only a few cases was this continuity preserved, favouring deep drainage as within the Piatra Craiului Mountains of Romania, where Avenul din Grind -540 m) is the deepest pothole in the region. For most mountain ranges in the area, an igneous or metamorphic core is surrounded by limestone. This setting favours the formation of relatively long caves with

active passageways, often tiered and sometimes including mazes of relict passages richly decorated with speleothems.

Romania

About 2% of the exposed land surface of Romania consists of karst (Onac & Cocean, 1996), but this figure is misleading, as in many cases Neogene or Quaternary deposits overlie older formations, which include carbonate and evaporate karst-forming rocks. The most important karst rocks are Mesozoic limestones, but caves are also recorded in dolomites, halite, conglomerates, and sandstones. In Romania, karst is mainly developed in the Southern and Western Carpathians, with the largest limestone area being located in the Banat Mountains (adjacent to the border with the former Yugoslavia).

The karst plateaux contain karren, dolines, uvalas, and poljes, whose development was favoured by the great thickness of carbonate deposits (600 to 2000 m). These plateaus may be found at 800 to 1200 m altitude in the Pădurea Craiului,Mehedinți, and Bihor Mountains, and also at 1800 to 2200 m in the Retezat Mountains, which show typical alpine karst (Onac & Cocean, 1996). Bar Karst is mostly located on the slopes of the Carpathians, and consists of longitudal limestone bars (stripes), isolated during the uplift of the mountain range. Surface rivers, formed on the crystalline basement, cut through the limestone ridges in spectacular gorges or, in many cases, through long caves. The most typical karst systems of this type appear in the Piatra Craiului, Vîlcan, Mehedinți, and Şureanu Mountains of the Southern Carpathians.

The most important karst of Romania is located in the Western Carpathians, mainly in the Pådurea Craiului and Bihor Mountains. Bihor Mountains includes a high plateau with many 200–300 m deep potholes. Some of the potholes contain river passages that are several kilometres long; Avenul V5 is 225 m deep and 10 km long. The second longest cave of Romania is the Humpleu—Poieniță system (39 km, -308 m), which includes a 5 km long underground stream with more than 30 sumps. The main features of this cave are the huge rooms (the Giants Room is $573 \times 111 \times 35$ m), as well as the richness and the variety of the speleothems. Among these are the remarkable calcite scale nohedron crystals, 30-80 cm long, which may weigh over 50 kg. Oxygen-isotope ratios reveal that they are of hydrothermal origin. Valea Rea Cave (19 km long), in the western Bihor Mountains is considered to be one of the world's richest caves with respect to its mineralogy. The 35 minerals described from this cave include barite, celestine, quartz, dickite, metatyuyamunite, gypsum, and malachite, with most of these supporting a hydrothermal genesis. In addition, the Bihor Mountains also host five caves with perennial ice deposits. The most famous is Ghetarul de la Scărișoara, which contains an ice mass 75000 cubic metres in volume. Pollen extracted from the lower part of the ice block gave an estimated age of 3500 years (Racovita & Onac, 2000).

The Pădurea Craiului Mountains have a karst terrain at altitudes of 400–800 m, where sinking streams follow long, branching, gently sloping caves, including Ciur Ponor (–203 m, 17 km) and Ponoraş (–211 m, 6 km). Peştera Vântului (Wind Cave), Romania's longest cave, is a resurgence with over 48 km of passages. It is basically a single-stream passage paralleled by three relict levels displaying outstanding horizontal and vertical meanders, and is also notable for its mineralogy (Onac, 1996), and geomicrobiology (Manolache & Onac, 2000).

In the Eastern Carpathians, the only significant karst area is the Rodnei Mountains—a network of alpine ridges. Here several Eocene limestone bodies contain influent caves, including Tăuşoare Cave (470 m deep and 16 km long), famous for its strange limestone balls, gypsum speleothems, and rare mirabilite, leonite, konyaite, and syngenite minerals (Onac *et al.*, 2001). Halite and gypsum occur in Miocene salt domes, diapirs, and massive salt beds protected by cap rocks. In the Vrancei Subcarpathians, the Peştera 6S de la Mânzălşti (3234 m long) is the secondlongest salt cave in the world. In the southeast of Dobrogea, Movile Cave (see separate entry) is a unique chemoautotrophically based cave ecosystem in which 34 invertebrate species are endemic.

In the Şureanu Mountains, a high karst plateau (at an altitude of 800 to 1200 m) is divided into two by the deep Strei Gorge. The main underground system is the 10 km long Şura Mare resurgence cave with a vertical range of 405 m. In the same area, Cioclovina Cave has been known since the late 19th century, when scientists visited it to search for cave bear bones and to investigate the 15–20-m thick phosphate deposit (Figure 2). Between 1912 and 1941 over 30000 m³ of guano phosphate were mined out and used as fertilizer, and thousands of cave bear skeletons from within the phosphate were ground up for the same purpose. In the upper layer of the phosphate deposit, Hallstadt ceramics, as well as skulls of *Homo sapiens fossilis* were found, and the cave is also famous for its many rare phosphate minerals, including crandallite, paratacamite, taranakite, collinsite, hydroxylellestadite, and berlinite.

On the Mehedinți Plateau in the southwestern Carpathians, the major cave system is Topolnița (20.5 km, -127 m), a threelevel streamway that underlies a vast network of

older passages. Spectacular karst landforms are concentrated at Ponoarele, including dissected limestone pavements, a natural bridge carrying a motor road, and the great lake of Zăton which is drained by the 5 km long Bulba Cave. In the same area, the richly decorated Cloşani Cave is used by the Institute of Speleology as an underground laboratory.

Yugoslavia (Serbia and Kosovo)

In Serbia, carbonate rocks crop out over a total area of 7803 km² in the Carpatho-Balkanides (eastern Serbia), and in the Inner Dinarides in the west (Figure 1). The most extensive karst, in Eastern Serbia, has swift-flowing springs (flow rates of $0.5-2 \text{ m}^2 \text{ s}^{-1}$), which drain massifs of Mesozoic limestone. The greatest concentration of long and deep caves occurs within the Miroć carbonate platform—an impressive karst plateau cut by deep dolines, on the right bank of the Danube Gorge. Six small parallel streams, originating on the impervious basement, sink into the limestone, forming essentially vertical caves with some large active passages. Among them, Rakin Ponor is the second deepest cave in the country –285 m) and Buronov Ponor (2.4 km, –187 m) is a beautiful cave, richly decorated, that intercepts the principal river with an average flow of *c*. 1 m³ s⁻¹ (Zlokolica *et al.*, 1996). The resurgence lies 5 m below the present level of the Danube in the artificial lake of Iron Gates Dam.

The Kučaj-Tupažnica carbonate platform is the continuation of the Banat karst in Romania, and contains most of Serbia's caves. In the Kučaj Mountains, the Dubašnica pothole (-276 m) consists of large shafts, including a single drop of 120 m. In the same area, Bogovinska Pećina (5842 m long) is a complex resurgence cave developed on three levels. The vauclusian karst spring, Vrelo Krupac, at the foot of Mount Svrlijiške Planine, discharges 150 1 s⁻¹ and has been explored by diving down to -83 m. On Mount Kalafat, the third-longest Serbian cave, Cerjanska Pećina (6025 m), is an active swallet with extensive allogenic sediments.

In the Inner Dinarides, the limestones are Triassic in age, and important karst areas include Lelić and the Gilijeva mountain. The karst of Pešter plateau contains the Ušački Pećinski system (6185 m), which includes an active passage from sink to resurgence.

The western part of Kosovo seems to be the area with the greatest speleological potential—not yet explored due to political instability in the area. Velika Klisura (8500 m long, 310 m deep), is the most important major cave, situated close to the border with Montenegro.

Bulgaria

Bulgaria has outcrops of carbonate rocks across 24% of its territory, hosting over 5000 caves. Mesozoic carbonate rocks form the main karst in the Stara Planina Mountains. There is a marked distinction between the karst and caves of the Stara Planina, in the central part of Bulgaria, and those of the Rilo-Rhodopes Mountains in the south. The most important caves in Bulgaria, including the longest (Douhlata Cave which is 18 km long) and the deepest (Raitchova Doupka, -377 m) are located in the western and central part of Stara Planina. The Shopov cave system (in the western part of Stara Planina) is considered to be one of the world's most mineralogically rich caves, with 41 mineral species, 18 of these being described only from that locality (Shopov, 1988). The upper part of the cave has a hydrothermal origin, while the lower levels are formed by the

dissolution of sulfuric acid produced by oxidation of iron sulfides in the upper part of the cave.

The large unbroken covered karst of the Dobroudja is characterized by a few short caves, dry valleys, and the presence of a sulfidic water aquifer at a depth of 400 m. Along the Danube Plain, Orlova Chuka Cave (near Ruse) in Lower Cretaceous limestone is 13437 m long, and Magura Cave (2500 m long, near Vidin) is renowned for its wonderful Neolithic and bronze age guano paintings.

In the western part of the Rhodopes Mountains and the northern part of the Pirin Mountains, karst develops on the Proterozoic marbles. Of the 50 known caves in the area, more than 10 are of hydrothermal origin. Historically, the Romans mined these for lead ore. The marble sequence in the Pirin Mountains is over 2000 m thick, with the potential for hosting some of the world's deepest caves. The Pirin National Park was founded in 1963 and added to UNESCO's World Heritage List in 1983. It hosts diverse and unique landscapes, including some 70 glacial lakes, caves, waterfalls, and pine forests. It is also the home to hundreds of endemic and rare species, many of which are representative of the Balkan Pleistocene flora. Unfortunately cave ice seals all of the high-altitude caves. In the eastern part of Rhodopes Mountains, more than 250 caves are known. The largest karst area in the Rilo-Rhodopes is south of Plovdiv, where the Trigrad Plateau (at an altitude of 1500 m) is an old corrosion surface that is now breached by hundreds of dolines and cut by several canyons 300 to 400 m deep (Nicod, 1982). The largest cave in the region is Jagodinskata (8500 m long).

Paleokarst is widely documented in Bulgaria, mainly from boreholes and mining activities. Mineral deposits connected with paleokarst include metasomatic lead-zinc ores, bauxites, gypsum, kaolin, and iron ore.

Moldova

Karst research in Moldova has received little attention, because the rocks that are susceptible to karstification crop out only in small areas in the northwest of the country and along the Nistru (Dniestr) Valley in the east (Figure 1). The karst features develop on Miocene gypsum (10–40 m thick) (Andrejchuk & Klimchouk, 1996) and the development of caves began under deepseated conditions during the Pliocene. Following the Prut Valley entrenchment into the gypsum during the Late Pleistocene, karstification processes were stimulated. Apart from the Zoloushka Cave (known as "Emil Racoviță— Cave by Moldova's speleolo-gists), which is 92 km in length (and similar to the Ukraine gypsum caves), all of the other caves are small.

EUROPE, CENTRAL

Central Europe covers Austria outside the Alps, Czechia, Hungary, Poland, and Slovakia. The region is a complex of karst areas covering the old Middle European Platform as well as the younger Western Carpathians and Carpathian Basin. Karst and cave areas are irregularly distributed (see Figure). The largest carbonate karst areas outcropping on the surface occur in southern Poland and in Slovakia (8000 km² and 2700 km², respectively). Although 15% of Austria is underlain by karstified rocks, only a tiny part of this karst lies outside the Alps. Carbonate rocks crop out over some 1.5% (1350 km²) of Hungary. In Czechia, limestone and dolomite outcrops support karsts of minor importance (less than 0.4% of territory, about 300 km²), but have been very well studied. The Krakow-Wielun Upland (Poland) with an area of 2500 km² and more than 1700 caves is the largest individual karst region in Central Europe.

The geological settings of karst in Central Europe range from Precambrian (marbles of Sudety Mountains) to late Quaternary (travertine of Bükk Mountains and Lower Tatra Mountains). The region is divided into two different tectonic units. Karst areas of Czechia and most of Poland are formed mostly by blocks of folded Paleozoic limestones, dolomites, and marbles belonging to the older Central European Platform. In South-Central Poland they are covered by sub-horizontal Mesozoic carbonate rocks. The southeastern part of the region has the small karst areas of the Western Carpathians and Carpathian Basin, on Alpine folded structures of Mesozoic carbonates.

In the Sudety Mountains (on the border of Poland and Czechia) karst is developed in crystalline limestones, Proterozoic marbles, and Carboniferous limestones. The longest cave in this area is the 2230 m Niedzwiedzia (Bear) Cave. In the Holy Cross Mountains in the north of the region, caves that developed in Devonian limestones are almost entirely filled with clastic sediments of a lower Triassic transgression (e.g. Chelosiowa Jama, a cave more than 3 km long). The surface karst landforms and some of the caves in this area are filled with sediments related to Pleistocene continental glaciations. Only the Holy Cross Mountains and the Silesia-Krakow highlands were within the

Europe, Central: Table 1. The longest caves in Central Europe.

range of the Scandinavian ice sheet, and caves were developed by proglacial waters at the carbonate base; these include the Szachownica Cave in the Krakow area. Mesozoic rocks of the Silesia-Krakow Upland have strongly developed paleokarst phenomena, which are the result of hydrothermal processes in the middle Triassic carbonate rocks (including zinc and lead ore deposits). They also have relict well-developed karst in upper Jurassic limestones with large fossil poljes and fragments of large hydrothermal caves.

Czechia has karst areas developed in small lenses of Paleozoic carbonate rocks surrounded by non-karst rocks. The Moravian Karst, on Devonian limestones in contact with the Brno igneous massif and clastic culm rocks, has the largest Central European fluviokarst system—Amaterska-Punkva Cave System, which includes show caves. The Bohemian Karst, on Carboniferous limestones near Prague has strongly developed upper Paleozoic paleokarst, revealed during exploitation of limestones in quarries.

Different conditions of karst are found in the Western Carpathians and the Carpathian Basin, where folded Mesozoic carbonates form high-mountain and plateau karst. High mountain (alpine) karst occurs in a small area of the Tatra Mountains in the Czerwone Wierchy massif, at an elevation of more than 2000 m, where the deepest cave systems in the region can be found. An important feature of the high-mountain karst of the Czerwone Wierchy range was the proximity of the Scandinavian ice sheet in the Pleistocene and severe climatic conditions associated with the glaciation of the Tatras. The Wielka Sniezna System in the Tatra is the largest recognized autochthonous karst system in the region (explored cave systems and sections of underground flow proved by tracing). Other areas of high-mountain karst occupy the highest part of Belanske Tatra and the Lower Tatra Mountains, where Demanovsky Cave System is the best explored active fluvial cave system.

The Slovak Karst, the Muran Plateau, and the Slovak Paradise plateau karst lie in the central part of the Inner Carpathians. Parts of the North Hungarian Mountain Range, Aggtelek-Rudabánya, and Bükk Mountains have a similar geological and morphological setting, and contain some of the most interesting caves in Central Europe, including Ochtinska Aragonite Cave, Dobšina Ice Cave, and the Baradla-Domica cave system.

The Transdanubian Mountains contain the karst areas of Bakony, Vértes, Pilis, and Buda Mountains, low mountains and plateaus at altitudes of 250–700 m, built from

Mesozoic and Tertiary carbonates. The Triassic Dachstein and Eocene limestones are the most important for karstification. Small patches of limestones were strongly karstified and denuded in the Cretaceous and Paleocene. The paleokarst features of the open-cast bauxite pits of the Bakony and Vértes Mountains are significant remains of this important regional karstification phase. Bauxite and manganese deposits are mined here in one of the most productive areas in Europe (see Bauxite Deposits in Karst).

In the Paleozoic basement of Central Europe small block structures occur, while the zones that separate them are sites of high tectonic activity. The results of this activity are both fossil and present-day hydrothermal phenomena, ore-bearing carbonate rock complexes, travertine deposition, gas emanation phenomena in caves, and specific hydrogeochemical environments. Although there are many significant fossil thermal water sites-several paleokarstic features within Paleozoic and Mesozoic carbonate rocks of the Middle European Platform in Czechia and Poland-some hydrothermal phenomena are still present in the Carpathians. The largest cave systems of thermal water origin are in the Buda Hills of Budapest, Hungary. These cave systems show strong tectonic control and have labyrinth plans. Most were created by the mixing corrosion effect of ascending warm waters and descending cold, meteoric waters. Pál-völgy Cave, with more than 7 km of network passage, is the longest cave in the area. A spectacular example of the influence of tectonic activity on the development of karst processes is represented by the Hranice karst in Czechia. A lens of Devonian limestone lies between the Carpathian Foredeep and the Bohemian Massif. Zbrašovské Aragonite Caves have features indicating development stages from cold phreatic, through hydrothermal, to the present-day vadose stage with emanation of juvenile CO_2 . In the caves there are "ponds" of CO₂, with atmospheric concentration of up to 80%. Hranicka Chasm, in the same area, is 274

Europe, Central: Table 2. The deepest caves in Central Europe.

m deep and filled with water that is hot at depth, with high contents of CO_2 and H_2S .

Because of their significant natural values most of the areas of carbonate karst in Central Europe are protected, with the national parks of Aggtelek, Slovak Paradise, Tatra and Lower Tatra Moutains, and Ojców, and regional parks in the Bohemian, Moravian, and Slovak karsts. In 2000, a unique underground conservation area was established within the Salt Mine in Wieliczka, the world's sole example of natural voids with halite crystals within salt-bearing formations. The caverns have volumes of 1000 m³ (Upper Crystal Cave) and 700 m³ (Lower Crystal Cave).

EUROPE, CENTRAL: ARCHAEOLOGICAL CAVES

The caves of the Central European limestone formations have attracted archaeologists since the 1850s. One of the earliest and most important finds was made in August 1856 when workers employed by a local quarrying company cleared out a small cave known as the "Kleine Feldhofer Grotte" in the former Neanderthal (German for Neander valley). They found a number of bone remains and a local specialist, J.C.Fuhlrott, was called. When he arrived, the cave had already been emptied and no additional observations regarding find circumstances were possible. What remained was a cavity of 3 m width, 2.4 m height, and 4.5 m length together with the incomplete remains of a human skeleton which today is world-famous as the *Homo sapiens neanderthalensis* type fossil.

The Neanderthal used to be a small, deeply incised gorge west of Düsseldorf. The gorge, cut through a bed of Devonian limestone by the River Düssel, was about 50 m deep and some 800 m long. At least nine caves were known in the gorge, but they were all destroyed during intensive limestone quarrying during the late 19th and early 20th centuries. Recent excavations of the valley bottom have established the approximate location of the Feldhofer Grotte as well as the adjacent Feldhofer Kirche. Middle Paleolithic as well as Upper Paleolithic stone artefacts, faunal remains, and human remains, some of which could even be refitted with the 1856 skeletal fragments, were recovered from the redeposited cave sediments (Schmitz & Thissen, 2000).

The mid-19th century witnessed the onset of systematic archaeological investigation of many Central European cave sites. The primary aims of these initial investigations were partly paleontological: to examine the large quantity of faunal remains of now extinct Ice Age fauna found particularly in caves, and especially to investigate the possibility of the contemporary existence of an Ice Age human. In the Jurassic limestone formation of the French Jura, Swiss Jura, Swabian Alb, and Franconian Alb these aims were readily fulfilled and over the years numerous paleolithic remains have been unearthed from caves within this region. The abundant caves and rock shelters of the Jurassic limestone formation are generally of karstic origin and they are still exposed to the eroding forces of running and percolating water. This means that walls and roof of the cavities are crumbling, leaving generally rough and irregular surfaces. Accordingly, parietal art is not preserved from the region (except perhaps for a few, albeit much debated, painted rock fragments reported from recent excavations). On the other hand, the caves of the Swabian Alb have yielded some of the oldest examples of mobile art objects as well as musical instruments belonging to the early Upper Paleolithic Aurignacian culture (approximately 30 to 34 000 BP) (Hahn, 1993).

The caves of Vogelherd, Geißenklösterle, and Hohlenstein Stadel have produced a series of delicate figurines carved of mammoth ivory. These include a number of fairly naturalistic animal plastics, a more schematic anthropomorphic engraving and an extraordinary lion-headed human figure (Figure 1). A flute made on a swan bone was also found in the Aurignacian layers of Geißenklösterle (Hahn & Münzel, 1995).

Many of the caves have been settled repeatedly throughout the Paleolithic, but during the extreme climatic conditions of the late Pleniglacial (approximately 20 to 23000 BP) the area appears to have been almost deserted. Again the Swabian Alb stands out through a remarkable cluster of cave sites: out of a total of five Gravettian settlement sites within this region, four are located in the Ach valley (Figure 2, area A). Three of these sites (Brillenhöhle, Geißenklösterle, and Hohler Fels Schelklingen) are directly connected by refitting of lithic artefacts, while the fourth site (Sirgenstein) displays close typological, technological, and not least raw material affinities with the former three, and thus very probably belongs to the same settlement pattern, i.e. the same course of events (Scheer, 1993). These observations may be interpreted as the result of either true or limited contemporaneity involving the seasonal movements of a few, or perhaps only one, human group. The Gravettian of southwestern Germany is chronologically separated from the preceding Aurignacian as well as the succeeding Magdalenian by some 3000 to 5000 radiocarbon years. Thus, the intimate connection of the four Ach valley cave sites may perhaps indicate that in this area Gravettian settlement was a more or less isolated, eventlike phenomenon.

During the Magdalenian (approximately 16 to 12000 BP), however, the situation changed markedly. As climatic conditions improved a number of hunter-gatherer groups moved in and settled throughout the region. Archaeological evidence suggests

Europe, Central: Archaeological Caves: Figure 1. Human figure with lion-head, mammoth ivory. Found in early Aurignacian levels in Hohlenstein Stadel, southwest Germany, c. 30000–34000 BP. Reproduced from Schmid (1989) by permission of Landesdenkmalamt
Baden-Württemberg. Original in Ulmer Museum.

that they were flexible, mobile, and generally opportunistic hunters, who knew how to successfully exploit the rich and varied resources of their new environment. They were characterized by a complex settlement and mobility pattern which also involved numerous cave and rock shelter dwellings. In fact these sheltered sites by far outnumber the open-air settlement sites from the period in question, and most of the find-bearing caves within the region have indeed yielded Magdalenian artefacts.

However, there is an obvious methodological problem concealed in these observations, as cave sites and open-air sites are

Europe, Central: Archaeological Caves: Figure 2. Late Pleistocene sites in southwest Germany and northwest Switzerland: 1: Magdalenian cave sites, 2: Late Paleolithic cave sites, 3: Magdalenian open-air sites, 4: Late Paleolithic open-air sites. A: the Ach valley. Hatched area: the mountainous region of the Jurassic limestone formation and the Black Forest. subject to markedly different site formation and preservation processes. Owing to their visibility, caves are more likely to be re-occupied than most open-air sites, and they are thus also more likely to be discovered and investigated by archaeologists. In other words, the pattern of sites known within the region is most likely not in accordance with the prehistoric distribution of sites. The Magdalenian open-air sites are especially likely to be missing or at least under-represented.

Nevertheless, it is evident that caves and rock shelters were a popular habitation form during the early Late Pleistocene, and it is likely that the succeeding Late Paleolithic period witnessed a veritable migration from the sheltered sites in the deeply incised Jurassic valleys to the much more exposed open-air sites of the surrounding lake and river regions (Figure 2) (Eriksen, 1997). During the Late Paleolithic the climate had again improved and shelter was no longer the primary factor in locational decision making. This pattern of use pertained during the following prehistoric periods and although the caves of the region were often sought out for shelter or even defensive purposes, or in recent time for storage (as beer or wine cellars), they never regained the habitational importance of the late Upper Paleolithic.

EUROPE, CENTRAL: HISTORY

The caves of Central Europe have been explored since the Middle Ages; for example many well-organized visits to the Dragon's Cave (Drachenhöhle) in Styria (Austria) have been reported since 1387. Most of the explorations of this time were connected with mining activities or mineral prospecting. From the 16th century, there are well-documented cave visits with detailed descriptions. The local people from Amberg explored the Breitenwinnerhöhle (Franconia, Germany) in 1535. The first mention of the "Caverna Lunaris" (later Mondmilchloch) in the Pilatus mountain (Switzerland), in a publication of 1555, is followed in later centuries by many other descriptions of this cave. From Lower Austria, detailed reports (deposited at the Austrian National Library) from a well-planned official expedition, and a second exploration tour to the Geldloch in the Ötscher mountain, both of them in the autumn of 1592, precisely describe nearly one kilometre of passages. Smocza Jama (Dragon's Den) beneath the Wawel royal castle in Krakow, first written about in *c*. 1190, became well known throughout Europe following its illustration in Münster's *Cosmographia* (1544 and many subsequent editions).

Since the 16th century, cave descriptions and also the first cave maps from Central European caves can be found in various books. In the Baroque period, the interest in curiosities and wonders of nature motivated explorations and special studies. The best documentation concerns the karst and caves of Slovenia and is published in the work *Die Ehre des Herzogthums Krain* by Johann Weichhard Freiherr von Valvasor (see entry on Speleologists). This is a historic, geographic, and cultural description of Krain, now part of Slovenia, published in 1689 in Laibach (now Ljubljana). From this important karst region, on the southeastern border of Central Europe, many further documents exist from the 17th and 18th centuries, the greatest interest being in Cerknica polje and its lake (see Cerknica Polje, Slovenia: History). During the same historic period, caves in the Harz mountains, especially the Baumannshöhle, as well as caves in Westphalia, such as the Kluterthöhle (both in Germany), were explored and described. Reports exist from caves in the Moravian karst (Czech Republic), in the central part of the Carpathian mountains (Slovakia and Hungary), and from many other regions.

By order of the Habsburg Emperor an important systematic research on the karst regions and caves in the Austro-Hungarian monarchy was made by Joseph Anton Nagel (see Speleologists), director of the imperial collections of natural history (the precursor of the Museum of Natural History in Vienna). He visited caves in Lower Austria (Geldloch) and Styria in 1747, and made two trips in 1748, the first in the Slovenian karst, and the second in the Moravian karst, where he visited the cave of Sloup and the abyss of Macocha. During a long trip to Hungary in 1751, he visited the cave of Demănova (Slovakia).He collected minerals and described his observations in long reports, with many illustrations made by artists participating on his travels.

Military interests during the wars between the Austro-Hungarian monarchy and the Turks resulted in documentation of the Veteranische Höhle near Orsova in a defile of the lower course of the Danube (Romania); 17 hand-drawn maps from 1788–1805 are preserved in the Austrian war archives. Other examples of activities at this time, are a further exploration of the Macocha abyss, with a map in 1784 and a description of the cave of Aggtelek (Hungary) published 1786; a plan of this cave exists from 1794. In the late 18th century, interest in paleontological finds grew and the caves of Franconia (Germany) have great importance for related discussions and studies—concerning in particular the cave bear.

In the Romantic period (first part of the 19th century), many caves in Central Europe were described in the guidebooks for travellers, while Ojców caves in Poland, popular since the 1780s, had possibly the world's first trained cave guides from *c*.1810. Many scientific observations and discoveries are documented from this time. The most important personality of this time is Adolf Schmidl (see Speleologists). He studied nearly all the karst and cave regions of the Austro-Hungarian monarchy (Classical karst, Lower Austria, Moravian karst, Hungaro-slovakian karst near Aggtelek), including the karst features in the Bihargebirge in Transylvania, now a part of Romania. In his publications, he introduced in 1850 the German term "Höhlenkunde" (cave science) still used today.

During the second part of the 19th century, systematic exploration of karst phenomena was developed in the Habsburg monarchy, and the term "karst" was first used as a scientific term (see Kras, Slovenia). The well-known work of Jovan Cvijić, *Das Karstphänomen* (1894), which summarized the results of his research, was published in Vienna (see Geoscientists). In the same year, also in Vienna, the first general overview on cave science in the German language, the book *Höhlenkunde* was published by Franz Kraus.

In general, the speleology of the late 19th century is characterized in Central Europe by prehistoric and paleontological studies, as well as by discoveries and explorations in the classical karst regions. Excavations in the Moravian karst were made by Heinrich Wankel (1821-97); observations on ice formations in alpine caves were made by Eberhard Fugger between 1869 and 1886. In Vienna, the first speleological society (Verein für Höhlenkunde) in the world with a scientific background, was founded in 1879 (see Exploration Societies), followed by two sections of cave explorers, organized into the alpine societies of German and Italian languages in Trieste in 1883. In Germany, the first officially organized speleological club (Schwäbischer Höhlenverein) was founded in 1889. The Verein für Höhlenkunde in Österreich (Speleological Society of Austria), founded in 1907 in Graz (Styria), was later the first Federation of different clubs in that country. In Moravia, the Höhlensektion des Naturwissenschaftlichen Klubs (Cave Section of the Club of Natural Sciences) was founded in 1908 in Brno. In 1910, the Gesellschaft für Höhlenforschung in Krain (Speleological Society of Carniola, now Slovenia) was founded in Laibach (Ljubljana), a Komitee für Höhlenforschung in der Geologischen Kommission des Königreichs Kroatien und Slawonien (Speleological Committee in the Geological Commission of Croatia) in Agram (Zagreb), and a further Speleological Committee in the Geological Society of Hungary in Budapest.

In the years before World War I, advances in understanding the hydrology of the karst from Istria to Bosnia, were made by Alfred Grund, Franz Katzer, and many others, and the high alpine cave systems in the Northern Limestone Alps were explored.

In the 1920s, cave tourism began to be an important economic factor and many show caves were opened to the public. Cave sediments were a focus for researches with observations of deposits containing bones of Pleistocene cave bears in the Drachenhöhle near Mixnitz (Styria). Many studies in all parts of Central Europe show the importance of sediments for different scientific problems, including the first steps to a modern relative chronology. In Romania (1920) and in Austria (1923), official Institutes of Speleology were founded. At the University of Vienna, lectures on speleology were given by Georg Kyrle from 1924 up to his death in 1937. In Italy, an Institute of Speleology was established in connection with the administration of the Grotta di Postumia (up to 1918 called Adelsberger Grotte, since 1945 Postojnska Jama), managed by G.A. Perco (Perko). In the Moravian karst, important exploration and exploitation work in caves was made by Karel Absolon.

On 28 June 1928, a Federal Law concerning the protection of caves, supplemented by a series of decrees in the following year, was agreed by the Austrian Parliament. It was the first special law in the world to give rules for cave documentation, for administration and management of commercial caves, and for the education of cave guides.

After World War II, national (or regional) speleological federations were founded or re-founded in all countries of Central Europe, and international collaboration became more important. The third (Austria, 1961), fourth (Yugoslavia, 1965), fifth (Germany, 1969), and sixth (Czechoslovakia, 1973) International Congress of Speleology, all held

with extended excursions, were held in Central Europe. Spectacular discoveries, great progress in the documentation of caves and karst phenomena, and new methods to determine the age of speleothems and development in karst water tracing have been the main fields of work in Central Europe from the 1960s to the present.

EUROPE, MEDITERRANEAN

Limestone crops out widely around the Mediterranean Basin, and many outstanding European karst areas are located relatively close to the Mediterranean coastline or are under the influence of Mediterranean climates in Spain, southern France, Italy, Malta, Slovenia, western Croatia, Bosnia-Herzegovina, Montenegro, Albania, Greece, and western Turkey. Karst in Mediterranean Europe is characterized by a heterogeneous patchwork of solutional landforms which shows few similarities, besides a clear predominance of bare rock features on the landscape.

The climatic patterns prevailing in Mediterranean Europe are characterized by high variability of annual precipitation, frequent severe summer drought periods, and the concentration of rainfall in irregular but intense downpours. The climate produces harsh conditions for plant communities and promotes enhanced denudation of soil and slope materials. In some areas annual rainfall exceeds 1000 mm, reaching 2000 mm in the mountains of Montenegro and Andalusia, Spain. However, over large areas different subhumid to semi-arid Mediterranean subclimates contribute to generating the great diversity of geomorphology and plant cover present in the Mediterranean Basin. Pleistocene glaciations did not directly affect most of the mediterranean areas during the repeated climatic changes of the Quaternary, although the higher mountains were subjected several times to cold, even periglacial, morphogenesis with some glaciers in Greece.

The Mediterranean climate is one of the most aggressive in respect of erosion, as a consequence of the great intensity of autumn storms that occur just after the severe summer drought period. Bioclimatic conditions are in general unfavourable for the maintenance of continuous vegetation cover over the karstified terrains. Furthermore, man has induced burning of the Mediterranean forests during the past 6000 years in order to obtain pasture and crop lands. Both factors encourage the dominance of different kinds of sclerophyllous shrubland and the retreat to more favourable places of the mature successional stages of plant cover, consisting basically of evergreen woods. Edaphic and

climatic factors determine the distribution of the various types of shrubland formations, some of which are called *matorral* in Spanish and *garrigue* in southern France. These low, often sparse, scattered scrub plant communities are considered to be caused by deforestation processes, triggered by human impacts on limestone terrains under the influence of the harsh climatic regime. Because of the steep topography and the scant plant cover protection, Mediterranean soils are frequently affected by degradation, and even desertification, processes. However, it seems clear that the present barrenness of the Mediterranean karst has been artificially increased by human intervention throughout the ages.

Karst landforms dominate over large areas of some geographical regions including Istria, Dalmatia, Herzegovina, Apulia, the Greek coast, the island of Majorca and several mountain ranges and plateaux of Provence, Languedoc, Campania, and Andalusia. In all these representative Mediterranean karstlands, barren rock surfaces prevail over soilcovered ground, for the reasons described above. Alpine and Mediterranean limestone terrains have become the model for bare-karst landscapes, as opposed to the coveredkarst types of central and northern Europe. In fact, the Dinaric karst, probably the best example of Mediterranean karst, has long been regarded in the geomorphological literature as a "classical" area for studying karst landforms.

Mediterranean caves are not very long, rarely exceeding 20 km in length, but generally have abundant speleothems, their growth being favoured by the prevailing bioclimatic conditions. Large chambers and relict caverns, partially filled with collapse boulders, clastic sediments, and speleothems are common throughout the region. Active drainage caves are locally important because of their lengths, as in the karsts of Languedoc and northern Catalonia (France), Sardinia (Italy), and southeastern Spain, where there are several caves longer than 10 km. Subsurface vertical shafts are abundant in the mountains, but only recently have explorations found karstic shafts deeper than 1000 m in Andalusia (Sima GESM; González-Ríos & Ramírez-Trillo, 1999) and Croatia (Kuhta & Bakšić, 2001). Some collapse landforms attain impressive dimensions, such as in the Crveno Jezero (Imotski, Croatia), a huge half-flooded chasm over 500 m deep and more than 200 m in diameter. Karren landscapes are especially remarkable in the Dinaric karst (Velebit range and Biokovo mountain) as well as in Majorca. Solution dolines stand out as the main surface features in the karsts surrounding the Adriatic coast (Slovenia, Dalmatia, Herzegovina, and Montenegro), and are also frequent in Spain and southern France. Poljes have a similar geographical distribution, and have been extensively described from Greece, Italy, Portugal, Spain, and especially the Dinaric karst, where some of the most famous poljes are located (see Dinaric Karst; Dinaride Poljes). The scarcity of water in these environments makes the karstic springs significant features for human settlements in the Mediterranean. Among several remarkable examples are the Ombla (Dubrovnik, Croatia) and the Fontaine de Vaucluse (Provence, France) which rank among the greatest springs of the world. Tufa deposits, karst corrosion surfaces, steep heads, and karst canyons are also frequent in the Mediterranean landscapes. As a whole, it appears that Mediterranean Europe contains many diverse karstic features, although rocky landscapes are the most widely represented.

Most of the Mediterranean countries are in relatively young orogenic belts, whose mountain chains run close to the coastline forming rugged terrains. The present configuration of the Mediterranean area consists of high and steep mountain ranges of the Alpine system, structured by complex folding and overthrusting. Regarding lithology, the carbonate rock substrates are more extensive than in most other regions of the world and give rise to some of the most typical soils and landscapes of the Mediterranean Basin. The majority of the mountain building corresponds to thick Mesozoic limestone outcrops, rising near to the sea shore and showing a rather sharp relief. Active tectonic uplift accounts for the high gradients and deeply dissected slopes observed in the coastal ranges.

Sea level acts as base level for many karsts surrounding the Mediterranean. Because of the proximity to the sea, coastal and karstic processes interact, producing specific littoral landforms and generating in those karst systems controlled by sea level, very unusual hydrological conditions. Caverns captured by marine abrasion, rock arches, the presence of steep-sided coves, and the drowning of large depressions and karst valleys as a result of postglacial sea-level rise, are examples of this kind of interacting geomorphological dynamics. The most striking features ob-

Europe, Mediterranean: Locations of karst sites in the Mediterranean referred to in the text.

served in these coastal karsts are the strong upwellings of fresh or brackish water that occur beyond the shore in the form of submarine springs. These springs, called *vrulje* in Dalmatia, are quite common all over the Mediterranean and in some cases the associated hydrostatic pressure changes can result in advance of salt-water intrusion and the existence of brackish springs inland. Besides the well-known littoral springs reported in the literature from France, Greece, and the Adriatic shore (including Istria, Dalmatia, and Montenegro), some other significant sites affected by sea-level change are the great flooded polje Skadarsko Jezero (on the border between Montenegro) and Neretva Plain at Metković (Herzegovina), the *calanques* of Provence including the long submarine cave spring of Port Miou (explored by divers), and the recent discoveries in eastern Majorca of submerged cave systems exceeding 5 km in length.

Caves, karst springs, and diverse limestone landforms were related in different ways to old human settlements all around the Mediterranean Sea. Archaeological remains, from Paleolithic times to very recent historical events, are frequently found in the caves, containing fairly well-preserved evidence of the past. Ancient civilizations, especially Greek and Roman cultures, invested many karstic sites with religious and mythological significance (see Caves in History: The Eastern Mediterranean). The interest in caves and karst sites remained throughout the ages and was the main drive for the earlier explorations made in the 17th, 18th, and 19th centuries (Shaw, 1992). Many references to caves appeared in the books of travellers in the 19th century and Martel's expeditions incorporated knowledge on Mediterranean caves into modern speleology.

Since the mid-20th century many Mediterranean limestone terrains and their celebrated karst sites have become well known due to massive tourism development in this part of Europe. Wild landscapes, great springs, and well-decorated show caves (Aellen & Strinati, 1975) are natural tourist resources of great importance for several southern European countries. Some of the most visited show caves in the world are located in the Mediterranean region, including the Coves del Drac (Majorca, Spain), Grotta di Castellana (Apulia, Italy), Cuevas de Nerja (Andalusia, Spain), and the Aven d'Orgnac, Grotte de Clamouse, and Grotte des Demoiselles (Languedoc, France). Among many spectacular landscape and water sceneries are the Argostoli sea-mills (Cephalonia, Greece), the deep spring called Fontaine de Vaucluse (Provence, France), the tufa waterfalls of Krka river (Dalmatia, Croatia) and the karst canyons of Samaria (Crete, Greece), Torrent de Pareis (Majorca, Spain), and Gorges du Verdon (Provence, France). These karst locations can each attract more than 100000 visitors per year.

EUROPE, MEDITERRANEAN: ARCHAEOLOGICAL AND PALEONTOLOGICAL CAVES

Greece has one of the world's most spectacular karst landscapes and was the subject of some of the earliest karstic studies from Thales and Aristotle to Pausanias. Limestone is the predominant rock in Greece, which in combination with a temperate climate that allows rapid infiltration of water and dissolution, has produced deep caves and large springs, attracting both animals and humans. Though Italy and Malta display smaller karstic landscapes, they contain caves with important fossiliferous deposits.

Ghar Dalam Cave was one of the earliest sites used by Neolithic man, who crossed to the Maltese islands around 7000 years ago. Even more remarkable than the presence of prehistoric man, are thousands of fossil animal bones. The cave, 145 m long, is formed in coralline limestone, 9 m above the Weid Dalam valley. It was first excavated by Arturo Issel in 1865 and excavations continued until 1922. Six distinct layers were revealed. The second lowest, about 125000 years old, contained the remains of *Hippopotamus pentlandi* and *Hippopotamus melitensis*, as well as the dwarf elephant *Elephas mnaidriensis* and *Elephas falconeri*. The fourth lowest layer, around 18000 years old, contains *Cervus elaphus* with brown bear, red fox, and wolf. The top layer is the Cultural layer, with pottery, "sling stones", and domestic animal remains. The fauna is Continental European and came to Malta via Sicily during a glacial phase. The dwarfism of some mammalian lineages started in Sicily and continued in Malta. Gigantism also appeared in some species, such as the dormouse *Leithia melitensis* and the giant lizard *Lacerta siculimelitensis*.

Guattari Cave is a small cave in Monte Circeo, Italy. Its entrance was discovered in 1939, having been closed for about 50000 years. The cave is famous for a Neanderthal skull, with an apparently artificially enlarged hole at its base, found on the cave floor within a circle of stones. It caused a sensation as a case for ritual cannibalism but it was later shown that the cave was a hyaena den and that the circle was a natural arc of stones. The hole at the base of the skull had hyaena tooth marks, evidence that the hole was made by hyaenas, as in the case of *Homo erectus* skulls from the Zhoukoudian cave in China.

Lamalunge Cave in Altamura is another Italian cave, where one of the most complete European hominids was discovered in 1993. Dating estimates vary from 130 to 400000 years BP. Because it is heavily encrusted in botryoidal (grape-shaped) speleothem, the skeletal remains have not been fully excavated. It is suggested that it is a pre-Neanderthal or an archaic *Homo sapiens*.

Corbeddu Cave near Oliena, Sardinia, is a karstic cave 110 m long, with four main chambers. Excavations started in 1982 by a Dutch-Italian team. It contains the oldest human bones from any Mediterranean island, dated at 20000 years BP and 8750 years BP. The Paleolithic sediments also contain the endemic deer *Megaloceros cazioti* and the ochotonid *Prolagus sardus*. The Neolithic layers are characterized by the presence of domesticated animal remains. The presence of small bone and enamel fragments between the teeth in the jaws of young deer, indicates the use of these jaws as tools.

Kokkines Petres (or Petralona Cave) in Chalkidiki (Greece), is one of the richest archaeological and paleontological caves in Europe. It was formed in late Jurassic limestone and was discovered by locals in 1959, who also discovered the skull of Petralona man in 1960. Small-scale excavations started in 1960 by J. Petrochilos. The skull was encrusted by a flowstone sheet, that had been hanging on the walls of the cave. This makes it difficult to find its position in the stratigraphic sequence. All dating studies by electron spin resonance (ESR) and U-series on material from the skull show an age of about 200000 years BP. The skull presents a mosaic of H. erectus, archaic, and Neanderthal-like characteristics. The fauna found in the cave is divided into two groups. The older group is of Villafranchian age (< 700000 years) and the younger is of the late middle and upper Pleistocene age. The Petralona skull belongs to the younger fauna. The older fauna includes taxa such as Pliohyaena perrieri, Ursus deningeri, Canis lupus mosbachensis, Xenocyon cf lycanoides, and Praemegaceros sp. The younger fauna includes Crocuta spelaea, Ursus spelaeus, Equus petraloniensis n. sp., Equus caballus piveteaui, Dicerorhinus hemitoechus, and Sus scrofa. The two faunas were found mixed on the cave floor, owing to episodes of water flooding as evidenced from trampling of the bones. Coprolites on the cave floor show that the cave was a carnivore den. The cave entrance was closed during the upper Pleistocene, as the top of a talus cone reached the entrance.

Maara Cave is the biggest cave in Greece. It has a subterranean river, 13 km in length, that forms the springs of Aggitis river. The fossil cave fauna represents the whole Pleistocene. Taxa include *Archidiskodon meridionalis, Mammuthus trogontheri, Mammuthus primigenius, Cervus elaphus, Coelodonta antiquitatis, and Ursus spelaeus.* Mousterian artefacts have also been found.

Loutraki-Almopia Caves are located in a gorge, 120 km north of Salonica. The area has been designated as a "speleological park", with tens of caves formed in intensely karstified Maestrichtian limestone. Late Paleolithic fauna, with numerous juve-

Europe, Mediterranean: Archaeological and Paleontological Caves: *Panthera* sp. skeleton from Dyros Cave, Greece, the first panther

fossil found in the Peloponnese. The cave has numerous bone deposits of extinct animals from the upper Pleistocene. (Photo by Costas Zoupis)

niles of Ursus spelaeus, Crocuta spelaea, Panthera pardus, Vulpes sp., Capra ibex, Dama sp., bovids, cervids, and foxes are found. Agios Georgios Cave in Kilkis, 50 km north of Salonica, is a hyaena den of C. crocuta spelaea with food remnants of Cervus elaphus, Megaceros sp., Bos primigenius, Equus hydruntinus, and Equus caballus cf. germanicus. Late Pleistocene fauna (12200± 2500 years BP).

The Maronia Cave near Komotini, Thrace, has been identified by some as the cave in which, according to Homer, Odysseus blinded the Cyclops Polyphemus. It contains Neolithic and upper Pleistocene deposits with horses, cervids, bovids, and rhinos. Peristeri Cave, a recently discovered karstic cave 67 m deep, overlooks the Louros river in Epirus. It contains animal bones, stone artefacts, and hearths of middle Paleolithic. Theopetra Cave in Thessaly Plain contains a continuous sequence from middle Paleolithic deposits of about 70000 years old to Chalcolithic, including Mesolithic deposits. Two partial skeletons were found, ¹⁴C dated at about 9000 and 16500 years BP respectively, and 46000 year-old hearths and human footprints are also reported to have been found.

Kapsia Cave in Mantinia polje, Peloponnese, usually floods once a year due to winter rains. The cave was first explored in 1892, by E.A.Martel and N.A.Siderides. It is remarkable for its human remains which suggest that about 50 people were drowned in the cave, after a big flood took place in the 4th or 5th century AD. There has been human presence since Neolithic times. Apidima Cave in the Taenaron peninsula, a massive karstic landscape, has produced two Neanderthal-like skulls. Two ESR dates, on material associated with the two skulls, have given ages of 20000 and 45000 years BP respectively. The fauna appears to be much older and includes *Megaceros, Panthera pardus, Lynx lynx*, and *Hippopotamus amphibious antiquus*. Nearby are the Dyros Caves, a complex of caverns, lakes, and rivers, with Neolithic finds and remains of *Panthera* sp. (see Figure).

Charkadio Cave in Tilos Island, north of Rhodes, documents the latest survival of elephant fauna in Europe in the form of *E. falconeri* 3500 years ago. It arrived on the island about 50 000 years ago. Deeper sediments show that deer survived till 140 000 years ago. Vamos Cave at Chania, Crete is an underwater sea cave where the new species *Elephas chaniensis* has been found. Fossil deer and seal bones have also been discovered.

EUROPE, NORTH

In Europe north of the Alps, geological or topographical factors restrict the development of extensive karst and deep caves (Figure 1). Most older rocks form complex basements where limestone formations are relatively thin—the one exception being the low plateaus of Carboniferous limestone. Most younger rocks form a relatively undeformed cover, with poorly lithified limestones, notably the Cretaceous chalk, that do not contain large cave systems. There are no young mountain ranges where folded limestones crop out over great ranges of altitude.

In Britain, the Lower Carboniferous limestones form significant areas of cavernous karst (Waltham *et al.*, 1997), notably in the Pennine Hills of northern England. The Peak District (see separate entry) in the southern Pennines has the largest single area of karst, with over 400 km² of rolling fluviokarst dissected by superimposed, dendritic, dry valleys, fresh since their periglacial modification in the Devensian. Further north, the Yorkshire Dales (see separate entry) sector of the Pennines was covered by Devensian ice and therefore has the best of Britain's glaciokarst, as well as being notable for its many fine and extensive cave systems. The outlying parts of the northern Pennines have even

more extensive limestone pavements on smaller outcrops of various Carboniferous limestones. Some of these are Upper Dinantian limestones (often known by their old name of Yoredale limestones), each less than 30 m thick within clastic rock se-

Europe, North: Figure 1. Location map of the main karst regions of northern Europe, including those described in their own entries.

quences. These also contain active and drained phreatic maze caves with kilometres of passages on joint networks with spacings of only a few metres. The Mendip Hills (see separate entry) of southern England were formed in thick, steeply dipping Lower Dinantian limestone with inclined cave networks, while Devon has a scatter of caves beneath isolated outcrops of folded Devonian limestones, including Kent's Cavern with its important Pleistocene bone sediments preserved under flowstone. The other British karst on pre-Carboniferous limestone is around Inchnadamph in Scotland, where stream caves underlie a glaciokarst on Durness dolomites.

Dinantian limestones also crop out in Wales (Ford, 1989). They form a broken low escarpment around the South Wales coalfield, where the gently dipping beds contain some very long cave systems. Under Mynydd Llangattwg, large phreatic conduits follow the strike of single bedding planes, but Pleistocene base-level lowering has allowed subsequent systems to establish further down-dip, and the older and younger caves have been linked by intersecting down-dip vadose inlets (Smart & Gardener, 1989). Ogofs Agen Allwedd and Daren Cilau each have over 30 km of passages, mainly beneath the cover of Namurian sandstone and therefore largely devoid of stalagmites and stalactites. Just to the south, Ogof Draenen (see separate entry) shows a comparable evolution but is a much longer cave. Just to the west, the sandstone cap of the Llangynidr Plateau is pocked with hundreds of large collapse dolines overlying extensive interstratal karst. Dan yr Ogof and Ogof Ffynnon Ddu lie on either side of the Swansea Valley; their long complexes of drained phreatic passages (17 and 51 km respectively), looping obliquely up and down bedding/joint intersections, have been rejuvenated by extensive vadose canyon development. Their evolution may span a million years, and some of the old passages are now well decorated with calcite. In North Wales a number of deep phreatic caves have been drained by mining activity, whose artificial drainage created a more recent version of the Pleistocene rejuvenations seen elsewhere in Britain. The limestone hills of Clwyd also host Britain's largest postglacial tufa deposits, at Caerwys (Pedley, 1987).

Ireland has large outcrops of Carboniferous limestone, a large proportion of which are now covered by glacial till and peat bogs. The best-exposed karst is close to the west coast. In Eire, the Burren glaciokarst (see separate entry) forms a large expanse of glaciated limestone pavements, replicated in the bare rock vistas of the windswept Aran Isles immediately offshore. Just south of the Burren, the shale-capped hills of County Clare provide allogenic drainage on to the limestone and into over 80 km of mapped caves, nearly all narrow twisting canyons cut below gently dipping bedding planes (Self, 1981). These include Doolin Cave, in which it is possible to walk dry beneath the Aille River while it is still flowing on the surface. The karst lowlands are noted for the turloughs-closed depressions that flood in most winters but have not yet evolved into poljes by lateral planation at a more mature and stable water table. Some permanent lakes drain underground. Among them is Lough Cong, with its boat canal that is normally dry because it was built across cavernous limestone by engineers not adequately familiar with karst. The highest limestone hills and therefore the deepest caves of Ireland are in County Fermanagh, in the Ulster sector. An excess of till restricts the extent of limestone pavements, but the glacial evolution of the karst is recorded in the many abandoned and rejuvenated caves.

Carboniferous limestone also occurs in Belgium, notably around the type localities of Dinant and Namur in the Ardennes. The Lesse River drains through a limestone hill at Han, where 10 km of cave passages form a cave network not yet fully connected (Figure 2). These are the only long caves in the Benelux countries, although dolines identify karst on many of the Ardennes plateaus.

Germany has a small area of spectacular glaciokarst in eastern Bavaria, where its border loops round a slice of the karst of Alpine Europe. Other than this, Germany's limestone karst is only significant in the low plateaus of the Schwäbischer and Frankischer Alber. These have over 6000 km² of fluviokarst terrains on soft Jurassic limestones. Most of the many caves are only small streamways, and few are longer than a kilometre. Where it crosses the western tip of the Schwäbischer Alb, the Danube loses about 6 m³ s⁻¹ of its flow into river-bed sinks, and this water rises from the Aach Spring, 12 km away and 170 m lower, at the head of a major tributary to the Rhine. There are similarities between the Schwäbische karst and the Cotswold karst on equivalent Jurassic limestones in England, but the latter has almost no caves, although it constitutes an economically important aquifer with a major component of cavernous flow.

The most extensive karst in northern Europe is on the Cretaceous Chalk (Figure 3), which has large outcrops in England, France, Germany, and Denmark. The best of the chalk fluviokarst is in southern England and northern France, where the soft, rolling landscape contains shallow dolines and dendritic dry valleys largely floored by solifluction debris from Pleistocene stages of periglacial weathering. Underground drainage is partly by diffuse flow, but is largely by flow through networks of fissures rarely large enough to be entered. The chalk in France is more indurated than that further north, and has the only known long caves, with many small vadose streamways over a kilometre long.

Scandinavia contains only small areas of karst, and little outside the outcrops of Lower Paleozoic carbonates of Nordland in Norway and the island of Gotland in Sweden. Narrow bands of limestone and marble in the folded basement rocks of Nordland have many caves in excellent examples of stripe karst (see Stripe Karst). The metamorphic grade of the marbles increases towards the higher and more westerly of the Caledonian nappes. This commonly provides attractive, dipping foliation, distinctive minerals including garnets, and folded interbeds of non-carbonate rocks, which can be seen in the many clean-washed stream passages that underlie older, phreatic passages, some of which are well decorated with calcite. Large numbers of caves occur in the county of Nordland in Norway (St Pierre & St Pierre, 1985), and also across the border in Sweden. Tjoarvekrajgge (13 km long and 500 m deep) and Okshola/Kristihola (11 km) are the longest in Nordland, and Sweden's longest marble cave is Korallgrottan, with nearly 6 km of passages. Råggejavre-Raige, 580 m deep from its plateau sink to its fjord-side entrance, lies in a narrow band of steeply dipping marble, close to the wall of Tysfjord, Nordland. The island of Gotland in Sweden has a large outcrop of Silurian limestone that contains the show cave of Lummelundagrottorna (5 km long). Scandinavia has numerous elevated sea caves (including Torghatten, 160 m long and nearly 30 m high and wide right through a mountain ridge; Figure 4), talus and fissure caves, and tunnel

caves on the Baltic coast that were excavated by the marine cobble abrasion but are now elevated up to 200 m altitude following isostatic rebound after the last glaciation. Iceland has no limestone, but has many small lava caves and ephemerally explorable glacier caves; the latter includes the Rivière de Kverkfjöll (2850 m long and 525 m deep) with subglacial stream trenches in volcanic rocks cut beneath an ice tunnel whose excavation was aided by fumarolic steam.

Metacarbonates (marbles) occur along the west coast of Spitsbergen and host relict caves and active hot springs. Almost all the caves are filled with ground ice, but their speleogenesis can be traced back to subglacial conditions as well as an important paleokarst legacy from the Devonian and to even earlier hydrothermal corrosion during the Caledonian. Active hot springs yield sulfide-containing waters of carbonate-sulfate-chloride types, with temperatures as high as 15°C. Abundant Permian evaporites (anhydrite) give rise to high sulfate content of groundwater, and gypsum precipitates in icings. Although the karst is presently in a permafrozen state there are active sub-permafrost aquifers, fed from the underside of polythermal glaciers. Hence, the area serves as a modern analog for subglacial karstification in northern Europe during the Pleistocene glaciations.

Europe, North: Figure 4. Daylight is silhouetted through the Torghatten cave in western Norway. The cave occupies the full width of the vertical band of marble that is visible in its roof. (Photo by Tony Waltham)

A belt of Permian and Triassic evaporite rocks provides discontinuous outcrops extending from central England to northern Germany. The best of the gypsum karst is in Germany's Harz Mountains (Kempe, 1996). Outcrops are scored by valleys dry since the early Pleistocene, are pitted with dolines, and have deeply pinnacled rockheads (bedrock surface on which unconsolidated sediment is deposited) largely mantled by soils of insoluble residues. Five caves reach lengths of 1500–2500 m, with drained phreatic passages and large breakdown rooms. Gypsum karst creates significant engineering hazards in parts of Germany and England. The most important salt karst occurs in the Cheshire Plain, England, where natural dissolution has created many surface depressions that are now flooded as meres (lakes), typically a kilometre across. Brine abstraction has increased the rates of groundwater circulation, and has therefore accelerated surface subsidence at many sites, with a significant impact on the towns and infrastructure that stand on the drift-covered salt outcrops.

EVAPORITE KARST

Evaporite deposits form in seas, lagoons, and internally drained lakes, where more water leaves the basin by evaporation than enters as rainfall, surface, and subsurface flow. Evaporite rocks are inorganic in origin and form by chemical precipitation in a concentrated solution. The most common evaporite rocks include gypsum, anhydrite, and halite, although other rarer salts can be significant locally in karst. Carbonates such as calcite and dolomite can also be of evaporitic origin; however, the term "evaporite karst" is normally employed to denote karst in the above-mentioned more soluble salts, most commonly in gypsum and halite. Under normal conditions, the solubility of gypsum is up to three orders of magnitude greater than that of calcite, but the solubility of salt is roughly 140 times greater than the solubility of gypsum. Where they are in contact with undersaturated water, evaporite rocks may dissolve at very high rates (see Dissolution: Evaporite Rocks).

Evaporite rocks underlie about 25% of the continental surface, although this fraction is greater in some major regions: 35–40% for the entire United States and the same figure for the former Soviet Union. Major epochs of evaporite deposition occurred in the late Cambrian, the Permian, the Jurassic, and the Miocene. Lesser but still significant episodes took place in the Silurian, the Devonian, the Triassic, and the Eocene. Ancient platform and basin-wide evaporite or combined evaporite/ carbonate/siliciclastic sequences often reach thicknesses exceeding 1000 m, and extend laterally across huge areas. Evaporite accumulation in the Quaternary was on a very much smaller scale. Penecontemporaneous evaporites are most often found in the arid and semi-arid zones, in the circumtropical desert areas that lie between 15 and 45° north and south of the equator. Modern evaporite accumulation locally occurs outside the major desert belts, in the strictly continental environment, in high mountain deserts, in the rain shadows of high mountain ranges, and in polar and circumpolar regions.

The variety of depositional settings in which evaporites can form ranges from deepwater, to subaerial, to lacustrine, so the mode of occurrence of evaporites and the associations of lithofacies are quite diverse. The picture is further complicated by the fact that evaporites are very susceptible to recrystallization, dissolution, and replacement. Gypsum deposited in the shallow subsurface is converted to anhydrite after burial, and back to gypsum as the sulfate re-enters the meteoric realm and is washed in cooler and fresher fluids. Sulfates and halides occur widely as rare to frequent interbeds in sequences containing carbonates and siliciclastic sediments, but also as massive beds. Individual beds of gypsum with thicknesses of 10–40 m are fairly common, although sequences of them may exceed 200–300 m. Massive salt units may reach more than 1000 m in thickness. When massive deposits of salt are buried by denser strata, they flow upward and approach the surface as diapirs or dykes. Diapirs may rise from original salt bodies occurring beneath several thousand metres of cover strata, disrupting and deforming them.

The karst that develops on evaporite deposits has many features in common with carbonate karst, but also has significant peculiarities imposed by the specific features of evaporite geology and dissolution processes. In characterizing evaporite karst, it is particularly important to refer to the overall settings of karst development, which are conveniently generalized by the evolutionary typology of karst types (Klimchouk & Ford, 2000). Types of karst are viewed as successive stages in geological/ hydrogeological evolution, from deposition through burial to re-emergence, between which the major boundary conditions, the overall circulation pattern and extrinsic factors and intrinsic mechanisms of karst development appear to change considerably. The different types of karst are marked by characteristic styles of karst system development, which are particularly distinct in evaporites.

As evaporites are much more soluble than carbonates, they are much less common in outcrops. This is one of the reasons why evaporite karst has received relatively little appreciation in the past in the mainstream of karstology, and has commonly been considered of limited significance. However, since the 1970s it has been increasingly realized that karst processes in evaporites such as gypsum and salt operate extensively when they occur below various types of cover beds within the upper few hundred metres of sedimentary sequences, with this type of setting being widely distributed over the continents. Under dramatically increasing human impacts such as construction, mining, and the exploitation of groundwater and hydrocarbon resources, intrastratal evaporite karst suffers more severe environmental problems and hazards than karsts in carbonates.

Syngenetic Evaporite Karst

Karst processes readily commence in freshly deposited evaporites. Syngenetic karst in ancient evaporites, probably common in continental settings, is sometimes recognized among the paleokarst features. Modern syngenetic karst is limited to salt lakes, where it develops in lake-bottom evaporite deposits of various compositions. It is fairly prominent in many salt lakes in the pre-Caspian lowland and the Altai region in Russia, in Central Asia, on the Qinghai-Xizang Plateau of Tibet, and in the Middle East and the United States. In addition to various sculpturing forms created by rainfall and inflowing surface streams, the most typical karst features are "windows", "cauldrons", and holes in the lake-bottom salt masses created by currents of groundwater rising from the aquifers that occur below the lakes.

Intrastratal Evaporite Karst

After burial by younger sediments, karstification in evaporites may be initiated at any of the stages of intrastratal development, particularly at some stage *en route* back to the surface. Where poorly permeable clays or shales surround evaporites in a stratified sequence, intrastratal karst may not develop at all, and any considerable karstification will not commence until the soluble unit is exposed to the surface. The entire sequence of intrastratal karst types includes deep-seated karst, subjacent karst, and entrenched karst. They differ according to the degree to which the evaporite units are covered by overlying rocks, and hence according to the hydrogeological setting.

Deep-seated Evaporite Karst

Deep-seated karst is not evident at the surface, and the soluble rock is not exposed. Its development is favoured where the evaporite units are sandwiched between or intercalated with carbonate or siliciclastic aquifers (Klimchouk, 2000). Dissolution may be initiated by two different hydrogeological mechanisms. In the first, transverse hydraulic communication, usually ascending, across a gypsum unit, is established

between the two surrounding aquifers, giving rise to maze cave patterns, provided that the proper structural prerequisites exist. Outstanding examples are the giant gypsum maze caves in the western Ukraine, which are presently relict where they were entrenched. Five of them occupy the top ranks in the list of the longest gypsum caves in the world (see table). In the deep-seated karst zone of this region, extensive cave systems still develop under confined settings through the transverse circulation mechanism, as evidenced by extensive data from exploratory drilling (see Ukraine Gypsum Caves and Karst). This mechanism is unlikely to occur in salt because in this rock the joints readily seal under lithostatic pressure. The second mechanism involves the attack of the base of the evaporite unit by solutions from the underlying aquifer. Once saturated, the water becomes heavier and returns to the aquifer, where it is replaced by less dense water. Such a system of natural convection may create vast isolated cavities in both gypsum and salt. Documented examples of this kind of speleogenesis in gypsum include numerous giant Schlotten-type caves in the Zechstein (the Upper Permian) gypsum in Germany (Kempe, 1996). Cavities of this type in both gypsum and salt are probably responsible for the initiation of vertical breakdown structures called "breccia

pipes", which are abundant in many deep-seated evaporite karsts, as illustrated by studies from the United States, Canada, China, and Russia. They have diameters ranging from a few tens to over 100 m (sometimes even measured in kilometres) and propagate by upward stopping from depths as great as 1200 m. When several closely spaced breccia pipes reach the surface, they may give rise to large (measuring from several hundreds of metres to tens of kilometres) often elongated depressions, termed solution subsidence troughs or solution-induced depositional basins. The latter term applies if the rate of sedimentation is approximately equal to the rate of subsidence, and the depressions do not have a strong topographic expression. Such features are reported in Canada, the southwestern United States, Russia (in the Urals and Siberia), and in other regions. Dissolution of salt units may occur from one side if they are laterally in contact with thick aquifers with active groundwater circulation. Over a long geological time-scale the process causes the dissolution front to recede along the margins of the major intrastratal salt deposits, leaving some of the world's largest solution-induced basins, such as those in the Prairie Provinces of Canada and Montana (the Devonian salt) or in the south of the Siberian platform of Russia (the Cambrian to Devonian sulfates and salt). Prolonged dissolution of evaporite beds leads to the formation of areally extensive brecciated horizons and disconformities, a very common end result of intrastratal evaporite karst formation (Friedman, 1997). Disruption and brecciation of the carbonate beds due to intrastratal dissolution of sulfates or salt is an important factor of deepseated carbonate karstification in complex interbedded sequences. Another important factor is the chemical interaction between carbonates and sulfates, which can greatly increase the solubility of dolomite, gypsum, and anhydrite (Palmer, 1995).

Deep-seated evaporite karst can be readily induced or enhanced by mining, drilling, or groundwater abstraction activities, which intensify groundwater circulation and enable undersaturated water to encounter and dissolve the evaporites (Klimchouk & Andrejchuk, 1996; Martinez, Johnson & Neal, 1998). This commonly results in the appearance of collapse and subsidence features, due to the re-activation of existing vertical breakdown structures or the formation of new ones. The solution mining of evaporite salts creates large cavities that occasionally collapse. Some of the largest sudden collapse dolines, up to a few hundreds of metres in diameter and in depth, occurred due to human-induced dissolution, either intentional or unintentional. Examples are abundant throughout the United States, Canada, Western Europe, western Ukraine, Russia, China, and other countries.

Subjacent Evaporite Karst

The re-emergence of evaporite units to the relatively shallow subsurface due to uplift causes local breaching of the hydrogeological confinement by erosion of the cover rocks and locally the evaporites. This represents the subjacent karst stage, marked by drastic changes in the hydrodynamics from confined through to semi-confined, to vadose and water table, the activation and localization of dissolution, and the distinct surface expression of various karst features. The latter include collapse and subsidence dolines (which form extensively at this stage due to a decrease in the hydraulic head and the removal of the buoyant support), dry valleys, and a range of hydrological karst phenomena, such as sinking streams, ponors, and springs. Subjacent karst in evaporites is well developed where substantial karstification is inherited from the preceding deepseated stage. Examples include the gypsum karsts of the margins of the Zechstein basin in Europe (northeastern England and northern and eastern Germany); the southwestern part of the western Ukrainian gypsum karst in the Miocene rocks; the pre-Ural karst areas and the Pinega region in the Permian sulfates of Russia; the gypsum karst areas of the margins of the Permian Basin (eastern New Mexico, northcentral Texas and western Oklahoma); and the predominantly salt karst of northeast Arizona in the United States. Because subjacent karst settings are transitional in terms of karst evolution, the respective karst areas are commonly adjacent to the areas of deep-seated or entrenched karst, or to both. They frequently lead to specific engineering problems, particularly the danger of subsidence.

Entrenched Evaporite Karst

Further erosional incision may create a situation where major valleys largely or entirely drain subhorizontal gypsum beds that remain capped with protective insoluble beds. This is entrenched karst, which is common on gypsum but rarely occurs on halite because most of the medium- to thin-bedded halite in the stratified sequences is dissolved during the previous stages. Entrenched gypsum karst may show well-preserved and accessible relict artesian caves (as in the Miocene gypsum of the western Ukraine, the Paleogene gypsum of the Paris Basin of France and the Permian gypsum of the pre-Urals region in Russia) and supports the formation of contemporary caves: mainly single-conduit or crudely branching caves that develop from swallow holes on the interfluves towards outlets on the valley slopes (as in the Permian gypsum of the western Oklahoma (United States) and the North Dvina region in Russia). A characteristic feature of many

entrenched gypsum karsts are vertical solution pipes ("chimneys") that develop from the overlying bed, commonly limestone or dolomite, across the gypsum bed in areas of focused percolation. Their density may be as high as 300 per square km.

Open and Denuded Evaporite Karst

Areas of open and denuded karst in evaporites, with the rocks exposed to the surface, are limited in extent because the evaporites are highly soluble. Open karsts are found mainly in arid and semi-arid environments and where the evaporite units are fairly thick. Examples of open gypsum karst include Zorbas in

Evaporite Karst: A fine polygonal karst of dolines each about 100 m across in the gypsum karst of Sivas, Turkey. (Photo by Tony Waltham)

southern Spain; the Central Apennines and Sicily in Italy; the Diebel Nador and Oranais areas in eastern and western Algeria; the Ar Rabitat/Bir area in northwest Libya; the Sivas region of Turkey (see Figure and Turkey entry); central and northern Somalia; and some mountain areas in the northern Caucasus in Russia and in Central Asia. Many other smaller areas are associated with the gypsum cap rocks of salt diapirs. The extensive Gypsum Plain in western Texas and New Mexico, United States, probably falls into the denuded karst category, which is a former intrastratal karst. Exposed gypsum karsts exhibit many surface features similar to those of carbonates. Contemporary cave development in open settings favours the formation of linear or crudely dendritic caves, which commonly carry sink streams. Where the vadose zone is thick, vertical pitches form in gypsum caves, as, for example, in the Central Apennines and Sicily in Italy, Zorbas in Spain, and the Gypsum Plain in the United States.

Open karsts in salt are small, and are most commonly associated with rising diapiric structures. Where extrusion of salt is rapid, diapirs may support dramatic landscapes with a relief of up to 900 m, with large salt cliffs, deep cirques, crevasses, and canyons, and various karst features. Outstanding examples are the Khodja-Mumyn and Khodja-Sartis

salt domes in the Pamir Mountains of Tadjikistan and the salt domes in the Zagros mountains of Iran. In the Tadjikistani sites, surface karst features are particularly abundant and include numerous dolines, deep collapses and shafts, various karren forms, pinnacles, and giant salt "mushrooms" capped with residual boulders of gypsum. Caves are also numerous, formed by captured ephemeral streams. They commonly begin with vertical shafts and continue as single subhorizontal passages, leading to outlets at base level. The largest known assemblage of salt caves is found in Mount Sedom near the Dead Sea in Israel (see Sedom Salt Karst entry), where over 100 caves with >20 km of passages have been surveyed, including the largest known salt cave, Malham Cave, explored for 5.7 km (Frumkin, 2000). Other noteworthy caves in halite are known from Spain, Romania, Hungary, Russia, Algeria, and Chile.

Mantled Evaporite Karst

Gypsum karst that has been mantled by glacial till, now partly exposed along the rims of river cliffs, has been described for Manitoba, Ontario, for the Maritime Provinces of Canada (Ford, 1997), and for Pinega and the North Dvina regions of Russia. Characteristic landforms include densely packed small suffosion dolines, vertical solution pipes, pinnacles, shlotten, and karst trenches. Similar topographies are known above river cliffs in some entrenched gypsum karsts (pre-Urals, Russia). Where the gypsum is deeply mantled, as in other parts of the abovementioned regions, karst features are represented mainly by collapse dolines and by small caves where the gypsum is locally incised by postglacial rivers. Areas within the major river valleys in the Erbo Basin of the Saragoza region of Spain show examples of the alluviated subtype of mantled gypsum karst.

EVOLUTION OF HYPOGEAN FAUNA

Hypogean fauna characterized by troglomorphisms have been used by virtually every school of thought in evolution in support of their theories, from 19th-century creationism to past and present neo-Lamarckism (including its derivatives of directional—"regressive"—evolution), and from the neutralist school to the selectionist/neo-Darwinian one. In fact, Darwin himself took a somewhat ambiguous position in the first edition of *On the Origin of the Species by Means of Natural Selection*, where he explained troglomorphism as a combination of both natural selection and use *vs.* disuse. In later editions he took a more neo-Lamarckian stance (for a review of these schools of thought, see Romero, 2001).

Evolution is opportunistic, and that is why life is ubiquitous on earth. The total number of troglomorphic species has been estimated to be between 50000 and 100000 (Culver & Holsinger, 1992). This number is considerable, given that most hypogean habitats: (1) are very reduced in space; (2) generally lack primary producers (plants); and, (3) have not been thoroughly explored, particularly in tropical regions where caves contain a very diverse fauna (Deharveng & Bedos, 2000).

Historically, most cave researchers have concentrated on hypogean animals that are troglomorphic. The hypogean fauna has thus been epitomized by animals displaying some kind of troglomorphism (see Table); however, not all hypogean faunas are troglomorphic. Surveys of cave fauna yield a large proportion of non-troglomorphic organisms; further, the proportion of troglomorphic organisms in caves is inversely proportional to latitude (Peck, 1988). The number of known hypogean fish species with troglomorphism is 86 (Romero & Paulson, 2001a) and 115 without troglomorphism (Poly, 2001). These data are consistent with the contention that a large proportion, perhaps even the majority, of hypogean animals worldwide are not troglomorphic. Therefore, colonization of the hypogean environment does not necessarily require morphological changes.

Some argue that hypogean environments are so "harsh" (i.e. poor in nutrients) that only "pre-adapted" organisms could survive in them (Holsinger, 2000). Available data do not support either generalization about the ecological conditions in caves or about the nature of the colonizing animals. First, animals that colonize caves can find food, reproductive niches, protection from predators, and a place for hibernation. Therefore, the hypogean environment can offer a number of ecological opportunities to many different species of many different taxa. That is why cave colonizers can undergo extensive adaptive radiations (leading to many differentiated populations and/or species) (e.g. Hoch & Howarth, 1999). Second, contrary to generalizations based on

troglomorphic organisms display all these characteristics at the same time.)					
Morphological	Physiological	Behavioural

Appendages	Lipid storage				

Evolution of Hypogean Fauna: List of some features catalogued as "troglomorphic". (Not all troglomorphic organisms display all these characteristics at the same time.)

studies of caves in temperate regions (e.g. Poulson & White, 1969), many caves are very rich in nutrients, particularly in tropical regions (e.g. Deharveng & Bedos, 2000), and some are even chemo-autotrophic, that is, rich in bacteria that produce organic matter by

oxidizing sulfur (see Movile Cave, Romania). Both types of caves tend to be very rich in species, and some of those species have large populations.

"Pre-adaptations" have been described as features such as nocturnal habits and hyperdevelopment of sensory organs in epigean species that are considered useful and even necessary in hypogean environments (Holsinger, 2000; Langecker, 2000). However, a recent study of hypogean fishes failed to show that all or even most fish families with troglomorphic representatives were taxa characterized by pre-adaptive features (Romero & Paulson, 200 1b). Furthermore, the Texas blindcat *Trogloglanis pattersoni*, found in deep aquifers, has rather minute barbels, which is unusual for other catfishes of its family (Ictaluridae) (Langecker & Longley, 1993). This is inconsistent with the notion that enlarged sensory organs are required to enhance survival potential in the hypogean environment. Therefore, "pre-adaptations" are neither necessary nor sufficient to that end.

Caves around the world have very variable conditions, with a wide range of temperature, water supply, and size. The only thing they have in common is that for most of their length no natural light is available. The two characteristics most closely correlated with light conditions are eyes and pigmentation. Animals that have been raised under conditions of total darkness display a lower degree of eye and pigment development (see Adaptation: Eyes); conversely, when troglomorphic animals are exposed during certain periods of time to light, they may redevelop, to a certain extent, both pigmentation and the visual apparatus.

This strongly suggests that many troglomorphic animals are derived from epigean species characterized by phenotypic plasticity. Phenotypic plasticity is the ability of a single genotype to produce more than one alternative form of phenotype in re sponse to environmental conditions. The direction and degree of response to environmental factors is known as the reaction norm, which is genetically variable and subject to natural selection. Natural selection may favour those individuals with a higher capacity to express specific traits under appropriate conditions. Phenotypic plasticity often provides a reproductive advantage over a genetically fixed one because environmentally induced phenotypes have a higher probability of conforming to prevailing environmental conditions than genetically fixed ones.

Lack of light can trigger heterochrony, i.e. changes in the timing of development of features. Examples are paedomorphs (animals that do not reach morphological maturity [metamorphs] reproducing as juveniles), and neotenes (animals with an unusually slow rate of growth). Many cave organisms are either paedomorphic or neotenic. Most troglobitic salamanders are paedomorphic, and half of all known paedomorphic salamanders are troglobites. Salamander evolution into a paedomorphic condition can be quite fast. Individuals living in the hypogean environment gain an advantage by becoming paedomorphic because this condition gives them the flexibility to survive in an unpredictable environment. Paedomorphosis in *Eurycea neotenes* seems to be a response to selection for the ability to pass dry periods in hypogean aquatic refugia (Sweet, 1977; see also Amphibia). Also, neoteny in hypogean animals is well documented for reduced body size, loss of scales, fin modifications, and reduced ossification.

Natural selection that favours paedomorphs/neotenes fixes their paedomorphic/neotenic alleles in the cave population. Given that most cave populations are small and subject to very similar selective pressures within the same cave, this

evolutionary process can take a relatively short period of time. In fact, paedomorphosis can be achieved via a major gene effect (a small genetic change generating a large phenotypic effect). Troglomorphic characteristics can arise via minor changes in developmental genes.

Only when there is a constant gene flow from the epigean environment can such changes be prevented. In this respect the recessive allele can be considered the "troglomorphic gene" because it manifests a morphologically and ecologically differentiated phenotype that is reproductively isolated from the epigean ancestor. This explanation is supported by the convergent nature of troglomorphic characteristics. Convergent evolutionary patterns are strong evidence of adaptation via natural selection. Isolation would later lead towards speciation (genetic differentiation from the epigean ancestor; see Speciation). Many troglomorphic organisms are believed to have recently invaded the hypogean environment, since their epigean ancestor is easily recognizable and can even interbreed with them to produce fertile hybrids.

The evolution of troglomorphic characteristics does not necessarily occur in parallel. This is because: (1) they are controlled by sets of genes independent of each other; (2) the degree of development of these characteristics is conditioned by their phylogenetic history; and (3) because the selective pressures behind each one of those characteristics may differ from cave to cave (Culver *et al.*, 1995; Romero & Paulson, 2001c). In addition to reduction/loss of phenotypic characteristics, many troglomorphic organisms exhibit enhancement of sensory systems (chemical and mechanical) that are favoured by natural selection, since these sensory systems increase the fitness (survival capabili-ties) by helping them to find food and mates. Complex, coordinated, and adaptive phenotypes can originate rapidly and with little genetic change, via correlated shifts in the expression of plastic traits. Composite characteristics, like those often observed among troglomorphic organisms, are produced by correlated phenotypic shifts that give the impression of a coevolved character set.

There are still grey areas in our understanding of the evolution of hypogean fauna. For example, we assume that behaviour plays a major role in the colonization of new niches, since behaviour is the most plastic part of the phenotype. Although changes in behaviour are well documented and present even in transitional forms, we do not know the role played by behaviour in the changes in other phenotypic characters. Behavioural changes usually precede external morphological evolution. Behavioural flexibility is thus the first condition for success in cave colonization. Only after colonization has taken place do morphological and physiological changes take place. Individual adaptability is the main target of selection. Behavioural invasion of a new environment by adults exposes the reaction norm of their progeny. Since hormonal production is closely linked to behaviour and hormones play a role in many developmental processes, there is a great potential for hormones to produce (or act as) developmental constraints. Therefore, the arrest in development of features could be due to diminishing hormonal production as a physiological consequence of the adaptation to the hypogean environment (i.e. many behaviours are no longer performed under conditions of darkness). This, in turn, could lead to the differential regulation of developmental genes.

The phenomenon of loss or reduction of phenotypic characteristics is not unique to troglomorphic organisms, and can be found among other animals such as parasites, deepsea creatures, and the inhabitants of highly turbid waters. Also, limblessness and flightlessness are common among faunas living on small islands and high mountains. The loss of limbs among cetaceans is an example of a major evolutionary novelty by default. Even humans show loss or reduction of a number of characteristics inherited from their ancestors (Diamond & Stermer, 1999). Thus, troglomorphisms can be explained using well-known evolutionary mechanisms, without needing to resort to neo-Lamarckian explanations or terminology such as "regressive evolution". The study of this phenomenon has been largely neglected in mainstream evolutionary biology due to the sense that evolutionary novelties mean addition, not subtraction, of characteristics, and because of the way in which this biological phenomenon has been used by neo-Lamarckians to advance their own cause of either inheritance of acquired characteristics or the notion that evolution has some sort of directionality (Romero, 2001).

EXPLORATION SOCIETIES

One hundred and fifty years ago, there were no cave exploration societies, some 100 years ago there were 15 or more, and now they are uncountable. This article is concerned with their development—why, when, and where they were formed, what effect they had on exploration and the publication of results, and how they spread out from the core of 19th-century European cave exploration activity. Recently the quantity of clubs has increased vastly, and an increasing proportion are devoted solely to the sporting aspects of caving. However, the motivated and progressive societies that achieve research results, both in exploration and cave study, are still similar in nature to those of 100 years ago.

The creation of cave exploration societies has had three main effects:

- 1. They bring together people with similar interests, stimulating deeper and longer-term involvement in the field;
- 2. By working together as a group, the members are able to undertake explorations that are technically more difficult and physically more demanding than those they could have done alone;
- 3. Their specialist cave publications not only increase the amount of speleological material published, but make it more readily available to people who have an immediate interest in it.

The locations of cave exploration societies are determined by the geography of the major karst areas, particularly those where karst scenery is widespread and spectacular. Another requirement is the presence of a sufficiently large educated population in or near the karst area.

The popularity of rock climbing and mountain exploration developed steadily in the 19th century, marked by the founding of the Alpine Club in 1857 and the Deutsche und Österreichische Alpenverein in 1862. Some of the earlier speleological groups were in fact offshoots of mountaineering clubs. The earliest known cave society was the Höhlenklub of Appenzell in eastern Switzerland, which existed in the early 1860s. Very little is known about it, for it evidently kept no records or minutes and did not publish its findings. Its members are known to have visited the caves of Wildkirchli and Dürr-Schrennen in 1863, for they wrote a short account of these in the visitors' book at the nearby inn. This Appenzell club was not heard of again and most certainly had no effect on the subsequent formation of the more scientific groups in Austria and Slovenia.

The first real speleological group was the Verein für Höhlenkunde, founded by Franz Kraus (1834–97). On 18 January 1879, he put a notice in a Viennese newspaper, inviting the attention of anyone who was interested. The response was good and after several months of preparation the Verein für Höhlenkunde was formally founded in Vienna on 19 December of the same year. Soon afterwards it published five issues of a bibliographical publication on caves, Literatur-Anzeiger, the first of which appeared on 17 February 1880. It was the world's first speleological periodical. Sixteen months after its formation, the group, which then had a membership of 44, became part of the Österreichischen Touristenclub as a separate Section für Höhlenkunde. Its new publication, the Mittheilungen of the Section, recorded the scientific exploration work of its members and was thus the earliest conventional speleological journal. A Karst Committee formed within the Section adopted a semi-professional approach to its work, which became increasingly associated with the practical problems of karst hydrology. Kraus succeeded in acquiring subsidies from two ministries in the Austrian government and also from the Südbahn Austrian railway company, and the Karst Committee's activities culminated in the sponsored cave work of Putick. The impetus spread over most of the Austro-Hungarian Empire, so that by the end of 1892 Kraus knew of 659 caves there.

Another very early cave group was the Section Küstenland des Deutschen und Österreichischen Alpenvereins. This "coastal section" had in fact been set up in 1873 but not with cave exploring in mind. It was only in 1883 that a cave section or Grottenabteilung was created, but from then on it was noted for the very difficult explorations that it carried out, including those of Skocjanske jame (Figure 1, and see separate entry) and Kacna jama. Its leaders were Anton Hanke (1840–91) and Jozef Marinitsch (1838–1915).

The first of the Italian cave societies also worked in Slovenia as well as that part of Italy close to the border. The Società degli Alpinisti Triestini was founded at Trieste on 23 March 1883. There were 73 founder members and the number soon grew to over 100. A subsection for caves, the Commissione Grotte, was formed and explored the Grotta Gigante, Trebiciano (329 m deep), the Abisso sopra Chiusa (227 m deep), and other deep caves (Figure 2). In 1885 this society merged with the still-existing Società Alpina delle Giulie. The total number of caves explored rose at an increasing rate, from four in 1883 to 230

Exploration Societies: Figure 1.

Exploration Societies: Figure 2. Zankajna jama in Croatia during exploration in 1925 when it was called Abisso Bertarelli, showing members of the Commissione Grotte of the Società Alpina delle Giulie (reproduced from their archives, with permission).

by 1900. The caves were recorded systematically and allocated catalogue numbers.

The influence of Austria and Italy was very evident in these first few groups working in Slovenia, which was then a part of Austria and close to the Italian border, but the Austrian influence was not quite as strong as it appears at first sight. Admittedly, the initial investigation came from Kraus, who continued to participate although he lived in Vienna, and the cave groups were administered as parts of Austrian societies. Many of the principal explorers and leaders, however, were local people: Hanke and Marinitsch were Slovenes and Hrasky was a Czech who lived and worked in Ljubljana; Putick was also a Czech.

It was in 1889 that the first purely Slav cave society was formed, a group called Anthron whose main discoveries were in the Postojna system. It cooperated closely with foreign explorers and E.A.Martel carried out his 1893 Postojna work with its members as well as with Kraus and Putick.

Of very great importance was the French Société de Spéléologie, founded in Paris by Martel in 1895 and concerned with specialist cave research as well as exploration. A great deal of the Society's influence was due to its publications, the *Bulletin* and the *Mémoires*. Together they comprised 98 numbers between 1895 and 1914, with a total of
4843 pages. Martel was the author of about 20 of the issues, including a special 810-page volume of annotated bibliography.

The wide scope of the Société de Spéléologie was signified in the first article of its original statutes, which read:

The Speleological Society has been founded in order to engage in the exploration, facilitate the general study and aid in the control or utilisation of all kinds of subterranean cavities, whether known or unknown, natural or artificial; to encourage and give grants to investigations bearing in any way on caverns; and in short to popularise and develop researches of every kind into the interior of the earth from practical as well as theoretical, utilitarian as well as scientific points of view.

In England, the Yorkshire Ramblers' Club was much more oriented towards the sporting aspects of cave exploring, although it did do a lot of useful original work. It was formed in Leeds in 1892, primarily as a mountaineering club. In Gaping Gill, where Martel had made the first descent of the main shaft in 1895, the Yorkshire Ramblers' Club pursued the exploration of the entire passage system at the bottom, surveying a total of about 1100 m by 1906.

The rate of cave exploration increased greatly after 1900, even quite early in the century. It has been estimated that in many countries the number of caves known increased by a factor of ten between 1892 and 1911. In the Trieste and Istria region alone the number rose from 230 in 1900 to 510 in 1920, and by 1937 the total was 3500. No figures have been published for the number of caves known in the world today but it is likely to be more than a quarter of a million.

At the beginning of the century, the societies were mainly interested in the discovery and exploration of new caves. They took this seriously and for the most part published their results, often with plans of the caves. Of the 19th-century groups, only the Commissione Grotte of the Società Alpina delle Giulie and the Yorkshire Ramblers' Club still survive and both of them continue to publish. New societies founded in Italy shortly after the turn of the century included the Società Speleologica Italiana (1903), the Circolo Speleologico Romano (1904) and a Commissione Grotte in the Fiume (=Rijeka) section of the Club Alpino Italiano (1904). In England, the Yorkshire Speleological Association was founded in 1906; it explored and surveyed about 8 km of difficult caves but disbanded in about 1914.

Most of these societies were interested to some degree in the specialist scientific aspects of caves, as well as in accurate surveying and recording. All of them, however, were and are entirely amateur; a few of the members may be professional speleologists in institutes or universities and the societies sometimes receive grants or subsidies to aid in particular projects, but they remain amateur organizations. The link between the amateur's recreational cave exploring and the work of the professional scientist is often close and sometimes indistinguishable. Dr Walther von Knebel in 1906 said of it:

Cave science depends upon the help of the layman for completion. It is not always possible for the expert to check and complete his studies. Cave sportsmen are as useful in cave science as, for example, Alpine sportsmen are for glaciology.

The amateur who enjoys working in caves for its own sake is often a willing collector of data, however time-consuming this may be. This type of society or group, with its combined interest in the scientific and recreational aspects of caves, has persisted throughout the 20th century. It includes or has included some of the most important national and local societies, for example the British Speleological Association, the Fédération Française de Spéléologie, the Société de Spéléologie, the National Speleological Society (United States), the South African Speleological Association, and the Sydney Speleological Society.

The very great growth in the numbers of cave societies or clubs formed in the 20th century has included many which are concerned solely with the sporting side of cave exploring. Some such groups, including the long-established Yorkshire Ramblers' Club, do seek new caves, often with notable success, and do publish their findings. In other cases, not even new discoveries are sought, but just the satisfaction of overcoming the physical difficulties of the exploration. The Leeds Ramblers' Club descended Gaping Gill in 1904 and continued to do so annually for many years, often without undertaking any original exploration there, and there are many later examples.

The vast increase in the number of societies is the result of many causes, including increased population, a larger proportion of people living in cities, the higher public profile of caving in the media, and the presence of even more clubs attracting recruits. An important influence in enlarging the total number of societies (although now masked by the causes given above) has been the growing internationalization of speleology. The entry for Speleologists in this Encyclopedia emphasizes Martel's role in spreading interest across Europe and even into the United States. Also, as the numbers of individual speleologists in the world has increased, their working abroad and their emigration has helped to start up similar activity in their new countries.

Two non-European countries are of particular interest in this respect, one whose cave work started surprisingly early, and the other surprisingly late. In Australia, where serious cave exploration and surveying was already going on in the 1880s, it was due not to amateurs in societies but to enthusiastic professionals working for the government, such as the surveyor, cave explorer, and writer Oliver Trickett. In the United States, on the other hand, despite Martel's already close links with American speleologists even before his visit there in 1912, it was not until 1939 that the first cave exploring society was founded: the Speleological Society of the District of Columbia, soon to be transformed into the National Speleological Society, which is now the world's largest cave society with over 12000 members. There had been talk of forming a national society in the 1930s, but it did not come to anything. It seems that at that time individual academics and cave explorers were too thinly spread over that vast country to provide a sufficient nucleus in any one place to form a group. There was certainly no equivalent of the Australian governmentled cave research.

To list the present-day societies and associations is difficult and has to be partly subjective, taking into account their size, new exploration, scientific work, publications, etc. The accompanying Table cannot be taken as listing the "top ten" or so, but certainly all those included are important and produce substantial results of a professional standard. In some countries (e.g. China), however, most exploration is institute-sponsored and, in others such as Poland, Spain, and Slovenia, the principal publications are from professional or academic institutions.

Exploration Societies: Some major present-day cave groups (arranged alphabetically). Specialist government and academic institutes are not included.

Association for Mexican Cave Studies	United States
British Cave Research Association	United Kingdsom
Ceska Speleogicka Společnost (Czech Speleological Society)	Czech Republic
Commissione Grotte "Eugenio Boegan", Società Alpina delle Giulie ("Eugenio Boegan" Cave Group of the Giulian Alpine Club)	Italy
Fédération Française de Spéléologie (Speleological Federation of France)	France
Jamarska zveza Slovenije (Speleological Association of Slovenia)	Slovenia
National Speleological Society	United States
New Zealand Speleological Society	New Zealand
Società Speleologica Italiana (Italian Speleological Society)	Italy
Société Suisse de Spéléologie (Swiss Speleological Society)	Switzerland
Spéléo-Club de Paris (Speleo Club of Paris)	France
Speleological Society of Japan	Japan
Speleološki odsjek HPD "Şeljezničar" (Cave section of the Croatian Mountaineering Club "Zeljezničar")	Croatia
Sydney Speleological Society	Australia
Verband der deutschen Höhlen- und karstforscher (Association of German Cave and Karst Researchers)	Germany
Verband Österreichischer Höhlenforscher (Association of Austrian Cave Researchers)	Austria

EXPLORING CAVES

Human beings have been exploring caves for thousands of years, initially with nothing more than a hand-held light. Recreational caving, the exploration of caves for pleasure and as a sporting challenge, is generally held to have begun in the late 19th century with the explorations of Édouard-Alfred Martel, and the number of participants increased greatly from the 1950s with the general increase in leisure time and improved transport. As cave exploration became more popular, specialized equipment was developed. Equipment has changed considerably over this period with an escalation of changes in the last 50 years. This entry examines what a human being needs to explore a cave.

Lighting

A source of lighting has always been the most important piece of caving equipment. Lights were originally burning materials, such as flaming torches or candles. For most of the 20th century, carbide lamps burning acetylene gas were the standard caving light and they are still used for expedition caving. The 20th century also saw the introduction of electric lights which have gradually replaced carbide lights for most caving uses. The capmounted miner's lamp together with a belt-worn acid battery was adopted for caving, and more recently specialized caving lights have been developed. Modern electric caving lights are water resistant with two sizes of bulbs to give high or low illumination, and usually incorporating a spare bulb. Both rechargeable and disposable batteries are used. For expedition use a carbide light with an electric backup is the norm. Electric caving lights have progressed from simple tungsten bulbs to higher performance halogen or krypton bulbs and recently the trend is towards LED lights which are robust, rarely fail, and being more efficient, offer longer battery duration.

Protection from Cold, Water, and Abrasion

Cave explorers in 1900 wore many layers of everyday clothing, tweed suits being particularly popular in Europe. Abundant army surplus gear from World War I and (mainly) World War II kept cavers clothed and equipped for many years, but during the 1960s, cavers began to use clothing borrowed from other outdoor sports. Woolly underwear came from mountaineering but oversuits were simply mechanics' overalls. For very wet caves or those requiring complete immersion, wetsuits originally used for diving became common, often hand-made by the owner or highly modified with extra neoprene pads to provide protection

Exploring Caves: Figure 1. The first exploration of the deep shaft of Tripa tis Nifis in Greece; the main belay is a good thread, but the rock is thin bedded, so back up belays are onto the piton and the rope of the pitch above. (Photo by Tony Waltham)

for knees and elbows. A thin oversuit was often worn over these wetsuits in an attempt to reduce damage from abrasion. In the early 21st century the most usual caving clothing in temperate areas is thermal underclothing in one or two layers with a specialized oversuit over the top. These oversuits can be very tough and waterproof and are used in all but the wettest caves. There is, however, some variation in clothing around the world from hot to cold climates. Protection against abrasion is usually important so even in the hottest caves thin oversuits tend to be worn.

Footwear has also progressed. Originally miners' boots made of leather or rubber and with steel toecaps and nailed soles were used. During the 1980s specialized caving rubber wellingtons or walking boots became popular, often worn with neoprene bootees. More recently there has been a move towards more specialized footwear, such as water boots, normally used for canoeing or canyoning and in the future it is likely that highly specialized boots will be produced with rigid toecaps and wetgrip soles.

Originally helmets were worn as protection against hitting the roof or being struck by falling rocks but more recently they have also provided a means of mounting the light and freeing hands for climbing and carrying. Early helmets were made of leather, cardboard, or plaited bamboo, and bamboo helmets are still manufactured and used in mines in China. Since the late 1960s there have been several technological advances, including the development of plastic and fibreglass helmets designed for mining with lamp brackets and shock-absorbing internal cradles added. Modern caving helmets are lightweight, comfortable, and capable of absorbing a considerable shock.

Vertical Equipment

Equipment for climbing or descending pitches has progressed enormously since the 1950s. Before this time, exploration of shafts often took place by people being lowered down on a rope or winch, a method that had not changed for several hundred years. Free climbing was originally attempted with nothing but the occasional hand line, but this severely limited the caves that could be explored. Rope ladders developed quickly from the late 19th century and some large drops were descended by natural fibre rope ladders with wooden rungs. Wire rope ladders with aluminium rungs replaced natural fibre rope ladders and several climbs of over 300 m were made using this equipment, including Provatina and Epos chasm in Greece in the 1960s. Ladders though were still heavy and easy to fall from, thus requiring an additional safety line. The largest drops continued to be descended using hand-operated or powered winches.

The real advance came with the first readily available synthetic ropes. During the late 1960s North Americans started using a single rope to descend and ascend caves—Single Rope Techniques (SRT) were born. Low stretch, abrasion-resistant ropes were developed and SRT spread rapidly throughout the world during the 1970s. The rope passed through a friction device attached to a caver's seat harness and friction reduced the speed of the descent. These devices were originally borrowed from climbing and the "figure of eight" remains popular but devices specialized to descend long drops on single ropes soon began to appear. The rappel rack was invented in the United States and is still the American descender of choice. The rack consists of a bent metal frame in the shape of a giant paper clip with a number of aluminium friction bars like ladder rungs across it, which the rope passes back and forwards between. In Europe fixed pulley or "bobbin"

devices were developed where the rope describes a tight "S" through the device to slow the descent by friction. Locking mechanisms have since been added.

To ascend a rope, short lengths of cord were originally tied with "prusik knots" around the rope which could be pushed up but would not slide down when under tension. Climbing a single rope has since been known as "prusiking" even though prusik knots which were cumbersome and slow were soon replaced by mechanical ascenders. The first mechanical ascenders-"Jumars"-revolutionized caving. Two distinct methods of climbing a rope developed: the sit/stand or frog, and the ropewalker. The frog uses two mechanical ascenders, one worn on the chest between a sit and chest harness, the other connected to the seat harness by a safety cord and with a long cord to a footloop. By standing on the long cord the chest ascender slides up the rope; then, while sitting back on the chest ascender, the second ascender can be lifted up the rope by hand. As both these devices are near hand/eye level, it is very simple to get the system on and off the rope allowing cavers to pass knots or easily change from one rope to another. In the United States, various forms of "ropewalking" developed. The ropewalker attaches one ascender to each foot with a third ascender or pulley at chest level to keep the body upright, and he ascends by a walking motion up the rope. This gives a considerable speed advantage over frog but is heavier and less manoeuvrable. Sit and stand systems are by far the most common techniques worldwide, although some people still use ropewalking systems, particularly for long pitches.

Vertical caving equipment has become more and more specialized with low stretch, highly abrasion-resistant ropes being further developed. Rope strengths have increased and thicknesses decreased: SRT began on 11 mm and 12 mm diameter ropes but by 2000 most exploration caving was being done on 8 mm to 9 mm rope. Most caving ropes are made from nylon, although for a time single metal wire ropes with special ascending and

Exploring Caves: Figure 2. Exploring a wide passage with limited air space over a long lake in Gua Sodong in the Gunung Sewu karst of Java. (Photo by Andy Eavis) descending devices were used. These gained some popularity in the former Soviet Union due to the unavailability of adequate nylon rope.

For very wet caves or surface canyons, floating rope is often used, although the strength and abrasion resistance are not as high as other caving ropes. Life jackets are also frequently worn where a considerable amount of swimming is involved in cave exploration.

Ropes and ladders were originally anchored to natural rock belays but these are not necessarily available or in the right place for a good "hang" away from water or loose rock. Hence, in Europe, and increasingly elsewhere, rock bolts have largely superseded natural anchors. Rock bolts are also placed in suitable positions for cavers to abseil through caves pulling the rope after them where exit is possible through a second entrance. Several types of masonry anchor were initially used before cavers settled on the 8 mm self-drilling anchor or "spit". These have an expansion sleeve that has its own drilling teeth cut onto each anchor. They were initially placed using a removable handle and hammer but portable hammer drills have now largely replaced arm-power and it is common to use less bulky expansion sleeves that require a smaller hole. Larger bolts held in by resin with an integral ring hanger ("P-bolts") are often used in high traffic caves as they deteriorate only gradually with use.

The development of rock bolting has enabled long descents of difficult caves to be done safely. It has also enabled climbs upwards to be made much more easily. Since the 1950s a variety of ways of climbing upwards have been developed, including solid lightweight ladders, scaling poles, and more recently, small platforms. Using advanced bolting techniques, cavers have climbed hundreds of metres up vertical or overhanging rock walls to discover high-level roof passages. Titan Shaft in Peak Cavern, Derbyshire (England) is an example where cavers have climbed for over 140 m. The downside is that with bolts so physically easy to place, many unnecessary bolts have been inserted, leading to considerable damage to popular caves.

When SRT was first used the harnesses were borrowed from the climbing world and the body weight rested mainly on the groin (British cavers spent many uncomfortable years in Willans harnesses). Development in harnesses led to leg loops where the weight is taken on wide straps around the buttocks. Specialized caving harnesses designed to be sat in for long periods with increased abrasion resistance and minimal water absorption were developed. Chest harnesses have been produced to pull up an ascender and to keep the caver more upright. Chest harnesses can be sewn like brassieres or simply a length of tape passed around the chest and over the shoulders.

Miscellaneous Caving Equipment

To carry all this equipment a variety of bags and containers have been developed. Originally ordinary rucksacks were used but they were very expensive and were rapidly destroyed by abrasion. Hence, special bags were developed in very tough materials with minimal folds and loops to get abraded or caught on projections. Waterproof bags are often used to keep equipment dry and as flotation devices to aid swimming and transport heavy equipment through flooded passages.

With caves being explored to ever greater lengths, the need has increased for underground camping. In a large cave, camps can be much like those on the surface and in cold or wet caves tents may even be transported underground and erected. In small caves hammocks with or without covers are often used, fixed with rock bolts across or even along the passage. Underground food is generally kept as lightweight as possible and is heated on a normal camping stove. Sleeping bags must always be made from synthetic fibres as down loses its warmth when wet.

New caves are becoming harder to find in many parts of the world and most new discoveries are now made by digging, climbing, or diving. Cave digging ranges from simple excavation of loose sediments with bare hands to almost mining a way through. Battery-powered electric drills are commonly used for shot holes to place explosives for enlarging passages or removing boulders. Bolts are used extensively for climbing although scaling poles are still used for smaller climbs. Cave diving has become a sport in its own right (see Diving in Caves). Surveying known cave passages can often suggest sites for digging or climbing (see Surveying in Caves).

The scope for finding new caves and for making new discoveries in known caves is still enormous and there are still many lesser-developed nations that have seen very little cave exploration. As political conditions change, cavers become wealthier, and travel gets even easier, these countries will become centres of cave exploration.

EXTRATERRESTRIAL CAVES

As Earth is a water-dominated, volcanically active planet, there are numerous solutional and volcanic mechanisms always at work creating subsurface voids. Hence, Earth is cave-rich, but not the only body in the Solar System to have caves, as both the Moon (Oberbeck, Quaide & Greeley, 1969) and Mars (Figure 1) are known to have lava tube caves. There are probably other types of caves on many other bodies in our Solar System

but direct evidence does not yet exist as exploration of the planets and smaller bodies is still at an early stage. Detection of subsurface voids has not yet been attempted on space missions.

Cave conditions within a planet's crust may be very different from those on the planetary surfaces that geologists have studied so far. On Earth, the cave environment often differs significantly from overlying surface conditions. For example, caves can maintain cool temperatures, saturated humidity, open pools, and sometimes permanent ice even when there is a hot desert on the surface. In most cases, the cave thermal regime will be more stable than at the surface because of insulation by surrounding material. For example, Mendell (in Horz, 1985) calculated that lunar lava tube interiors will remain at a constant -20° C (at depths greater than 30 cm) despite mean surface temperature fluctuations of more than 300° C (-233° C minimum at polar night to+130^{\circ}C at equatorial noon).

Classifications of extraterrestrial caves are based on knowledge of Earth caves and the fundamental physical processes responsible for their formation (see Table). This categorization helps geologists imagine possible cave types that could form under radically different extraterrestrial conditions, and to develop cave-detection protocols for future planetary missions.

Why are caves on other planets plausible? A primary mechanism for cave formation involves cracking of crustal material, often followed by other enlargement mechanisms. On any planet with a solid surface, application of an energy source (either internal or external) will result in cracking. Those cracks then provide the basis for cave formation by a variety of terrestrial and possibly other non-terrestrial mechanisms (see Table). Heat flow from the planetary interior drives the type of plate tectonics that we have on Earth, resulting in crustal movements and deformation. Uplift, faulting, and earthquakes can all result in surface and subsurface cracks ultimately leading to speleogenesis. In the case of planets like Mars with lower internal heat flow, little or no plate tectonic activity has ever existed. However, the majority of rocky planets, larger asteroids, and moons have an early history of significant heat flow and crustal melting. Other kinds of tectonism not involving large plate motions can occur, typically involving expansion and contraction and both producing cracking. Surface cracks can also result from impact cratering. Many other Solar System bodies are heavily cratered including Earth's Moon, and many moons of the gas giant planets, for example Ganymede and Callisto orbiting Jupiter, and Mimas and Dione orbiting Saturn. In the case of some of the moons around gas giant planets (e.g. the Jovian moon Io), tidal flexure, caused by a moon's close proximity to the enormous gravitational pull of its primary planet, has caused extremely active surface geological processes including extensive fissure formation (Moore et al., 1999). Tectonic caves can be created by processes as simple as crumbling or non-fluid undercutting in faults, scarps, and other cracks (see Talus Caves). Subsequent enlargement can occur via freezing expansion of ice. Large blocks of igneous materials can crack off and slide, thus creating voids and passage. Mass wasting of boulders can also create labyrinths, for example perhaps disaggregating scarp crests along margins of sites like Vastitas Borealis on Mars.

Extraterrestrial Caves: Mars images showing lava tubes (arrows) in a variety of volcanic landscapes. Viking Orbiter Camera Image; NASA.

A second major cave formation mechanism involves melting and resolidification of materials, as in the case of lava tube caves. Though the volcanically active eras of bodies such as Mars or the Moon are long past, very large lava tubes (3–10 times sizes typical for Earth) appear to be the norm due to the lesser gravity of those bodies (Bunnell, 1991) and possibly to their magmatic composition (Keszthelyi, 1995). The morphological evidence of lava tubes is easily seen in lunar images as strings of collapse features near the tube ends, for example at the western end of Mare Imbrium. Features on the flanks of Martian volcanoes like Olympus Mons also appear as lava tube strings radiating from central volcanic sources just as we see them on Earth (see Figure). Tidal flexure volcanism on Io may have produced lava tubes (Peale, Cassen & Reynolds, 1979). The history of Venus is also dominated by massive, global volcanism of unrivalled proportions (Sakimoto, Crisp & Baloga, 1997) and Venus may prove to have lava tubes (Zimbelman, 1998). On bodies with gravity less than Earth's, less lava flow trenching erosion will occur; thus formation of some lava tube types that we find on our planet (see Volcanic Caves) may be rare on bodies like the Moon and Mars.

Besides volcanoes that emit melted rock in the type of volcanism familiar on Earth, the cold, icy moons of Jupiter show evidence of volcanism involving supercooled water, other fluids, and ices known as "cryovolcanism" (Wilson, Head & Pappalardo, 1997). This process could produce caves that have no terrestrial counterparts, for example ice tubes, cryotumuli, or other as yet unimagined speleological objects. In addition, because

of very low global temperatures, glacier caves could be permanent features on icy moons rather than the transient phenomena that they are on Earth.

Permafrost caves caused by ground ice suffosion (Ford, 1997; see also Piping Caves) and interaction with karst terrain (Pinneker & Shenkman, 1991) are known from the high latitude regions of Earth. Similar processes can be imagined in circumpo- lar regions of Mars, on icy satellites, or even icy asteroids or comets with periodic sublimation of ices occurring each time they pass perihelion. Ice sapping features are clearly visible on Mars, although the specific details of this process on a planet with a hyperarid surface (drier than any site on Earth), extremely low temperatures (lower than anywhere on Earth), and ground ice cannot be directly compared to related processes on Earth. Seasonal or longer-term cycles of thawing, gargantuan episodic floods, and subsequent sublimation of liquid into the tenuous atmosphere could have created very unusual subterranean passages.

Dissolution speleogenesis on Earth requires the presence of liquid water (often as weak carbonic acid or more aggressive sulfuric acid) and soluble rock. On cold planets and moons, non-water liquids, for example liquid nitrogen, liquid ammonia, or ethane, could conceivably dissolve rocky and icy materials depending upon the solubilities of those materials at the relevant temperatures. Whether carbonates and other evaporites exist on other planets is unclear. However, the early history of Mars as a wetter, warmer environment with a CO2-dominated atmosphere has fueled speculation that carbonates may have formed abundantly during its early history and remain as deposits today. As Mars is a sulfur-rich planet, large standing water bodies would have had abundant sulfur to form evaporite minerals like gypsum. However, these minerals have not yet been directly detected on the Martian surface. Orbital spectroscopic detection of surface minerals has proven difficult beneath the well-mixed, globally distributed surface fine materials coating Mars. If caves did form in soluble materials during early wet Martian eras, they may have been preserved by subsequently dry and relatively inactive later periods. Thus, the average lifetime of any solution caves on Mars could greatly exceed their counterparts on Earth unless destroyed by impact or buried by wind-blown fines. In the latter case the caves may subsequently be revealed by wind-excavation.

Extraterrestrial Caves: Possible extraterrestrial (ET) cave types. Extraterrestrial caves can be formed by mechanisms that are common speleogenetic processes on Earth but there is an entire array of different processes and conditions that may produce caves of radically different properties than those we are familiar with on Earth.

Site Type	Possible Parent Material	Earth Formation Mechanisms	Possibile Unique ET Mechanisms
Solutional Caves (True "Karst")	Soluble rock	Dissolution of rock by solvent	
Epigenic caves	Limestone, dolomite, gypsum, other soluble rocks or minerals	Weak carbonic acid (groundwater or rain and dissolved CO ₂) organic	Other non-water liquid solvents, e.g. liquid CO_2 on Mars, or liquid N_2 on

		acids	Titan
Hypogenic caves	Limestone, dolomite, gypsum, other soluble rocks or minerals	Strong sulfuric acid (subsurface H ₂ S in solution at water table)	Sulfur-rich crust, e.g. on Mars, may make hypogenic caves more likely
Other karstic caves	Quartzite, sandstone, arkoses, opalinized silicates, etc.	Water dissolution of parent rock, decementation, tafoni formation	Other non-water liquid solvents, e.g. liquid CO ₂ on Mars, or liquid N ₂ on Titan
Pseudokarst Caves Lava tubes or bubbles	Meltable or vaporizable solid Basalt, andesite, etc.	Melting or other phase transition Molten rock with differential cooling of outer surface	Scale of tubes larger than Earth in lower gravitational fields, e.g. 0.38 g on Mars
Sub-ice volcanic caves	Ice masses overlaying volcanic terrain	Lava/ice or lava/permafrost interactions	Lava interactions with CO ₂ ice or iceclathrate interactions, ground ice sublimation
Glacier caves	Ice masses	Thermal and pressure- induced localized melting in water ice	Melting in super-cooled water ice, and other ices, e.g. CO ₂ , methane, or ammonia ice
Ice volcanism	Ice crusts with subsurface liquid and/or vapor	None known for Earth	Ice-covered bodies, e.g. Europa, Callisto, other outer planets' moons
Subsidence caves	Permafrost, ice/sediment complexes	Permafrost voids	Ground ice sapping and subsequent collapse and void formation on Mars or cold moons
Volatile labyrinths	Icy breccia or rubble	None known for Earth	Sublimation or boiling of ground ices, e.g. on perihelion passage by comets
Tectonic and Fracture Caves	Solid rock and ices	Faulting, rifting, other tectonic movements	Cratering and subsequent fracturing
Erosional Caves	Solid materials	Weathering effects	
Piping Caves	Unconsolidated materials	Subsurface erosion of particles by water, "suffosion" in arid environments	Subsurface erosion of particles by nonwater solvents
Sea caves	Solid rock, welded tuff, ice	Water action (waves, floods) against rock	Massive flood events, e.g. on Mars Large bodies of water in the geological past

Wind-scoured caves	Solid rock, welded tuff, ice	Wind blasting of abrasive particles against rock	Global or regional dust storms on Mars Aeolian caves on Venus
Thermokinetic caves	Solid rock	Thermal expansion and contraction, spalling, exfoliation	Thermal regimes and unique physical effects much hotter and much colder than Earth.

On Earth, solutional caves are not restricted to limestones and evaporites but form in sandstones, arkoses, quartzites, granites, and other rock types, although the lower solubilities and greater resistance to weak acids of these rocks means that caves are much less common than in carbonate rocks. Typically, void is created by dissolution of cements between grains rather than in bulk rock. Cemented grain materials result from a sedimentary past. The status of such deposits on other planets is as yet unknown although recent images of Mars show apparently stratified cliff faces at sites like Chandor Chasma, possibly indicating sedimentary layers.

The scientific value of caves on other worlds could be immense. Apart from intrinsic interest in their very presence and mode of formation, they could also contain repositories of materials (e.g. frozen volatiles, unique minerals, or biological remains) extremely valuable for understanding formation and subsequent history of the bodies on which the caves may be found.

FILMS IN CAVES

The first cine film showing a cave was taken by Harry Short and released in Britain on 22 October 1896. *A Sea Cave Near Lisbon* was 80 ft long (one foot of film equated to about one second on screen) and was shot using daylight—capturing movement on film was an infant science, and suitable artificial light sources were not available. The crude cine cameras of the time, then as now, exposed a series of pictures on a length of film that was moved in front of the lens in a series of jerks. This effectively fixed the exposure and required very bright, continuous lights for filming underground. It was this factor, more than any other, that prevented early film makers from venturing underground.

However, an avid public expected and demanded entertainment from the new movie industry, and caves as a subject were experimented with many times. A series of suggestions to dramatize Rider Haggard's *King Solomon's Mines* in Cango Caves, a popular show cave in South Africa, failed due to a lack of finance, until in 1919 the Universal Film Manufacturing Co. included underground footage as part of a film financed by the Smithsonian Institute of Washington DC. The company used magnesium flares for lighting, but the fumes produced appalling conditions and "the smoke descended in clouds. The volunteers sent their flares flying and the party ran for it through the narrow going ...and helter skelter close on the heels of each other men, women and children ran for their lives..." (Anon, quoted in Howes (1989), p.245.

Clearly, magnesium was far from suitable, yet for many years it remained the only option and, in 1924, several newsreels were made in Carlsbad Caverns, New Mexico, one of which concentrated on W.T.Lee's expedition for *National Geographic*. The cave—with its easily accessible, beautifully decorated passages—remained a prime location for many years, with productions usually linked to "travelogue interest" or "education". Other productions included Louis Mercanton's 1922 film *Phroso*, shot in the Grottes de St-Cézaire in France, and the 1928 Czech film *Demanovske Jeskyne*, these concentrating on show caves and elements such as stalactites and stalagmites, which were deemed to appeal to a paying audience.

Although education in a broad sense was instrumental in developing underground filming, cave exploration by amateur cameramen also played a part. Between 1925 and 1927, Russell Trall Neville made a 16 mm film, *In the Cellars of the World*, which was the first to depict a cave as being explored for fun. Neville's remarkable production culminated in a lengthy underground camp in Old Salts Cave in Kentucky.

Such films were expensive and difficult to produce. Notably, the only other early attempt was made in England by E.K. Tratman. His experiments began in 1933 and in 1937 around 5000 ft of film was shot, resulting in an edited 500 ft, 11–minute film of "real" caving on Mendip. For lighting, Tratman resorted to Tilley paraffin lamps, extending his exposures by filming at half speed, with cavers walking at half speed so that their movement appeared correct when projected.

Electric lights, coupled with greatly increased film sensitivity, aided further advances, but after World War II the influence of education and exploration waned in favour of Hollywood fiction, when caves were freely used as ready-made "sets". Carlsbad Caverns remained popular, and the excellent *Cave of Outlaws* (directed by William Castle) was shot there in 1951 (see photo). Other Carlsbad-based films include *King Solomon's Mines* (1950, Compton Bennett & Andrew Marton) and *The Spider* (1958, Bert I.Gordon). The latter is of interest as it was based partly on stills shot in the caverns, with the closing scenes (the spider impaled on a stalagmite) using a painting.

It is easy to recognize that commercial show caves, with their ease of access, will form the bulk of such locations although, when the influence of television is added to that of Hollywood, even these may be supplanted by mines, quarries, and artificial constructions purporting to be caves. Among "big name" films, the underground sequences in *Star Wars* (1977, George Lucas) were shot in the sandstone "caves" at Matmata in Tunisia, and in *Indiana Jones and the Last Crusade* (1989), Steven Spielberg's backdrop was the "caves" at Petra in Jordan. Bronson Caverns in California—where at least 50 films have been shot, including

Films in Caves: The making of *Cave of Outlaws* in Carlsbad Caverns in 1951. From the archives of the Carlsbad Caverns National Park.

representations of the Bat Cave from Batman movies—comprises a man-made tunnel; part of *Star Trek VI: The Undiscovered Country* (1991, Nicholas Meyer) was shot there.

Many classic books have been made into films, including Mark Twain's *The* Adventures of Tom Sawyer which, with its intrinsic cave scene, screened in 1930 and again in 1938 (Norman Taurog), this being perhaps the best of a series of remakes (Tom Sawyer was shot in 1973 in Howe Caverns in New York state, director Don Taylor). Jules Verne's Journey to the Center of the Earth (1959, Henry Levin) was shot in Carlsbad Caverns and received three Academy Award nominations. In 1953 The Secret Cave, based on Thomas Hardy's novel Our Exploits at West Poley, was filmed in Somerset for the Children's Film Foundation (John Durst). The inferior Exploits at West Poley was made at the Elstree studios (1985, Dirmuid Lawrence).

While the 1985 cave appeared convincing and real, the often false appearance of sets does nothing to improve any film; witness *Battle Beneath the Earth* (1967, Montgomery Tully) where the United States is to be invaded by Chinese armed forces through caves and tunnels which run under the Pacific. The 1960s television series *of Star Trek* is a classic example of cheaper production values, where flat floors and movable formations form an essential element of alien caverns. In *Grim* (1995, Paul Matthews) a team of "spelunkers" investigates monster-laden caves in Virginia—these being shot in Clearwell Caves (natural passages modified by iron miners) in the United Kingdom. The film lives up to its title.

If any generalizations can be made, fiction-based films inevitably fill their caves with formations or are subdued to the level of a mere backdrop. The plot invariably contains a sensuous female, such as in *The Cavern*, a war movie where six soldiers are trapped underground with Rosanna Schiaffino (1966, Edgar G.Ulmer), or an underground river that has to be free-dived to escape some awful fate, a theme borrowed from *King Solomon's Mines*. *Broken Arrow* (1996, John Woo) serves as an example, though with the decency to include a convincing, custom-made cave from Foam-Tec, while Sean Connery as James Bond made his underwater escape through Lucayan Caverns, Bahamas, in *Never Say Never Again* (1983, Irvin Kershner). A film with a different approach is *Ace in the Hole* (later retitled *The Big Carnival:* 1951, Billy Wilder), which found Kirk Douglas in a media circus culminating in the death of a trapped miner, a plot transparently based on the 1925 death of caver Floyd Collins in Kentucky's Sand Cave.

One arena ignored thus far is that of modern, specialist cavermade films which concentrate on exploration, usually for television consumption. Of the scores of active film makers, Sid Perou has gained international acclaim for his work, beginning with *Sunday at Sunset Pot* in 1967 and continuing with series such as *Beneath the Pennines, The World About Us, Realm of Darkness,* and *Hidden Depths;* he received an Emmy award for *Mysteries Underground* (1992), a film about Lechuguilla Cave in New Mexico. That an interest in caves exists outside the caving community is witnessed not only by the success of films such as those by Perou and Belgium-based Phillipe Axell (with his *Caves of Europe* series), but also with the 2001 release of *Journey into Amazing Caves* (Stephen Judson), an IMAX film concentrating on cave exploration and science, which became the highest-grossing large-format film of the year.

With the rise in small and light, high-definition digital video cameras and viable lighting units, technology has placed underground filming within the reach of all sport cavers. If a prediction is possible, rather than relying on recreating exploration for the sake of the camera, the future will see a rise in cavers recording their sport as it happens, presenting original discoveries directly to the audience.

FLORAL RESOURCES

The principal driving force for karst solution processes is the uptake of carbon dioxide and organic acids by percolation water. This occurs in the root zone of the vegetation that covers the limestone. Thus, changes to the vegetation on karst, as a result of clearance, fire, or climatic change, may provoke major changes in hydrology and limestone solution. For this reason alone, the conservation and management of the floral resources of limestone areas is of very high priority. In addition, the distinctive vegetation of limestone areas is a valuable resource for biodiversity conservation, for traditional medicines, and for wildlife habitat.

Soils on carbonate bedrock (see separate entry) are usually thin and deficient in most macronutrients, except for calcium and magnesium. In addition, trace elements may also be lacking. The rapid abstraction of underground water in karst areas means that plants and other organisms are subject to episodic and pro- longed periods of drought. The sparse and often patchy vegetation (Figure 1) provides little shade, resulting in a greater range of soil temperatures. Those plants that are out-competed on other lithologies, and therefore survive in this harsh environment, are termed calcifuges. Some plants possess specific adaptations to the calcium-rich environment and show a high fidelity to limestone and other carbonate rocks; they are termed calciphiles. Many of the traditional Mediterranean herbs, such as rosemary and lavender, are calciphiles (Gams *et al.*, 1993). Exceptions to this are found in the shaded and damper habitats of limestone gorges, dolines, and crevices, in which more water-demanding species may find a refuge and flourish.

Floral Resources: Figure 1. Sparse limestone vegetation on the limestone slopes of the Cirque des Navacelles, France. (Photo by David Gillieson)

The specific conditions of the karst environment may produce physiological adaptations in plants which advantage them in this harsh environment. Reduced vegetation cover, and thus increased exposure to sunlight, enhance photosynthesis, often leading to an excess of carbon. This excess may be stored as protective structures such as thorns and woody stems, or as plant defensive compounds such as volatile oils (lavender and rosemary), phenols, and tannins. These render the leaves unpalatable to grazers, whether arthropods or vertebrates. These compounds may have value for pharmaceuticals or perfume manufacture.

Native plants growing on limestone are frequently displaced by exotic species, creating management problems. Most plant species can be classified according to their life strategies—their life-forms, resistance to disturbance, rates of seed production, and viability (Grime, 1977). Highly competitive species, such as blackberries, grow rapidly, resist disturbance, bear copious viable seed, and may inhibit the establishment and growth of other species near them, by poisoning the soil (allelopathy). Stress-tolerating plants, such as figs and eucalypts, have adaptations to ensure adequate water supply (deep roots, high rootshoot ratios), to resist fire (resistant bark, lignotubers, and vegetative reproduction), and to exploit low levels of nutrients (root fungi associations and high root hydrogen ion production) (Figure 2). Ruderal species, such as dandelions and St John's Wort, habitually colonize disturbed habitats. They have tuberous energy stores, very effective seed dispersal, and easily pollinated flowers. In general, stress-tolerating plants are more numerous on limestone soils with some ruderals present, but highly competitive species are rare. Those native species that are stress

Floral Resources: Figure 2. A lone rowan tree survives on the bare limestone pavement of the Yorkshire Dales, England. (Photo by David Gillieson)

tolerators are very susceptible to displacement by exotic species when the disturbance regime is altered radically.

The specific conditions of karst environments described above exert a strong ecological pressure on any colonizing species. These may respond in two ways; local extinction, or adaptation by accelerated evolution, often after an initial fall in the population. In the process, isolated populations in this highly fragmented environment are likely to develop into new species (Figure 3). Many of these limestone-adapted species simply can-

Floral Resources: Figure 3. A rare One Leaf Plant (*Monophyllea* sp.) in the entrance of Clearwater Cave, Mulu, Sarawak. This plant is endemic to the twilight zone of caves in Borneo. (Photo by David Gillieson)

not survive anywhere else. The extreme and varied conditions in limestone areas may result in unusual geographic affinities of a local flora. For example, in the Zhuang region of China, limestone areas support a much higher proportion of southern tropical species (88%) than adjoining non-limestone areas (Vermeulen & Whitten, 1999). In northern Thailand, limestone areas contain temperate plant species at the extreme southern limit of their range in Indo-China. In New Guinea, upper montane forests on limestone contain many plants of Gondwanan origin, while at lower elevations, on the same lithologies, the flora is dominated by Indo-Malayan species.

The most abundant lower plants on limestone are the bryophytes, or mosses and liverworts. These primitive plants can reproduce vegetatively, withstand dessication and have defensive chemical compounds to resist predation by most insects, snails, and bacteria. Many of the bryophytes on limestone are also found on buildings (cement and stone) and share affinities with those found on alkaline or calcareous soils elsewhere (Downing, Ramsay & Schofield, 1991). Some species curl up and enter suspended animation during droughts, expanding rapidly and becoming green after a rainstorm. Others survive in permanently cool and damp sites, especially around springs and cave entrances. In the tropics, a diverse microflora coats stalactites and rock surfaces in the twilight zone of caves. These may have a significant role in the limestone solution process. We know very little about the ecology of limestone microflora, especially in the area of biogeomorphology.

Most karsts have a low natural fire frequency, due to the shielding effects of limestone outcrops and reduced ground cover. In the impounded karsts of eastern Australia, natural fire frequencies are poorly documented but the fire interval may be 35 to 50 years or greater (Holland, 1994). Under these conditions, relict vegetation types may survive, for example, the vine thickets of North Queensland or the monospecific *Acacia* scrubs on the Bendethera karst, New South Wales. Limestone bedrock retains little water, so during drought the vegetation tends to dry out and become flammable. Fires sweeping up the slopes may burn the margins of karst vegetation or become accelerated and burn summit areas. This may not only destroy the vegetation but also the thin soil, leading to its erosion and abstraction down open joints. In Great Britain, there are rare fern species which are now largely restricted to limestone outcrops. In these karsts, soil erosion only occurs immediately after fires, with minimal erosion in the intervening periods.

Surface vegetation regulates the flow of water into the karst through interception, the control of litter and roots on soil infiltration, and the bacterial production of carbon dioxide in the root zone. The metabolic uptake of water by plants, especially trees, may regulate the quantity of water available to feed speleothems. Trees in particular are like large carbon dioxide pumps, releasing 20–25% of the atmospheric gas uptake through root respiration (Aley, 1994). The free vertical drainage of most limestone soils creates special conditions for evapotranspiration, gas exchange, and root penetration. Large eucalypts act as water pumps, taking up 250–270 litres per day for each tree of river red gum (*Eucalyptus camaldulensis*). Tree roots can penetrate to depths of 30–50 m in search of water, especially the figs in seasonally humid climates of northern Australia (Gillieson, 1996). The penetration of tree roots aids the enlargement of bedrock fissures in karst and ensures the high degree of secondary porosity characteristic of limestone terrains.

Floral Resources: Figure 4. A plant collector selling medicinal herbs and roots collected from the limestone forests of Mount Emei, China. (Photo by David Gillieson)

Large trees are usually sparse on limestone areas, thus they are of lesser interest to commercial forestry. Local people often harvest firewood and building timber from karst areas. Of more importance is an array of small forest products harvested for traditional medicines (Figure 4), for food (fungi and fruits), for handicrafts such as baskets, and for flowers. Some wild limestone plants, such a slipper orchids in Southeast Asia, are heavily collected and this may lead to local depletion or extinction. Many of these plants are easily cultivated so there is little justification for the practice.

FLUVIOKARST

Fluviokarst may be defined as a landscape on carbonate rocks where the dominant landforms are valleys cut by surface rivers. Sweeting (1972, p.259) gives a broader definition, stating that "Fluviokarst is formed by the combined action of fluvial and karst processes". However, this is too broad since fluvial processes are involved in the development of virtually all karst landforms, including dolines and poljes which would not be considered as fluviokarst landforms. The term appears to have been first used in English by Roglic (1964) who used it in preference to the "halbkarst" (halfkarst) of Grund (1914) and the more widely used equivalent, "merokarst", introduced by Cvijić (1924). As originally used, a merokarst was envisaged as containing both fluvial and karstic elements as a result of having developed on thin sequences of limestones interbedded with other rocks (particularly marly beds) or on impure limestones. Mechanical erosion was considered to be more important than dissolution in the development of merokarst leading to a dominance of valley forms. Ford (1980) noted that limestones of low purity may display a low density of small dolines in an otherwise fluvial landscape. Such an assemblage can also develop in rocks with less than 50% carbonate minerals, such as calcareous sandstones, and Birot (1954) used the term "parakarst" for this type of development.

In addition to the term merokarst, Cvijić (1924) used "holokarst" to describe a fully karstic landform assemblage and "transitional karst" to describe a landform assemblage intermediate between holokarst and merokarst. His major example was the Causses of France (see France, Southern Massif Central) where there is a thick limestone sequence but "the karst basis formed by the impermeable bed is not so deep as in the holokarst and therefore the karstic evolution is more rapid; normal valleys are much more frequent than in the holokarst..." Sweeting (1972, p.253). Sweeting (1972) and Ford (1980) followed Roglic (1964) in considering parakarst, merokarst, and transitional karst as all being types of fluviokarst. On this basis, Sweeting suggests that many of the karstlands described in western and central Europe are fluviokarstic. However, in the majority of these karsts the valley forms are associated with allogenic rivers and take the form of through or blind valleys (see Valleys in Karst). Again this usage seems to be too broad and instead it is

suggested that the term fluviokarst should only be used where the land surface over a wide area is largely dissected by valleys, the majority of which have their heads in the karst. There may be dolines in varying densities on the interfluves but these are not the dominant landform. As defined, fluviokarst may be seen as one end member in a continuous sequence of surface landform assemblages on carbonate rocks, the other being polygonal karst where the whole surface is pitted by dolines with little or no trace of any previous valley form. The latter represents an extreme form of a holokarst.

Active fluviokarst would be expected on karst rocks under two specific conditions. First, where the karst development is young and/or the hydraulic gradient is very low, the karst conduit system is not yet able to drain all of the surface and open channels remain above ground, at least in headwater areas. Such systems are not common but there are good examples in Canada. Second, in dry regions subject to seasonal torrential rains, there are regular dendritic valley patterns heading in the karst rocks and draining to their perimeter. These valleys are carved by channelled runoff at the height of storms but at all other times the epikarst can drain any surface water and there may be substantial caverns below. Dolines tend to be rare on interfluves or along the valleys and may be entirely absent. Examples include much of the highlands north and south of Jerusalem, the Edwards Plateau, Texas, and gypsum highlands on the south side of the Ebro valley in Spain.

Fluviokarsts that are dominated by dry valleys are more common than active fluviokarsts. The English Peak District and the chalklands of southern England provide good examples that are discussed below.

The geology and caves of the Peak District are described in a separate entry but briefly, Carboniferous (Dinantian) limestones crop out over some 520 km² and are surrounded by lithologies that support surface drainage, although only in the northern half of the area are these higher than the limestones. The basement rocks are several hundred metres beneath the surface and have had no influence on surface landform evolution and little, if any, influence on the inception and development of conduits and caves. Virtually no perennial surface drainage exists on the limestone and only two allogenic-fed rivers maintain flow across the karst. However, the limestone plateau is dissected by a dense dendritic system of valleys that are dry for all, or most, of the year (see photograph in Valleys in Karst entry). Most of these valleys have their heads entirely within the karst and either drain out of it or are tributary to the main allogenic rivers. The limestone sequence is thick (up to 1800 m) and the limestones are of high purity, in contrast to the common situation in a merokarst. Instead, it is generally accepted that these valleys have been inherited by the limestone after originating on an impermeable clastic cover. Their desiccation largely reflects gradual karstification of drainage, aided by regional water-table lowering in response to downcutting by major rivers. However, not all the desiccation was natural, as dewatering via mine soughs affects some rivers, most notably the Lathkill's middle reaches, which dry up every summer. Dry valleys were probably reactivated under Pleistocene periglacial conditions when the ground froze and extensive screes developed.

The Cretaceous Chalk crops out over large areas of southern England and northwestern France (see map in Europe, North entry). Although it is a relatively weak rock, the outcrops are surrounded by even weaker clays and sands, and consequently the Chalk generally forms relatively high ground, commonly as a series of escarpments. Surface flow is rare on the escarpments but dry valleys are common, forming steep coombes on the scarp faces and large dendritic systems on the dip slopes. Many valleys have springs at their lower ends, and winter rises of the water table create seasonal surface streams, known as bournes. The dry valleys are largely floored by solifluction debris from Pleistocene stages of periglacial weathering (Paterson, 1977), and formation under permafrost conditions is one of several hypotheses for valley origin (Smith, 1975). However, Smith argues that while the valleys would certainly have been reactivated under periglacial conditions, as in the Peak District, they were formed by surface streams and initial desiccation followed gradual karstification of drainage. Periglacial valley carving and/or deepening action was also important on the Mendip Hills (see separate entry) where Cheddar Gorge is a classic example of fluviokarst.

There is little doubt that in the early evolution of most, though by no means all, limestone areas there was surface drainage, and fluvial valley development. Where the limestone outcrop is relatively narrow and there are large allogenic rivers then karstification of drainage is likely to result in a landscape dominated by blind and through valleys with dolines on the interfluves. Where the outcrop is wider, and allogenic inputs are proportionately less, then a dendritic valley network is more likely to form on the limestone. Where recharge is dispersed then the valleys are likely to remain as the dominant landform following karstification of drainage and the landscape is best described as a fluviokarst. More concentrated recharge is likely to favour the growth of dolines that dissect the valleys (as is happening in the Mendip Hills) and may ultimately form a polygonal karst (see model for the Waitomo District of New Zealand in Gunn, 1986).

FOLKLORE AND MYTHOLOGY

There are few features in the landscape that have so excited the imagination, and are as deeply embedded in the folklore of societies throughout the world, as caves. Associations range from the historical, or quasi-historical, to the fantastic and mythological and are recorded in orally transmitted traditions, legends, and place-names.

The historical association of a particular cave with a notable, or notorious, individual is a widespread phenomenon and well-authenticated cases are not uncommon. Bonnie Prince Charlie is reliably recorded to have sheltered in caves in Glenmoriston and on South Uist during his time as a fugitive after the Battle of Culloden, and Hardin County's cave in Cave-in-Rock State Park, Illinois, is associated with the notorious Harpe brothers' outlaw gang. Because of their interesting and romantic associations, such well-authenticated cases often become incorporated in community tradition and give rise to a number of quasihistorical associations with such figures. The fugitive Prince is traditionally associated with a large number of caves in the western Highlands, and caves on the islands of Arran, Jura, and Rathlin are each claimed as the hiding place of Robert the Bruce in 1306. The simple naming of caves as "The King's Cave", "The Spaniard's Cave", and "Smugglers' Lair" marks a further step away from historical reality, but one that has nevertheless some basis in fact.

A further step is marked by the association of caves with individuals whose historicity is uncertain but who have become traditional icons; Robin Hood's Cave in Derbyshire, England, and King Arthur's Cave in Gwent, Wales, are obvious examples. Such ahistorical beings have a partly mythological status, and it is in the realm of myth that caves make their most potent contribution to folklore.

Caves play many parts in the mythologies of the world, but three main roles are widespread. First, they are often seen as the route to the underworld; the Xibalba of the Central American Maya, the Tartarus of classical Greece, and Dante's Inferno. As such, they function as passages between worlds and across liminal or boundary zones, into which mortals pass and are transformed. The transforming nature of caves is a theme in its own right, although related to caves as passages to and from the underworld.

Secondly, caves are commonly seen as sources of power and creative energy. According to the ancient Greeks, Zeus was born in a cave on Crete, while ancient Japanese mythology attributed the fall of night to the retreat to a cave of the sun-goddess Amaterasu. According to some traditions, the Aztecs of Mexico City—the Tenochcas—originated in a group of caves before descending to establish their settlements on islands in the lakes. For many traditional societies in Australia, caves and rock shelters are associated with the heroic ancestors of the Creation Period, such as the Wandjina cult of the Western Kimberleys. These ancestral beings commonly feature in cave paintings that are traditionally believed to have been created by the Wandjina themselves, and which require repainting and restoration at intervals, in order to ensure the continuation of the social order and the natural resources on which the communities depend.

A related theme is the role of caves as a source of wisdom and knowledge. In ancient Greece and Rome, caves were the theatres for oracular pronouncements, as in the case of the Sybil of Cumae, Italy. In Christian Europe, from medieval to modern times, caves have been the scene of visionary experiences such as the manifestation of the Madonna in the grotto at Lourdes, France, or the Archangel Michael in the cave at Monte Saintangelo, Italy.

Thirdly, caves are widely seen as the abode of gods, demons, spirits, ancestors, and various malevolent forces often personified in the form of giants—such as the one-eyed cyclops Polyphemus of Homeric legend or the Polynesian "Giant with Teeth of Fire", or dragons. Before the advent of scientific paleontology the discovery of bones in caves was taken as proof of their use by dragons, and the Slovenian Olm, *Proteus*, a blind cave salamander, was regarded as dragon-fry.

The cave-dwelling monster is a powerful image in mythologies from many parts of the world, and the related myth of the dragon-slaying hero is widespread—examples spanning the globe from the Maori hero Pitaka, slayer of the taniwha (dragon) Kataoare, to the Nordic legend of Sigurd the Volsung (Richard Wagner's Siegfried), who killed the dragon Fafnir. The legend of Fafnir also provides an example of the theme of caves as places of transformation, for Fafnir was originally a giant but transformed himself into a dragon in order to guard the treasure that had been stolen from Andavi the dwarf. The subject of caves as repositories of gold, silver, and other valuables is a further worldwide aspect of cave mythology. Such myths probably owe their origins to the discovery of votive deposits within caves, or grave goods accompanying cave burials.

FOOD RESOURCES

Availability of food resources in hypogean environments is an important limiting factor for cave-dwelling animals, because it produces a strong selective pressure at the metabolic level on troglobitic and troglophilic species. However, availability of food resources does not on its own determine the distribution of species. Caves in the Mediterranean region are characterized by a deficiency of food resources while in tropical caves the trophic material is extremely abundant; yet, paradoxically, the former represents a true reservoir of relict or "living fossil" troglobites which are rare or absent in the latter. There are both ecological and biogeographical explanations for the situation, in which a variety of biotic and abiotic, and recent or geohistorical factors play essential roles.

Food chains in caves are substantially simple to describe. In fact, they are formed by few links or, in extreme cases, by only two links (Figure 1). From an energetic point of view, caves do not represent a closed system since there is an "exogenous"

Food Resources: Figure 1. Scheme of

trophic net in the cave ecosystem. *am*, endogenous autotrophic microflora; *c*, carnivorous; *cs*, clay-slime; *d*, detritivorous; *em*, eterotrophic microflora; *g*, guano; *gf*, growth factors (aminoacids, vitamins, oligoelements, fatty acids, mineral salt); *od*, organic deposits; *se*, slime eater.

trophic energy flow from outside to inside the cave in addition to an "endogenous" flow, which takes place within the cave. The balance between energetic input and output makes cave populations stable. If caves were exclusively controlled by an endogenous flow, that is if they were a closed and isolated system, the energetic cycles would be likely to result in a natural and continuous energetic fall which would destroy the ecosystem in a short time. Therefore, even a low external input is required for a more or less constant trophic balance, although there are some exceptions. Movile Cave (southern Dobrogea, Romania) is a closed system where the primary energy is provided by hydrogen sulfide which is abundant in the cave water (see Movile Cave, Romania). A biofilm (see separate entry) composed of chemiolithic-autotrophic microbial material (sulfobacteria) is present at the water surface, where it represents the starting point of the cave trophic cycle.

The metabolic demands of certain stygobitic animals can be very low. Thus, the blind prawn *Typhlocaris salentina* is adapted to feed on guano (see below) that lies on the bottom of cave pools. Experimental results suggest that another stygobitic crustacean, *Spelaeomysis bottazzii*, is able to survive for years by scraping small amounts of imported or fossil biomass from the surface of soft calcareous rocks, in waters absolutely lacking primary production (Ariani, 1982) (Figure 2).

Inside caves the following food zones can be recognized: vegetation zone (with algae, bryophytes, and phanerogams); clay slime; water; air; and organic sediments (see Sediments: Biogenic). Each zone is distinct and, within them, qualitatively simple but well characterized biocoenoses (or communities of living creatures) can be described.

The vegetation zone is represented by the part of the cave entrance which is illuminated during the day. In this area there is an abundant trogloxenic fauna inhabiting shadowy cracks, mosses, rocks, and stagnant waters. Some of these species act as "shuttles" between internal and external cave environments. Troglobites rarely penetrate into this zone, generally only for temporary feeding necessities. In vertically developed caves, fallen vegetation provides the deepest biotopes with plenty of organic substances such as pieces of plants, dry leaves, pollen, and seeds, which on decomposing, feed a considerable number of bacteria and fungi.

Food Resources: Figure 2. (A) Male individual of *Typhlocaris salentina* Caroli. (B) The faecal material of *Spelaeomysis bottazzi* Caroli, before HCl treatment and (C) after treatment. This technique demonstrated the

presence of calcium carbonate. (From Ariani, 1982, reproduced with permission)

In horizontally developed caves, the (always passive) transport of organic material from the vegetation zone towards the interior, instead takes place through different vehicles such as draughts, rivulet waters, men, and animals (anemocorous, hydrocorous, or zoocorous transport, respectively). Clay slime, usually present in groundwaters, represents a biotope of great biological interest because it is very rich in trophic resources. Water contains different quantities of both microorganisms and oligoelements, partly of endogenous origin and partly coming from epigean environments. Underground water essentially consists of meteoric water infiltrated into the subsoil and occasionally contaminated by seawater intruding into the land mass.

The synthesizing activity of bacteria and other autotrophic organisms can be considered the first stage of an endogenous flow. Although the cave darkness implies the absence of green plants and photosynthesis, a microflora is nevertheless frequently present which is able to produce biological energy from inorganic substrata (CO_2 , H_2S , FeO_2). Ferrobacteria are rather common in caves, where they extract energy from substrata rich in iron oxides. Nitrobacteria and Sulfobacteria draw nitrogen from the atmosphere and sulfur from sulphuric thermal waters, respectively, thus obtaining energy (see Microorganisms in Caves).

Bacteria and fungi are present everywhere inside caves, in soil, in clay mud, on rocks and speleothems, in the air, in the dripping water, in underground rivers and lakes, and obviously in decomposing vegetables and animals. A considerable quota of microorganisms has been reported from a kind of clayeyslimy concretion termed "foval" (Camassa, 1997). Fovals are brown-greyish formations that can be found in different positions in the caves, on the floor, or on the rocky walls (Figure 3). By microscopic observations (partly after laboratory culture) on foval materials, several microflora components have been identified, such as *Mucor mucedo*, *Mucor racemosus*, *Geotrichum* sp., and *Nitrospina gracilis*. The exceptionally high concentration of bacteria and micromycetes, the presence of nematodes and abundant organic scraps is indicative of an intense biological activity that probably produces organic substances and growth factors (aminoacids, proteins, vitamins, fatty acids) useful for cave biocoenoses (for example at Frasassi Caves, Italy).

Clayey sediment is absolutely essential for the colonization of cave pools by animals. Laboratory studies (Gounot, 1960) showed that reproduction in captivity of *Niphargus* and other aquatic amphipods was successful only after addition of cave clayey slime to the aquariums. In fact, the presence of this substratum assured the survival of the young *Niphargus*. Similarly, it is known that the proteus (*Proteus anguinus*) takes nourishment and growth factors from slime during the first year of life.

Marine and lake slime-eaters feed on both organic remains and microorganisms present in the sediment; similarly cave slime-eaters utilize not only exogenous organic substances present in the substratum but also living microorganisms in consequence of the discovery of autochthonous microflora in underground slimes (Jefferson, 1965). These autochthonous, autotrophic components include Thiobacteria that generate energy by oxidization of hydrogen sulfide, and Ferrobacteria (such as *Leptothrix*) oxidizing the

hydrate ferrous carbonate. A third group of autotrophic bacteria (Nitrosobacteria) that utilize nitrates, is also supposed to be involved in energy production inside some caves. According to Caumartin (1964), Thiobacteria and Ferrobacteria are in competition with eterotrophic micro-organisms which come from the surface. Chodorowski (1959) reported bacteria performing such different functions as proteolysis, denitrification, and nitrogen fixation, and that play a role in sulfur and phosphor cycles in Polish caves. Clay slimes of a temporary lake in Baradla Cave (Hungary) were found to have a microflora comparable to that from farm soils of the same region, with nitrogen-fixing, nitrifiant, cellulose-lytic, and denitrifiant bacteria.

Among solid substrata in caves, particular biotopes are represented by speleothems and "montmilch" (or moonmilk). Their microfloras have been extensively studied as they were thought to be implicated in the alteration processes through which these formations are made (Mason-Williams, 1959; Pochon *et al.*, 1964).

Aerial microflora are scarce because of the high degree of humidity that causes particles suspended in air to precipitate. This particle complex mainly or entirely consists of bacteria conveyed by air currents from outside or, in show caves, by visitors (Mason-Williams & Benson-Evans, 1958).

Besides bacteria, other microorganisms can be found in cave environments. Though the deepest parts of caves are marked by complete darkness, they are occasionally inhabited by autotrophic algae carried in by waters from epigean biotopes (Mason-Williams & Benson-Evans, 1958; Palik, 1960). It was also observed (Palik, 1960) that some algae are able to live in caves in eterotrophic conditions. Other important elements of cave biocoenoses are represented by Protista, often abundant in clayey slime or groundwaters, and by micromycetes which can be found as saprophytes on organic substrates of caves (decomposing animals and vegetables, and guano). All microbiological compo nents of caves, especially the autotrophic ones, can be considered fundamental to the preservation of a fragile ecological equilibrium in the underground ecosystem; they represent the base of the food pyramid, that is the primary producer of all trophic factors essential for most of the cave-dwelling species.

Caves open directly to the external environment are of teninhabited by colonies of bats or by troglophilic birds such as Collocalia (a Chinese swallow) and Steatornis (the wellknown "guácharo"). These animals generally produce a large quantity of faecal material (guano) which is deposited on the bottom of caves and partially along walls where the animals cling or nest. Sometimes bat populations are so numerous that guano layers reach a considerable thickness, up to several metres (see Guano). Guano represents a considerable trophic resource with a special biocoenosis. A large number of organisms such as protozoans, mycetes, nematodes, and insects (Collembola, Coleoptera, Diptera) are so connected to the presence of guano that they have attained specialized physiological and structural characteristics, and occupy a unique ecological niche. These organisms are termed "guanobites" and represent, where present, the second link of the food chain. The importance of this trophic resource inside a cave is immediately clear. Guano is produced by animals that normally go out of the cave to feed; this implies the introduction into the cave ecosystem of organic material rich in nourishing substances such as proteins, fats, carbohydrates, mineral salts, oligoelements, and vitamins, most of which could not be synthesized by autochthonous microflora. In addition, a great number

of organisms, mainly parasites of bats or cave-dwelling birds, are deposited into the cave by the guano: these include protozoans, fungi, roundworms, flatworms, mites, and millions of bacteria.

FORESTS ON KARST

Many of the karst areas of the world are forested, or were forested prior to human activity. Since karst is widely dispersed around the world, the majority of the forest types present in the world exist, to at least some extent, on karst. With some notable exceptions, forests on karst are commonly less economically productive than nearby forests on non-karst areas. In many cases, this is because the autochthonous soils on carbonate karst (see Soils entry) are so shallow and/or rocky, that they have less moisture storage capacity than soils on nearby non-karst areas. In addition, soils in karst areas are often more prone to nutrient impoverishment than non-karst soils. The steep terrain also

makes logging expensive and often hazardous. Gams (1991) concluded that the original meaning of the term karst was a forestless, stony, and waterless landscape. He further concluded that the absence of forests in the Dinaric karst region lasted for centuries and was a direct result of human activity, designed to clear the land for the pasturage of animals. Many other karst areas of the world have also experienced dramatic episodes of deforestation, with attendant damage to soil and water resources.

Karst areas, in regions with high precipitation distributed throughout the year, may support significant forests. Some spectacular temperate rainforest on karst exists in coastal portions of southeastern Alaska; this area receives about 2500 to 5000 mm of precipitation per year, and the precipitation is evenly distributed throughout the year. Much of this karst is developed on carbonate rocks with extremely high purity. The derived soils are predominantly organic and relatively shallow, but precipitation is high enough that moisture depletion of the karst soils seldom limits tree growth. The underlying karst groundwater system provides effective drainage for the overlying soils. In contrast, many adjacent non-karst areas are peat lands or have poor forest growth because the soils are waterlogged and lack effective natural drainage.

In some karst locations, much of the soil is derived from allogenic sources, such as alluvial and colluvial soils. Loess deposits (windblown glacial materials) of Pleistocene age blanket some karst areas and are often of sufficient thickness to support valuable forests, or (if cleared) good farmland. The majority of karstlands with good soils (and thus potentially good forests) are areas where much of the soil is derived from allogenic sources. For example, the King Country karst on North Island, New Zealand was originally thickly forested, although much of the forest has been logged and replaced by pasture. In this area, the limestone is covered by a thick mantle of volcanic ash and it is on this that the forest grew.

In most non-karst landscapes, runoff water flows primarily on the surface and by throughflow to streams; relatively little water moves directly downward into the groundwater system and laterally out of springs. In many karst landscapes, groundwater recharge predominates over surface runoff. Groundwater recharge can transport plant nutrients beyond the reach of tree roots in relatively short distances, whereas with surface runoff, more distance is available in which the landscape can detain the water-transported nutrients. As a result, forests in karst areas are commonly deficient in one or more plant nutrients, and are more likely to experience nutrient impoverishment than are forests in most non-karst areas. In addition, trace elements are often limiting or lacking.

Timber harvesting in some karst areas is likely to increase erosion and result in the introduction of sediment and organic matter into dolines and sinking streams (Aley & Aley, 1984). Where well-developed karst groundwater systems exist, sediment and both suspended and dissolved organic matter may adversely impact the water quality of springs. An illustration of these issues is provided by some karst areas in the Tongass National Forest in Alaska (Aley *et al.*, 1993). Groundwater tracing has demonstrated that dolines in some areas, under consideration for timber harvesting, rapidly transport water to spring-fed streams, which provide essential spawning habitat for salmon. Pulses of sediment and organic matter, derived from timber harvest and timber access roads, can clog gravels in spawning areas and deplete dissolved oxygen concentrations critical to salmon eggs and fry. Under present forest policies, hydrological investigations are conducted in karst areas of the Tongass National Forest, prior to detailed planning for
timber harvest. The results of the hydrological investigations have removed some areas from timber harvest and have added karst-specific constraints to some planned harvests.

Concerns have been raised about timber harvesting in karst areas on Vancouver Island, British Columbia, Canada. Many of the issues have been similar to those encountered on the Tongass National Forest; although the species composition is different, the harvest units in Canada have been larger than those in Alaska, and burning after harvest has been used at a few Canadian locations. Stokes and Griffiths (2000) prepared a valuable manual on karst inventory systems and principles for the Research Branch of the British Columbia Ministry of Forests. This manual includes an excellent summary of resource vulnerability classification and mapping approaches used in forested karst areas around the world. As is the case in Alaska, groundwater tracing investigations are recognized in British Columbia as a valuable part of resource vulnerability assessments.

Huntoon (1991, 1992) describes hydrologic and other impacts resulting from the massive deforestation that has occurred since 1958, in the subtropical south China karst. Approximately 100 million people live in the south China karst belt, and the greatest poverty in the nation is located in this region. Inadequate water supplies have long been a problem in south China, and the area is characterized by a severe annual flood—drought cycle. Deforestation, primarily for charcoal production for industrialization, has depleted the "green reservoir" of forests, which in turn has increased rates of surface and groundwater runoff and sediment production. Essential community water supply springs, at the base of karst towers, have ceased flowing and residents must now transport water from distant wells. The amplitude of the flood—drought cycles has been increased, which has in turn rendered useless many formerly productive fields in karst depressions.

Afforestation of karst areas may impact on underlying cave systems. For example, in some karst areas of Australia, eucalypt forests (which are relatively conservative of water) have been replaced with pine plantations. Clearance and replanting with pines was accompanied by soil erosion and the pines were planted at a greater density. In consequence, evapotranspiration rates increased and less water entered the karst groundwater system and associated caves. Similarly, at Lehman Caves, Nevada, decades of fire suppression has enabled trees, such as junipers and pinyon pines, to invade lands overlying the caves. The forest vegetation uses more water than the previous cover of shrubs (primarily sagebrush, *Artemesia* sp.), and an apparent result has been the drying of speleothems in the caves.

FRANCE: BIOSPELEOLOGY

France is one of three countries where research on subterranean fauna began in the 19th century (the others being Slovenia and the United States). The first species of blind cave beetles and spiders were discovered in Pyrenean caves—which have one of the world's highest levels of subterranean biodiversity, including several of the most troglomorphic species such as the cave beetles *Aphaenops* (Figure 1) and *Hydraphaenops*.

In France about 650 exclusively subterranean (troglobitic and stygobitic) species are known. Most of them are recorded from the Pyrenees, the southern Massif Central, the Alps, and the Jura mountains. They inhabit a broad spectrum of habitats: karstic caves, interstitial MSS (Mesovoid Shallow Substratum), phreatic aquifers, and interstitial river habitats. Almost all are endemic; several *Speonomus* beetles show micro-endemism within an area of a few square kilometres; some Leptodirinae and Trechinae species are each only found in one cave. In the Pyrenees the range of terrestrial subterranean invertebrates is not limited to caves, but includes the whole karstic subterranean system and micro-voids of the MSS in rocks other than limestone. Some are "living fossils" from ancient groups now absent from surface habitats; others have actively colonized the cave habitats, especially the MSS and subterranean rivers.

Coleoptera with 186 troglobitic species represents the main terrestrial cave-dwellers; they consist of small populations of carnivorous Trechinae, *Aphaenops, Hydraphaenops, Trichaphaenops, Geotrechus, Duvalius,* and *Typhlotrechus* at the top of the food chain, and large populations of detritivorous Leptodirinae, with *Speonomus* and *Troglophyes* lines in the Pyrenees, *Diaprisius* in the southern Massif Central, and *Cytodromus* lines in Provence, Alps, and Jura with *Royarella, Troglodromus,* and *Isereus. Isereus xambeui*

inhabits cold caves in Grande Chartreuse Mountain. Usually, Leptodirinae populations are larger than Trechinae, estimated at 30000 to 50000 individual Leptodirinae in caves and their interstitial systems in the Pyrenees.

Spiders are represented by 33 species, mainly Leptonetidae (*Leptoneta*) and Linyphiidae (*Troglohyphantes*), and a tropical

France: Biospeleology: Figure 1. *Aphaenops laurenti,* Grotte de Bordes de Crues a Seix en Couserans (Ariège).

relict, *Telema tenella*, in some caves of the Eastern Pyrenees. In the entrance and twilight zone the troglophilic *Meta* weave webs and cocoons. Three harvestmen families have troglobitic species in Pyrenees; Ischyropsalidae with *Ischyropsalis pyrenaea*, Travuniidae with blind and depigmented *Arbasus caecus* and reducedeyed *Abasola sarea*, and Phalangodidae with *Scotolemon lucasi* in caves and the MSS in Ariège. Four species of extremely tiny Palpigradida *Eukoenenia* are found, each known by less than ten specimens. 33 species of troglobitic Pseudoscorpiones are known. The caves of the karst running along the south of the Massif Central are the habitat of *Chthonius* (seven species), *Neobisium* (three species), one *Spelyngochthonius*, and one *Roncochthonius*,

nine species are known from Pyrenean caves, six from the Alps, four from Jura, and two in Corsica.

Considering the aquatic fauna, Crustacean Copepoda (60 species), Amphipoda (36 species), and Isopoda (29 species) are the most numerous. *Niphargus* inhabit all types of subterranean water and are the most representative of aquatic fauna in France (Figure 2); their ecology and biology have been extensively studied by the team at Lyon. Other Amphipoda, *Ingolfiella* and *Salentinella*, are mainly inhabitants of interstitial waters. The tiny Copepoda Cyclopidae and Harpacticidae are also well represented in karstic aquifers, groundwater, and interstitial water. *Gelyella droguei* found in Languedocian karst became the type of a new sub-order of Copepoda (Gelyelloida). Thousands of specimens are washed out of the karst through springs during flooding of cave streams, as for example in the karst system of Baget near Moulis; the subterranean aquatic populations are abundant but only a small proportion can be collected in caves.

Isopoda Stenasellidae *Stenasellus* with four relict species are found widely in karstic and interstitial habitats, whereas the asellid *Asellus aquaticus*—a surface species that occasionally invades groundwater and caves—is found in many caves in its more or less blind and depigmented form. Two Sphaeromatidae species are known: *Caecosphaeroma virei* in Jura and *C. burgundum* found in Jura and Charente. Two Cirolanidae species have been collected from caves, *Faucheria faucheri* in Languedoc and the eastern Pyrenees, and *Sphaeromides raymondi*, limited to some caves in Languedoc; Microparasellidae (*Microcharon*) inhabits interstitial waters. Syncarida, a primitive relict family, are mainly represented in interstitial water in southern France and Corsica by eight genera, including *Bathynella*, *Parabathynella*, and *Gallobathynella*. A single species of Decapoda, *Troglocaris inermis*, inhabits karstic water north of Montpellier; it has a phylogenetic relationship with Caucasian species.

Of the vertebrates, 12 species of bats regularly use caves to reproduce, hibernate, and rest during the day.

Several subterranean systems in France have been studied extensively over a long period of time: the Cent Fons system north of Montpellier; the system of Dorvan Massif in Jura; the interstitial aquatic habitats of the Rhône; and in the Pyrenees, the karst system of Baget, Le Goueil di Her, the interstitial habitat of Lachein, Nert streams near Moulis, Sainte-Catherine Cave near Moulis, Pigailh Cave, the MSS of Ravin de la Tir in Ariège, the cave fauna and MSS of Mt Canigou, and La Verna chamber of the Pierre Saint-Martin. The "Laboratoire souterrain du CNRS" with its two cave laboratories in the central Pyrenees at Moulis has been internationally important in biospeleological study. Since 1952 more than one hundred species from the Pyrenees and also from outside France have been reared in these cave laboratories. From the 1950s, experiments were carried out on the Slovenian cave salamander Proteus anguinus, and Moulis now has the only permanent and reproductive captive population in the world. Later species studied include the troglophilic Euproctus asper, a salamander endemic from the Pyrenees; from the Crustacea, several species of Niphargus (Amphipoda), Stenasellus and several terrestrial Onisciidae (Isopoda), aquatic Oligochaeta Pelodrilus leruthi, several species of Copepoda: Cyclopidae and Harpacticidae, one Mysidacea from Cuba, and the Decapoda: Troglocaris', from Arachnida, four spiders, four Opiliones Ischyropsalis and Scotolemon, one Amblypygi from Cuba; from myriapoda, two Diplopoda from the Pyrenees; and from Insecta, several Collembola, around 14 species of Coleoptera Leptodirinae (Speonomus

and *Bathysciola* from the Pyrenees, *Closania* and *Drimeotus* from Romania), and one Orthoptera, *Dolichopoda linderi*. Adaptations to cave life have been demonstrated in these

France: Biospeleology: Figure 2. *Niphargus virei* Chevreux (Niphargidae). Male (30.0 mm).

species in the laboratory: low level of fecundity, enlarged eggs, low speed of development, long adult lifespan (around 50 years for *Proteus*, 20 for *Troglocaris*, 10 for *Telema*), low resistance to diyness, disappearance of circadian rhythms, changes in behaviour, behavioural sexual barriers between species, development of chemo-hygroreceptors, and mechanoreceptors for low air flow in *Aphaenops*.

In 1979, the Société Internationale de Biospéologie was founded from Moulis and Lyon. The Society organizes a symposium on cave life and animals every two years, in different countries.

In France, the conservation of cave fauna is just beginning. All cave beetles— *Aphaenops, Hydraphaenops,* and *Trichaphaenops*—and Mollusca Hydrobiidae are protected; four caves and their fauna are protected National Nature Reserves, and another more extensive project is under consideration in Ariège. Bats and sev eral of their cave habitats are protected by the European Bern and Bonn Conventions, and by French legislation.

FRANCE: HISTORY

France has extensive karst, and caves have been described for a very long time by local historians, who took great pride in them. Caves close to large cities, at the foot of the massifs, or on the plateaus, attracted the first curious observers: the cave of Cuves de Sassenage (Isère) was first described in 1534. At the same time, caves and potholes were visited for practical reasons, such as for mineral exploitation, cheese maturation, and as a place of refuge. Historical remains have been found at the bottom of the Gouffre de Padirac (Lot) and the foot of Aven Noir (Aveyron).

The 1780s saw spectacular progress: several classic caves were discovered, such as the caves of Campan (Hautes-Pyrénées) and the caves of Osselles (Doubs), and explorations that were extremely difficult for the period were realized. Several known caves were extended in this way, such as the cave of La Balme (Isère) whose underground lake was explored, first by boat then by swimming, and several known but as yet unexplored caves were descended, such as the entrance shaft of the grotte des Demoiselles (Hérault) and Tindoul de la Vayssière (Aveyron).

In the 19th century it was first paleontologists, then archaeologists, who carried out most underground investigations. For example from 1880–82, the naturalist and paleontologist J.A. Lucante (1880, 1882) listed nearly two thousand caves and shafts in the whole of France. It was in this context that Édouard-Alfred Martel, who dominates the history of French speleology, appeared (see Speleologists entry). Born in 1859, his first love was the mountains, but in June 1888, he made two great exploration discoveries in caves: in the Grands Causses he discovered the lower level of the Dargilan cave (Lozère), and at Bramabiau (Gard) he carried out the first through-exploration of the underground river from end to end (Martel, 1889). The following year, he descended the large caves of Rabanel (Hérault) and Mas Raynal (Aveyron) and began to explore the underground Padirac River (Martel, 1890). His speleological career had begun: between 1888 and 1913 he undertook 26 annual campaigns throughout France, with a taste, however, for the medium-altitude massifs: Jura, Provence, Languedoc, Lot, and the Dordogne occupied him more than the Alps and the Pyrenees, where his visits were fewer and more specific.

Using more lightweight equipment than the Austrian explorers of the period he explored hundreds of caves, the descent of a large shaft taking only a few days of preparation. Many collaborators throughout the country (such as L.Armand, F. Mazauric, O.Decombaz, and E.Fournier) carried out their own extensive searches, and also

accompanied Martel in the caves that they discovered. A small group of speleologists became organized in this way: Martel founded the Société de Spéléologie in 1895 and the journal *Spelunca* was launched the same year. However, World War I halted this impetus and ended speleology under Martel's leadership, though Martel himself continued to study and publish (e.g. Martel, 1921).

From 1920 to 1930, several great figures emerged in the wake of Martel. Norbert Casteret (see Speleologists entry) surveyed the central Pyrenees in several solo explorations: in 1935, he reached a depth of 243 m in the Gouffre Martel (Ariège), the deepest cave known in France at the time. Robert de Joly was interested especially in the Causses of Languedoc, discovering there the Aven Orgnac (Ardèche). In 1930, he created the Spéléo-Club de France, which in 1935 became the Société Spéléologique de France. French speleology progressed via a series of technological innovations (especially wire ladders), which meant obstacles that had stopped Martel could be overcome, such as the large shafts of Chourum Martin (Hautes-Alpes), descended by de Joly in 1929. It was also at this time that explorations of large cave systems began, such as at Henne-Morte (Haute-World War IL Garonne) and Dent de Crolles (Isère), which continued during

After 1945, speleological activity started again quickly and clubs were formed in Paris, Lyon, Nice, and Périgueux. The first congress of the International Speleological Union (UIS) took place in Paris in 1953. Many large expeditions were organized, and the world depth record was broken three times in France in less than ten years: in 1947, at Trou du Glaz (Isère), due to the connection of P.40 to Guiers-Mort Cave (-603 m); in 1953, at Pierre Saint-Martin (Pyrenees, -689 m); and in 1956 at the Gouffre Berger (Isère) where the depth of 1000 m was reached and exceeded for the first time (-1122 m). Casteret remained very active in this period, and his influence on the new generation of cavers was profound: in 1957, at the age of 60, he carried out another expedition to Henne-Morte.

This breadth of activity led in 1963 to the creation of the Fédération Française de Spéléologie, to which the great majority of French speleologists are affiliated. The first French speleological inventories were published, either by massif, or by local region. Single rope technique (SRT), a technological revolution established at the beginning of the 1970s, spread through the French school of caving and made several new discoveries possible: in 1979, Jean-Bernard Cave (Haute-Savoie) became the world's deepest known cave, replaced in 1998 by the neighbouring Mirolda Cave which was then 1616 m deep but was extended to 1733 m early in 2003 (see Morphometry of Caves). Around Henne-Morte Cave, the vast network of the Réseau Felix Trombe, whose length exceeds 100 km, was progressively explored and surveyed. Progress in cave diving also produced many discoveries and resolved some old speleological problems, such as the connection between Padirac Cave and the Finou resurgence, which was explored in September 1995.

Since 1980, French expeditions abroad have been equally divided between neighbouring countries (e.g. Spain and Austria) and more distant destinations: Algeria, China, and Papua New Guinea, where the first 1000 m deep cave in the southern hemisphere, Muruk cave, was explored by a French team. French speleology remains very active with more than 8000 cavers affiliated to over 600 clubs. The Fédération publishes exploration results and research through its two journals *Spelunca* and *Karstologia*, thus combining the sporting and scientific aspects of the discipline.

FRANCE, SOUTHERN MASSIF CENTRAL

Around the southern margin of the Massif Central, the Causses are a series of plateaus with very fine fluviokarst on gently folded limestones. The region is also notable for its caves with exceptionally fine aragonite speleothems, especially around the south of the Causses (particularly the Montagne Noire), in the Montpelier area, and in the foothills of the Pyrenees.

Causses

The Causses are extensive karstified limestone plateaus that are the remnants of ancient erosion surfaces. They are mainly undulating, with a dry stone-covered surface that is dissected by dry valley networks and by dolines ("sotches"), some of which contain siliceous deposits. Surface landforms include runiform relief ("pechs"), particularly on dolomites. The rocks form a monoclinal sedimentary series, bordered on the northern side by the Hercynian basement of the Massif Central. Marly Liassic rocks form an impermeable basement overlain by Jurassic and Cretaceous limestones and dolomites. Limestone is thought to have first become exposed in the late Jurassic, and evidence for a very ancient (late Cretaceous-early Tertiary) karst developed in a tropical climate is provided by traces of bauxite, sometimes in the shape of pisoliths, and by red clays, yellow sand, and quartz pebbles. Landform evolution continued through the Tertiary with phases of surface lowering and tectonic rejuvenation, partic ularly during the Oligocene and Miocene, with some local interruptions by volcanic activity. During the Pleistocene cold periods, the area was subject to severe nival conditions but was not glaciated. This accounts for the extensive frost-shattered debris on the Causse surfaces; some of this debris still forms sparsely vegetated felsenmeer, while elsewhere it is a significant component of the stony soils.

From north to south it is possible to distinguish the Périgord and Quercy Causses, the Grands Causses (Sauveterre, Méjean, Montagne Noir, and the Larzac which is one of the largest plateaus, reaching > 1000 km²), and the Minervois and Garrigues Causses. The relief in parts of the Périgord-Quercy Causses resembles relict tropical cone karst, albeit altered by periglacial weathering during the Pleistocene, and Pelissier (1999) describes paleokarst in the Quercy Causses. The Grand Causses (850–1100 m above sea level) are bounded by major cuestas and separated by deep valleys such as the Lot, or by spectacular canyons, up to 600 m deep, such as those of the Tarn, Jonte, and Dourbie. All of the canyons and gorges have been formed by allogenic rivers although their discharge is added to by springs which drain the surrounding Causses plateaus. The area is noted for extremely heavy rainfall events particularly in the spring when 24-hour totals of up to 950 mm have been recorded.

The Causses contain many fine caves, including the Gouffre de Padirac (in the Causse de Gramat) with its large entrance shaft and a long extensive underground river lying beneath abandoned passages richly decorated with calcite. The Aven d'Orgnac (in the Ardèche) has a large chamber with many tall "plate" or "palm tree" type stalagmites and is also extremely well endowed with helicities, shields, and monocrystalline stalactites. Both caves featured prominently in early French exploration, E.A.Martel being associated with Padirac while Orgnac contains a vase with the ashes of its discoverer, Robert de Joly (see also France: History). More recently, the Doux de Coly has been explored by divers (see Diving in Caves) to reveal an active phreatic tunnel over 5000 m long beneath the Quercy Causse.

Aragonite Caves

Although aragonite is quite common as a cave mineral (see Speleothems: Carbonate) it is rarely found in such profusion as in a series of caves in the Montagne Noire. In several of these caves the aragonite is a beautiful blue colour due to copper mineralization. The Barrencs de Fournes (Blue Cave) is listed as one of the ten most important mineralogical caves in the world (Hill & Forti, 1997). It has been sealed since 1974 to ensure total

protection but is the reference site for blue aragonite and is claimed to contain unique forms. More accessible is the Grotte de Limousis, a 2 km long show cave that contains "Le Lustre", a huge hanging aragonite cluster estimated to weigh about 9 tonnes and probably the largest single cluster known. A second tourist cave, the "Giant Hole", part of the 17 km long Grotte de Cabrespine, is also superbly decorated with both coralloid and acicular aragonite together with large calcite shields and a profusion of more common calcite speleothems. The smaller Grotte de l'Asperge contains spectacular, and possibly unique, acicular blue aragonite frostwork, blue coralloid aragonite, and a pale blue aragonite stalagmite, while the nearby PN77 cave contains brown and white-tipped tubular aragonite stalactites that have not been reported from anywhere else in the world. Also in the Montagne Noire region, the Grotte du Mont Marcou contains rare green aragonite speleothems (the colouration being due to nickel) and the Grotte Pousselière contains acicular aragonite and aragonite balls.

Outside the Causses, in the Montpelier region, the Grottes de la Clamouse is a popular tourist site that contains extensive deposits of coralloid and acicular aragonite, with hydromagnesite on some of the acicular tips, and a wide range of calcite speleothems, some of which have overgrowths of aragonite making the cave of particular interest. In the Pyrenees the most important sites for aragonite are the TM71 and André Lachambre caves. In TM71 the main aragonite is in a spectacular blue cluster and there are also unusual red speleothems and pure white monocrystalline triangular calcite stalagmites. Many of the 25 km of passages in André Lachambre are encrusted with pure white aragonite from floor to ceiling and this, together with cave pearls, hydromagnesite formations, and a unique vein of talc which crosses the cave passage, makes the cave one of the most spectacular in the world. The Gouffre d'Esparros also contains spectacular calcite and aragonite speleothems; part of the entrance series has been opened as a show cave with extensive instrumentation to measure tourist impacts on the cave climate. Two other notable sites in the Pyrenees are the Grotte de la Cigalère, a protected site containing rare gypsum speleothems, which include black gypsum, iron hydroxide and manganese hydroxide minerals, and large gypsum flowers and the Laboratoire souterrain du CNRS with its two cave laboratories at Moulis which has been internationally important in biospeleological study since 1952.

France, Southern Massif Central: Figure 1. Aragonite and hydromagnesite, Réseau André Lachambre. (Photo by John Gunn)

A common element to all the caves with aragonite is that they are formed in Jurassic dolomite or Paleozoic meta-dolomite, as aragonite is only deposited where the host rock contains over 7.5% Mg (Cabrol, 1979). Cabrol and Coudray (1982) found

France, Southern Massif Central: Figure 2. Water droplet at the end of fine aragonite needles, Réseau André Lachambre. (Photo by John Gunn)

that, as well as speleothems that contain one or more carbonate minerals as a result of diagenesis, there are some complex speleothems displaying successive deposition of calcite and aragonite minerals. They suggested that the spatial and temporal distribution of these speleothems with respect to their morphology and mineralogical features indicate that there were cycles of primary deposition and diagenetic alteration associated with changes in local climate driven by regional climatic changes.

FRASASSI CAVES, ITALY

The Frasassi Caves are located in central Italy, on the eastern slopes of the Apennines some 40 km from the Adriatic. They developed in a small anticline ridge deeply dissected by the Sentino Gorge (Figure 1). The caves constitute one of the most famous Italian karst systems, partly because they host the most-visited show caves in the country. Speleological explorations of the area took place mainly from 1950 to 1980, but some large cavities have been known at least since Procaccini Ricci's 1809 *Memoria sulla Grottadi Frasassi nei dintorni di Fabriano*. The Frasassi system is of particular scientific interest, and is presently one of the best examples of a cave with sulfide water circulation: in its lower branches, hyperkarstic speleogenetic mechanisms are active, and an unusual ecosystem dominated by chemiosynthetic organisms has been documented.

Several caves, over 25 km in length, open along the steep walls of a gorge from 200 m above sea level (corresponding with the river bed) up to 500 m. They generally consist of networks of dendritic horizontal passages in which wide chambers alternate with smaller tubes: the Ancona Abyss, the largest chamber, has a volume of about one million cubic metres. The whole system consists of several superimposed and interconnected levels, the genesis of which is related to the different steps in the deepening of the base level.

The lower series, present mainly in the Fiume-Vento system, developed during the Middle and Upper Pleistocene, under geomorphological and hydrogeological conditions similar to the present day. It contains speleothems dated to 200000 BP, and can be correlated with the alluvial deposits just outside the Frasassi Gorge. The upper levels, developed mainly in the Buco Cattivo and Mezzogiorno—Frasassi caves, show a different morphology, as a consequence of evolution under different hydrogeological settings.

Frasassi Caves, Italy: Figure 1.

Block diagram of the Frasassi karst system, with the caves of Buco Cattivo, Grotta del Fiume—Grotta Grande del Vento and Grotta del Mezzogiorno-Grotta di Frasassi in the limestone either side of the Frasassi Gorge of the Sentino River.

The lower parts of the system are in contact with a sulfide aquifer, fed by rising waters from buried evaporitic formations and by seeping meteoric water. The phreatic waters are cold and rich in Cl⁻, Na⁺, and SO₄²⁻, with a rather high H₂S content (up to 18 mg l⁻¹). The saline content varies throughout the year, being controlled by the mixing ratio between meteoric and sulfide waters: therefore higher values (about 2 g l⁻¹) occur at the end of the summer.

The presence of H_2S and its consequent oxidation allows secondary cave minerals to develop: gypsum is forming extensively in the lower part of the system, while thick gypsum deposits (up to 2 m or more, with a total volume of over 10000 m³) are present in the upper dry series. Their prevailing occurrence is as white microcrystalline replacement crusts over the limestone walls, or as thick precipitated deposits over the floor (Figure 2). Large prismatic crystals of gypsum are common, and their genesis is related to the diagenesis of the microcrystalline deposits and to the seepage of supersaturated waters into clay deposits. Other cave minerals related to the sulfur cycle (halloysite, barite, and jarosite) have been detected in the Frasassi Caves.

Most of the redox processes develop in the interface between sulfide waters and the cave atmosphere, and they are responsible for the speleogenesis of the whole karst system. The hyperkarst corrosion to limestone is active in both the epiphreatic and the vadose zone, but gypsum deposition occurs only in the latter because supersaturation cannot be reached in the vadose groundwater. Where H₂S is released in the cave atmosphere, the limestone is highly corroded and partially covered by gypsum crusts associated with a few crystals of elemental sulfur. The intensity of this reaction has been measured using limestone tablets with a known surface area and weight: the average weight loss was about 15 mg cm⁻² a⁻¹ both in the groundwater and in the atmosphere.

The sulfur cycle is also responsible for the development of autotrophic microorganisms, which produce organic matter using the chemical energy released during sulfur oxidation (chemosynthesis). This organic matter is an important trophic support for a rich and complex community of invertebrates.

Bacterial colonies always cover the bottom of the flooded galleries, but they are also present in the aerated zone, where microbial films, some millimetres thick, may give rise to mucous stalactites (mucolites): the dripping water from these formations has a pH<1, being rich in H_2SO_4 .

Measurements of C and N stable istotopes prove that the whole ecosystem in the sulfide caves is chemoautotrophic. In other areas, which are sparsely populated, the sulfide ones always show a noticeably high density of highly specialized fauna: seven new species have been detected so far, of which six have a distribution area restricted to the sulfide part of the system.

In 1974 a part of the cave was transformed into a show cave, the entrance of which is an artificial tunnel into the Ancona Abyss. The show cave has an average of 350000 visitors per year and up to 6000 visitors per day. However, this heavy tourist traffic has had practically no impact on the cave microclimate, thanks to its very large volume and to three sliding doors in the artificial tunnel. The main environmental parameters have been monitored since 1980 at 10 different stations, and have been analysed periodically by a scientific committee, in order to determine the intervention needed to preserve the cave environment.

GEOPHYSICAL DETECTION OF CAVES AND KARSTIC VOIDS

Finding an underground opening is one of the most challenging exploration targets for a geophysicist. In addition to locating caves for exploration or scientific research, mapping hidden karst is necessary when engineering projects are planned in rock formations known to contain caves, because karstic voids and doline collapses can compromise the integrity of building foundations, dams, and bridges. Clay-filled voids in paleokarst can also jam rock-boring machines. Proper use of geophysical exploration for karstic voids can often help geotechnical engineers develop an effective programme of test borings and grouting, since if the bore spacing is greater than the cavity dimensions it is possible to miss it completely.

Geophysical methods employ indirect, non-intrusive observations to characterize and map variations in the physical properties of what lies concealed beneath the ground surface. All geophysical techniques require contrasts of some physical property (density, electrical resistivity, magnetic susceptibility, seismic velocity) between subsurface structures. Although void space in rock may represent an enormous contrast in physical properties that can be advantageous to an investigator seeking concealed caves, underground karst openings are frequently small, irregular targets whose effects are easily masked by those of surface irregularities. Techniques useful for deep exploration usually do so at the expense of resolution and accuracy; conversely, techniques capable of generating high-resolution images of shallow features are often based on highfrequency signals that are rapidly attenuated as they propagate through deeper soil and rock.

Bedrock voids, whether filled with air, water, or sediment, constitute "missing mass" in comparison to solid rock. The negative density contrast is identifiable as a local reduction in the Earth's gravitational acceleration (g) measured at the surface. Microgravity surveys conducted to locate bedrock voids involve densely spaced measurements, high precision elevation control, and sensitive gravity meters. Rybakov *et al.* (2001) used an automated gravity meter and measurements on a 5 m grid to survey about 2000 m² per day. Although the LaCoste and Romberg "G" meter (the industry standard) is read to a precision of 0.001 mGal (or about a millionth of the Earth's normal gravitational acceleration), true accuracy is seldom better than 0.01 mGal. To reduce the gravity observations to gravity anomalies, observed gravity must be separated from theoretical gravity, which varies according to latitude, elevation and surrounding

topography, and geological material. Gravity on the Earth's surface decreases with elevation at a rate of about 0.197 mGal m^{-1} , so the elevation of each gravity station must be determined to an accuracy of 5 cm if reduced gravity variations of 0.01 mGal are to be significant. Tidal variations of as much as 0.3 mGals must be calculated or monitored, and the gravitational effects of neighbouring hills and valleys must be calculated and separated from the cavity's effect.

Interpretation of gravity anomalies is limited by ambiguities regarding shapes of structures which could be responsible for the anomaly (Figure 1). Moreover, voids may still be present where no anomaly is detected, due to a combination of additive and negative anomalies. Total volume of void space can be estimated, subject to assumptions or independent information regarding the average density of surrounding bedrock and the material filling caves and fractures (air-filled cavities create the largest anomaly; waterfilled cavities create an anomaly effect of only 60% that of the same cavity containing air; and rubble or mud-filled cavities only about 40% that of air). Sophisticated computer analysis of data from closely spaced points allows anomalies to be distinguished by both their amplitude and their wavelength, which decrease and increase respectively with depth to a cavity. Data processing can apply filtering to separate the effects due to anomalies at different depths. Spectacular results have been obtained in surveys over old mines, where the voids form simple and recognizable shapes, but the random shapes and complexity of karstic cavities make them more difficult to identify in microgravity surveys: fractured rock around the cavity, and collapse features associated with caves can give an enhanced anomaly and a false picture of the size of the void

Gravity anomaly: shallow cave

Geophysical Detection of Caves and Karstic Voids: Figure 1. Gravity anomaly calculated for a horizontal cave, 3 metres in diameter and

centered 6 metres under the surface, in dense (2700 kg m⁻³) limestone. Forward models such as this example help the geophysicist determine grid spacing and minimum acceptable accuracy prior to designing an appropriate field exploration strategy.

(Chamon & Dobereiner, 1988). In karst, the old guideline that voids can only be recognized at depths less than twice their diameter is still appropriate. Gravity mapping of caves in mountainous areas is restricted by the difficulty in calculating with precision the large topographic effect of nearby mountains and valleys. Gravity mapping of soil-mantled karst requires use of an additional, independent method for determining the buried topography. However, gravity can be used in urban areas where cultural noise obscures electrical and magnetic signals. A negative gravity anomaly must be due to some form of missing rock, and this makes the data singularly accessible to the engineer who has to ensure safe ground for structural foundations.

Ground-penetrating radar (GPR) is one of the newer geo-physical methods, and one of the most successful in detecting shallow caves (Chamberlain et al., 2000). Pulses of lowfrequency (10 to 1500 MHz) electromagnetic energy penetrate the ground and are partially or totally reflected from rock or soil boundaries with contrasting electrical properties (notably their dielectric constants, or permittivities). Air-filled voids and layers of water-saturated sediment are strong radar reflectors. The reflected signals are detected on the ground surface and are collated by computer to produce the ground profiles; a series of parallel profiles can be combined to generate gridded 3-D images of the subsurface. GPR has been used to map joints enlarged by dissolution under thin soils, and may have the potential for mapping the cross-sectional shape of caves that are not too deeply buried by conductive overburden. The selection of radar frequency is probably the most important choice when undertaking a GPR survey, since lower frequencies (10-300 MHz) allow depth penetration to several tens of metres, but they will fail to detect small diameter anomalies. Frequencies of 500 MHz and greater provide excellent resolution, but they limit the subsurface depth penetration of the GPR to less than 5 m. Radar signals penetrate well into dry sandy soils and into carbonate rocks to map features at depths of several tens of metres. In contrast, clay-rich soils attenuate GPR signals and can restrict depth interrogation to depths of just 1 m. Lateral reflections limit the use of GPR in rugged terrain. Roadbeds are penetrated by GPR, and a transmitter/receiver towed by a car can be used to detect karstic voids developing under the highway. GPR is a relatively new technology that should become increasingly functional as field geophysicists discover ways to enhance its capabilities.

Electromagnetic induction measurements (EM) also use electromagnetic waves transmitted into the ground. Where the waves encounter electrical conductors in the ground, they induce electrical currents in these conductors, which in turn generate electromagnetic waves that can be collected at the surface by an antenna. The method can be useful for mapping karst where the voids in bedrock are filled with clay or water. Clay-filled fractures and caves partly filled with water conduct electrical signals far better

than does carbonate bedrock, and often produce high-amplitude anomalies. EM measurements have proven more cost-effective than exhaustive test drilling for locating vertical clay-filled fractures prior to expansion of limestone quarries. On the other hand, air-filled fractures or voids are transparent to EM signals and are difficult to detect. However, caves that extend above the water table do not block the signal generated by conductive ground water, and so the water-filled part of the cave can be detected. The major limitation of EM measurements is their ambiguity. It may be difficult to isolate changes in depth to bedrock from lateral changes in electrical conductivity. It is sometimes possible to discriminate EM conductivity variations due to changes in depth to bedrock, from those due to waterfilled karst, by using an instrument such as the Geonics EM34–3 and making conductivity measurements at three different frequencies in both the vertical and horizontal dipole modes. The EM34–3's lowest operating frequency is 400 Hz and its depth of exploration can vary from 60 to 100 m. EM instruments can provide more useful, albeit less detailed, information than can GPR in karst that is mantled by several metres of wet clay soil.

Electrical resistivity surveys also utilize contrasting electrical properties to characterize and map buried rock. Electrical current is transmitted directly into the ground through a pair of electrodes, which results in a voltage change measured between a second pair of electrodes. The apparent resistivity (p_a) of the ground can be calculated, and since low-porosity bedrock usually exhibits an electrical resistivity higher than overlying sediment, the buried topography can be interpreted. Electrical resistivity measurements should usually yield values consistent with EM conductivity, because apparent resistivity is simply the inverse of apparent conductivity, except when encountering subsurface voids. An air-filled cave is opaque to electrical currents but transparent to EM signals. It is unfortunate that air-filled caves and clay-filled caves have opposite resistivity characteristics, and some site investigation surveys have encountered problems where effects from a mixture of open and filled caves cancel each other out. When resistivity soundings indicate a highly resistive subsurface where an EM reading indicates a conductive subsurface, this discrepancy is probably due to a cave that extends both above and below the water table. Electrical resistivity profiles using arrays that simultaneously map lateral and vertical variations in apparent resistivity reveal caves even more clearly when data are interpreted using commercial inversion software on desktop computers.

Finding hidden caves or voids that might be large enough for direct human exploration has been less successful than profiling potential collapse areas in geotechnical investigations. Resistivity tomography has been successfully used to resolve known cavities, for example 20×30 m cavities at a depth of 10-20m at Harrison's Cave in Barbados (Shi, Morgan & Wharton, 1997), but proving the existence of as yet-undiscovered caves with resistivity remains elusive, perhaps because explorers may not be able to drill potential sites.

The induced polarization and self-potential methods have been tested as cave detection methods at Indian Echo Caverns, Pennsylvania (Sogade, Vichabian & Morgan, 1999; Vichabian & Morgan, 1999) and at Kartchner State Caverns, Arizona (Lange, 1999). The induced polarization method utilizes the difference between chargeability of air and water-saturated rock, while preferential infiltration of groundwater towards air-filled cavities in sedimentary rocks is thought to cause self-potential anomalies. Sogade,

Vichabian and Morgan were able to resolve a 20×3m cavity at a depth of 20 m. As with the resistivity method, detection of known cave passages is yet to be demonstrated.

Seismic reflection surveys can detect voids because the large negative reflection coefficient that exists between air and rock or water and rock generates an echo that is not only strong but which exhibits a phase reversal. A reflection from the overburdenbedrock contact is a compression, while that from a void begins as a dilation. Single sets of ground-based seismic data have often failed to produce interpretable results, but tomographic sections produced by computer analysis of larger banks of data (obtained from seismic velocities measured on hundreds of ray paths between multiple positions in boreholes) have proved more useful. The development of three-dimensional seismic tomography (3dT) is again dependent on powerful computer software, but has produced some impressive images of complex karstic voids in unseen ground (Figure 2). This is currently the most promising tool in geophysical searches for caves, but does represent a major investigation incorporating boreholes unless underground access is already available (as on a tunnel project).

Strategy

A prospecting strategy has to be developed for any specific set of potential karstic ground conditions and the choice of method depends on the degree of certainty required. Electrical dipoledipole resistivity profiles are often the most reliable method for locating shallow air-filled caves. This method can approximate the size, shape, and depth of air-filled voids, but survey depth is usually limited to 20 m or less. Slopes where talus conceals cave entrances are usually too steep for other geophysical methods. Gravity surveys can distinguish heavily karstified zones from nearby areas with a lower overall void space, but gravity tells us little about the size and shape of individual voids. Seismic reflection and ground-penetrating radar usually image only the top of an air-filled void, and seismic tomography demands expensive exploration infrastructure and data processing. Locating hidden caves challenges even the experienced geophysicist, and nonspecialists are unlikely to achieve success on their first attempts, despite having extensive technical backgrounds in related fields.

In locating buried topography of karstic terrains (such as dolines that are filled, covered, or concealed by sediment, usually glacial drift), microgravity profiles and EM measurements provide good reconnaissance tools, followed up by test drilling or by slower, more labour-intensive methods (electrical resistivity,

Geophysical Detection of Caves and Karstic Voids: Figure 2. An image of

a doline beneath a road in Pennsylvania produced by 3-D seismic tomography between sources and receivers in an array of five boreholes. The debris-filled cave passage descending steeply through rock beneath a soil cover 20 m deep was subsequently verified by further drilling. (Courtesy of 3dT/NSA Engineering) seismic reflection) capable of providing better subsurface images of identified conductivity highs and gravity lows. Geophysical exploration relies on sophisticated instruments and data analysis. The method selected is often determined by the needs of the investigator and the nature of the target, and even an experienced geophysicist might not know until field work begins which field strategies and instrument deployments will provide adequate information most efficiently in any given setting.
